Warwick, J.J. and Cale, W.G., 1987, Determining likelihood of obtaining a reliable model, J. Env. Eng., 113(5), 1102-1119

Appendix I: Model Calibration Examples

- *Calibration of models in the Murray-Darling Basin*

In the Murray-Darling Basin, in order to preserve water quality, water reliability and the environment, a decision was made in 1995 to restrict water use to the 1993/94 level of development. Computer models of the major tributary streams are now used at the end of each year to determine the annual use target for the previous season based on that level of development. Rules are in place to ensure that long term usage is maintained at the agreed level. Because the models now define the overall water rights of each valley, there are legal requirements to calibrate models and each model is independently audited and certified as being unbiased before being approved as fit for purpose. The key model output of interest is water use but emphasis is also placed on the modeling of downstream flow which impacts the rights of downstream regions. Each model must be calibrated over at least ten years and this often means that changes in infrastructure, operating rules and growth in demand have to be incorporated into the calibration run. Calibration reports contain plots of modeled and observed water use, storage behavior and flow and statistics such as mean error, correlation coefficients and standard errors. The aim of calibration is to ensure that the model is unbiased and to give confidence to stakeholders.

An issue that is sometimes raised with model development is the role of calibration, where the model is fine-tuned to match the observed data, and validation where the model is tested against data that was not used in the calibration process to get an independent assessment of the model's accuracy. For the Murray River, because of the variability of our climate, we like to calibrate our model against a long period of data including the most recent years when the current operating rules were being used and the historical data is generally the most reliable. Validation is considered to be less important and is typically carried out using the two or three years of data available following the completion of model calibration.

- *Use of models for Allocating Water in Texas*

Recent legislation in Texas revised the State Water Planning process and mandated the development of water allocation models for every river basin in the state (http://www.tnrcc.state.tx.us/permitting/waterperm/wrpa/permits.html). Similar to the Murray – Darling situation, these models are used to provide estimates of reliability for all permitted water diversions in the state as well as analysis of the effects of all permit applications. Naturalized, or predevelopment, time series of flows were constructed for the basins, and then the effects of developments were added in to achieve models of the current situation. The process of developing the basin models was an iterative, peer reviewed calibration process subject to stakeholder comment at several critical junctures. The naturalized flows and subsequent development of the basins now form an accepted and legal basis for future water allocations. Currently, similar activities are ongoing to provide calibrated and verified models of the state's groundwater aquifers and usage.

Subject: Comments on the Draft Environmental Assessment and Findings of No Significant Impact for the *2010-2011 Water Transfer Program*

Dear Messrs. Hubbard and Messer:

AquAlliance, the California Sportfishing Protection Alliance, and the California Water Impact Network ("the Coalition") submit the following comments and questions for the Draft Environmental Assessment ("EA") and Findings of No Significant Impact ("FONSI"), for the *2010-2011 Water Transfer Program* ("Project"). We also provide comments about the purpose and need for the 2010-2011 state and federal water transfer programs that are mirror images of the 2009 Drought Water Bank.

The Bureau of Reclamation's draft environmental review of the Project does not comply with the requirements of National Environmental Policy Act ("NEPA"), 42 U.S.C. §4321 *et seq.* First, we believe that the Bureau needs to prepare an environmental impact statement ("EIS") on this proposal, as we believed for the 2009 Drought Water Bank ("DWB") that allowed up to 600,000 acre-feet (AF) of surface water transfers, up to 340,000 AF of groundwater substitution, and significant crop idling. The *2010-2011 Water Transfer Program* seeks approval for 200,000 AF of CVP related water and suggests that the EA covers non-CVP transfer water. Unfortunately, the non-CVP water appears late in the EA (section 3.18 Cumulative impacts), where the table identifies the non-CVP water (p. 3-107), but does not supply a sub-total. When added, non-CVP water equals 195,910 AF of additional water for transfers. The EA reveals that "the cumulative total amount potentially transferred from all sources would be up to 392,000 acre feet," (p. 3-108) but the actual cumulative number is 395,910 AF of CVP and non-CVP water**.** The failure to supply sub-totals and the mathematical carelessness leaves the reader wondering what other liberties have been taken within the 2010-2011 Water Transfer Program.

Bureau reliance on the EA itself violates NEPA requirements because, among other things, the EA fails to provide a reasoned analysis and explanation to support the Bureau's proposed finding of no significant impact. The EA contains a fundamentally flawed alternatives analysis, and treatment of the chain of cause and effect extending from project implementation leading to inadequate analyses of nearly every resource, growth inducing impacts, and cumulative impacts. An EIS would afford the Bureau, DWR, the State Water Resources Control Board, and the California public far clearer insight into how, where, and why the *2010-2011 Water Transfer Program* might or might not be needed. The draft EA/FONSI as released this month fails to provide adequate disclosure of these impacts.

Second, California Environmental Quality Act (CEQA) analysis of the 2010-2011 Water Transfer Program is completely absent at the programmatic level. Is the negligence in this regard due to the present litigation that challenges the 2009 Drought Water Bank exemption? The Project's actual environmental effects —which are similar to the 2009 DWB, the Sacramento Valley Water Management Agreement, and the proposed 1994 Drought Water Bank (for which a final Program Environmental Impact Report was completed in November 1993) – are not presented in the EA, FONSI, or in any CEQA document. The Sacramento Valley Water Management Agreement was signed in 2002 and the need for a programmatic EIS/EIR was clear and initiated, but never completed. In 2000, the Governor's Advisory Drought Planning Panel report, *Critical Water Shortage Contingency Plan* promised a program EIR on a drought-response water transfer program, but was never undertaken. Twice in recent history, the state readily acknowledged that CEQA review for a major drought water banking program was appropriate. So, the Bureau's failure to conduct scientifically supported environmental review in an EIS and DWR's negligence to provide CEQA review reflects an end-run around established law through the use of water transfers, and is therefore vulnerable to legal challenge under the National Environmental Protection Act ("NEPA") and CEQA.

Finally, we also question the merits of and need for the Project itself. The existence of drought conditions at this point in time is highly questionable and reflects the state's abandonment of a sensible water policy framework. Our organizations believe the Bureau's EA/FONSI and the absence of DWR's programmatic review go too far to help a few junior water right holders at the expense of agriculture, communities, and the environment north of the Delta. The 2010-2011 Water Transfer Program will directly benefit the areas of California whose water supplies are the least reliable by operation of state water law. Though their unreliable supplies have long been public knowledge, local, state, and federal agencies in these areas have failed to stop blatantly wasteful uses and diversions of water and to pursue aggressive planning for regional water self-sufficiency.

The proposed Project will have significant effects on the environment—both standing alone and when reviewed in conjunction with the multitude of other plans and programs (including the non-CVP water that is mentioned in the EA cumulative impacts section) that incorporate and are dependent on Sacramento Valley water. Ironically, the Bureau appears to recognize in its cumulative impacts discussion that there is potential for significant adverse impacts associated with the Project, but instead of conducting an EIS as required, attempts to assure the public that the 2010-2011 Water Transfer Program will be deferred to the "willing sellers" through individual "monitoring and mitigation programs" as well as through constraining actions taken by both DWR and Bureau professional staff whose criteria ought instead be incorporated into the Proposed Action Alternative (EA at p. 2-1, FONSI at p. 1-9). It is impossible to evaluate whether or not the mitigation and monitoring pans will be adequate to relieve the Bureau and DWR of responsibility for impacts from the Project (including the non-CVP water transfers). The language used in the EA (p.3-25) and the *Draft Technical Information for Water Transfers in 2010* (November 2009) (p. 26-31) fail to pass the blush test (details below).Of course, this is not a permissible approach under NEPA; significant adverse impacts should be mitigated—or avoided altogether as CEQA normally requires.[1] Moreover, in light of the wholly inadequate monitoring and mitigation planned for the 2010-2011 Water Transfer Program's extensive water transfer program, the suggestion that the public should be required to depend on the insufficient monitoring to provide the necessary advance notice of "significant adverse impacts" is an unacceptable position.

We incorporate by reference the following documents:

- Butte Environmental Council's letter to DWR regarding the Drought Water Bank Addendum from Lippe Gaffney Wagner LLP, 2009.
- Butte Environmental Council's letter to DWR regarding the Drought Water Bank Addendum.
- Multi-Signatories letter regarding the Drought Water Bank, 2008.
- Professor Kyran Mish's White Paper, 2008.
- Professor Karin Hoover's Declaration, 2008.

---

[1] Perhaps even more telling, the Bureau actually began its own Programmatic EIS to facilitate water transfers from the Sacramento Valley and the interconnected actions that are integrally related to it, but never completed that EIS and now has impermissibly broken out this current segment of the overall Program for piecemeal review in the present draft EA. See 68 Federal Register 46218 (Aug 5, 2003) (promising a Programmatic EIS on these related activities, "include[ing] groundwater substitution in lieu of surface water supplies, conjunctive use of groundwater and surface water, refurbish existing groundwater extraction wells, install groundwater monitoring stations, install new groundwater extraction wells…" *Id.* At 46219. See also http://www.usbr.gov/mp/nepa/nepa_projdetails.cfm?Project_ID=788 (current Bureau website on "Short-term Sacramento Valley Water Management Program EIS/EIR").

I. The Bureau and DWR Must Prepare an Environmental Impact Statement/ Environmental Impact Report on the Proposed 2010-2011 Water Transfer Program

We strongly urge the Bureau to withdraw this inadequate environmental document and instead prepare a joint EIS/R on the 2010-2011 Water Transfer Program, before approval by the State Water Resources Control Board (SWRCB), in order to comply with both NEPA and CEQA requirements for full disclosure of human and natural environmental effects.

NEPA requires federal agencies to prepare a detailed environmental impact statement on all "major Federal actions significantly affecting the quality of the human environment . . . ." 42 U.S.C. §4332(2)(C). This requirement is to ensure that detailed information concerning potential environmental impacts is made available to agency decision makers and the public before the agency makes a decision. *Robertson v. Methow Valley Citizens Council*, 490 U.S. 332, 349 (1989). CEQA has similar requirements and criteria.

Under NEPA's procedures, an agency may prepare an EA in order to decide whether the environmental impacts of a proposed agency action are significant enough to warrant preparation of an EIS. 40 C.F.R. §1508.9. An EA must "provide sufficient evidence and analysis for determining whether to prepare an [EIS]" (*id.*), and must demonstrate that it has taken a "'hard look' at the potential environmental impact of a project." *Blue Mountains Biodiversity Project v. Blackwood*, 161 F.3d 1208, 1212 (9th Cir. 1998) (internal quotation marks omitted). However, the U.S. Court of Appeals for the Ninth Circuit has cautioned that "[i]f an agency decides not to prepare an EIS, it must supply a convincing statement of reasons to explain why a project's impacts are insignificant." *Id.* (internal quotation marks omitted). The Bureau has not provided a convincing statement of reasons explaining why the DWB's impacts are not significant. So long as there are "substantial questions whether a project *may* have a significant effect on the environment," an EIS must be prepared. *Id.* (emphasis added and internal quotation marks omitted). Thus, "the threshold for requiring an EIS is quite low." *NRDC v. Duvall*, 777 F. Supp. 1533, 1538 (E.D. Cal. 1991). Put another way, as will be shown through our comments, the bar for sustaining an EA/FONSI under NEPA procedures is set quite high, and the Bureau fails to surmount it on the 2010-2011 Water Transfer Program.

NEPA regulations promulgated by the Council on Environmental Quality identify factors that the Bureau must consider in assessing whether a project may have significant environmental effects, including:

(1) "The degree to which the possible effects on the human environment are highly uncertain or involve unique or unknown risks." 40 C.F.R. §1508.27(b)(5).
(2) "The degree to which the effects on the quality of the human environment are likely to be highly controversial." *Id.* §1508.27(b)(4).
(3) "Whether the action is related to other actions with individually insignificant but cumulatively significant impacts. Significance exists if it is reasonable to anticipate on a cumulatively significant impact on the environment. Significance

cannot be avoided by terming an action temporary or by breaking it down into small component parts." *Id.* §1508.27(b)(7).

(4) "The degree to which the action may establish a precedent for future actions with significant effects or represents a decision in principle about a future consideration." *Id.* §1508.27(b)(6).

(5) "The degree to which the action may adversely affect an endangered or threatened species or its habitat that has been determined to be critical under the Endangered Species Act of 1973." *Id.* §1508.27(b)(9).

Here, the Bureau has failed to take a hard look at the environmental impacts of the Project. As detailed below, there are substantial questions about whether the 2010-2011 Water Transfer Program's proposed water transfers will have significant effects on the region's environmental and hydrological conditions especially groundwater, the interactions between groundwater and surface streams of interest in the Sacramento Valley region, and the species dependent on aquatic and terrestrial habitat. There are also substantial questions about whether the 2010-2011 Water Transfer Program will have significant adverse environmental impacts when considered in conjunction with the other related water projects that have occurred in the last decade and that are underway and proposed in the region. The Bureau simply cannot rely on the EA/FONSI for the foreseeable environmental impacts of the proposed 2010-2011 Water Transfer Program and still comply with NEPA's requirements.

A. The Proposed Action Alternative is poorly specified making it difficult to identify chains of cause and effect necessary to analyze adequately the alternative's environmental effects.

The Proposed Action Alternative is poorly specified and needs additional clarity before decision makers and the public can understand the human and environmental consequences of the 2010-2011 Water Transfer Program. The EA describes the Proposed Action Alternative as one reflecting the Bureau's intention to approve transfers of Central Valley Project water from willing sellers who contract with the Bureau ordinarily to use surface water on their croplands. Up to 200,000 AF of CVP water are offered from these sellers, according to Table 2-1 of the EA. In contrast to the EA/FONSI for the 2009 Drought Water Bank, the EA contains no "priority criteria" to determine water deliveries and simply acknowledges that water will be transfered to agricultural and urban interests (p. 3-88). The EA fails to indicate how much water has been requested by the buyers of CVP or non-CVP water, which is also in contrast to the EA/FONSI and DWR's addendum for the 2009 Drought Water Bank. This denial of information further obfuscates the need for the Project.

The EA/FONSI's statement of purpose and need (p. 1-1) states specifically that, "To help facilitate the transfer of water throughout the State, Reclamation and the Department of Water Resources (DWR) are considering whether they should approve and facilitate water transfers between willing sellers and buyers." This paragraph omits coherent discussion of need. Merely stating that, "The transfer water would be conveyed, using CVP or SWP facilities, to water users that are at risk of experiencing water shortages in 2010 and 2011 due to drought conditions and that require supplemental water supplies to meet anticipated demands," lacks specificity and rigor. The purpose and need should also state that this transfer program would be subject to specific criteria for prioritizing transfers.

The EA's description of the proposed action alternative needs to make clear what would occur if sale criteria are in fact applied and if exceptions will be allowed, and if so, by what criteria would exceptions be made.. Do both Project agencies lack criteria to prioritize water transfers? What is the legal or policy basis to act without providing priority criteria? Without foundational criteria, the public is not provided with even a basic understanding of the need for the Project.

There is considerable ambiguity over just how many potential sellers there are and how much water they would make available. The EA states that, "Entities that are not listed in this table [2-1] may decide that they are interested in selling CVP water, but those transfers may require supplemental NEPA analysis to allow Reclamation to complete the evaluation of the transfers," (p. 2-3 and 2-4). Allowing a roving Project location is not permissible and avoids accurate analysis of all impacts including growth inducing and cumulative impacts.

Absent buyers' request numbers and the potential for the participation of unknown additional sellers signals that neither the Bureau nor DWR have a clear idea what the 2010-2011 Water Transfer Program is intended to be. This problem contributes greatly to and helps explain the poorly rendered treatment of causes and effects that permeate the Bureau's EA. The project agencies, decision-makers, and the public all face a moving target with the 2010-2011 Water Transfer Program. Such discrepancies reflect hasty consideration and poor planning by project proponents. Nor can the agencies reasonably attribute their inadequate environmental reviews on lack of warning. The Governor, Senator Dianne Feinstein, and congressional representatives from the San Joaquin Valley have all made fear of drought a centerpiece of their water statements in 2008 and 2009. Yet DWR and the Bureau apparently are not able to present a stable Project with clear needs and criteria.

From data available in the EA and the Addendum, it is not possible to determine with confidence just how much water is requested by potential urban and agricultural buyers. There is no attempt to describe how firmly tendered are offers of water to sell or requests to purchase. Guessing at the possible requests based on the 2009 DWB where there were between 400,000 and 500,000 AF of presumably urban buyer requests[2] alone (which had priority over agricultural purchases, according to the 2009 DWB priorities) and a cumulative total of less than 400 TAF from willing sellers, which is also true for the 2010-2011 Water Transfer Program (with just over half that coming from CVP water), it would appear that many buyers are not likely to have their needs addressed by the 2010-2011 Water Transfer Program. If so, the Bureau and DWR should state

---

[2] Neither DWR's Addendum nor the Bureau's EA specify numerical requests for the cities of Huron, Avenal, Coalinga, and the Avenal State Prison making it impossible to have a firmer number for the amount of urban request for water. Our estimate assumes SCVWD's 30,000 AF and MWD's 300,000 AF requests are for entirely urban uses of DWB-purchased water.

the likelihood that many requests will not be fulfilled in order to achieve a full and correct environmental compliance treatment of the proposed action. Such an estimate is necessary for accurate explication of the chains of cause and effect associated with the 2010-2011 Water Transfer Program—and which must propagate throughout a NEPA document for it to be adequate as an analysis of potential natural and human environmental effects of the proposed project. We have additional specific questions:

- What are the requests of the San Luis and Delta Mendota Water Authority (SLDMWA)? Is the request for an agricultural use or an urban use of Project water? If it is entirely for agricultural uses, how likely is it to be fulfilled under the non-stated Project priorities for water sales?
- What are the specific urban requests for water made by Avenal State Prison, and the cities of Avenal, Huron, and Coalinga, nested within the SLDMWA request?
- Will sale criteria be premised on full compliance with all applicable environmental and water rights laws? If so, how will cumulative impacts be analyzed under CEQA?

If priority criteria were revealed, how will intervening economic factors beyond the control of the Project be analyzed? Given the added uncertainty, an EIS should be prepared to provide the agencies with advance information and insight into what the sensitivity of the program's sellers and buyers are to the influences of prices—prices for water as well as crops such as rice, orchard and vineyard commodities, and other field crops. It is plausible that crop idling will occur more in field crops, while groundwater substitution would be more likely for orchard and vineyard crops. However, high prices for rice—the Sacramento Valley's largest field crop—would undermine this logic, and could lead to substantial groundwater substitution. These potential issues and impacts should be recognized as part of the 2010-2011 Water Transfer Program description and should directly apply to the Agriculture and Land Use, and Socioeconomic sections of the EA, because crop prices are key factors in choices potential water sellers would weigh in deciding whether to idle crops, substitute groundwater, or decline to participate in the DWB altogether. The EA is inadequate because it fails to identify and analyze the market context for crops as well as water that would ultimately influence the size and scope of the 2010-2011 Water Transfer Program.

Rice prices are high because of conditions for the grain in the world market. Drought elsewhere is a factor in reduced yields, but growing populations in south and east Asia demand more rice and the rice industry has struggled to meet that demand.[3]

This is very important. The Bureau tacitly admits that the Bureau—and by logical extension, DWR—has no idea how many sales of what type (public health, urban, agricultural) can be expected to occur. Put another way, there is a range of potential outcomes for the 2010-2011 Water Transfer Program, and yet the Bureau has failed utterly to use the EA to examine a

---

[3] "Panic over rice prices hits California," *AZCentral.com*, April 24, 2008; UN News Service, "Bumper rice harvests could bring down prices but poor may not benefit, warns UN," 25 February 2009; "Era of cheap rice at an end in Taiwan: COA," *The China Post*, March 5, 2009; Jim Downing, "Sacramento Valley growers se rice prices soar," *Sacramento Bee*, 18 January 2009.

reasonable and representative range of alternatives as it concerns how the priority criteria would be established and affect Project transfers. And DWR has not bothered to conduct an appropriate level of review under CEQA...

Nor does the 2010-2011 Water Transfer Program prevent rice growers (or other farmers) from "double-dipping." It appears to us they could opt to turn back their surface supplies from the CVP and the State Water Project and substitute groundwater to cultivate their rice crop—thereby receiving premiums on both their CVP contract surface water as well as their rice crop this fall when it goes to market. There appear to be no caps on water sale prices to prevent windfall profits to sellers of Sacramento Valley water in the event that groundwater is substituted in producing crops—especially for crops where market prices are high, such as in rice. The DWB in the 1990s capped water prices at $125/acre-foot, much to the disappointment of some water sellers at that time. Why are the state and federal projects encouraging such potential windfall profits at a time when many others suffer through this recession?

As stated, neither the Bureau nor DWR state how much of these transfers would go to public health, urban or agricultural buyers. The EA must also (but fails to) address the ability and willingness of potential buyers to pay for Project water given the supplies that may be available. Historically, complaints from agricultural water districts were registered in the comments on the Draft EWA EIS/R and reported in the Final EIS/R in January 2004 indicating that they could not compete on price with urban areas buying water from the EWA. Given the DWB's priority criteria, will agricultural water buyers identified in Table 2-2 of the EA be able to buy water when competing with the likes of the Santa Clara Valley Water District and the Metropolitan Water District, representing two of the wealthiest regions of California? As a matter of statewide water, infrastructure, and economic policy, is it wise to foment urban versus agricultural sector competition for water based solely on price? Shouldn't other factors be considered in allocating water among our state's regions? This fails dramatically to encourage regions to develop their own water supplies more efficiently and cost-effectively without damage to resources of other regions.

Full disclosure of each offer of and each request for 2010-2011 Water Transfer Program water should be provided as part of the EA. This is necessary so the public can understand and have confidence in the efficacy of the Project's purpose and need, benefit from full disclosure of who requests what quantity of water and for what uses, and so that the public may easily verify chains of cause and effect. Urban application of transferred surface water is not examined in the EA/FONSI, as though how urban buyers would use their purchased water had no environmental effects. Since the dry period in California has lasted for over three years, how will purchased water be used and conserved? What growth inducing impacts will transferred water facilitate?

Nor is a hierarchy of priority uses among urban users for purchasing Project water presented. Could purchased water be used for any kind of landscaping, rather than clearly domestic purposes or strictly for drought-tolerant landscaping? We cannot tell from the EA/FONSI narrative. How can the citizens of California be assured that water purchased through the 2010-

2011 Water Transfer Program will not be used wastefully, in violation of the California Constitution, Article X, Section 2?

Will urban users need their Project purchased water only in July through September, or is that the delivery period preferred in the DWB because of ecological and fishery impact constraints on conveyance of purchased water?

Should agricultural water users be able to buy any Project water, how will DWR and the Bureau assure that transferred water for irrigation is used efficiently? Many questions are embedded within these concerns that DWR and the Bureau should address, especially when they approach the State Water Resources Control Board to justify consolidating their places of use in their respective water rights permits:

- How much can be expected to be purchased by agricultural water users, given the absence of any criteria, let alone priority criteria, in the 2010-2011 Water Transfer Program?
- How much can be expected to be consumptively used by agricultural water buyers?
- How much can be expected to result in tailwater and ag drainage?
- How much can be expected to add to the already high water table in the western San Joaquin Valley?
- What selenium and boron loads in Mud Slough and other tributaries to the San Joaquin River may be expected from application of this water to WSJ lands?
- What mitigation measures are needed to limit such impacts consistent with the public trust doctrine, Article X, Section 2 of the California Constitution, the Porter-Cologne Water Quality Control Act, and California Fish and Game Code Section 5937?

In other words, the most important chains of cause and effect—extending from the potential for groundwater resource impacts in the Sacramento Valley to potential for contaminated drainage water from farm lands in the western San Joaquin Valley where much of the agricultural buyers are located—are ignored in the Bureau's EA/FONSI and completely missing due to DWR's failure to comply with CEQA.

Will more of surface water transfers go to urban users than to ag users? The EA's silence on this is disturbing, and highlights the absence of priority criteria. What assurances will the Bureau and DWR provide that criteria exist or will be developed and how will these criteria be presented to the public and closely followed?

- The more that goes to urban water agencies the less environmental impacts there would be on drainage impaired lands of the San Joaquin Valley, a neutral to beneficial impact of the Project's operation on high groundwater and drainage to the SJR.
- However, the more Project water goes to agricultural users than to urban users, the higher would be groundwater levels, and more contaminated the groundwater would be in the western San Joaquin Valley and the more the San Joaquin River would be negatively affected from contaminated seepage and tailwater by operation of the Project.

The EA fails to provide a map indicating where the cumulative sources of the Project are located, and where the service areas are to which water would be transferred under the 2010-2011 Water Transfer Program.

Two issues concerning water rights are raised by this EA/FONSI:

- **Consolidated Place of Use.** Full disclosure of what the consolidated places of use for DWR and USBR would be, since the permit request to SWRCB will need NEPA coverage. Why is the flexibility claimed for the consolidated place of use necessary to this year's water transfer program? Couldn't the transfers be facilitated through transfer provisions of the Central Valley Project Improvement Act? Will the consolidation be a permanent or temporary request be limited to the duration of the governor's 2009 emergency declaration or of just the 2010-2011 Water Transfer Program? When is the 2010-2011 Water Transfer Program scheduled to sunset? How do the consolidated place of use permit amendments to the SWP and CVP permits relate to their joint point of diversion? Why doesn't simply having the joint point of diversion in place under D-1641 suffice for the purpose of the Project?
- **Description of the water rights of both sellers and buyers.** This would necessarily show that buyers clearly possess junior water rights as compared with those of willing sellers. Lack of full disclosure of these disparate rights is needed to help explain the actions and motivations of buyers and sellers in the 2010-2011 Water Transfer Program, otherwise the public and decision makers have insufficient information on which to support and make informed choices.
    - **Sacramento Valley water rights** – correlative groundwater rights, riparian rights and CVP settlement contract rights
    - **San Joaquin Valley water rights** – CVP contract rights only, junior-most contractors within the CVP priority system (especially Westlands Water District).
    - **Priority of allocations among water contractors within the CVP and SWP.**

To establish a proper legal context for these water rights, the Project Action Alternative section of the EA/FONSI should also describe more extensively the applicable California Water Code sections about the treatment of water rights involved in water transfers.

Thus, there are many avenues by which the 2010-2011 Water Transfer Program is a poorly specified program for NEPA and CEQA purposes, leaving assessment of its environmental effects at best murky, and at worst, risky to all involved, especially users of Sacramento Valley groundwater resources.

B. Correcting the EA's poorly specified chains of cause and effect forces consideration of an expanded range of alternatives.

The Proposed Action Alternative need not have sophisticated forecasts of prices for rice and other commodities. Instead, for an adequate treatment of alternatives, the EA should have examined several reasonable scenarios beyond simply the 2010-2011 Water Transfer Program and a "no action" alternative. Three reasonable permutations would have considered relative proportions of crop idling versus groundwater substitution (e.g., high/low, low/high, and equal proportions of crop idled water and groundwater substitution). Other reasonable drought response alternatives that can meet operational and physical concerns merit consideration and analysis by the Bureau includes:

- Planned permanent retirement of upslope lands in the western San Joaquin Valley where CVP-delivered irrigation water is applied to lands contaminated with high concentrations of selenium, boron and mercury, and which contribute to high water table and drainage problems for lowland farmers, wetlands and tributaries of the San Joaquin River. Retirement of these lands would permanently free up an estimated 3 million acre-feet of state and federal water during non-critical water years. Ending irrigation of these lands would also result in substantial human environmental benefits for the San Joaquin River, the Bay-Delta Estuary, and the Suisun Marsh from removal of selenium, boron, and salt contamination. Having such reasonable and pragmatic practices in place would go a long way to eliminate the need for drought water banks in the foreseeable future.
- More aggressive investment in agricultural and urban water conservation and demand management among CVP and SWP contractors even on good agricultural lands, including metering of all water supply hook-ups by all municipal contractors, statewide investment in low-flush toilets and other household and other buildings' plumbing fixtures, and increased capture and reuse of recycled water. Jobs created from such savings and investments would represent an economic stimulus that would have lasting job and community stability benefits as well as lasting benefits for water supply reliability and environmental stabilization.

C. The 2010-2011 Water Transfer Program EA fails to specify adequate environmental baselines, or existing conditions, against which impacts would be assessed and mitigation measures designed to reduce or avoid impacts.

The 2010-2011 Water Transfer Program environmental review by the Bureau incorporate by reference for specific facets of their review the 2003/2004 and 2007/2008 Environmental Water Account EIS/R documents. In both cases, these environmental reviews were conducted on a program whose essential purpose is to "provide protection to at-risk native fish species of the Bay-Delta estuary through environmental beneficial changes in State Water Project/Central Valley Project operations at no uncompensated water cost to the Projects' water users. This approach to fish protection involves changing Project operations to benefit fish and the acquisition of alternative sources of project water supply, called the 'EWA assets,' which the EWA agencies use to replace the regular Project water supply lost by pumping reductions."

The two basic sets of actions of the EWA were to:

- Implement fish actions that protect species of concern (e.g., reduction of export pumping at the CVP and SWP pumps in the Delta); and

- Increase water supply reliability by acquiring and managing assets to compensate for the effects of the fish actions (such as by purchasing water from willing sellers for instream flows that compensates the sellers for foregone consumptive use of water).

Without going into further detail on the EWA program, there is no attempt by the EWA agencies to characterize its environmental review as reflective of water transfer programs generally; the EWA was a specific set of strategies whose purpose was protection of fish species of concern in the Delta, not drought aid for junior water right-holding areas of California. One consequence of this attempt to rely on the EWA EIS/R is that it makes the public's ability to understand the environmental baseline of the 2010-2011 Water Transfer Program impossible, because environmental baselines, differing purpose and need for the project, and many relevant mitigation measures are not readily available to the public. Merely referring to the EWA documents (e.g.) p. 3-47) mocks NEPA and CEQA missions to inform the public adequately about the environmental setting and potential impacts of the proposed project's actions. Moreover, a Water Transfer Program for urban and agricultural sectors is plainly not the same thing as an Environmental Water Account.

Another consequence is that the chains of cause and effect of an EWA versus a 2010-2011 Water Transfer Program are entirely different because of their different purposes. While the presence of water purchases, willing sellers, and requesting buyers is similar, the timing of EWA water flows are geared to enhancing and protecting fish populations; the water was to flow in Delta channels to San Francisco Bay and the Pacific Ocean. In stark contrast, the DWB's water flows focus water releases from the SWP and CVP reservoirs to be exported for deliveries in the July through September period, whereas EWA assets would be "spent" year-round depending on the specific need to protect fish. EWA was about purchasing water to provide instream flows in the Delta, while the DWB is to acquire water to serve consumptive uses outside of the Delta.

Furthermore, to tease out the various ways in which the EWA review—itself a two-binder document consisting of well over 1,000 pages—could be used to provide appropriate environmental compliance for the DWB is not even attempted by DWR and the Bureau which at least has staff that could have been assigned to undertake it; yet they do not. It is therefore well beyond the reach of non-expert decision-makers and the public, and the use of the EWA EIS/R as the basic environmental review for the DWB therefore violates both NEPA and CEQA.

Nor is any attempt made in the EWA EIS/R to characterize the EWA as a "program level" environmental review off of which a Water Transfer Program-like project could perhaps legitimately tier. In our view, this reliance on the EWA EIS/R obscures the environmental baselines of the DWB from public view, inappropriately conflates the purposes of two distinct environmental reviews, and flagrantly violates NEPA and CEQA. This could only be redressed by preparation of an EIS/R on the 2010-2011 Water Transfer Program.

Finally, the most significant baseline condition omitted in the Bureau's inadequate and DWR's negligent reporting relates to Sacramento Valley groundwater resources, discussed in the next section.

D. Scientific uncertainties and controversy about Sacramento Valley groundwater resources merit consideration that only an EIS can provide.

There is substantial evidence that the 2010-2011 Water Transfer Program may have significant impacts on the aquifer system underlying the project and the adjacent region that overlies the Tuscan Formation. This alone warrants the preparation of an EIS.

Additionally, an EIS is necessary where "[a] project['s] … effects are 'highly uncertain or involve unique or unknown risks.'" *Blue Mountains Biodiversity Project*, 161 F.3d at 1213 (quoting 40 C.F.R. §1508.27(b)(5)). Here, the draft EA/FONSI fails to adequately address gaps in existing scientific research on the hydrology of the aquifer system and the extent to which these gaps affect the Bureau's ability—and by logical extension, DWR's ability—to assess accurately the Project's environmental impacts.

1. Existing research on groundwater conditions indicates that the 2010-2011 Water Transfer Program may have significant impacts on the aquifer system.

The EA fails to describe significant characteristics of the aquifers that the 2010-2011 Water Transfer Program proposes to exploit. These characteristics are relevant to an understanding of the potential environmental effects associated with the 2010-2011 Water Transfer Program's potential extraction of up to 154,237 AF of groundwater (p, 2-4 and 3-107). First, the draft EA/FONSI fails to describe a significant saline portion of the aquifer stratigraphy of the 2010-2011 Water Transfer Program area. According to Toccoy Dudley, former Groundwater Geologist with the Department of Water Resources and former director of the Butte County Water and Resources Department, saline groundwater aquifer systems of marine origin underlie the various freshwater strata in the northern counties of Butte, Colusa, Glenn, and Tehama ("northern counties"). The approximate contact between fresh and saline groundwater occurs at a depth ranging from 1500 to 3000 feet. (Dudley 2005) (A list of all references cited in these comments can be found at the end of this letter.)

Second, the EA fails to discuss the pressurized condition of the down-gradient portion of the Tuscan formation, which underlies the northern counties Project area. Dudley finds that the lower Tuscan aquifer located in the Butte Basin is under pressure. "It is interesting to note that groundwater elevations up gradient of the Butte Basin, in the lower Tuscan aquifer system, are higher than the ground surface elevations in the south-central portion of Butte Basin. This creates an artesian flow condition when wells in the central Butte Basin are drilled into the lower Tuscan aquifer." (Dudley 2005). The artesian pressure indicates recharge is occurring in the up-gradient portions of the aquifer located along the eastern margin of the Sacramento Valley.

Third, the EA fails to describe the direction of movement of water through the Lower Tuscan Formation that underlies the northern counties. According to Dudley: "From Tehama County south to the city of Chico, the groundwater flow direction in the lower Tuscan is westerly toward the Sacramento River. South of Chico, the groundwater flow changes to a southwesterly direction along the eastern margin of the valley and to a southerly direction in the central portion of the Butte Basin." (Dudley 2005)

Fourth, the draft EA fails to disclose that the majority of wells used in the Sacramento Valley are individual wells that pump from varying strata in the aquifers. The thousands of domestic wells in the target export area that are vulnerable to groundwater manipulation and lack historic monitoring. The Bureau's 2009 DWB EA elaborated on this point regarding Natomas Central MWC (p. 39) stating that, "Shallow domestic wells would be most susceptible to adverse effects. Fifty percent of the domestic wells are 150 feet deep or less. Increased groundwater pumping could cause localized declines of groundwater levels, or cones of depression, near pumping wells, possibly causing effects to wells within the cone of depression. As previously described, the well review data, mitigation and monitoring plans that will be required from sellers during the transfer approval process will reduce the potential for this effect."

As the latter statement makes clear (even though this information was excluded from the Project EA), the Bureau hopes that individual mitigation and monitoring plans created by the sellers will reduce the potential for impact, but there is no assurance in the EA that it will reduce it to a level of insignificance for the thousands of well owners in the Sacramento Valley. The Coalition questions the adequacy of individual mitigation and monitoring plans and suggests that an independent third party, such as USGS, oversee the mitigation and monitoring program and not the Bureau and DWR. After the fiasco in Butte County during the 1994 Drought Water Bank and with the flimsy, imprecise proposal for mitigation and monitoring in the 2010-2011 Water Transfer Program (see details below), the agencies lack credibility as oversight agencies.

Fifth, the draft EA fails to provide recharge data for the aquifers. Professor Karin Hoover, Assistant Professor of hydrology, hydrogeology, and surficial processes from CSU Chico, found in 2008 that, "Although regional measured groundwater levels are purported to 'recover' during the winter months (Technical Memorandum 3), data from Spangler (2002) indicate that recovery levels are somewhat less than levels of drawdown, suggesting that, in general, water levels are declining." According to Dudley, "Test results indicate that the 'age' of the groundwater samples ranges from less than 100 years to tens of thousands of years. In general, the more shallow wells in the Lower Tuscan Formation along the eastern margin of the valley have the 'youngest' water and the deeper wells in the western and southern portions of the valley have the 'oldest' water," adding that "the youngest groundwater in the Lower Tuscan Formation is probably nearest to recharge areas." (Dudley 2005). "This implies that there is currently no active recharge to the Lower Tuscan aquifer system (M.D. Sullivan, personal communication, 2004)," explains Dr. Hoover. "If this is the case, then water in the Lower Tuscan system may constitute fossil water with no known modern recharge mechanism, and, once it is extracted, it is gone as a resource," (Hoover 2008).

All of these aquifer characteristics are important to a full understanding of the environmental impacts of the 2010-2011 Water Transfer Program because there are numerous indications that other aquifer strata associated with the Lower Tuscan Formation are being operated near the limit of overdraft and could be affected by the 2010-2011 Water Transfer Program (Butte County 2007). The Bureau has not considered this important historic information in the draft EA. According to Dudley, the Chico area has a "*long term average decline in the static groundwater level of about 0.35 feet-per-year*." (2007) (emphasis added.) Declining aquifer levels are not limited to the Chico Municipal area. This trend of declining aquifer levels in Chico, Durham and the Cherokee Strip is illustrated in a map submitted with this comment letter (CH2M Hill 2006).

Declining groundwater elevations have been observed specifically in Butte County. A 2007 Butte Basin Groundwater Status Report describes the "historical trend" in the Esquon Ranch area as showing "seasonal fluctuation (spring to fall) in groundwater levels of about 10 to 15 feet during years of normal precipitation and less than 5 feet during years of drought." The report further notes: "Long-term comparison of spring-to-spring groundwater levels shows a decline of approximately 15 feet associated with the 1976-77 and 1986-94 droughts (Butte Basin Water Users Association, 2007). The 2008 report indicates that, "The spring 2008 groundwater level measurement was approximately three feet higher than the 2007 measurment, however it was still four feet lower than the average of the previous ten spring measurements. Fall groundwater levels are approximately nine feet lower than the averages of those measured during either of the previous drought periods on the hydrograph. At this time it appears that there may be a downward trend in groundwater levels in this well," (Butte Basin Water Users Association, 2008).Thus, "*it appears that there may be a downward trend in groundwater levels in this well*." *Id.* (emphasis added).

Groundwater elevations in the Pentz sub-area in Butte County also reveal significant historical declines. The historical trend for this sub-area "…shows that the average seasonal fluctuation (spring to fall) in groundwater levels averages about 3 to 10 feet during years of normal precipitation and approximately 3 to 5 feet during years of drought. Long-term comparison of spring-to-spring groundwater levels shows a decline in groundwater levels during the period of 1971-1981, perhaps associated with the 1976-77 drought. Since a groundwater elevation high of approximately 145 feet in 1985 the measured groundwater levels in this well have continued to decline. Recent groundwater level measurements indicate that the groundwater elevation in this well is approximately 15-25 feet lower than the historical high in 1985. *Id.* Water elevations at the Pentz sub-area well have been monitored since 1967. "Since 1985 spring groundwater levels in this well have been declining and the spring 2009 measurement hit an historic low level ten feet below historical high levels and continues the downward trend on the hydrograph." *Id.* The Pentz area is located east of U.S. 99, in the eastern, upslope portion of the Tuscan aquifer. Further evidence of changing groundwater levels appear in the Vina sub-region of Butte County, where water elevations have been monitored since 1947 at well 23N/01W09E001M . The historical averages, including 2008 data, are; Spring=156 feet and Fall=150 feet (Butte County p. 37-38). Unfortunately, the groundwater level measurement at this well in 2008 was the lowest recorded since 1994 (Butte County p. 38). Rock Creek, which is also in the Vina sub-unit once held water all year and salmon fishing was robust prior to the 1930s (Hennigan 2010). Declining groundwater levels have caused the valley portion of Rock Creek to run completely dry each year and have also been noticed with Hennigan Farms' wells since the 1960s. For example, a 1968 well had to be lowered 40 feet in 1974, another well constructed in 1978 had to be lowered 20 feet in 2009, and an old 1940s flood pump was lowered in the early 1960s, lowered again in 1976 when it was converted to a pressure pump, and lowered again in 1997 (Hennigan 2010).

In light of this downward trend in regional groundwater levels, the Bureau's EA should closely analyze replenishment of the aquifers affected by the proposed 2010-2011 Water Transfer Program. The draft EA fails to provide any in-depth assessment of these issues. For example, the EA fails to discuss the best available estimates of where groundwater replenishment occurs. Lawrence Livermore National Laboratory analyzed the age of the groundwater in the northern counties to shed light on this process: "Utilizing the Tritium (H3) Helium-3 (He3) ratio, the age of each sample was estimated. Test results indicate that the "age" of the groundwater samples ranges from less than 100 years to tens of thousands of years,: (Dudley et al. 2005). As mentioned above, Dudley opines that the youngest groundwater in the Lower Tuscan Formation is probably nearest to recharge areas. (2005).

Are isotopic groundwater data available for other regions in the Sacramento Valley? If so, they would be crucial for all concerned to understand the potential impacts from the proposed 2010-2011 Water Transfer Program. For example, the EA states, "The WFA area that could be affected by the proposed action includes only the 'North Area' bounded on the north and east by the Sacramento County line, by the Sacramento River on the west, and by the American River on the south." EA at p. 34. If this is the area in Sacramento County that is identified as most vulnerable to groundwater impacts, yet two major rivers surround it, shouldn't the Bureau understand the hydrologic relationship between the groundwater basin and the rivers? If that understanding exists, where is it presented in the EA? It is well known that the Sacramento River is already a losing river south of Princeton.

The City of Sacramento proposes to transfer surface water into the state water market and substitute 3,000 AF of groundwater (EA p.2-4), but the *Sacramento County Water Agency Water Management Plan* indicates that intensive use of this groundwater basin has resulted in a general lowering of groundwater elevations that will require extensive conservation measures to remediate. The Sacramento County Water Agency has devised a plan to help lead the city to a sustainable groundwater use to avoid problems associated with unrestrained overuse. The most reliable strategy is to reduce demand. Integrating the City's water supply into the state water supply would obviously increase demand and make the SCWA goals impossible to achieve.

The Bureau should prepare an EIS that discloses the fallacies inherent in its policies and actions. The need for almost 400,000 AF of water south of the Delta springs from failed business planning. The Bureau and DWR must acknowledge this and further disclose that their agencies are willing to socialize the risks taken by corporate agribusiness and developers while facilitating private profit. Instead of asking northern California water districts and municipal water purveyors to place their own water at risk as well as the water of their neighboring communities and thousands of residential well owners, water quality, fisheries, recreation, stream flow, terrestrial habitat, and geologic stability, the Bureau and DWR must disclose all the uncertainty in the 2010-2011 Water Transfer Program and then evaluate the risks with scientific methodology. This has clearly not been done.

2. The 2010-2011 Water Transfer Program proposes to rely on inadequate monitoring and mitigation to avoid the acknowledged possibility of significant adverse environmental impacts.

The draft EA and the Draft Technical Information for Water Transfers in 2010 referenced in the EA (Bureau and DWR 2009) require "willing sellers" to prepare individual monitoring and mitigation plans and to conduct the monitoring with oversight provided by the Bureau and DWR (p. 3-24 and 3-25). This fails to provide the most basic framework for governmental authority to enforce the state's role as trustee of the public's water in California, let alone a comprehensive and coordinated structure, for a very significant program that could transfer up to 154,239 AF of water from the Sacramento Valley. (Recall that DWR believes it has environmental compliance coverage for up to 600,000 AF of water sales from the Sacramento Valley, including 340,000 AF in groundwater substitution alone under the Governor's 2009 emergency exemption) The draft EA further defers responsibility to "willing sellers" for compliance with local groundwater management plans and ordinances to determine when the effects of the proposed extraction become "adverse," (p. 3-25). "Each district will be required to confirm that the proposed groundwater pumping will be compatible with state and local regulations and groundwater management plans," (EA at p. 3-25). It is not acceptable that the draft EA and the Draft Technical Information for Water Transfers in 2010 merely provide monitoring direction to "willing sellers" without identifying rigorous standards for the risks at hand, specific actions, acceptable monitoring and reporting entities, or funding that will be necessary for this oversight.

The Coalition proposes instead that the Bureau and DWR require, at a minimum, that local governments select independent third-party monitors, who are funded by surcharges on Project transfers paid by the buyers, to oversee the monitoring that is proposed in lieu of Bureaus and DWR staff, and that peer reviewed methods for monitoring be required. If this is not done, the Project's proposed monitoring is insufficient and cannot justify the significant risk of adverse environmental impacts.

For example, the EA and the Draft Technical Information for Water Transfers in 2010 fail to identify standards that would be used to monitor the 2010-2011 Water Transfer Program's impacts. It fails to identify any specific monitoring protocols, locations (particularly in up-gradient recharge portions of the groundwater basins), and why chosen locations should be deemed effective for monitoring the effects of the proposed groundwater extraction. It also fails to describe how the objectives in the Draft Technical Information for Water Transfers in 2010 will be met and by whom (EA at p.3-24 and 3-25). Moreover, it fails to provide a mitigation strategy for review and comment by the public, but defers this vital mitigation planning effort to future documents created by "willing sellers," (EA at p.3-24 and 3-25) despite the fact that the EA acknowledges the potential for significant impacts. For example:

- Surface water and groundwater interact on a regional basis, and, as such, gains and losses to groundwater vary significantly geographically and temporally. In areas where groundwater levels have declined, such as in Sacramento County, streams that formerly gained water from groundwater now lose water to the groundwater system through seepage (EA at p. 3-12).
- . *Groundwater substitution transfers would alter ground water levels and potentially affect natural and managed seasonal wetlands and riparian communities, upland habitats and wildlife species depending on these habitats.* As a part of groundwater substitution transfers, the willing sellers would use groundwater to irrigate crops and decrease use of surface water. Pumping additional groundwater would decrease groundwater levels in the vicinity of the sellers' pumps. Natural and managed seasonal wetlands and riparian communities often depend on surface water/groundwater interactions for part or all of their water supply. Under the Proposed Action, subsurface drawdown related to groundwater substitution transfers could result in hydrologic changes to nearby streams and marshes, potentially affecting these habitats. Reduced groundwater elevations could also affect trees that access groundwater as a source of water through taproots in addition to extensive horizontal roots that use soil moisture as a water source. Decreasing groundwater levels could reduce part of the water base for species within these habitats (EA at p. 3-53 and 3-54).

The reader is directed to the Draft Technical Information for Water Transfers in 2010 to discover the minimal objectives and required elements of the monitoring and mitigation component of the Project. "The seller must implement an effective mitigation program to verify and correct problems that could arise due to transfer-related groundwater pumping," but the reader and possibly the sellers are left wondering what exactly is an "effective mitigation plan" since there is no particular guidance to manage and analyze the very complex hydrologic relationships internal to groundwater and connected to surface waters. Certainly the public has no idea or ability to comment, which fails the full disclosure mandate in NEPA and CEQA. Located on pages 30 and 31 of the Draft Technical Information for Water Transfers in 2010 is a brief list of a "number of potential impacts [that] are sufficiently serious that they must be avoided or mitigated for a project to continue."

- Contribution to long-term conditions of overdraft;
- Dewatering or substantially reducing water levels in nonparticipating wells;
- Measurable contribution to land subsidence;
- • Degradation of groundwater quality that substantially impairs beneficial uses or violates water quality standards; and
- Affecting the hydrologic regime of wetlands and/or streams to the extent that ecological integrity is impaired.

The Draft Technical Information for Water Transfers in 2010 continues with suggestions to curtail pumping lower bowls, and pay higher energy costs to ease the impacts to third party wells owners (p. 30 and 31). While this bone thrown at mitigation is appreciated, the glaring omissions are notable. The Draft Technical Information for Water Transfers in 2010 completely fails to mention, even at a very general level, how individual well owners will determine and prove where the impacts to their wells are coming from, that water quality and health could become a significant impact for impacted wells and users and streams, and that there are no mitigation measures even mentioned for streams and wetlands. There also appears to be no consideration for species monitoring, just “practices” or “conservation measures” to “minimize impacts to terrestrial wildlife and waterfowl,” (Draft Technical Information p. 16). And please disclose why the 2009 DWB Biological Opinion is a reference to guide “specific practices on page 17 of the Draft Technical Information for Water Transfers in 2010.

Another example of the inadequacy of the proposed monitoring is that the draft EA fails to include any coordinated, programmatic plan to monitor stream flow of creeks and rivers located in proximity to the “willing sellers” that will evacuate more water than used historically. The potential for immediate impacts would be very close to water sellers’ wells, but the long term impacts could be more subtle and more geographically diverse. What precautions has the Bureau and DWR made for the cumulative impacts that come not only from this two-year Project, but in combination with the water sales from the last three years and those that are planned by the Bureau into the future (see list in g, iv below)? Bureau and DWR water transfers are not just one or two year transfers, but many serial actions in multiple years by the agencies, sellers, and buyers without the benefit of comprehensive environmental analysis under NEPA and CEQA.

As discussed above, adequate monitoring is vital to limit the significant risks posed by the Project to the health of the region’s groundwater, streams, and fisheries (more discussion below). One unfortunate example is the EA’s focus on groundwater substitution impacts that reflect the priority for water accounting and payment accuracy as opposed to the impacts to the groundwater system and streams. “The implementation of groundwater substitution pumping can lower the groundwater table and may change the relative difference between the groundwater and surface water levels. This change has a direct impact on the volume that a seller receives credit for being transferred,” (EA p.3-22 and 3-23). Moreover, to the extent this Project is conceived as a two-year drought or hardship program that will provide knowledge for future groundwater extraction and fallowing, its failure to include adequate monitoring protocols is even more disturbing and creates the risk of significant long-term and even irreversible impacts from the Project.

a. The Bureau’s assertion that the Project may be modified or halted in the event of significant adverse impacts to hydrologic resources is an empty promise in light of the wholly inadequate monitoring provided for in the 2010-2011 Water Transfer Program. Knowing that the Bureau and DWR knowingly violated the X2 standard in the Delta in February 2009 does little to instill confidence from the Coalition in non-specific program and mitigation criteria.

The EA repeatedly illustrates that there is potential for significant injury to other groundwater users, water quality, streams, flora and fauna, and the soil profile (p. 3-12, 3-23, 3-24, 3-53, 3-54). Chapter three contains numerous examples that illustrate the need for an EIS since there is insufficient, comprehensive planning for, let alone preparation to mitigate, adverse environmental impacts:

- *Acquisition of water via groundwater substitution or cropland idling would change the rate and timing of flows in the Sacramento River compared to the No Action Alternative.*
- *In Figure 3.2-2, groundwater substitution pumping results in a change in the groundwater/surface water interaction characteristics. In this case, the water pumped from a groundwater well may have two impacts that reduce the amount of surface water compared to pre-pumping conditions. These mechanisms are:*
    - *Induced leakage. The lowering of the groundwater table causes a condition where the groundwater table is lower than that the water level in the surface water. This conditions causes leakage out of the surface water.*
    - *Interception of groundwater. The placement of groundwater substitution pumping may intercept groundwater that may normally have discharged to the surface water (i.e., water that has already percolated into the ground may be pumped out prior the water reaching the surface water and being allowed to enter the "gaining" stream).*
- *The changes in groundwater flow patterns (e.g., direction, gradient) due to increased groundwater substitution pumping may result in changes in groundwater quality from the migration of reduced quality water.*
- *Groundwater substitution transfers would alter ground water levels and potentially affect natural and managed seasonal wetlands and riparian communities, upland habitats and wildlife species depending on these habitats.*
- *Rice land idling transfers would reduce habitat and forage for resident and migratory wildlife populations.*
- *Water transfers could change reservoir releases and river flows and potentially affect special status fish species and essential fish habitat.*
- *Water transfers could affect fisheries and aquatic ecosystems in water bodies, including Sacramento and American River systems, the Sacramento-San Joaquin Delta, San Luis Reservoir, and DWR and Metropolitan WD reservoirs in southern California.*
- *Increased groundwater pumping for groundwater substitution transfers would increase emissions of air pollutants.*

The Bureau thus recognizes the potential for significant decline in groundwater levels as a result of the proposed activity (EA at p. 3-23, 3-24, 3-53, 3-54). This acknowledgement alone is sufficient to require a full EIS. Moreover, as detailed below, the monitoring proposed by the 2010-2011 Water Transfer Program is so inadequate that there can be no guarantee that adverse impacts will be discovered, or that they will be discovered in time to avoid significant environmental impacts.

Glenn County will have groundwater substitution if the Project moves forward. The County realizes that its management plan may not be sufficient for the challenges presented by this Project and the myriad others and cautions that "[s]ince the groundwater management plan is relatively new and not fully implemented, the enforcement and conflict resolution process has not been vigorously tested," (http://www.glenncountywater.org/management_plan.aspx). Moreover, the Glenn County Groundwater Management Plan does not have any provisions to monitor or protect the environment. The 2010-2011 Water Transfer Program EA fails to disclose the inadequacies of this and other local ordinances and plans.

b. Monitoring based on the Glenn County Groundwater Management Plan is inadequate. Since the Bureau omitted discussion of the Glenn County Groundwater Management Plan in the 2010-2011 Water Transfer Program, we refer to the language used in the 2008 Stony Creek Fan EA/FONSI that explained that the existing Glenn County groundwater management plan will ensure the testing project will have no significant adverse effects on groundwater levels: "This Finding of No Significant Impact (FONSI) is based upon the following: … Implementation of the Glenn County Groundwater Management Plan during the aquifer performance testing plan will ensure that the proposed action will not result in any significant adverse effect to existing groundwater levels." Stony Creek Fan EA/FONSI at p. 2.

But the Butte County Department of Water and Resource Conservation explains that local plans are simply not up to the task of managing a regional resource:

> *Glenn County does not have an export ordinance because it relies on Basin Management Objectives (BMO) to manage the groundwater resource, and subsequently to protect third parties from transfer related impacts. Recently, Butte County also adopted a BMO type of groundwater management ordinance. Butte County, Tehama County and several irrigation districts in each of the four counties have adopted AB3030 groundwater management plans. All of these groundwater management activities were initiated prior to recognizing that a regional aquifer system exists that extends over more than one county and that certain activities in one county could adversely impact another. Clearly the current ordinances, AB3030 plans, and local BMO activities, which were intended for localized groundwater management, are not well suited for management of a regional groundwater resource like that theorized of the Lower Tuscan aquifer system.*

(Butte County DWRC 2007)[4]

c. The EA fails to propose real time monitoring for land subsidence. Third-party independent verification, perhaps by scientists from the U.S. Geological Survey, should be incorporated by DWR and the Bureau into the project description of the 2010-2011 Water Transfer Program. We applaud the initiation of a regional GPS network in the Sacramento

---

Valley, but remain concerned about the 13 existing extensometers in the Sacramento Valley that measure land subsidence, and a Global Positioning System land subsidence network established by one county (EA p. 13). The remaining responsibility is again deferred to the "willing sellers." Unfortunately, voluntary monitoring by pumpers does not strike us as a responsible assurance given the substantial uncertainties involved in regional aquifer responses to extensive groundwater pumping in the Sacramento Valley.

Not only is there a failure to discuss real time monitoring for subsidence, there also is no discussion regarding delayed subsidence that should also be monitored according to the findings of Dr. Kyran Mish, Presidential Professor, School of Civil Engineering and Environmental Science at the University of Oklahoma. Dr. Mish notes: "It is important to understand that *all* pumping operations have the potential to produce such settlement, and when it occurs with a settlement magnitude sufficient enough for us to notice at the surface, we call it *subsidence*, and we recognize that it is a serious problem (since such settlements can wreak havoc on roads, rivers, canals, pipelines, and other critical infrastructure)," (Mish 2008).. Dr. Mish further explains that "[b]ecause the clay soils that tend to contribute the most to ground settlement are highly impermeable, their subsidence behavior can continue well into the future, as the rate at which they settle is governed by their low permeability." *Id.* "Thus simple real-time monitoring of ground settlement can be viewed as an *unconservative* measure of the potential for subsidence, as it will generally tend to underestimate the long-term settlement of the ground surface." *Id.* (emphasis added).

The EA acknowledges the existence and cause of serious subsidence in one area of the valley. "The area between Zamora, Knights Landing, and Woodland has been most affected (Yolo County 2009). Subsidence in this region is generally related to groundwater pumping and subsequent consolidation of aquifer sediments," (EA p. 3-13). This fact alone illustrates the need for more extensive analysis throughout the export area in an EIS.

d. The 2010-2011 Water Transfer Program EA fails to require streamflow monitoring. The 2009 DWB EA/FONSI deferred the monitoring and mitigation planning to "willing sellers," but even that requirement has been completely eliminated. We can't emphasize enough the importance of frequent and regular streamflow monitoring by either staff of the project agencies or a third, independent party such as the USGS, paid for by Project transfer surcharges mentioned above. It is clear from existing scientific studies and the EA that the Project may have significant impacts on the aquifers replenishment and recharging of the aquifers, so the 2010-2011 Water Transfer Program should therefore require extensive monitoring of regional streams. The radius for monitoring should be large, not the typical two to three miles as usually used by DWR and the Bureau. Though not presented for the 2010-2011 Water Transfers Program, the *Stony Creek Fan Aquifer Performance Testing Plan,* which is a much smaller project, recognized that there may be a drawdown effect on the aquifer by considering results from a DWR Northern District spring 2007 production well test (EA/FONSI p. 28). However, it did not assess the anticipated scope of that effect—or even what level of effect would be considered acceptable. Moreover, the results from that test well indicate that the recharge source for the solitary production well "is most likely from the foothills and mountains, to the east and north"—which at a minimum is more than fifteen miles away. (DWR, Glenn-Colusa Irrigation District Aquifer Performance Testing Glenn County, California).

The Butte County Department of Water and Resource Conservation have identified streams that must be monitored to determine impacts to stream flows that would be associated with pumping the Lower Tuscan Aquifer. These "[s]treams of interest" are located on the eastern edge of the Sacramento Valley and include: Mill Creek, Deer Creek, Big Chico Creek, Butte Creek, and Little Dry Creek (The Butte County DWRC 2007). The department described the need and methodology for stream flow gauging:

> *The objective of the stream flow gaging is to determine the volume of surface water entering into or exiting the Lower Tuscan Aquifer along perennial streams that transect the aquifer formation outcropping for characterization of stream-aquifer interactions and monitoring of riparian habitat. Measurement of water movement into or out of the aquifer will allow for testing of the accuracy of the Integrated Water Flow Model, an integrated surface water-groundwater finite differential model developed for the eastern extent of the Lower Tuscan aquifer.*
>
> *Two stream gages will be installed on each of five perennial streams crossing the Lower Tuscan Formation to establish baseline stream flow and infiltration information. The differences between stream flow measurements taking upstream and downstream of the Lower Tuscan Formation are indications of the stream-aquifer behavior. Losses or gains in stream volume can indicate aquifer recharge or discharge to or from the surface waters.*
> *Id.*

As evident in the following conclusory assertions, the draft EA/FONSI fails to define the radius of influence associated with the aquifer testing and thus entirely fails to identify potential significant impacts to salmon:

> "An objective in planning a groundwater substitution transfer is to ensure that groundwater levels recover to their typical spring high levels under average hydrologic conditions. Because groundwater levels generally recover at the expense of stream flow, the wells used in a transfer should be sited and pumped in such a manner that the stream flow losses resulting from pumping peak during the wet season, when losses to stream flow minimally affect other legal users of water," (EA p. 2-7).

As mentioned above, streamflow monitoring is not a requirement of the Project, which is unfathomable. Monitoring of flow on streams associated with the Lower Tuscan Formation is particularly important to the survival of Chinook salmon which use these "streams of interest" to spawn and where salmon fry rear. Intensive groundwater pumping would likely lower water table elevations near these streams of interest, decreasing surface flows, and therefore reducing salmon spawning and rearing habitat through dewatering of stream channels in these northern counties. This would be a significant adverse impact of the Project and is ignored by the EA.

A similar effect has been observed in the Cosumnes River, where "[d]eclining fall flows are limiting the ability of the Cosumnes River to support large fall runs of Chinook salmon," (Fleckenstein, et al 2004). This is a river that historically supported a large fall run of Chinook Salmon. *Id.* Indeed, "[a]n early study by the California Department of Fish and Game . . . estimated that the river could support up to 17,000 returning salmon under suitable flow conditions." *Id.*, citing CDFG 1957 & USFWS 1995. But "[o]ver the past 40 years fall runs ranged from 0 to 5,000 fish according to fish counts by the CDFG (USFWS 1995)," and "[i]n recent years, estimated fall runs have consistently been below 600 fish, according to Keith Whitener," (Fleckenstein, *et al*. 2004). Indeed, "[f]all flows in the Cosumnes have been so low in recent years that the entire lower river has frequently been completely dry throughout most of the salmon migration period (October to December)." *Id.*

Research indicates that "groundwater overdraft in the basin has converted the [Cosumnes River] to a predominantly losing stream, practically eliminating base flows…." (Fleckenstein, *et al*. 2004). And "investigations of stream-aquifer interactions along the lower Cosumnes River suggest that loss of base flow support as a result of groundwater overdraft is at least partly responsible for the decline in fall flows." *Id.* Increased groundwater withdrawals in the Sacramento basin since the 1950s have substantially lowered groundwater levels throughout the county." *Id.*

The draft EA acknowledges the potential for impacts to special status fish species from altered river flows and commits to maintaining flow and temperature requirements already in place (p. 3-59). The coalition would like to have greater assurance of a commitment considering that the Bureau and DWR failed to meet the X2 standard in February 2009. The Bureau and DWR should make X2 compliance and streams of interest monitoring in real time part of their permit amendment applications to the SWRCB this spring. If stream levels are affected by groundwater pumping, then pumping would cease.

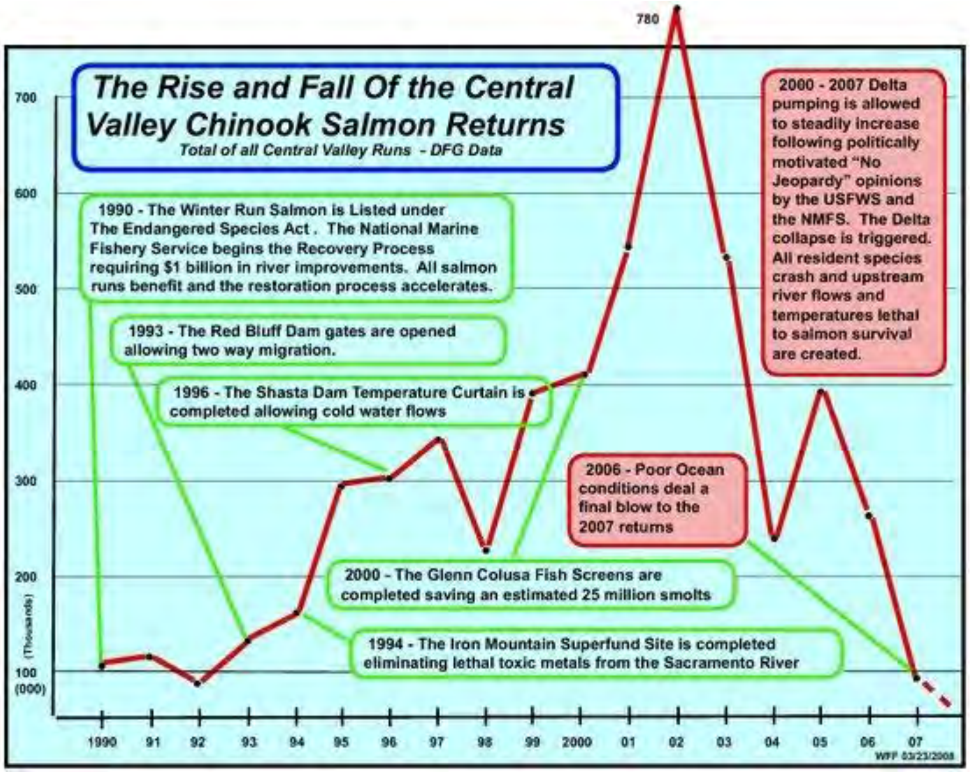
Unfortunately, the draft EA fails to anticipate possible stream flow declines in important salmon rearing habitat in the 2010-2011 Water Transfer Program area. Many important streams, such as Mud Creek, are located within the 2010-2011 Water Transfer Program and flows through probable Tuscan recharge zones, yet are not mentioned in the EA (also see comments above regarding Rock Creek). While a charged aquifer is likely to add to base flow of this stream, a de-watered aquifer would pull water from the stream. According to research conducted by Dr. Paul Maslin, Mud Creek provides advantageous rearing habitat for out-migrating Chinook salmon (1996). Salmon fry feeding in Mud Creek grew at over twice the rate by length as did fry feeding in the main stem of the Sacramento River. *Id.*

Another tributary to the Sacramento River, Butte Creek, hosts spring-run Chinook salmon, a threatened species under the Endangered Species Act. 64 Fed. Reg. 50,394 (Sept. 16, 1999).

Butte Creek contains the largest remaining population of the spring-run Chinook and is designated as critical habitat for the species. *Id*. at 50,399; 70 Fed. Reg. 52,488, 52,590-91 (Sept. 2, 2005). Additionally, Butte Creek provides habitat for the threatened Central Valley steelhead. *See* 63 Fed. Reg. 13,347 (Mar. 19, 1998); 70 Fed. Reg. at 52,518. While Butte Creek is mentioned in the EA (p. 2-11, 3-4, 3-49, 3-57), the only protection afforded this vital tributary are statements that cropland idling will not occur adjacent to it, yet that is contradicted on page 3-19. The Bureau should not overlook the importance of rearing streams, and should not proceed with this Project unless and until adequate monitoring and mitigation protocols are established.

Existing mismanagement of water in California's rivers, creeks, and groundwater has already caused a precipitous decline in salmon abundance. There is no mention of the fall-run salmon numbers in the main stem Sacramento River or its essential tributaries despite the fact that their numbers dropped precipitously in 2007 (see graphic below) 2008, and 2009. After the commercial salmon fishery was closed for two years for fear of pushing these fish to extinction, scientists are waiting until February 2010 to determine if the commercial and sport fishing seasons will open this year. As noted above, the EA casually asserts that maintaining flow and temperature requirements in the main stem will be sufficient to protect aquatic species, but it fails to consider the impacts of almost 400,000 AF of water transfers, fallowing, and groundwater substitution on the tributaries. How much additional pumping does the Project represent, given CVP and SWP contractual commitments, available reservoir supplies, and other environmental restrictions south of the Delta? The EA and DWR's missing environmental review are silent on this.

Where are the data to support assertions that impacts to aquatic species will be below a level of significance? Habitat values are also essential to many other special status species that utilize the aquatic and/or riparian landscape including, but not limited to, giant garter snake, bank swallow, greater sandhill crane, American shad, etc. Where is the documentation of the potential impacts to these species?



Graphic is courtesy of Dick Pool.

In addition to the direct decline in the salmon populations is the food chain affect that will influence species such as killer whales.

3. The EA fails to address the significant unknown risks raised by the 2010-2011 Water Transfer Program's proposed groundwater extraction.

The EA fails to identify and address the significant unknown risks associated with this Project. There are substantial gaps in scientists' understanding of how the aquifer system recharges.

The EA fails to reveal the scientifically known and unknown characteristics of the Lower Tuscan aquifer. Expert opinion and experience is offered by Professor Karin Hoover from CSU Chico who asserts that: "[T]o date there exists no detailed hydrostratigraphic analysis capable of distinguishing the permeable (water-bearing) units from the less permeable units within the subsurface of the Northern Sacramento Valley. In essence, the thickness and extent of the water-bearing units has not been adequately characterized." (p. 1)

Though the Project fails to disclose the limitations in knowledge of the geology and hydrology of the northern counties, it was disclosed in 2008 in the EA for the *Stony Creek Fan Aquifer Performance Testing Plan* (Testing Plan EA). It revealed that there is also limited understanding of the interaction between the affected aquifers, and how that interaction will affect the ability of the aquifers to recharge. The Testing Plan EA provides:

> *The Pliocene Tuscan Formation lies beneath the Tehama Formation in places in the eastern portion of the SCF Program Study Area, although its extent is not well defined. Based on best available information, it is believed to occur at depths ranging between approximately 300 and 1,000 feet below ground surface. It is thought to extend and slope upward toward the east and north, and to outcrop in the Sierra Nevada foothills. The Tuscan Formation is comprised of four distinct units: A, B C and D (although Unit D is not present within the general project area). Unit A, or Upper Tuscan Formation, is composed of mudflow deposits with very low permeability and therefore is not important as a water source. Units B and C together are referred to as the Lower Tuscan Formation. Very few wells penetrate the Lower Tuscan Formation within the SCF Program study area.*

(The Testing Plan EA/FONSI at p. 23). The Tehama Formation, however, generally behaves as a semi-confined aquifer system and the EA contains no discussion of its relationship with the adjoining formations. Nor is there any discussion of the role of the Pliocene Tehama Formation as "the primary source of groundwater produced in the area," (DWR 2003).

The EA fails to offer any in-depth analysis of which strata in the aquifers will be most likely affected by the 2010-2011 Water Transfer Program's proposed extraction of groundwater. Thousands of domestic wells are in the upper layers of the aquifers are not even considered in the EA. In addition, the EA provides no assessment of the interrelationship of varying strata in the aquifers in the Sacramento Valley or between the aquifers themselves.

The EA fails to provide basic background information regarding the recharge of groundwater. The documents states, "Groundwater is recharged by deep percolation of applied water and rainfall infiltration from streambeds and lateral inflow along the basin boundaries," (EA p. 3-10). How was the conclusion reached that applied water leads to recharge of the aquifer? Where are the supporting data? This claim is unsubstantiated by any of the work that has been performed to date. For example, the RootZone water balance model used by a consultant with Glenn Colusa Irrigation District, Davids Engineering, was designed to simulate root zone soil moisture. It balances incoming precipitation and irrigation against crop water usage and evaporation, and whatever is left over is assigned to "deep percolation." Deep percolation in this case means below the root zone, which is anywhere from a few inches to several feet below the surface, depending on the crop. There is absolutely no analysis that has been performed to insure that applied water does, indeed, recharge the aquifer. For example, if the surface soils were to dry out, water that had previously migrated below the root zone might be pulled back up to the surface by capillary forces. In any case, the most likely target of the "deep percolation" water in the Sacramento Valley is the unconfined, upper strata of the aquifer and possibly the Sacramento River. The EA has not demonstrated otherwise.

A public hearing concerning the Monterey Agreement was held in Quincy on November 29, 2007 and hosted by DWR. At the hearing Barbara Hennigan presented the following testimony: "So for the issues of protecting the water quality, protecting the stream flow in the Sacramento, one of the things that we have learned is that the Sacramento River becomes a permanently losing stream at the Sutter buttes. When I first started looking at the water issues that point was at Grimes south of the [Sutter B]uttes, now it is at Princeton, moving north of the buttes. As the Sacramento becomes a losing stream farther and farther north because of loss of the Lower Tuscan Aquifer, that means that it, there will be less water that the rest of the State relies on," (http://www.water.ca.gov/environmentalservices/docs/mntry_plus/comments/Quincy.txt). How and when will the Bureau and DWR address this enormously important condition and amplify the risk to not only the northstate, but the entire State of California?

4. The EA contains numerous errors and omissions regarding groundwater resources.

There are numerous errors, omissions, and negligence in addressing existing conditions before and with the Project in Section 3.2 Groundwater Resources. The failure to address stated problematic conditions and the lack of accuracy in this section of so many elemental issues and facts raises questions about the content of the entire EA and FOSI. A partial list of statements and questions follows.

- On pages 3-10, 3-12, and 3-13 of the EA the Sierra Nevada [mountain range] and "Coast ranges" are identified, but there is no mention of the southern Cascade Range that is a prominent geologic feature of the northern Sacramento Valley and a significant contributor to the hydrology of the region.
- Page 3-12 mentions "major tributaries" to the Sacramento River, but omits the northern rivers the McCloud and the Pit. It also mentions "Stony, Cache, and Putah Creeks," but fails to mention Battle, Mill, Big Chico, and Butte creeks. These omissions again reflect an odd lack of understanding of the Cascade Range.
- The EA states quite straightforwardly on page 3-12 that, "Surface water and groundwater interact on a regional basis, and, as such, gains and losses to groundwater vary significantly geographically and temporally. In areas where groundwater levels have declined, such as in Sacramento County, streams that formerly gained water from groundwater now lose water to the groundwater system through seepage." This knowledge alone requires substantive environmental review under NEPA and CEQA.
- Page 3-12. "Groundwater production in the basin has recently been estimated to be about 2.5 million acre-feet or more in dry years." What is the citation for this assertion?
- Page 3-12. "Historically, groundwater levels in the Basin have remained steady, declining moderately during extended droughts and recovering to pre-drought levels after subsequent wet periods. DWR extensively monitors groundwater levels in the basin. The groundwater level monitoring grid includes active and inactive wells that were drilled by different methods, with different designs, for different uses. Types of well use include domestic, irrigation, observation, and other wells. The total depth of monitoring grid wells ranges from 18 to 1,380 feet below ground surface.". As presented above, groundwater levels have been changing, historically. Since the Bureau and DWR have access to a monitoring grid, for NEPA and CEQA compliance, they must present current facts, not general statements that relate to social science.
- Page 3-12. "In general, groundwater flows inward from the edges of the basin and south parallel to the Sacramento River. In some areas there are groundwater depressions associated with extraction that influence local groundwater gradients." Where are the groundwater depressions? How have they affected groundwater gradients? How will the Project exacerbate a negative existing condition?
- Page 3-12. "Prior to the completion of CVP facilities in the area (1964-1971), pumping along the west side of the basin caused groundwater levels to decline. Following construction of the Tehama-Colusa Canal, the delivery of surface water and reduction in groundwater extraction resulted in a recovery to historic groundwater levels by the mid to late-1990s." Please provide the citation(s).
- Pg 3-15 "According to the SWRCB, there are no elevated concentrations of arsenic or selenium in the Sacramento Groundwater Basin." The GAMA domestic well Project, Tehama County Focus Area, 2009, Arsenic in Domestic and Public Wells indicates variable levels of arsenic in the cited basin. The study found that, "Fourteen percent of

the wells [in the Tehema County focus area] had concentrations of both arsenic and iron above their associated CDPH MCLs or secondary MCLs."

- Page 3-15. "The State Water Code (Section 1745.10) requires that for short term water transfers, the transferred water may not be replaced with groundwater unless the following criteria are met (SWRCB 1999)…" The Project is not a short term water transfer, but a set of serial actions in multiple years by the agencies, sellers, and buyers without the benefit of comprehensive environmental analysis under NEPA and CEQA.
- Page 3-16. "California Water Code Section 1810 and the CVPIA protect against injury to third parties as a result of water transfers. Three fundamental principles include (1) no injury to other legal users of water; (2) no unreasonable effects on fish, wildlife or other in-stream beneficial uses of water; and (3) no unreasonable effects on the overall economy or the environment in the counties from which the water is transferred. These principles must be met for approval of water transfers." The disclosures and analyses contained in the EA, FONSI, and its appendices are inadequate to satisfy the California Water Code requirements and the Bureau's requirements under NEPA. DWR has clearly failed its obligations under CEQA by providing no disclosure or analysis.

E. Other resource impacts flowing from corrected chains of cause and effect are unrecognized in the EA and should be considered in an EIS instead.

Regarding surface water reservoir operations in support of the 2010-2011 Water Transfer Program, we have several questions and concerns:

- Regarding fisheries, we note that the Bureau intends to comply with the State Water Resources Control Board's Water Rights Orders 90-05 and 91-01 in order to provide temperature control at or below 56 degrees Fahrenheit for anadromous fish, their redds, and hatching wild salmonid fry, and to provide minimum instream flows of 3,250 cubic feet per second (cfs) between September 1 and February 28, and 2,300 cfs between March 1 and August 31. How will the Bureau and DWR comply with Fish and Game Code Section 5937—to keep fish populations below and above their dams in good condition, as they approve transfers of CVP water from willing CVP contractors to willing buyers? We urge this compliance effort be integrated with the streams of interest and groundwater monitoring programs we recommended above.

- We also find confusing the EA's treatment of instream flows for fisheries. On one hand, minimum flows and temperature criteria established in the above-mentioned water rights orders is to be adhered to by the Bureau for the Sacramento River. The necessity for April and May storage is not well explained.

- Concerning the social and economic effects of the proposed 2010-2011 Water Transfer Program, crop idling transfers will delete fields from production and result in employment impacts on Sacramento Valley's agricultural labor market at a time when the national recession is at its worst. The lack of descriptive information about what crops are to be idled by specific "willing sellers" means that a reasonably plausible estimate of employment impacts in the Sacramento Valley are unavailable, rendering the EA inadequate from this standpoint. Has the Bureau reviewed the President's policies on economic recovery to be certain that its water transfer program that would shift employment impacts from one Valley to another rather than work to increase employment generally is consistent with the intent of the President and Congress? What would be the effects of employment shifting on the poverty rates of Sacramento Valley counties? Such an estimate, provided with basic information about what acreages of specific crops are to be idled, is within the reach of the Bureau to make.

- On its own terms, the Bureau's EA makes no attempt to establish baseline agricultural crop acreages for each agricultural county offering or seeking DWB water in order to calculate and apply its 20 percent threshold for limiting economic impacts to agriculture in selling counties. Moreover, this 20 percent threshold needs to be incorporated into the description of the Proposed Action Alternative, since it appears to be an integral part of DWB actions.

- Regarding public health and safety, the EA negligently denies the potential for impacts (p.3-1). Fluctuating domestic wells can lead to serious contamination from heavy metals and non-aqueous fluids. Additionally, there are numerous hazardous waste plumes in Butte County, which could easily migrate with the potential increased groundwater pumping proposed for the Project. All of this must be disclosed and analyzed.

In general, the 2010-2011 Water Transfer Program EA/FONSI—and by logical implication, DWR's actions—consistently avoids full disclosure of existing conditions and baseline data, rendering their justifications for the 2010-2011 Water Transfer Program at best incoherent, and at worst, dangerous to groundwater users and resources, and to vulnerable fisheries in tributary streams of the Sacramento River.

F. The 2010-2011 Water Transfer Program is likely to have a cumulatively significant impact on the environment.

The draft EA/FONSI does not reveal that the current Project is part of a much larger set of plans to develop groundwater in the region, to develop a "conjunctive" system for the region, and to integrate northern California's groundwater into the state's water supply. These are plans that the Bureau, together with DWR and others, have pursued and developed for many years. Indeed, one of the plans—the short-term phase of the Sacramento Valley Water Management Program—is the subject of an ongoing scoping process for a Programmatic EIS that has not yet been completed.

In assessing the significance of a project's impact, the Bureau must consider "[c]umulative actions, which when viewed with other proposed actions have cumulatively significant impacts and should therefore be discussed in the same impact statement." 40 C.F.R. §1508.25(a)(2). A "cumulative impact" includes "the impact on the environment which results from the incremental impact of the action when added to *other past, present and reasonably foreseeable future actions* regardless of what agency (Federal or non-Federal) or person undertakes such other actions." *Id.* §1508.7. The regulations warn that "[s]ignificance cannot be avoided by terming an action temporary or by breaking it down into small component parts." *Id.* §1508.27(b)(7).

An environmental impact statement should also consider "[c]onnected actions." *Id.* §1508.25(a)(1). Actions are connected where they "[a]re interdependent parts of a larger action and depend on the larger action for their justification." *Id.* §1508.25(a)(1)(iii). Further, an environmental impact statement should consider "[s]imilar actions, which when viewed together with other *reasonably foreseeable or proposed agency actions*, have similarities that provide a basis for evaluating their environmental consequences together, such as common timing or geography." *Id.* §1508.25(a)(3) (emphasis added).

As detailed below, instead of assessing the cumulative impacts of the proposed action as part of the larger program that even the Bureau has recognized should be subject to a programmatic EIS (but for which no programmatic EIS has been completed), the Bureau has attempted to separate this program and approve it through an inadequate EA. Further, the Bureau has failed to take into account the cumulative effects of other groundwater and surface water projects in the region, the development of "conjunctive" water systems, and the anticipated further integration of Sacramento Valley surface and ground water into the state water system.

G. The Environmental Assessment Fails to Meet the Requirements of NEPA.

Even if an EIS were not clearly required here, the draft EA/FONSI prepared by the Bureau violates NEPA on its own. As discussed above, the draft EA does not provide the analysis necessary to meet NEPA's requirements and to support its proposed finding of no significant impact. Further, as outlined above, the draft document fails to provide a full and accurate description of the proposed Project, its relationship to myriad other water transfer and groundwater extraction projects, its potentially significant adverse effects on salmon critical habitat in streams of interest tributary to the Sacramento River, and an assessment of the cumulative environmental impacts of the 2010-2011 Water Transfer Program when considered together with other existing and proposed water programs.

Additionally, the draft EA/FONSI fails to provide sufficient evidence to support its assertions that the 2010-2011 Water Transfer Program would have no significant impacts on the human or natural environments, neither decision makers nor the public are fully able to evaluate the significance of the 2010-2011 Water Transfer Program's impacts. These informational failures complicate the Coalition's efforts to provide meaningful comments on the full extent of the potential environmental impacts of the DWB and appropriate mitigation measures. Accordingly, many of the Coalition's comments include requests for additional information.

1. The EA Fails to Consider a Reasonable Range of Alternatives.

NEPA's implementing regulations call for analysis of alternatives is "the heart of the environmental impact statement," 40 C.F.R. §1502.14, and they require an analysis of alternatives within an EA. *Id.* §1408.9. The statute itself specifically requires federal agencies to:

> *study, develop, and describe appropriate alternatives to recommended courses of action in any proposal which involves unresolved conflicts concerning available uses of resources.*

42 U.S.C. §4332(2)(E). Here, because the Bureau's EA considers only the proposed Project and a "No Action" alternative, the EA violates NEPA.

The case law makes clear that an adequate analysis of alternatives is an essential element of an EA, and is designed to allow the decision maker and the public to compare the environmental consequences of the proposed action with the environmental effects of other options for accomplishing the agency's purpose. The Ninth Circuit has explained that "[i]nformed and meaningful consideration of alternatives … is … an integral part of the statutory scheme." *Bob Marshall Alliance v. Hodel*, 852 F.2d 1223, 1228 (9th Cir. 1988) (holding that EA was flawed where it failed adequately to consider alternatives). An EA must consider a reasonable range of alternatives, and courts have not hesitated to overturn EAs that omit consideration of a reasonable and feasible alternative. *See People ex rel. Van de Kamp v. Marsh*, 687 F.Supp. 495, 499 (N.D. Cal. 1988); *Sierra Club v. Watkins*, 808 F.Supp. 852, 870-75 (D.D.C. 1991).

Here, there are only two alternatives presented: the No Action and the Proposed Action. The lack of *any* alternative action proposal is unreasonable and is by itself a violation of NEPA's requirement to consider a reasonable range of alternatives.

Even more significantly, there are numerous other alternative ways to ensure water is allocated reliably when California experiences dry hydrologic years. We described several elements of reasonable alternatives above. These are the alternatives that should have been presented for the Bureau's draft EA/FONSI on the 2010-2011 Water Transfer Program to comply with NEPA. 42 U.S.C. § 4332(2)(E).

2. The EA Fails to Disclose and Analyze Adequately the Environmental Impacts of the Proposed Action

The discussion and analysis of environmental impacts contained in the EA is cursory and falls short of NEPA's requirements and stems from having an unclear and poorly described narrative for the proposed 2010-2011 Water Transfer Program. It obscures realistic chains of cause and effect, which in turn prevent accurate and comprehensive accounting of environmental baselines and measurement of the DWB's potential impacts. NEPA's implementing regulations require that an EA "provide sufficient evidence and analysis for determining whether to prepare an

[EIS].” 40 C.F.R. §1508.9(a). For the reasons discussed above, the EA fails to discuss and analyze the environmental effects of the water transfers, crop idling, and groundwater substitution proposed by the 2010-2011 Water Transfer Program. The Bureau must consider and address the myriad of environmental consequences that are likely to flow from this proposed agency action.

Along with our significant concerns about the adequacy of the proposed monitoring, the draft EA/FONSI also fails to explain what standards will be used to evaluate the monitoring data, and on what basis a decision to modify or terminate the pumping would be made. In light of the document’s silence on these crucial issues, the draft EA/FONSI’s conclusion that there will not be significant adverse impacts withers quickly under scrutiny.

3. The EA Fails to Analyze Cumulative Impacts Adequately.

The Ninth Circuit Court makes clear that NEPA mandates “a useful analysis of the cumulative impacts of past, present and future projects.” *Muckleshoot Indian Tribe v. U.S. Forest Service*, 177 F.3d 800, 810 (9th Cir. 1999). Indeed, “[d]etail is required in describing the cumulative effects of a proposed action with other proposed actions.” *Id.* The very cursory cumulative effects discussion contained in the EA plainly fails to meet this standard.

As discussed in Part I.C. above, the proposed DWB does not exist in a vacuum, and is in addition to a broader program to develop regional groundwater resources and a conjunctive use system. The 2010-2011 Water Transfer Program is also only one of several proposed and existing projects that affect the regional aquifers. The existence of these numerous related projects makes an adequate analysis of cumulative impacts especially important.

4. The Bureau Has Failed to Consider the Cumulative Impact of Other Groundwater Development and Surface Water Diversions Affecting the Region

In addition to the improper segmentation evident in the draft EA/FONSI, the assessment of environmental impacts is further deficient because the Bureau has failed to consider the cumulative impacts of the proposed groundwater extraction when taken in conjunction with other projects proposed for the development of groundwater and surface water.

The Bureau and its contractors are party to numerous current and reasonably foreseeable water programs that are related to the water transfers contemplated in the DWB including the following:

- Sacramento Valley Integrated Regional Water Management Plan (2006)
- Sacramento Valley Regional Water Management Plan (January 2006)
- Stony Creek Fan Conjunctive Water Management Program
- Sacramento Valley Water Management Agreement (Phase 8, October 2001)

- Draft Initial Study for 2008-2009 Glenn-Colusa Irrigation District Landowner Groundwater Well Program
- Regional Integration of the Lower Tuscan Groundwater Formation into the Sacramento Valley Surface Water System Through Conjunctive Water Management (June 2005)
- Stony Creek Fan Aquifer Performance Testing Plan for 2008-09
- Lower Tuscan Integrated Planning Program, a program funded by the Bureau that will "integrate the Lower Tuscan formation aquifer system into the management of regional water supplies."
- Annual forbearance agreements (2008 had an estimated 160,00 acre feet proposed).

We briefly describe some of their key elements here.

Stony Creek Fan Conjunctive Water Management Program. The SCF Aquifer Plan is part of and in furtherance of the Stony Creek Fan Conjunctive Water Management Program ("SCF Program"). This program is being carried out by GCID, Orland-Artois and Orland Unit Water Association.

The long-term objective of the SCF Program is the development of a "regional conjunctive water management program consisting of a direct and in-lieu recharge component, a groundwater production component, and supporting elements.…" (SVWMA: Project 8A Stony Creek Fan Conjunctive Water Management Program ("SVWMA Project 8A"), at 8A-1). The potential supply from such a program was estimated at 50,000 af per year to 100,000 af per year. *Id.*

The SCF Program has 3 Phases: (1) a feasibility study; (2) a demonstration project; and (3) project implementation. Phase I of the SCF Program has already been completed. The SCF Aquifer Plan described in a draft EA/FONSI is part of Phase II of the larger SCF Program. Phase III of the SCF Program will implement the program's goal of integrating test and operational production wells into the water supply systems for GCID, Orland-Artois, and Orland Unit Water Association for long-term groundwater production in conjunction with surface water diversions.

The Bureau is well aware of the SCF Program, but declined to analyze the environmental effects of the program as a whole, and simply considered the effects of an isolated component of the larger program. Indeed, the Bureau recently awarded a grant to GCID to fund the SCF Program. The Bureau's grant agreement states that the SCF Program "target[s] the Lower Tuscan Formation and possibly other deep aquifers in the west-central portion of the Sacramento Valley … as the source for all or a portion of the additional groundwater production needed to meet [the SCF Partners'] respective integrated water management objectives." BOR Assistance Agreement No. 06FG202103 at p. 2. The agreement further provides that provides that "[a]dditional test wells and production wells will be installed within the Project Area." *Id.*

Moreover, the Bureau's own description of the reasons for not choosing the "No Action" alternative indicate the Bureau's recognition that the primary goal of the SCF Aquifer Plan is to realize the objectives of the SCF Program – "increas[ing] reliable water supplies through conjunctive management of groundwater and surface water" at a fast pace. *See* EA/FONSI at p. 5. The Bureau was obligated to assess the potentially significant environmental impacts associated with such conjunctive management of groundwater and surface water, and wholly failed to do so.

There are serious concerns raised by the proposal to engage in conjunctive management of groundwater and surface water that are not addressed in the EA. For example, in 1994, following seven years of low annual precipitation, Western Canal Water District and other irrigation districts in Butte, Glenn and Colusa counties exported 105,000 af of water extracted from the Tuscan aquifers to buyers outside of the area. This early experiment in the *conjunctive use* of the groundwater resources – conducted without the benefit of environmental review – caused a significant and immediate adverse impact on the environment (Msangi 2006). Until the time of the water transfers, groundwater levels had dropped but the aquifers had sustained the normal demands of domestic and agricultural users. The water districts' extractions, however, lowered groundwater levels throughout the Durham and Cherokee areas of eastern Butte County (Msangi 2006). The water level fell and the water quality deteriorated in the wells serving the City of Durham (Scalmanini 1995). Irrigation wells failed on several orchards in the Durham area. One farm never recovered from the loss of its crop and later entered into bankruptcy. Residential wells dried up in the upper-gradient areas of the aquifers as far north as Durham.

<u>The SCF Program is a Component of the Sacramento Valley Water Management Program.</u> The Sacramento Valley Water Management Program (Phase 8) ("SVWMP") also includes the SCF Program as one of its elements. (SVWMA Project 8A at pp. 8A-1 to 8A-13).

The SVWMP recognizes that the SCF Program "has the potential to improve operational flexibility on a regional basis resulting in measurable benefits locally in the form of predictable, sustainable supplies, *and improved reliability for water users' elsewhere in the state*." *Id.* at p. 8A-2 (emphasis added). By piecemealing this program improperly and analyzing only the small component of the SCF Program, the Bureau has failed to assess the environmental impacts associated not just with the anticipated conjunctive use of the groundwater, but also the effect of the anticipated export of water to other regions of the state.

Additionally, approximately seven years ago, on August 5, 2003, the Bureau published a notice in the Federal Register announcing its intention to prepare a programmatic EIS to analyze the short-term phase of the SVWMP. 68 Fed. Reg. 46218, 46219 (Aug. 5, 2003). Like the SVWMP, this "Short-term Program" for which the Bureau stated its intent to conduct a programmatic EIS included implementation of the SCF Program. *Id.* at 46219, 46220.

<u>The SCF Program is Also a Component of the Sacramento Valley Integrated Regional Water Management Program.</u> The Bureau has been working with GCID and others to realize the

Sacramento Valley Integrated Regional Water Management Program ("SVIRWMP"). SVIRWMP is comprised of a number of sub-regional projects, including the SCF Program. *See* SVIRWMP, Appendix A at A-5; BOR Assistance Agreement No. 06FG202103. Here again, even though the SCF Aquifer Plan is clearly a necessary component of the SCF Program – which is in turn a component of the SVIRWMP – the draft EA/FONSI failed to even acknowledge, let alone assess, the cumulative impacts of these related projects.

Most obviously, the draft EA wholly fails to assess the impact of the Bureau's *Sacramento Valley Regional Water Management Plan (2006)* (SVRWMP) and the forbearance water transfer program that the Bureau and DWR facilitate jointly. As noted above, the Programmatic EIS for the 2002 Sacramento Valley Water Management Agreement or Phase 8 Settlement was initiated, but never completed, so the SVRWMP was the next federal product moving the Phase 8 Settlement forward. The stated purpose of the Phase 8 Settlement and the SVRWMP are to improve water quality standards in the Bay-Delta and local, regional, and statewide water supply reliability. In the 2008 forbearance program, 160,000 af was proposed for transfer to points south of the Delta. To illustrate the ongoing significance of the demand on Sacramento Valley water, we understand that GCID alone entered into "forbearance agreements" to provide 65,000 af of water to the San Luis and Delta Mendota Water Association in 2008, 80,000 af to State Water Project contractors in 2005, and 60,000 af to the Metropolitan Water District of Southern California in 2003.

Less obvious, but certainly available to the Bureau, are the numerous implementation projects that Phase 8 signatories are pursuing, such as Glenn Colusa Irrigation District's (GCID) 2008 proposal to divert groundwater pumped from private wells to agricultural interests in the District. *See* Attach. (GCID Proposed Negative Declaration, GCID Landowner Groundwater Well Program for 2008-09). Additionally, the draft EA does not consider the cumulative effect of the Lower Tuscan Integrated Planning Program, a program funded by the Bureau that will "integrate the Lower Tuscan formation aquifer system into the management of regional water supplies." Grant Agreement at 4. This program, as described by the Bureau, will culminate in the presentation of a proposed water management program for the Lower Tuscan Formation for approval and implementation by the appropriate authorities. Clearly, the cumulative impact of this program and the 2010-2011 Water Transfer Program's proposed groundwater extraction should have been assessed.

Finally, with the myriad projects and programs that are ignored in the EA and have never been analyzed cumulatively, the EA finally discloses that there could be a *devastating* impact to groundwater: "The reduction in recharge due to the decrease in precipitation and runoff in the past years in addition to the increase in groundwater transfers would lower groundwater levels. Multi-year groundwater acquisition under cumulative programs operating in similar areas of the Sacramento Valley could further reduce groundwater levels. Groundwater levels may not fully recover following a transfer and may experience a substantial net decline in groundwater levels over several years. This would be a substantial cumulative effect," (EA p. 3-108). While the honesty is refreshing, the lack of comprehensive monitoring, mitigation, and project cessation mechanisms is startling. This alone warrants the preparation of an EIS.

Here again, the current document does not discuss or analyze these potential impacts, their potential scope or severity, or potential mitigation efforts. Instead, it relies on the existence of local ordinances, plans, and oversight with the monitoring and mitigation efforts of individual "willing sellers" to cope with any adverse environmental effects. However, as we have shown above, for example, the Glenn County management plan is untested and does not provide adequate protection and monitoring of the region's important groundwater resources. To further clarify the inadequacy of relying on local plans and ordinances, Butte County's Basin Management Objectives have no enforcement mechanism and Butte County's Chapter 33, while it requires CEQA review for transfers that include groundwater, has never been tested. As one can see, there is very limited local protection for groundwater and no authority to influence pumping that is occurring in a different county.

5. The 2010-2011 Water Transfer Program is likely to serve as precedent for future actions with significant environmental effects.

As set forth above, this Project is part of a broader effort by the Bureau and DWR to develop groundwater resources and to integrate GCID's water into the state system. For these reasons, the 2010-2011 Water Transfer Program is likely to "establish a precedent for future actions with significant effects or represents a decision in principle about a future consideration" (40 C.F.R. §1508.27(b)(6)), and should be analyzed in an EIS.

6. The 2010-2011 Water Transfer Program has potential adverse impacts for a threatened species.

As the Bureau of Reclamation is well aware, the purpose of the ESA is to conserve the ecosystems on which endangered and threatened species depend and to conserve and recover those species so that they no longer require the protections of the Act. 16 U.S.C. § 1531(b), ESA § 2(b); 16 U.S.C. § 1532(3), ESA §3(3) (defining "conservation" as "the use of all methods and procedures which are necessary to bring any endangered species or threatened species to the point at which the measures provided pursuant to this chapter are no longer necessary"). "[T]he ESA was enacted not merely to forestall the extinction of species (i.e., promote species survival), but to allow a species to recover to the point where it may be delisted." *Gifford Pinchot Task Force v. U.S. Fish & Wildlife Service*, 378 F3d 1059, 1069 (9th Cir. 2004). To ensure that the statutory purpose will be carried out, the ESA imposes both substantive and procedural requirements on all federal agencies to carry out programs for the conservation of listed species and to insure that their actions are not likely to jeopardize the continued existence of any listed species or result in the destruction or adverse modification of critical habitat. 16 U.S.C. § 1536. *See NRDC v. Houston*, 146 F.3d 1118, 1127 (9th Cir. 1998) (action agencies have an "affirmative duty" to ensure that their actions do not jeopardize listed species and "independent obligations" to ensure that proposed actions are not likely to adversely affect listed species). To accomplish this goal, agencies must consult with the Fish and Wildlife Service whenever their actions "may affect" a listed species. 16 U.S.C. § 1536(a)(2); 50 C.F.R. § 402.14(a). Section 7 consultation is required for "any action [that] may affect listed species or critical habitat." 50 C.F.R. § 402.14. Agency "action" is defined in the ESA's implementing regulations to "mean all activities or programs of any kind authorized, funded, or carried out, in whole or in part, by Federal agencies in the United States." 50 C.F.R. § 402.02.

The giant garter snake ("GGS") is an endemic species to Central Valley California wetlands. (Draft Recovery Plan for the Giant Garter Snake ("DRP") 1). The giant garter snake, as its name suggests, is the largest of all garter snake species, not to mention one of North America's largest native snakes, reaching a length of up to 64 inches. Female GGS tend to be larger than males. GGS vary in color, especially depending on the region, from brown to olive, with white, yellow, or orange stripes. The GGS can be distinguished from the common garter snake by its lack of red markings and its larger size. GGS feed primarily on aquatic fish and specialize in ambushing small fish underwater, making aquatic habitat essential to their survival. Females give birth to live young from late July to early September, and brood size can vary from 10 to up to 46 young. Some studies have suggested that the GGS is sensitive to habitat change in that it prefers areas that are familiar and will not typically travel far distances. The EA discloses that one GGS study in Colusa County revealed the "longest average movement distances of 0.62 miles, with the longest being 1.7 miles, for sixteen snakes in 2006, and an average of 0.32 miles, with the longest being 0.6 miles for eight snakes in 2007. However, in response to droughts and other changes in water availability, the GGS has been known to travel up to 5 miles in only a few days, but the impacts on GGS survival and reproduction from such extreme conditions are unknown due to the deficiency in data and analysis.

Flooded rice fields, irrigation canals, and wetlands in the Sacramento Valley can be used by the giant garter snake for foraging, cover and dispersal purposes. The draft EA fails to comprehensively analyze the movements and habitat requirements for the federal and state-threatened giant garter snake and yet again defers responsibility to a future time. The 2009 Biological Assessment acknowledged the failure of Bureau and DWR to complete the Conservation Strategy that was a requirement of the 2004 Biological Opinion. (BA at p. 19-20) [The BA appears to have no page numbers] What possible excuse delayed this essential planning effort?

The 2010-2011 Water Transfer Program also proposes to delete or modify other mitigation measures previously adopted as a result of the EWA EIR process to substantially reduce significant impacts, but without showing they are infeasible. For example, the Bureau and DWR propose to delete the 160 acre maximum for "idled block sizes" for rice fields left fallow rather than flooded and to substitute for it a 320 acre maximum. (See 2003 Draft EWA EIS/EIR, p. 10-55; 2004 Final EWA EIS/EIR, Appendix B, p. 18, Conservation Measure # 4.) There is no evidence to support this change. In light of the agencies failure to complete the required Conservation Strategy mentioned above and the data gathered in the Colusa County study, how can the EA suggest that doubling the fallowing acreage is in any way biologically defensible? The agencies additionally propose to delete the mitigation measure excluding Yolo County east of Highway 113 from the areas where rice fields may be left fallow rather than flooded, except in three specific areas. (See 2004 Final EWA EIS/EIR, Appendix B, p. 18, Conservation Measure # 2.) What is the explanation for this change? What are the impacts from this change?

Deleting these mitigation measures required by the EWA approval would violate NEPA and CEQA's requirements that govern whether, when, and how agencies may eliminate mitigation measures previously adopted under NEPA and CEQA. (See *Napa Citizens for Honest Government v. Napa County Board.*

The 2010-2011 Water Transfer Program fails to include sufficient safeguards to protect the giant garter snake and its habitat. The EA concludes, "The frequency and magnitude of rice land idling would likely increase through implementation of water transfer programs in the future. Increased rice idling transfers could result in chronic adverse effects to giant garter snake and their habitats and may result in long-term degradation to snake populations in the lower Sacramento Valley. In order to avoid potentially significant adverse impacts for the snake, additional surveys should be conducted prior to any alteration in water regime or landscape," (p. 3-110). To address this significant impact the Bureau proposes relying on the 2009 DWB Biological Opinion, which was a one-year BO. The expired BO highlights the Bureau and DWR's avoidance of meeting federal and state laws stating, "This office has consulted with Reclamation, both informally and formally, approximately one-half dozen times over the past 8 years on various forbearance agreements and proposed water transfers for which water is made available for delivery south of the delta by fallowing rice (and other crops) or substituting other crops for rice in the Sacramento Valley. Although transfers of this nature were anticipated in our biological opinion on the environmental Water Account, that program expired in 2007 and, to our knowledge, no water was ever made available to EWA from rice fallowing or rice substitution. The need to consult with such frequency on transfers involving water made available from rice fallowing or rice substitution suggests to us a need for programmatic environmental compliance documents, including a programmatic biological opinion that addresses the additive effects on giant garter snakes of repeated fallowing over time, and the long-term effects of potentially large fluctuations and reductions in the amount and distribution of rice habitat upon which giant garter snakes in the Sacramento Valley depend," (p.1-2). The Coalition agrees with the U.S. Fish and Wildlife Service that programmatic environmental compliance is needed under the Endangered Species Act, NEPA, CEQA, and the California Endangered Species Act.

It is conspicuously noticeable that there isn't a claim of a less-than-significant impact for the Giant Garter Snake (*Thamnophis gigas*), in the EA/FONSI. There is really no conclusion reached due to the fundamental absence of science for the species. The Bureau should also prepare an EIS because the 2010-2011 Water Transfer Program will likely have significant environmental effects on the Giant Garter Snake, a listed threatened species under the federal Endangered Species Act and California Endangered Species Act. 40 C.F.R. §1508.27(b)(9).

II. Purpose and Need Issues of the 2010-2011 Water Transfer Program

A. The Purpose and Need Section of the EA/FONSI fails to specify the policy framework upon which the 2010-2011 Water Transfer Program is based.

Avoiding the requirements of the California Environmental Quality Act (CEQA) for the 2010-2011 Water Transfer Program does not reflect the actual environmental effects of the proposal—which are similar to the proposed 1994 Drought Water Banks and for which a final Program Environmental Impact Report was completed in November 1993. In 2000, the Governor's Advisory Drought Planning Panel report, *Critical Water Shortage Contingency Plan* promised a program EIR on a drought-response water transfer program, but was never undertaken. Twice in recent history, the state readily acknowledged that CEQA review for a major drought water banking program was appropriate. So, the 2009 DWB Notice of Exemption and complete avoidance of CEQA review for the 2010-2011 Water Transfer Program reflects an end-run around established water law through the use of water transfers, and is therefore vulnerable to legal challenge under the California Environmental Quality Act.

We question the merits of and need for the 2010-2011 Water Transfer Program itself. The existence of drought conditions at this point in time is highly questionable and reflects the state's abandonment of a sensible water policy framework given our state and national economic recession and tattered public budgets. Our organizations believe the agencies continue to go too far to help a few junior water right holders, and that at bottom the 2010-2011 Water Transfer Program is not needed. The Project intends to directly benefit the areas of California whose water supplies are the least reliable by operation of state water law. Though their unreliable supplies have long been public knowledge, local, state, and federal agencies in these areas have failed to stop blatantly wasteful uses and diversions of water and to pursue aggressive planning for regional water self-sufficiency.

The EA/FONSI's statement of purpose and need on page 1-2 states specifically that, "The purpose of the Proposed Action is to help facilitate the transfer of water throughout the State from willing sellers of CVP water upstream of the Delta to buyers that are at risk of experiencing water shortages in 2010 and 2011." This paragraph and the section that it is in omit a coherent discussion of need. The purpose and need should also state that this transfer program would be subject to specific criteria and delineate priorities, but they are absent.

The EA/FONSI makes no attempt to place the 2010-2011 Water Transfer Program into the context of the 2005 California Water Plan that the state recently completed. It appears to us that this plan is largely on the shelf now, perhaps because of the state's dire fiscal problems. It does contain many good recommendations concerning increasing regional water self-sufficiency. However, our review of the 2005 California Water Plan reveals no mention of the 2000 Critical Water Shortage Reduction Marketing Program or any overarching drought response plan that the state could have planned for in 2005, but did not. We sadly conclude that the state of California has no meaningful adopted drought response policy, save for gubernatorial emergency declarations to suspend protective environmental regulations. This is not a sustainable water policy for California.

The purpose and need section of the EA/FONSI *and the 2009 Governor's drought emergency declaration* cry out for placing the 2010-2011 Water Transfer Program into a policy framework. What is the state doing otherwise to facilitate regional water self-sufficiency for these areas with the least reliable water rights? How does the 2010-2011 Water Transfer Program fit into the state and federal government's water and drought policy framework? Instead, the state and federal response to this third consecutive dry year falls back on simply the Drought Water Bank model that ran into environmental and water users' opposition in 1991 and 1992. Is anybody home at our water agencies?

B. The 2010-2011 Water Transfer Program is not needed because the state's current allocation system—in which the federal Bureau of Reclamation participates—wastes water profligately.

The incentive from the state's lax system of regulation of California's State Water Project and Central Valley projects is to deliver the water now, and worry about tomorrow later. Indeed, the State Water Resources Control Board (SWRCB) has been AWOL for decades. In response to inquiries from the Governor's Delta Vision Task Force last fall, the SWRCB acknowledged that while average runoff in the Delta watershed between 1921 and 2003 was 29 million acre-feet annually, the 6,300 active water right permits issued by the SWRCB is approximately 245 million acre-feet. In other words, **water rights on paper are 8.4 times greater than the real**

water in California streams diverted to supply those rights on an average annual basis. *And the SWRCB acknowledges that this "water bubble" does not even take account of the higher priority rights to divert held by pre-1914 appropriators and riparian water right holders, of which there are another 10,110 disclosed right holders.* Many more remain undisclosed.

Like federal financial regulators failing to regulate the shadow financial sector, subprime mortgages, Ponzi schemes, and toxic assets of our recent economic history, the state of California has been derelict in its management of scarce water resources here. This in no way justifies suspension of environmental and water quality regulations, for which the Governor's drought emergency declaration calls. We supplement our comments on this matter of wasteful use and diversion of water by incorporating by reference the joint complaint to the State Water Resources Control Board of the California Water Impact Network and the California Sportfishing Protection Alliance on public trust, waste and unreasonable use and method of diversion as additional evidence of a systematic failure of governance by the State Water Resources Control Board, the Department of Water Resources and the U.S. Bureau of Reclamation, filed with the Board on March 18, 2008 (attached).

We question the Bureau and DWR's contention of continued dry conditions, since the current storms have greatly increased reservoir levels throughout California. Non-state and non-federal reservoirs indicate conditions fast approaching normal for their facilities: Bullard's Bar in Yuba County is at 99 percent of the 15-year average for this time of year, EBMUD's Pardee Lake is at 97 percent of normal, San Francisco's Hetch Hetchy Reservoir on the Tuolumne River is at 152 percent of normal, while Don Pedro Reservoir on the same river is at 106 percent. The CVP's Millerton and Folsom reservoirs are below average for this time of year, but with the strong storms California is now getting through this week and into next, their storage figures are likely to improve dramatically when snowpack melts. These two reservoirs must provide water to the agricultural San Joaquin River Exchange Contractors first, and they have among the most senior rights on that river. Rice growers in the Sacramento Valley are generally expecting close to full deliveries from the CVP and their Yuba River water supplies. The CVP's own New Melones Reservoir on the Stanislaus River, which contributes to Delta water quality as well as to meeting eastern San Joaquin Valley irrigation demands, is at 87 percent of normal for this time of year.

Moreover, the SWP's terminal reservoirs at Pyramid (104 percent of average) and Castaic (99 percent of average) Lakes are right at about normal storage levels for this time of year, presumably because DWR has been releasing water from Oroville for delivery to these reservoirs.

The fact that reservoirs of the CVP with more senior responsibilities in the water rights hierarchy do well with storage for this time of year suggests that at worst this will be a year of below normal runoff in 2010—hardly a drought scenario. Low storage levels at Oroville, Shasta and San Luis may easily be attributed to redirected releases to terminal reservoirs or groundwater banks in the San Joaquin Valley and Tulare Lake Basin—these latter storage venues and their current performance are not disclosed on DWR's Daily Reservoir Storage levels web site. Still, given what is known, from what these reservoir levels indicate many major cities and most Central Valley farmers are very likely to have enough water for this year.

The ones expecting to receive little water this year do so because of the low priority of their water service contracts within the Central Valley Project—their imported surface supplies are therefore less reliable in dry times. It is the normal and appropriate functioning of California‘s system of water rights law that makes it so. Among those with more junior water contractor allocations, the Metropolitan Water District and the Santa Clara Valley Water District are the wealthiest regions and the agencies most capable of undertaking aggressive regional water self-sufficiency actions. They should be further encouraged and assisted to do so through coherently formulated state and federal water policies and programs.

On the agricultural side, the Bureau and DWR's efforts appear to benefit mainly the few western San Joaquin Valley farmers whose contractual surface water rights have always been less reliable than most—and whose lands are the most problematic for irrigation. In excess of 1 million acres of irrigated land in the San Joaquin Valley and the Tulare Lake Basin are contaminated with salts and trace metals like selenium, boron, arsenic, and mercury. These lands should be retired from irrigation to stop wasteful use of precious fresh water resources. This water drains back—after leaching from these soils the salts and trace metals—into sloughs and wetlands and the San Joaquin River carrying along these pollutants. Retirement of these lands from irrigation usage would help stem further bioaccumulation of these toxins that have settled in the sediments of these water bodies.

The 2010-2011 Water Transfer Program would exacerbate pumping of fresh water from the Delta, which has already suffered from excessive pumping in earlier years of this decade. Pumped exports cause reverse flows to occur in Old and Middle Rivers and can result in entrainment of fish and other organisms in the pumps. Pumping can shrink the habitat for Delta smelt as well, since less water flows out past Chipps Island through Suisun Bay which Delta smelt often prefer. Our organizations share the widely held view that operation of the Delta export pumps is the major factor causing the Pelagic Organism Decline (POD) and in the deteriorating populations of fall-run Chinook salmon. The State Water Resources Control Board received word in early December that the Fall Midwater Trawl surveys for September and October showed the lowest abundance indices for Delta smelt, American shad, and striped bass in history. The index for longfin smelt is the third lowest in history. 2009 was the second consecutive year where no commercial fishing of fall-run Chinook fish will be allowed because of this species‘population decline. While it is too early to know, 2010 could be the third straight year where no commercial fishing will be allowed, which would be unprecedented. Operation of the DWB at a time when others refrain from taking these fish and other organisms strikes us as a consummate unwillingness on the part of the State of California and the U.S. Bureau of Reclamation to share in the sacrifices needed to help aquatic ecosystems and anadromous fisheries of the Bay-Delta Estuary recover.

New capital facilities should be avoided to save on costly, unreliable, and destructive water supplies that new dams and canals represent. Moreover, these facilities would need new water rights; yet the most reliable rights in California are always the ones that already exist—and of those, they are the ones that predate the California State Water Project and the federal Central Valley Project. We should apply our current rights far more efficiently—and realistically—than we do now. California should instead pursue a "no-regrets" policy incorporating aggressive water conservation strategies, careful accounting of water use, research and technological innovation, and pro-active investments.[5]

III. Conclusion

The Bureau's EA/FONSI states on page 3-16:

> *California Water Code Section 1810 and the CVPIA protect against injury to third parties as a result of water transfers. Three fundamental principles include (1) no injury to other legal users of water; (2) no unreasonable effects on fish, wildlife or other in-stream beneficial uses of water; and (3) no unreasonable effects on the overall economy or the environment in the counties from which the water is transferred.*

We unreservedly state to you that the draft EA/FONSI on the proposed 2010-2011 Water Transfer Program appears to describe a project that would fail all three of these tests as currently described. The 2010-2011 Water Transfer Program clearly has the potential to affect the human and natural environments, both within the Sacramento Valley as well as in the areas of conveyance and delivery. It is entirely likely that injuries to other legal users of water, including those entirely dependent on groundwater in the Sacramento Valley, will occur if this project is approved. Groundwater, fishery and wildlife resources are likely also to suffer harm as instream users of water in the Sacramento Valley. And the economic effects of the proposed DWB are at best poorly understood through the EA/FONSI. To its credit, at least the Bureau studied the proposed project, while DWR has completely avoided CEQA, thereby enabling the agency to ignore these potential impacts.

Taken together, the Bureau and DWR treat these serious issues carelessly in the EA/FONSI, and in DWR's specious avoidance of CEQA review. In so doing, they deprive decision makers and the public of their ability to evaluate the potential environmental effects of this Project, and violate the full-disclosure purposes and methods of both the National Environmental Policy Act and the California Environmental Quality Act.

Assessing Southern California's Future Water Strategies*, August 2008, and Lisa Kresge and Katy Mamen, *California Water Stewards: Innovative On-farm Water Management Practices*, California Institute for Rural Studies, January 2009.

None of the signatory organizations to this letter received notice from the Bureau that this EA/FONSI had been released on January 5, 2010. With the Coalition's 2009 DWB comments on the EA/FONSI, we had the following request: *Our organizations request advance notification of any meetings that address this proposed Project or any other BOR projects in Butte, Colusa, Glenn, or Tehama counties that require consideration of NEPA/CEQA as well as water rights applications that will be needed as the 2010-2011 Water Transfer Program moves forward. Please add C-WIN, CSPA, BEC, and the Center for Biological Diversity to your basic public notice list on this Project, and send us each any additional documents that pertain to this particular Project.* While we do find record of a news release about the EA/FONSI on the Bureau's Mid-Pacific Region web site, we believe the Bureau has not met its obligations under NEPA for providing adequate public outreach to solicit review and comment of its environmental review documents in this matter. We learned of the Water Transfer Program on January 14th more than halfway through the review period set by the Bureau. Bureau staff rejected our request for additional time to review the documents, much to our disappointment. Please add our names and email addresses to all future environmental review news releases.

Subject: Comments on Environmental Reviews for the *2009 Drought Water Bank.*

Dear Ms. Victorine and Mr. Hendrick:

Butte Environmental Council, the California Sportfishing Protection Alliance, the Center for Biological Diversity, and the California Water Impact Network ("the Coalition") submit the following comments and questions for the Draft Environmental Assessment ("EA") and Findings of No Significant Impact ("FONSI"), for the *2009 Drought Water Bank* ("DWB" or "Project"). We also provide comments about the purpose and need for the 2009 Drought Water Bank, the Governor's recent drought emergency declaration, and the CEQA Notice of Exemption to cover this project's implementation with mitigation measures from the 2003 and 2007 Environmental Water Account environmental documents.

The Bureau of Reclamation's draft environmental review of the California Department of Water Resources ("DWR's") DWB does not comply with the requirements of National Environmental Policy Act ("NEPA"), 42 U.S.C. §4321 *et seq*. First, we believe that the Bureau needs to prepare an environmental impact statement ("EIS") on this proposal that could allow up to 600,000 acre-feet (AF) of surface water transfers, up to 340,000 AF of groundwater substitution, and significant crop idling. Bureau reliance on the EA itself violates NEPA requirements because, among other things, the EA fails to provide a reasoned analysis and explanation to support the Bureau's proposed finding of no significant impact. The EA contains a fundamentally flawed alternatives analysis, and treatment of the chain of cause and effect extending from project implementation leading to inadequate analyses of nearly every resource and cumulative impacts.

An EIS would afford the Bureau, DWR, the State Water Resources Control Board, and the California public far clearer insight into how, where, and why the DWB might or might not be needed. The draft EA/FONSI as released this month fails to provide adequate disclosure of these impacts.

Second, exemption of the 2009 DWB from the requirements of the California Environmental Quality Act (CEQA) does not reflect the actual environmental effects of the proposal—which are similar to the proposed 1994 Drought Water Banks and for which a final Program Environmental Impact Report was completed in November 1993. In 2000, the Governor's Advisory Drought Planning Panel report, *Critical Water Shortage Contingency Plan* promised a program EIR on a drought-response water transfer program, but was never undertaken. Twice in recent history, the state readily acknowledged that CEQA review for a major drought water banking program was appropriate. So, DWR's Notice of Exemption reflects an end-run around established water law through the use of water transfers, and is therefore vulnerable to legal challenge under the California Environmental Quality Act.

Finally, we also question the merits of and need for the DWB project itself. The existence of drought conditions at this point in time is highly questionable and reflects the state's abandonment of a sensible water policy framework given our state and national economic recession and tattered public budgets. Our organizations believe the Governor's drought emergency declaration goes too far to help a few junior water right holders, and that at bottom, the 2009 Drought Water Bank is not needed. The DWB will directly benefit the areas of California whose water supplies are the least reliable by operation of state water law. Though their unreliable supplies have long been public knowledge, local, state, and federal agencies in these areas have failed to stop blatantly wasteful uses and diversions of water and to pursue aggressive planning for regional water self-sufficiency.

The proposed DWB will have significant effects on the environment—both standing alone and when reviewed in conjunction with the multitude of other plans that incorporate and are dependent on Sacramento Valley water. Ironically, the Bureau appears to recognize in its cumulative impacts discussion that there is potential for significant adverse impacts associated with the DWB, but instead of conducting an EIS as required, attempts to assure the public that the 2009 DWB will be deferred to the "willing sellers" through individual "monitoring and mitigation programs" as well as through constraining actions taken by both DWR and Bureau professional staff whose criteria ought instead be incorporated into the Proposed Action Alternative. EA at p. 37, FONSI at p. 3, 4, 5, 6, 7. Of course, this is not a permissible approach under NEPA; significant adverse impacts should be mitigated—or avoided altogether as CEQA normally requires.[1] Moreover, in light of the wholly inadequate monitoring planned for the 2009

---

[1] Perhaps even more telling, the Bureau actually began its own Programmatic EIS to facilitate water transfers from the Sacramento Valley and the interconnected actions that are integrally related to it, but never completed that EIS and now has impermissibly broken out this current segment of the overall Program for piecemeal review in the present draft EA. See 68 Federal Register 46218 (Aug 5, 2003) (promising a Programmatic EIS on these related activities, "include[ing] groundwater substitution in lieu of surface water supplies, conjunctive use of groundwater

DWB's extensive water transfer program, the suggestion that the public should be required to depend on that insufficient monitoring to provide the necessary advance notice of "significant adverse impacts" is an unacceptable position.

- Professor Karin Hoover's Declaration, 2008.

I. The Bureau and DWR Must Prepare an Environmental Impact Statement/ Environmental Impact Report on the Proposed 2009 Drought Water Bank

We strongly urge the Bureau and DWR to withdraw these inadequate environmental documents and instead prepare a joint EIR/S on the 2009 DWB, before approval by the State Water Resources Control Board (SWRCB), in order to comply with both NEPA and CEQA requirements for full disclosure of human and natural environmental effects.

NEPA requires federal agencies to prepare a detailed environmental impact statement on all "major Federal actions significantly affecting the quality of the human environment . . . ." 42 U.S.C. §4332(2)(C). This requirement is to ensure that detailed information concerning potential environmental impacts is made available to agency decision makers and the public before the agency makes a decision. *Robertson v. Methow Valley Citizens Council*, 490 U.S. 332, 349 (1989). CEQA has similar requirements and criteria.

Under NEPA's procedures, an agency may prepare an EA in order to decide whether the environmental impacts of a proposed agency action are significant enough to warrant preparation of an EIS. 40 C.F.R. §1508.9. An EA must "provide sufficient evidence and analysis for determining whether to prepare an [EIS]" (*id.*), and must demonstrate that it has taken a "'hard look' at the potential environmental impact of a project." *Blue Mountains Biodiversity Project v. Blackwood*, 161 F.3d 1208, 1212 (9th Cir. 1998) (internal quotation marks omitted). However, the U.S. Court of Appeals for the Ninth Circuit has cautioned that "[i]f an agency decides not to

---

and surface water, refurbish existing groundwater extraction wells, install groundwater monitoring stations, install new groundwater extraction wells…" *Id.* At 46219. See also http://www.usbr.gov/mp/nepa/nepa_projdetails.cfm?Project_ID=788 (current Bureau website on "Short-term Sacramento Valley Water Management Program EIS/EIR").

prepare an EIS, it must supply a convincing statement of reasons to explain why a project's impacts are insignificant." *Id.* (internal quotation marks omitted). The Bureau has not provided a convincing statement of reasons explaining why the DWB's impacts are not significant. So long as there are "substantial questions whether a project *may* have a significant effect on the environment," an EIS must be prepared. *Id.* (emphasis added and internal quotation marks omitted). Thus, "the threshold for requiring an EIS is quite low." *NRDC v. Duvall*, 777 F. Supp. 1533, 1538 (E.D. Cal. 1991). Put another way, as will be shown through our comments, the bar for sustaining an EA/FONSI under NEPA procedures is set quite high, and the Bureau fails to surmount it with its report on the 2009 DWB.

NEPA regulations promulgated by the Council on Environmental Quality identify factors that the Bureau must consider in assessing whether a project may have significant environmental effects, including:

(1) "The degree to which the possible effects on the human environment are highly uncertain or involve unique or unknown risks." 40 C.F.R. §1508.27(b)(5).
(2) "The degree to which the effects on the quality of the human environment are likely to be highly controversial." *Id.* §1508.27(b)(4).
(3) "Whether the action is related to other actions with individually insignificant but cumulatively significant impacts. Significance exists if it is reasonable to anticipate on a cumulatively significant impact on the environment. Significance cannot be avoided by terming an action temporary or by breaking it down into small component parts." *Id.* §1508.27(b)(7).
(4) "The degree to which the action may establish a precedent for future actions with significant effects or represents a decision in principle about a future consideration." *Id.* §1508.27(b)(6).
(5) "The degree to which the action may adversely affect an endangered or threatened species or its habitat that has been determined to be critical under the Endangered Species Act of 1973." *Id.* §1508.27(b)(9).

Here, the Bureau has failed to take a hard look at the environmental impacts of the DWB. As detailed below, there are substantial questions about whether the 2009 DWB's proposed water transfers will have significant effects on the region's environmental and hydrological conditions especially the interactions between groundwater and surface streams of interest in the Sacramento Valley region. There are also substantial questions about whether the 2009 DWB will have significant adverse environmental impacts when considered in conjunction with the other related water projects underway and proposed in the region. The Bureau simply cannot rely on the EA/FONSI for the foreseeable environmental impacts of the proposed 2009 DWB and still comply with NEPA's requirements.

A. The Proposed Action Alternative is poorly specified making it difficult to identify chains of cause and effect necessary to analyze adequately the alternative's environmental effects.

The Proposed Action Alternative is poorly specified and needs additional clarity before decision makers and the public can understand the human and environmental consequences of the 2009 Drought Water Bank. The EA describes the Proposed Action Alternative as one reflecting the Bureau's intention to approve transfers of Central Valley Project water from willing sellers who contract with the Bureau ordinarily to use surface water on their croplands. Up to 208,000 AF of CVP water are on offer from these sellers, according to Table 1 of the EA. "Priority criteria" are described in the EA indicating that sales will be prioritized for water-short public health, urban, and then agricultural uses, in that order. Table 2 of the EA indicates that as much as 839,117 AF has been requested.

The EA/FONSI's statement of purpose and need states specifically that "the purpose of the proposed action is to help facilitate the transfer of water throughout the State from willing sellers of CVP water upstream of the Delta to buyers that are at risk of experiencing water shortage in 2009." This paragraph omits coherent discussion of need. The purpose and need should also state that this transfer program would be subject to specific criteria for prioritizing transfers, as described on page 6: "It is anticipated that water made available to [potential buyers] from the DWB would be prioritized as flows: existing health and safety domestic needs, municipal supply subject to water shortage contingency plan measures, and agricultural irrigation for existing crops and livestock subject to water shortage contingency plan measures."

The EA's description of the proposed action alternative needs to make clear what would occur if the sale criteria are in fact applied. Are both project agencies applying them, or just one and not the other? What is the legal or policy basis authorizing use of these criteria? Will exceptions be provided, and if so, by what criteria would exceptions be made?

Taken together with DWR's March 4th Addendum to the EWA EIS/R, there is considerable ambiguity over just how many potential sellers there are and how much water they would make available to the DWB. This is reflected in different numbers in the two environmental documents justifying the DWB. The following table shows the discrepancies across these uncoordinated environmental reviews:

Comparison of Environmental Review Parameters for the 2009 Drought Water Bank	**DWR Addendum, March 4th**	**Bureau EA, March 4th**
Narrative project description present in document?	No	Yes
DWB sale criteria discussed?	No	Yes
Total potential water for sale (AF)	533,435	389,328
Total potential water requests (AF)	818,905	839,117
Total potential water sales covered by environmental compliance with the EWA EIS/R (AF)	600,000	Not described.

Absence of agreement among these documents on basic facts of the 2009 DWB signals that neither the Bureau nor DWR have a clear idea what the DWB is. This problem contributes greatly to and helps explain the poorly rendered treatment of causes and effects that permeate the Bureau's EA. The project agencies, decision-makers, and the public all face a moving target with the 2009 Drought Water Bank. Such discrepancies reflect hasty consideration and poor planning by project proponents. Nor can the agencies reasonably attribute their inadequate environmental reviews on lack of warning. The Governor has made fear of drought a centerpiece of his recent water statements since at least last June. Yet DWR and the Bureau apparently have not agreed on these basic facts making up the DWB.

From data available in the EA and the Addendum, it is not possible to determine with confidence just how much water is requested by potential urban and agricultural buyers. There is no attempt to describe how firmly tendered are offers of water to sell or requests to purchase. With between 400,000 and 500,000 AF of presumably urban buyer requests[2] (which have priority over agricultural purchases, according to the DWB priorities) and a cumulative total of less than 400 TAF from willing sellers (with just over half that coming from CVP water), it would appear that many agricultural buyers are not likely to have their needs addressed by the 2009 DWB? If so, the Bureau and DWR should state the likelihood that all urban requests and perhaps no agricultural requests will be fulfilled in order to achieve a full and correct environmental compliance treatment of the proposed action. Such an estimate is necessary for accurate explication of the chains of cause and effect associated with the 2009 DWB—and which must propagate throughout a NEPA document for it to be adequate as an analysis of potential natural and human environmental effects of the proposed project. We have additional specific questions:

- Within the request of the San Luis and Delta Mendota Water Authority (SLDMWA), its requesters include SCVWD in Table 2 of the EA/FONSI. Is this request for an agricultural use or an urban use of DWB water? At 30,000 acre-feet, it represents one-sixth of SLDMWA's 180,000 acre-feet request. If it is entirely for agricultural uses, how likely is it to be fulfilled under DWB priorities for water sales?
- What are the specific urban requests for water made by Avenal State Prison, and the cities of Avenal, Huron, and Coalinga, nested within the SLDMWA request?
- Sale criteria should be premised on full compliance with all applicable environmental and water rights laws.

Application of DWB priority criteria will depend on intervening economic factors beyond the control of the DWB. Given this uncertainty, an EIS should be prepared to provide the agencies with advance information and insight into what the sensitivity of the program's sellers and buyers are to the influences of prices—prices for water as well as crops such as rice, orchard and vineyard commodities, and other field crops. It is plausible that crop idling will occur more in field crops, while groundwater substitution would be more likely for orchard and vineyard crops. However, high prices for rice—the Sacramento Valley's largest field crop—would undermine

---

[2] Neither DWR's Addendum nor the Bureau's EA specify numerical requests for the cities of Huron, Avenal, Coalinga, and the Avenal State Prison making it impossible to have a firmer number for the amount of urban request for water. Our estimate assumes SCVWD's 30,000 AF and MWD's 300,000 AF requests are for entirely urban uses of DWB-purchased water.

this logic, and could lead to substantial groundwater substitution. We have further extensive concerns about this, described below.

On page 96, the EA finally acknowledges this reality of crop prices:

> *"Hydrologic conditions change the supply of water available for transfers, which would shift the price of water. The difference in supply of water in a wet and dry year amounts to millions of acre-feet. The regional source of the water plays a role in pricing as well. Also, agricultural prices could also affect supply of water transfers. Small changes in agricultural prices can have a large effect on water transfer supply because net returns in farming are very responsive to agricultural prices. These factors are not controlled by participants in the market."*

This statement is actually not a matter of cumulative effects, but an integral part of the chains of cause and effect that affect how the DWB would unfold in the human and natural environments. It should be recognized as part of the 2009 DWB description and should directly apply to the Agriculture and Land Use, and Socioeconomic sections of the EA, because crop prices are key factors in choices potential water sellers would weigh in deciding whether to idle crops, substitute groundwater, or decline to participate in the DWB altogether. The EA and Addendum are inadequate because they fail to identify and analyze the market context for crops as well as water that would ultimately influence the size and scope of the DWB in 2009.

Rice prices are high because of conditions for the grain in the world market. Drought elsewhere is a factor in reduced yields, but growing populations in south and east Asia demand more rice and the rice industry has struggled to meet that demand.[3]

This is very important. The Bureau tacitly admits that the Bureau—and by logical extension, DWR—has no idea how many sales of what type (public health, urban, agricultural) can be expected to occur. Put another way, there is a range of potential outcomes for the 2009 DWB, and yet the Bureau has failed utterly to use the EA to examine a reasonable and representative range of alternatives as it concerns how the priority criteria would affect DWB transfers. And DWR did not bother to conduct an appropriate level of review under the California Environmental Quality Act.

Nor does the 2009 DWB prevent rice growers (or other farmers) from "double-dipping." It appears to us they could opt to turn back their surface supplies from the CVP and the State Water Project and substitute groundwater to cultivate their rice crop—thereby receiving premiums on both their CVP contract surface water as well as their rice crop this fall when it goes to market. There appear to be no caps on water sale prices to prevent windfall profits to sellers of Sacramento Valley water in the event that groundwater is substituted in producing crops—

---

[3] "Panic over rice prices hits California," *AZCentral.com*, April 24, 2008; UN News Service, "Bumper rice harvests could bring down prices but poor may not benefit, warns UN," 25 February 2009; "Era of cheap rice at an end in Taiwan: COA," *The China Post*, March 5, 2009; Jim Downing, "Sacramento Valley growers se rice prices soar," *Sacramento Bee*, 18 January 2009.

especially for crops where market prices are high, such as in rice. The DWB in the 1990s capped water prices at $125/acre-foot, much to the disappointment of some water sellers at that time. Why are the state and federal projects encouraging such potential windfall profits at a time when many others suffer through this recession?

As stated, neither the Bureau nor DWR state how much of these transfers would go to public health, urban or agricultural buyers. The EA must also (but fails to) address the ability and willingness of potential buyers to pay for DWB water given the supplies that may be available. Historically, complaints from agricultural water districts were registered in the comments on the Draft EWA EIS/R and reported in the Final EIS/R in January 2004 indicating that they could not compete on price with urban areas buying water from the EWA. Given the DWB's priority criteria, will agricultural water buyers identified in Table 2 of the EA be able to buy water when competing with the likes of the Santa Clara Valley Water District and the Metropolitan Water District, representing two of the wealthiest regions of California? As a matter of statewide water, infrastructure, and economic policy, is it wise to foment urban versus agricultural sector competition for water based solely on price? Shouldn't other factors be considered in allocating water among our state's regions? This fails dramatically to encourage regions to develop their own water supplies more efficiently and cost-effectively without damage to resources of other regions.

Full disclosure of each offer of and each request for DWB water should be provided as part of the EA. This is necessary so the public can understand and have confidence in the efficacy of the DWB, benefit from full disclosure of who requests how much DWB water and for what uses, and so that the public may easily verify chains of cause and effect. Urban application of transferred surface water is not examined in the EA/FONSI, as though how urban buyers would use their purchased water had no environmental effects. Since the dry period could last beyond 2009, how will purchased water be used and conserved?

Nor is a hierarchy of priority uses among urban users stated in the criteria for purchasing DWB water. Could purchased water be used for any kind of landscaping, rather than clearly domestic purposes or strictly for drought-tolerant landscaping? We cannot tell from the EA/FONSI narrative. How can the citizens of California be assured that water purchased through the DWB will not be used wastefully, in violation of the California Constitution, Article X, Section 2?

Will urban users need their DWB purchased water only in July through September, or is that the delivery period preferred in the DWB because of ecological and fishery impact constraints on conveyance of purchased water?

Should agricultural water users be able to buy any DWB water, how will DWR and the Bureau assure that transferred water for irrigation is used efficiently? Many questions are embedded within these concerns that DWR and the Bureau should address, especially when they approach the State Water Resources Control Board to justify consolidating their places of use in their respective water rights permits:

- How much can be expected to be purchased by agricultural water users, given the priority criteria of the 2009 Drought Water Bank?
- How much can be expected to be consumptively used by agricultural water buyers?
- How much can be expected to result in tailwater and ag drainage?
- How much can be expected to add to the already high water table in the western San Joaquin Valley?
- What selenium and boron loads in Mud Slough and other tributaries to the San Joaquin River may be expected from application of this water to WSJ lands?
- What mitigation measures are needed to limit such impacts consistent with the public trust doctrine, Article X, Section 2 of the California Constitution, the Porter-Cologne Water Quality Control Act, and California Fish and Game Code Section 5937?

In other words, the most important chains of cause and effect—extending from the potential for groundwater resource impacts in the Sacramento Valley to potential for contaminated drainage water from farm lands in the western San Joaquin Valley where much of the agricultural buyers are located—are ignored in the Bureau's EA and DWR's Notice of Exemption based upon its EWA EIS/R Addendum.

Will more of surface water transfers go to urban users than to ag users given the 2009 DWB priority criteria? The EA's silence on this is disturbing, and suggests that the DWB's priority criteria may not be that important to the actual functioning of the DWB. What assurances will the Bureau and DWR provide that these criteria will be closely followed?

- The more that goes to urban water agencies the less environmental impacts there would be on drainage impaired lands of the San Joaquin Valley, a neutral to beneficial impact of the DWB's operation on high groundwater and drainage to the SJR.
- However, the more DWB water goes to agricultural users than to urban users, the higher would be groundwater levels, and more contaminated the groundwater would be in the western San Joaquin Valley and the more the San Joaquin River would be negatively affected from contaminated seepage and tailwater by operation of the DWB.

The EA fails to provide a map indicating where the sources of the DWB are located, and where the service areas are to which water would be transferred under the DWB.

Two issues concerning water rights are raised by this EA/FONSI:

- **Consolidated Place of Use.** Full disclosure of what the consolidated places of use for DWR and USBR would be, since the permit request to SWRCB will need NEPA coverage. Why is this consolidated place of use sought by the project agencies? Does consolidation mean that each project agency has the other's place of use, effectively a merger of the permits for DWB purposes? If so, the EA should state so. Will the consolidation be a permanent or temporary request be limited to the duration of the governor's emergency declaration or of just the 2009 DWB? When is the 2009 DWB scheduled to sunset? How do the consolidated place of use permit amendments to the

SWP and CVP permits relate to their joint point of diversion? Why doesn't simply having the joint point of diversion in place under D-1641 suffice for the purpose of the DWB?

- **Description of the water rights of both sellers and buyers.** This would necessarily show that buyers clearly possess junior water rights as compared with those of willing sellers. Lack of full disclosure of these disparate rights is needed to help explain the actions and motivations of buyers and sellers in the DWB, otherwise the public and decision makers have insufficient information on which to support and make informed choices.
    - **Sacramento Valley water rights –** correlative groundwater rights, riparian rights and CVP settlement contract rights
    - **San Joaquin Valley water rights –** CVP contract rights only, junior-most contractors within the CVP priority system (especially Westlands Water District).
    - **Priority of allocations among water contractors within the CVP and SWP.**

To establish a proper legal context for these water rights, the Project Action Alternative section of the EA/FONSI should also describe the applicable California Water Code sections about the treatment of water rights involved in water transfers.

Thus, there are many avenues by which the 2009 DWB is a poorly specified program for NEPA and CEQA purposes, leaving assessment of its environmental effects at best murky, and at worst, risky to all involved, especially users of Sacramento Valley groundwater resources.

B. Correcting the EA's poorly specified chains of cause and effect forces consideration of an expanded range of alternatives.

The Proposed Action Alternative need not have sophisticated forecasts of prices for rice and other commodities. Instead, for an adequate treatment of alternatives, the EA should have examined several reasonable scenarios beyond simply the 2009 DWB and a "no action" alternative. Three reasonable permutations would have considered relative proportions of crop idling versus groundwater substitution (e.g., high/low, low/high, and equal proportions of crop idled water and groundwater substitution). Other reasonable drought response alternatives that can meet operational and physical concerns merit consideration and analysis by the Bureau include:

- Planned permanent retirement of upslope lands in the western San Joaquin Valley where CVP-delivered irrigation water is applied to lands contaminated with high concentrations of selenium, boron and mercury, and which contribute to high water table and drainage problems for lowland farmers, wetlands and tributaries of the San Joaquin River. Retirement of these lands would permanently free up an estimated 3 million acre-feet of state and federal water during non-critical water years. Ending irrigation of these lands would also result in substantial human environmental benefits for the San Joaquin River, the Bay-Delta Estuary, and the Suisun Marsh from removal of selenium, boron, and salt contamination. Having such reasonable and pragmatic practices in place would go a long way to eliminate the need for drought water banks in the foreseeable future.

- More aggressive investment in agricultural and urban water conservation and demand management among CVP and SWP contractors even on good agricultural lands, including metering of all water supply hook-ups by all municipal contractors, statewide investment in low-flush toilets and other household and other buildings' plumbing fixtures, and increased capture and reuse of recycled water. Jobs created from such savings and investments would represent an economic stimulus that would have lasting job and community stability benefits as well as lasting benefits for water supply reliability and environmental stabilization.

C. The 2009 DWB EA fails to specify adequate environmental baselines, or existing conditions, against which impacts would be assessed and mitigation measures designed to reduce or avoid impacts.

The 2009 DWB environmental reviews by DWR and the Bureau incorporate by reference for specific facets of their review the 2003 and 2007 Environmental Water Account EIS/R documents. In both cases, these environmental reviews were conducted on a program whose essential purpose is to "provide protection to at-risk native fish species of the Bay-Delta estuary through environmental beneficial changes in State Water Project/Central Valley Project operations at no uncompensated water cost to the Projects' water users. This approach to fish protection involves changing Project operations to benefit fish and the acquisition of alternative sources of project water supply, called the 'EWA assets,' which the EWA agencies use to replace the regular Project water supply lost by pumping reductions."

The two basic sets of actions of the EWA were to:

- Implement fish actions that protect species of concern (e.g., reduction of export pumping at the CVP and SWP pumps in the Delta); and
- Increase water supply reliability by acquiring and managing assets to compensate for the effects of the fish actions (such as by purchasing water from willing sellers for instream flows that compensates the sellers for foregone consumptive use of water).

Without going into further detail on the EWA program, there is no attempt by the EWA agencies to characterize its environmental review as reflective of water transfer programs generally; the EWA was a specific set of strategies whose purpose was protection of fish species of concern in the Delta, not drought aid for junior water right-holding areas of California. One consequence of this attempt to rely on the EWA EIS/R is that it makes the public's ability to understand the environmental baseline of the 2009 Drought Water Bank impossible, because environmental baselines, differing purpose and need for the project, and many relevant mitigation measures are not readily available to the public. This mocks NEPA and CEQA missions to inform the public adequately about the environmental setting and potential impacts of the proposed project's actions. Moreover, a Drought Water Bank is plainly not the same thing as an Environmental Water Account.

Another consequence is that the chains of cause and effect of an EWA versus a DWB are entirely different because of their different purposes. While the presence of water purchases, willing sellers, and requesting buyers is similar, the timing of EWA water flows are geared to enhancing and protecting fish populations; the water was to flow in Delta channels to San Francisco Bay and the Pacific Ocean. In stark contrast, the DWB's water flows focus water releases from the SWP and CVP reservoirs to be exported for deliveries in the July through September period, whereas EWA assets would be "spent" year-round depending on the specific need to protect fish. EWA was about purchasing water to provide instream flows in the Delta, while the DWB is to acquire water to serve consumptive uses outside of the Delta.

Furthermore, to tease out the various ways in which the EWA review—itself a two-binder document consisting of well over 1,000 pages—could be used to provide appropriate environmental compliance for the DWB is not even attempted by DWR and the Bureau which at least has staff that could have been assigned to undertake it; yet they do not. It is therefore well beyond the reach of non-expert decision-makers and the public, and the use of the EWA EIS/R as the basic environmental review for the DWB therefore violates both NEPA and CEQA.

Nor is any attempt made in the EWA EIS/R to characterize the EWA as a "program level" environmental review off of which a DWB-like project could perhaps legitimately tier. In our view, this reliance on the EWA EIS/R obscures the environmental baselines of the DWB from public view, inappropriately conflates the purposes of two distinct environmental reviews, and flagrantly violates of NEPA and CEQA. This could only be redressed by preparation of an EIS/R on the 2009 DWB.

Finally, the most significant baseline condition omitted in the Bureau and DWR's inadequate reporting relates to Sacramento Valley groundwater resources, discussed in the next section.

D. Scientific uncertainties and controversy about Sacramento Valley groundwater resources merit consideration that only an EIS can provide.

There is substantial evidence that the 2009 DWB may have significant impacts on the aquifer system underlying the project and the adjacent region that overlies the Tuscan Formation. This alone warrants the preparation of an EIS.

Additionally, an EIS is necessary where "[a] project['s] … effects are 'highly uncertain or involve unique or unknown risks.'" *Blue Mountains Biodiversity Project*, 161 F.3d at 1213 (quoting 40 C.F.R. §1508.27(b)(5)). Here, the draft EA/FONSI fails to adequately address gaps in existing scientific research on the hydrology of the aquifer system and the extent to which these gaps affect the Bureau's ability—and by logical extension, DWR's ability—to assess accurately the Project's environmental impacts.

1. Existing research on groundwater conditions indicates that the 2009 DWB may have significant impacts on the aquifer system.

The EA fails to describe significant characteristics of the aquifers that the 2009 DWB proposes to exploit. These characteristics are relevant to an understanding of the potential environmental effects associated with the 2009 DWB's potential extraction of up to 340,000 acre feet ("af") of groundwater. Environmental Water Account 2003 EIS/EIR Record of Decision at p. 11; Draft Supplemental Environmental Water Account 2007 EIS/EIR at p. ES-6; 2009 Drought Water Bank addendum 12/17/08 at p. 2, 3, 9; 2009 Drought Water Bank addendum 3/4/09 at p. 2, 3, 9. First, the draft EA/FONSI fails to describe a significant saline portion of the aquifer stratigraphy of the 2009 DWB area. According to Toccoy Dudley, former Groundwater Geologist with the Department of Water Resources and former director of the Butte County Water and Resources Department, saline groundwater aquifer systems of marine origin underlie the various freshwater strata in the northern counties of Butte, Colusa, Glenn, and Tehama ("northern counties"). The approximate contact between fresh and saline groundwater occurs at a depth ranging from 1500 to 3000 feet. (Dudley 2005) (A list of all references cited in these comments can be found at the end of this letter.)

Second, the EA fails to discuss the pressurized condition of the down-gradient portion of the Tuscan formation, which underlies the northern counties Project area. Dudley finds that the lower Tuscan aquifer located in the Butte Basin is under pressure. "It is interesting to note that groundwater elevations up gradient of the Butte Basin, in the lower Tuscan aquifer system, are higher than the ground surface elevations in the south-central portion of Butte Basin. This creates an artesian flow condition when wells in the central Butte Basin are drilled into the lower Tuscan aquifer." (Dudley 2005). The artesian pressure indicates recharge is occurring in the up-gradient portions of the aquifer located along the eastern margin of the Sacramento Valley.

Third, the EA fails to describe the direction of movement of water through the Lower Tuscan Formation that underlies the northern counties. According to Dudley: "From Tehama County south to the city of Chico, the groundwater flow direction in the lower Tuscan is westerly toward the Sacramento River. South of Chico, the groundwater flow changes to a southwesterly direction along the eastern margin of the valley and to a southerly direction in the central portion of the Butte Basin." (Dudley 2005).

Fourth, the draft EA fails disclose that the majority of wells used in the Sacramento Valley are individual wells that pump from varying strata in the aquifers. The draft EA incorrectly asserts that, "Groundwater users in the basin pump primarily from deeper continental deposits." EA at p. 24. Contradicting this assertion, the EA later states that, "Fifty percent of the domestic wells are 150 feet deep or less," for the Natomas Central Mutual Water Company. (EA at p. 30) Why is the information not provided for other areas of the Sacramento Valley? The thousands of domestic wells in the northern counties are as susceptible as the wells in the Natomas Central MWC. The EA expands the discussion regarding Natomas Central MWC on page 39 stating that, "Shallow domestic wells would be most susceptible to adverse effects. Fifty percent of the domestic wells are 150 feet deep or less. Increased groundwater pumping could cause localized declines of groundwater levels, or cones of depression, near pumping wells, possibly causing effects to wells within the cone of depression. As previously described, the well review data, mitigation and monitoring plans that will be required from sellers during the transfer approval process will reduce the potential for this effect." As the latter statement makes clear, the Bureau hopes that the individual mitigation and monitoring plans will reduce the potential for impact, but there is no assurance in the EA to the thousands of well owners in the Sacramento Valley that it will reduce it to a level of insignificance. The Coalition questions the adequacy of individual mitigation and monitoring plans and suggests that an independent third party, such as USGS, oversee the mitigation and monitoring program. After the fiasco in Butte County during the 1994 Drought Water Bank and with the flimsy, imprecise proposal for mitigation and monitoring in the 2009 DWB, the agencies lack credibility as oversight agencies.

Fifth, the draft EA fails to provide recharge data for the aquifers. Professor Karin Hoover, Assistant Professor of hydrology, hydrogeology, and surficial processes from CSU Chico, finds that, "Although regional measured groundwater levels are purported to 'recover' during the winter months (Technical Memorandum 3), data from Spangler (2002) indicate that recovery levels are somewhat less than levels of drawdown, suggesting that, in general, water levels are declining." According to Dudley, "Test results indicate that the 'age' of the groundwater samples ranges from less than 100 years to tens of thousands of years. In general, the more shallow wells in the Lower Tuscan Formation along the eastern margin of the valley have the 'youngest' water and the deeper wells in the western and southern portions of the valley have the 'oldest' water," adding that "the youngest groundwater in the Lower Tuscan Formation is probably nearest to recharge areas." (Dudley 2005). "This implies that there is currently no active recharge to the Lower Tuscan aquifer system (M.D. Sullivan, personal communication, 2004)," explains Dr. Hoover. "If this is the case, then water in the Lower Tuscan system may constitute fossil water with no known modern recharge mechanism, and, once it is extracted, it is gone as a resource," (Hoover 2008).

All of these aquifer characteristics are important to a full understanding of the environmental impacts of the 2009 DWB because there are numerous indications that other aquifer strata associated with the Lower Tuscan Formation are being operated near the limit of overdraft and could be affected by the 2009 DWB. (Butte County 2007). The Bureau has not considered this important historic information in the draft EA. According to Dudley, the Chico area has a "*long term average decline in the static groundwater level of about 0.35 feet-per-year*." (Dudley 2007) (Emphasis added.) Declining aquifer levels are not limited to the Chico Municipal area. This trend of declining aquifer levels in Chico, Durham and the Cherokee Strip is illustrated in a map submitted with this comment letter. (CH2M Hill 2006).

Declining groundwater elevations have been observed specifically in Butte County. A 2007 Butte Basin Groundwater Status Report describes the "historical trend" in the Esquon Ranch area as showing "seasonal fluctuation (spring to fall) in groundwater levels of about 10 to 15 feet during years of normal precipitation and less than 5 feet during years of drought." The report further notes: "Long-term comparison of spring-to-spring groundwater levels shows a decline of approximately 15 feet associated with the 1976-77 and 1986-94 droughts. (Butte Basin Water

Users Association, 2007.) The 2008 report indicates that, “The spring 2008 groundwater level measurement was approximately three feet higher than the 2007 measurement, however it was still four feet lower than the average of the previous ten spring measurements. Fall groundwater levels are approximately nine feet lower than the averages of those measured during either of the previous drought periods on the hydrograph. At this time it appears that there may be a downward trend in groundwater levels in this well.” (Butte Basin Water Users Association, 2008.) Thus, “*it appears that there may be a downward trend in groundwater levels in this well*.” *Id.* (emphasis added).

Groundwater elevations in the Pentz sub-area in Butte County also reveal significant historical declines. The historical trend for this sub-area “…shows that the average seasonal fluctuation (spring to fall) in groundwater levels averages about 3 to 10 feet during years of normal precipitation and approximately 3 to 5 feet during years of drought. Long-term comparison of spring-to-spring groundwater levels shows a decline in groundwater levels during the period of 1971-1981, perhaps associated with the 1976-77 drought. Since a groundwater elevation high of approximately 145 feet in 1985 the measured groundwater levels in this well have continued to decline. Recent groundwater level measurements indicate that the groundwater elevation in this well is approximately 15-25 feet lower than the historical high in 1985. *Id.* Water elevations at the Pentz sub-area well have been monitored since 1967. “Since 1985 spring groundwater levels in this well have been declining, and the spring 2008 measurement remained ten feet below historical high levels and continues the downward trend on the hydrograph.” *Id.* (Emphasis added.)

Both the Pentz and Esquon Ranch areas are located east of U.S. 99, in the eastern portion of the Tuscan aquifer.

In light of this downward trend in regional groundwater levels, the Bureau’s EA should closely analyze replenishment of the aquifers affected by the proposed 2009 DWB. The draft EA fails to provide any in-depth assessment of these issues. For example, the EA fails to discuss the best available estimates of where groundwater replenishment occurs. Lawrence Livermore National Laboratory analyzed the age of the groundwater in the northern counties to shed light on this process: “Utilizing the Tritium (H3) Helium-3 (He3) ratio, the age of each sample was estimated. Test results indicate that the “age” of the groundwater samples ranges from less than 100 years to tens of thousands of years,: (Dudley et al. 2005). As mentioned above, Dudley opines that the youngest groundwater in the Lower Tuscan Formation is probably nearest to recharge areas. (2005).

Are isotopic groundwater data available for other regions in the Sacramento Valley? If so, they would be crucial for all concerned to understand the potential impacts from the proposed 2009 DWB. For example, the EA states, “The WFA area that could be affected by the proposed action includes only the ‘North Area’ bounded on the north and east by the Sacramento County line, by the Sacramento River on the west, and by the American River on the south.” EA at p. 34. If this is the area in Sacramento County that is identified as most vulnerable to groundwater impacts, yet two major rivers surround it, shouldn't the Bureau understand the hydrologic relationship between the groundwater basin and the rivers? If that understanding exists, where is it presented in the EA? It is well known that the Sacramento River is already a losing river south of Princeton.

The Bureau should prepare an EIS that considers this and other existing research to evaluate the 2009 DWB's anticipated effect on regional hydrology.

2. The 2009 DWB proposes to rely on inadequate monitoring to avoid the acknowledged possibility of significant adverse environmental impacts.

The draft EA relies deflects responsibility of the Bureua and DWR for monitoring to individual "willing sellers." EA at p. 21. This fails to provide the most basic framework for governmental authority to enforce the state's role as trustee of the public's water in California, let alone a comprehensive and coordinated structure, for a very significant program that could transfer up to 389,328 af of water from the Sacramento Valley. (Recall that DWR suggests potential sale of water up to 533,000 AF, and believes it has environmental compliance coverage for up to 600,000 AF of water sales from the Sacramento Valley, including 340,000 AF in groundwater substitution alone.) The draft EA further defers responsibility to local groundwater management plans and ordinances to determine when the effects of the proposed extraction become "adverse." EA at p. 22. "As described in Section 3.2, well reviews and monitoring and mitigation plans will be implemented under the proposed action to minimize potential effects of groundwater substitution. Well reviews, monitoring and mitigation plans will be coordinated and implemented in conjunction with local ordinances, basin management objectives, and all other applicable regulations." EA at p. 10. The draft EA merely provides monitoring direction to "willing sellers" without identifying specific actions, responsible agencies, or funding that will be necessary for this oversight. This is unacceptable.

We propose instead that the Bureau and DWR require at a minimum that local governments select independent third-party monitors, who are funded by surcharges on DWB transfers paid by the buyers, to oversee the monitoring that is proposed in lieu of Bureaus and DWR staff. EA at p. 41-45.

Otherwise, the DWB's proposed monitoring is insufficient and cannot justify the significant risk of adverse environmental impacts. For example, the EA fails to identify standards that would be used to monitor the 2009 DWB's impacts. It fails to identify any specific monitoring protocols, locations (particularly in up-gradient recharge portions of the groundwater basins), and why chosen locations should be deemed effective for monitoring the effects of the proposed groundwater extraction. It also fails to describe how the objectives in the Drought Water Transfer White Paper will be met and by whom. EA at p.43. Moreover, it fails to provide a mitigation strategy for review and comment by the public, but defers this vital mitigation planning effort. EA at p.43. Another example of the inadequacy of the proposed monitoring is that the draft EA fails to include any plan to monitor stream flow of creeks located in the presumed recharge area for the Lower Tuscan Formation located on the eastern edge of the Sacramento Valley.

Adequate monitoring is vital to limit the significant risks posed by the DWB to the health of the region's groundwater, streams, and fisheries, as discussed below. Moreover, to the extent this Project is conceived as a one-year drought program that will provide knowledge for future groundwater extraction, its failure to include adequate monitoring protocols is even more disturbing and creates the risk of significant long-term and even irreversible impacts from the DWB.

a. The Bureau's assertion that the DWB will be modified or halted in the event of significant adverse impacts to hydrologic resources is an empty promise in light of the wholly inadequate monitoring provided for in the DWB. Knowing that the Bureau and DWR knowingly violated the X2 standard in the Delta in February 2009 does little to instill confidence from the Coalition in non-specific program and mitigation criteria.

The EA repeatedly illustrates that there is potential for significant injury to other groundwater users, water quality, streams, flora and fauna, and the soil profile, EA at p. 36-41. Page 36 alone has numerous examples that illustrate the need for an EIS since there is insufficient, comprehensive planning for, let alone preparation to mitigate, adverse environmental impacts:

- *Crop idling and groundwater substitution transfers under the proposed action could affect groundwater resources. Changes in groundwater levels could cause secondary effects. Declining groundwater levels could result in: 1) increased groundwater pumping cost due to increased pumping depth, 2) decreased yield from groundwater wells due to reduction in the saturated thickness of the aquifer, 3) reduced groundwater in storage, and 4) decrease of the groundwater table to a level below the vegetative root zone, which could result in environmental effects.*
- *Groundwater pumping within the vicinity of a surface water body could change the existing interactions between surface and groundwater, potentially resulting in decreased stream flows and levels, with potential adverse effects to the riparian habitat and downstream users. The pumping of groundwater near wetland habitats could also result in adverse environmental effects.*
- *Excessive groundwater extraction from confined and unconfined aquifers could result in a lowering of groundwater levels and, in confined aquifers, a decline in water pressure. The reduction in water pressure results in a loss of support for clay and silt beds, which subsequently compress, causing a lowering of the ground surface (land subsidence). The compaction of fine-grained deposits, such as clay and silt, is permanent. The possible consequences of land subsidence are 1) infrastructure damage and 2) alteration of drainage pattern.*
- *Changes in groundwater levels or in the prevailing groundwater flow regime could cause a change in groundwater quality through a number of mechanisms. One mechanism is the potential mobilization of areas of poorer quality water, drawn down from shallow*

> *zones, or drawn up into previously unaffected areas. Changes in groundwater gradients and flow directions could also cause (or speed) the lateral migration of poorer quality water. Artificial or enhanced recharge of the aquifer with water of poorer quality, or even different geochemical constituents, could also have an adverse effect on existing conditions. Geochemical differences between the recharged water and groundwater could affect resultant groundwater quality through geochemical processes such as precipitation, bacterial activity, ion exchange, and adsorption.*

The Bureau thus recognizes the potential for significant decline in groundwater levels as a result of the proposed activity. EA at p. 36, 37. This acknowledgement alone is sufficient to require a full EIS. Moreover, as detailed below, the monitoring proposed by the 2009 DWB is so inadequate that there can be no guarantee that adverse impacts will be discovered, or that they will be discovered in time to avoid significant environmental impacts.

Glenn County is noticeably omitted from the list of counties with some local regulatory authority. EA at p. 28-29. Glenn County does have a Groundwater Management Plan (adopted in August 2001), albeit inadequate. The Bureau's own 2008 EA for the GCID Seven Wells Project cautioned that "[s]ince the groundwater management plan is relatively new and not fully implemented, the enforcement and conflict resolution process has not been vigorously tested." Moreover, the Glenn County Groundwater Management Plan does not have any provisions to monitor or protect the environment. The 2009 DWB EA fails to explain why this management plan, as inadequate as it is, is not discussed nor is the absence of local protection mentioned.

b. Monitoring based on the Glenn County Groundwater Management Plan is inadequate. Since the Bureau omitted discussion of the Glenn County Groundwater Management Plan in the 2009 DWB, we refer to the language used in the 2008 Stony Creek Fan EA/FONSI that explained that the existing Glenn County groundwater management plan will ensure the testing project will have no significant adverse effects on groundwater levels: "This Finding of No Significant Impact (FONSI) is based upon the following: … Implementation of the Glenn County Groundwater Management Plan during the aquifer performance testing plan will ensure that the proposed action will not result in any significant adverse effect to existing groundwater levels." Stony Creek Fan EA/FONSI at p. 2.

But the Butte County Department of Water and Resource Conservation explains that local plans are simply not up to the task of managing a regional resource:

> *Glenn County does not have an export ordinance because it relies on Basin Management Objectives (BMO) to manage the groundwater resource, and subsequently to protect third parties from transfer related impacts. Recently, Butte County also adopted a BMO type of groundwater management ordinance. Butte County, Tehama County and several irrigation districts in each of the four counties have adopted AB3030 groundwater management plans. All of these groundwater management activities were initiated prior to recognizing that a regional aquifer system exists that extends over more than one*

> *county and that certain activities in one county could adversely impact another. Clearly the current ordinances, AB3030 plans, and local BMO activities, which were intended for localized groundwater management, are not well suited for management of a regional groundwater resource like that theorized of the Lower Tuscan aquifer system.*

(Butte County DWRC 2007).[4]

c. The EA fails to propose real time monitoring for land subsidence. Third-party independent verification, perhaps by scientists from the U.S. Geological Survey, should be incorporated by DWR and the Bureau into the project description of the 2009 DWB. The draft EA/FONSI relies on very few existing extensometers in the Sacramento Valley that measure land subsidence, and a Global Positioning System land subsidence network established by one county. EA/FONSI at p. 26 and 32. The remaining responsibility is again deferred to the "willing sellers." Unfortunately, voluntary monitoring by pumpers does not strike us as a responsible assurance given the substantial uncertainties involved in regional aquifer responses to extensive groundwater pumping in the Sacramento Valley.

Not only is there a failure to discuss real time monitoring for subsidence, there also is no discussion regarding delayed subsidence that should also be monitored according to the findings of Dr. Kyran Mish, Presidential Professor, School of Civil Engineering and Environmental Science at the University of Oklahoma. Dr. Mish notes: "It is important to understand that *all* pumping operations have the potential to produce such settlement, and when it occurs with a settlement magnitude sufficient enough for us to notice at the surface, we call it *subsidence,* and we recognize that it is a serious problem (since such settlements can wreak havoc on roads, rivers, canals, pipelines, and other critical infrastructure)." (Mish 2008). Dr. Mish further explains that "[b]ecause the clay soils that tend to contribute the most to ground settlement are highly impermeable, their subsidence behavior can continue well into the future, as the rate at which they settle is governed by their low permeability." *Id.* "Thus simple real-time monitoring of ground settlement can be viewed as an *unconservative* measure of the potential for subsidence, as it will generally tend to underestimate the long-term settlement of the ground surface." *Id.* (emphasis added).

d. The 2009 DWB EA fails to require stream flow monitoring, choosing to defer the monitoring and mitigation planning to "willing sellers." We also urge incorporation of frequent and regular streamflow monitoring by either staff of the project agencies or a third, independent party such as the USGS, paid for by DWB transfer surcharges mentioned above. It is clear from existing scientific studies and the EA that the DWB may have significant impacts on the aquifers replenishment and recharging of the aquifers, and the 2009 DWB should therefore require extensive monitoring of regional streams. The radius for monitoring should be large, not the typical two to three miles as usually used by DWR and the Bureau. Though not presented for the

---

DWB, the *Stony Creek Fan Aquifer Performance Testing Plan, which is a much smaller project,* recognized that there may be a drawdown effect on the aquifer by considering results from a DWR Northern District spring 2007 production well test (EA/FONSI p. 28). However, it did not assess the anticipated scope of that effect—or even what level of effect would be considered acceptable. Moreover, the results from that test well indicate that the recharge source for the solitary production well "is most likely from the foothills and mountains, to the east and north"—which at a minimum is more than fifteen miles away. (DWR, Glenn-Colusa Irrigation District Aquifer Performance Testing Glenn County, California).

The Butte County Department of Water and Resource Conservation has identified streams that must be monitored to determine impacts to stream flows that would be associated with pumping the Lower Tuscan Aquifer. These "[s]treams of interest" are located on the eastern edge of the Sacramento Valley and include: Mill Creek, Deer Creek, Big Chico Creek, Butte Creek, and Little Dry Creek. (The Butte County DWRC 2007). The department described the need and methodology for stream flow gaging:

> *The objective of the stream flow gaging is to determine the volume of surface water entering into or exiting the Lower Tuscan Aquifer along perennial streams that transect the aquifer formation outcropping for characterization of stream-aquifer interactions and monitoring of riparian habitat. Measurement of water movement into or out of the aquifer will allow for testing of the accuracy of the Integrated Water Flow Model, an integrated surface water-groundwater finite differential model developed for the eastern extent of the Lower Tuscan aquifer.*
>
> *Two stream gages will be installed on each of five perennial streams crossing the Lower Tuscan Formation to establish baseline stream flow and infiltration information. The differences between stream flow measurements taking upstream and downstream of the Lower Tuscan Formation are indications of the stream-aquifer behavior. Losses or gains in stream volume can indicate aquifer recharge or discharge to or from the surface waters.*

Id.

As evident in the following conclusory assertions, the draft EA/FONSI narrowly defines the radius of influence associated with the aquifer testing and thus entirely fails to identify potential significant impacts to salmon:

> "Interaction with Surface Water - Pumping close to the Sacramento River, and close to tributaries could reduce channel flows. This reduction in channel flows could adversely affect riparian and aquatic habitats, including wildlife refuge habitat, as well as downstream water users… Groundwater pumping for groundwater substitution transfers could reduce flows in nearby surface water bodies. (EA at p. 38)

Monitoring of flow on streams associated with the Lower Tuscan Formation is particularly important to the survival of Chinook salmon which use these “streams of interest” to spawn and where salmon fry rear. Intensive groundwater pumping would likely lower water table elevations near these streams of interest, decreasing surface flows, and therefore reducing salmon spawning and rearing habitat through dewatering of stream channels in these northern counties. This would be a significant adverse impact of the DWB and is ignored by the EA.

A similar effect has been observed in the Cosumnes River, where “[d]eclining fall flows are limiting the ability of the Cosumnes River to support large fall runs of Chinook salmon.” This is a river that historically supported a large fall run of Chinook Salmon. *Id.* Indeed, “[a]n early study by the California Department of Fish and Game . . . estimated that the river could support up to 17,000 returning salmon under suitable flow conditions.” *Id.*, citing CDFG 1957 & USFWS 1995. But “[o]ver the past 40 years fall runs ranged from 0 to 5,000 fish according to fish counts by the CDFG (USFWS 1995),” and “[i]n recent years, estimated fall runs have consistently been below 600 fish, according to Keith Whitener.” (Fleckenstein, *et al*. 2004). Indeed, “[f]all flows in the Cosumnes have been so low in recent years that the entire lower river has frequently been completely dry throughout most of the salmon migration period (October to December).” *Id.*

Research indicates that “groundwater overdraft in the basin has converted the [Cosumnes River] to a predominantly losing stream, practically eliminating base flows….” (Fleckenstein, *et al*. 2004). And “investigations of stream-aquifer interactions along the lower Cosumnes River suggest that loss of base flow support as a result of groundwater overdraft is at least partly responsible for the decline in fall flows.” *Id.* Increased groundwater withdrawals in the Sacramento basin since the 1950s have substantially lowered groundwater levels throughout the county.” *Id.*

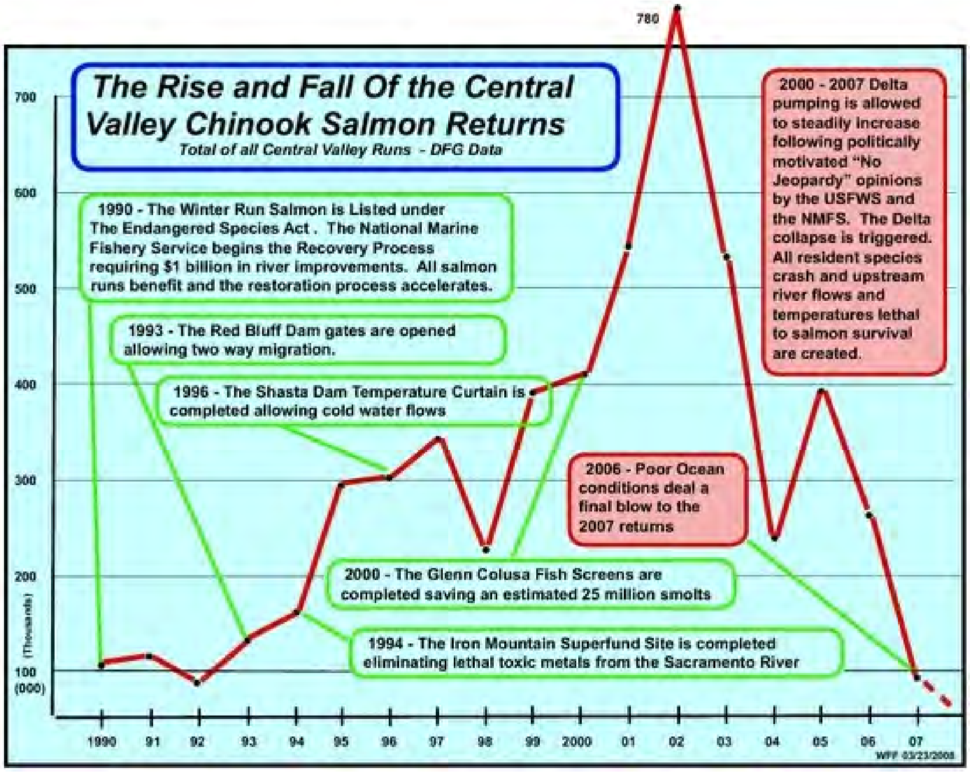
The draft EA acknowledges the potential for impacts to special status fish species from altered river flows and commits to maintaining flow and temperature requirements already in place. (EA at p. 70) The coalition would like to have greater assurance of this commitment after the Bureau and DWR’s failure in February 2009 to meet the X2 standard. The Bureau and DWR should make X2 compliance and streams of interest monitoring in real time part of their permit amendment applications to the SWRCB this spring. If stream levels are affected by groundwater pumping, then pumping would cease.

Unfortunately, the draft EA fails to anticipate possible stream flow declines in important salmon rearing habitat in the 2009 DWB area. Mud Creek is located within the 2009 DWB and flows through probable Tuscan recharge zones. While a charged aquifer is likely to add to base flow of this stream, a de-watered aquifer would pull water from the stream. According to research conducted by Dr. Paul Maslin, Mud Creek provides advantageous rearing habitat for out-migrating Chinook salmon. (Maslin 1996). Salmon fry feeding in Mud Creek grew at over twice the rate by length as did fry feeding in the main stem of the Sacramento River. *Id.*

Another tributary to the Sacramento River, Butte Creek, hosts spring-run Chinook salmon, a threatened species under the Endangered Species Act. 64 Fed. Reg. 50,394 (Sept. 16, 1999). Butte Creek contains the largest remaining population of the spring-run Chinook and is designated as critical habitat for the species. *Id*. at 50,399; 70 Fed. Reg. 52,488, 52,590-91 (Sept. 2, 2005). Additionally, Butte Creek provides habitat for the threatened Central Valley steelhead. *See* 63 Fed. Reg. 13,347 (Mar. 19, 1998); 70 Fed. Reg. at 52,518. The Bureau should not overlook the importance of rearing streams, and should not proceed with this Project unless and until adequate monitoring and mitigation protocols are established.

Existing mismanagement of water in California's rivers, creeks, and groundwater has already caused a precipitous decline in salmon abundance. There is no mention of the fall-run salmon numbers in the main stem Sacramento River or its essential tributaries despite the fact that their numbers dropped precipitously in 2007 (see graphic) and 2008. For the second year in a row, the commercial salmon fishery is closed for fear of pushing these fish to extinction. As noted above, the EA casually asserts that maintaining flow and temperature requirements in the main stem will be sufficient to protect aquatic species, but it fails to consider the impacts of up to 600,000 af of water transfers, fallowing, and groundwater substitution on the tributaries. How much additional pumping does the DWB represent, given CVP and SWP contractual commitments, available reservoir supplies, and other environmental restrictions south of the Delta? The EA and DWR's Addendum are silent on this.

Where are the data to support assertions that impacts to aquatic species will be below a level of significance? Habitat values are also essential to many other special status species that utilize the aquatic and/or riparian landscape including, but not limited to, giant garter snake, bank swallow, greater sandhill crane, American shad, etc. Where is the documentation of the potential impacts to these species?



Graphic is courtesy of Dick Pool.

In addition to the direct decline in the salmon populations is the food chain affect that will influence species such as killer whales.

3. The EA fails to address the significant unknown risks raised by the 2009 DWB's proposed groundwater extraction.

The EA fails to identify and address the significant unknown risks associated with this Project. There are substantial gaps in scientists' understanding of how the aquifer system recharges.

While the EA asserts that the Lower Tuscan is an isolated layer in the aquifer, expert opinion and experience suggest otherwise. Professor Karin Hoover from CSU Chico asserts that: "[T]o date there exists no detailed hydrostratigraphic analysis capable of distinguishing the permeable (water-bearing) units from the less permeable units within the subsurface of the Northern Sacramento Valley. In essence, the thickness and extent of the water-bearing units has not been adequately characterized." (p. 1)

Though the Projects fails to disclose the limitations in knowledge of the geology and hydrology of the northern counties, it was disclosed in 2008 in the EA for the *Stony Creek Fan Aquifer Performance Testing Plan* (Testing Plan EA). It revealed that there is also limited understanding of the interaction between the affected aquifers, and how that interaction will affect the ability of the aquifers to recharge. The Testing Plan EA provides:

> *The Pliocene Tuscan Formation lies beneath the Tehama Formation in places in the eastern portion of the SCF Program Study Area, although its extent is not well defined. Based on best available information, it is believed to occur at depths ranging between approximately 300 and 1,000 feet below ground surface. It is thought to extend and slope upward toward the east and north, and to outcrop in the Sierra Nevada foothills. The Tuscan Formation is comprised of four distinct units: A, B C and D (although Unit D is not present within the general project area). Unit A, or Upper Tuscan Formation, is composed of mudflow deposits with very low permeability and therefore is not important as a water source. Units B and C together are referred to as the Lower Tuscan Formation. Very few wells penetrate the Lower Tuscan Formation within the SCF Program study area.*

The Testing Plan EA/FONSI at p. 23 (emphasis added). The Tehama Formation, however, generally behaves as a semi-confined aquifer system and the EA contains no discussion of its relationship with the adjoining formations. Nor is there any discussion of the role of the Pliocene Tehama Formation as "the primary source of groundwater produced in the area." (DWR 2003).

The EA fails to offer any in-depth analysis of which strata in the aquifers will be most likely affected by the 2009 DWB's proposed extraction of groundwater. The EA incorrectly states that, "Groundwater users in the basin pump primarily from deeper continental deposits." EA at p. 24. The majority of wells are in the upper layers of the aquifers since they are for domestic use, which is not even considered in the EA. In addition, the EA provides no assessment of the interrelationship of varying strata in the aquifers in the Sacramento Valley or between the aquifers themselves.

The EA fails to provide basic background information regarding the recharge of groundwater. The documents states, "Groundwater is recharged by deep percolation of applied water and rainfall infiltration from streambeds and lateral inflow along the basin boundaries." EA at p. 24. How was the conclusion reached that applied water leads to recharge of the aquifer? Where are the supporting data? This claim is unsubstantiated by any of the work that has been performed to date. For example, the RootZone water balance model used by a consultant with Glenn Colusa Irrigation District, Davids Engineering, was designed to simulate root zone soil moisture. It balances incoming precipitation and irrigation against crop water usage and evaporation, and whatever is left over is assigned to "deep percolation." Deep percolation in this case means below the root zone, which is anywhere from a few inches to several feet below the surface, depending on the crop. There is absolutely no analysis that has been performed to insure that applied water does, indeed, recharge the aquifer. For example, if the surface soils were to dry out, water that had previously migrated below the root zone might be pulled back up to the surface by capillary forces. In any case, the most likely target of the "deep percolation" water in the Sacramento Valley is the unconfined aquifer and possibly the Sacramento River. The EA has not demonstrated otherwise.

E. Other resource impacts flowing from corrected chains of cause and effect are unrecognized in the EA and should be considered in an EIS instead.

Regarding surface water reservoir operations in support of the 2009 DWB, we have several questions and concerns:

- We do not understand from the EA/FONSI which BiOps will govern the DWB's environmental compliance with the Endangered Species Act. The Bureau's EA is confusing at best on this point. Compare pages 8, 9, 22, and 70. We note that reliance on the 2004 OCAP biological opinions on Delta smelt and anadromous fisheries were declared unlawful by a federal judge in 2008 and should not be relied on.
- CVPIA water transfer rules should be stated as part of the "affected environment." Do they permit transfers to non-CVP urban water districts?

Regarding fisheries, we note that the Bureau intends to comply with the State Water Resources Control Board's Water Rights Orders 90-05 and 91-01 in order to provide temperature control at or below 56 degrees Fahrenheit for anadromous fish, their redds, and hatching wild salmonid fry, and to provide minimum instream flows of 3,250 cubic feet per second (cfs) between September

1 and February 28, and 2,300 cfs between March 1 and August 31. How will the Bureau and DWR comply with Fish and Game Code Section 5937—to keep fish populations below and above their dams in good condition, as they approves transfers of CVP water from willing CVP contractors to willing buyers? We urge this compliance effort be integrated with the streams of interest and groundwater monitoring programs we recommended above.

We also find confusing the EA's treatment of instream flows for fisheries. On one hand, minimum flows and temperature criteria established in the above-mentioned water rights orders is to be adhered to by the Bureau for the Sacramento River. The necessity for April and May storage is not well explained as well as the reasons that surface water releases from Shasta would occur in the July through September period. Why?

Concerning the social and economic effects of the proposed 2009 DWB, we note that UC Davis researcher Richard Howitt and his colleagues predict loss of 60,000 to 80,000 farm-related jobs in the Central Valley due to crop idling from drought effects and curtailed project deliveries for irrigation (though not specifically attributable to EA/FONSI activities). The EA neither identifies nor comments on this seemingly credible finding. Howitt, et al, do reasonably conclude that the bulk of these potential impacts are in the western San Joaquin and Tulare and Kern County areas where water rights for imported supplies are the most unreliable.

(Given the facts that DWB buyer requests exceed water supplies offered by potential sellers, and that the DWB priority criteria favor public health and municipal buyers over agricultural buyers, it does seem to us that the state and federal government should identify and commit to permanent mitigations for these acute economic dislocations resulting from drought. However, we would dispute, as discussed below, that this year's hydrologic conditions constitute a drought.)

On its own terms, the Bureau's EA makes no attempt to establish baseline agricultural crop acreages for each agricultural county offering or seeking DWB water in order to calculate and apply its 20 percent threshold for limiting economic impacts to agriculture in selling counties. Moreover, this 20 percent threshold needs to be incorporated into the description of the Proposed Action Alternative, since it appears to be an integral part of DWB actions.

In general, the 2009 DWB EA/FONSI—and by logical implication, DWR's Addendum—consistently avoids full disclosure of existing conditions and baseline data, rendering their justifications for the 2009 DWB at best incoherent, and at worst, dangerous to groundwater users and resources, and to vulnerable fisheries in tributary streams of the Sacramento River.

F. The 2009 DWB is likely to have a cumulatively significant impact on the environment.

The draft EA/FONSI does not reveal that the current Project is part of a much larger set of plans to develop groundwater in the region, to develop a "conjunctive" system for the region, and to integrate northern California's groundwater into the state's water supply. These are plans that the

Bureau, together with DWR and others, have pursued and developed for many years. Indeed, one of the plans—the short-term phase of the Sacramento Valley Water Management Program—is the subject of an ongoing scoping process for a Programmatic EIS that has not yet been completed.

In assessing the significance of a project's impact, the Bureau must consider "[c]umulative actions, which when viewed with other proposed actions have cumulatively significant impacts and should therefore be discussed in the same impact statement." 40 C.F.R. §1508.25(a)(2). A "cumulative impact" includes "the impact on the environment which results from the incremental impact of the action when added to *other past, present and reasonably foreseeable future actions* regardless of what agency (Federal or non-Federal) or person undertakes such other actions." *Id.* §1508.7. The regulations warn that "[s]ignificance cannot be avoided by terming an action temporary or by breaking it down into small component parts." *Id.* §1508.27(b)(7).

An environmental impact statement should also consider "[c]onnected actions." *Id.* §1508.25(a)(1). Actions are connected where they "[a]re interdependent parts of a larger action and depend on the larger action for their justification." *Id.* §1508.25(a)(1)(iii). Further, an environmental impact statement should consider "[s]imilar actions, which when viewed together with other *reasonably foreseeable or proposed agency actions*, have similarities that provide a basis for evaluating their environmental consequences together, such as common timing or geography." *Id.* §1508.25(a)(3) (emphasis added).

As detailed below, instead of assessing the cumulative impacts of the proposed action as part of the larger program that even the Bureau has recognized should be subject to a programmatic EIS (but for which no programmatic EIS has been completed), the Bureau has attempted to separate this program and approve it through an inadequate EA. Further, the Bureau has failed to take into account the cumulative effects of other groundwater and surface water projects in the region, the development of "conjunctive" water systems, and the anticipated further integration of Sacramento Valley surface and ground water into the state water system.

G. The Environmental Assessment Fails to Meet the Requirements of NEPA.

Even if an EIS were not clearly required here, the draft EA/FONSI prepared by the Bureau violates NEPA on its own. As discussed above, the draft EA does not provide the analysis necessary to meet NEPA's requirements and to support its proposed finding of no significant impact. Further, as outlined above, the draft document fails to provide a full and accurate description of the proposed Project, its relationship to myriad other water transfer and groundwater extraction projects, its potentially significant adverse effects on salmon critical habitat in streams of interest tributary to the Sacramento River, and an assessment of the cumulative environmental impacts of the 2009 DWB when considered together with other existing and proposed water programs.

Additionally, the draft EA/FONSI fails to provide sufficient evidence to support its assertions that the 2009 DWB would have no significant impacts on the human or natural environments, neither decision makers nor the public are fully able to evaluate the significance of the 2009 DWB's impacts. These informational failures complicate the Coalition's efforts to provide meaningful comments on the full extent of the potential environmental impacts of the DWB and appropriate mitigation measures. Accordingly, many of the Coalition's comments include requests for additional information.

1. The EA Fails to Consider a Reasonable Range of Alternatives.

NEPA's implementing regulations call analysis of alternatives "the heart of the environmental impact statement," 40 C.F.R. §1502.14, and they require an analysis of alternatives within an EA. *Id.* §1408.9. The statute itself specifically requires federal agencies to:

> *study, develop, and describe appropriate alternatives to recommended courses of action in any proposal which involves unresolved conflicts concerning available uses of resources.*

42 U.S.C. §4332(2)(E). Here, because the Bureau's EA considers only the proposed Project and a "No Action" alternative, the EA violates NEPA.

The case law makes clear that an adequate analysis of alternatives is an essential element of an EA, and is designed to allow the decision maker and the public to compare the environmental consequences of the proposed action with the environmental effects of other options for accomplishing the agency's purpose. The Ninth Circuit has explained that "[i]nformed and meaningful consideration of alternatives … is … an integral part of the statutory scheme." *Bob Marshall Alliance v. Hodel*, 852 F.2d 1223, 1228 (9th Cir. 1988) (holding that EA was flawed where it failed adequately to consider alternatives). An EA must consider a reasonable range of alternatives, and courts have not hesitated to overturn EAs that omit consideration of a reasonable and feasible alternative. *See People ex rel. Van de Kamp v. Marsh*, 687 F.Supp. 495, 499 (N.D. Cal. 1988); *Sierra Club v. Watkins*, 808 F.Supp. 852, 870-75 (D.D.C. 1991).

Here, there are only two alternatives presented: the No Action and the Proposed Action. The lack of *any* alternative action proposal is unreasonable and is by itself a violation of NEPA's requirement to consider a reasonable range of alternatives.

Even more significantly, there are numerous other alternative ways to ensure water is allocated reliably when California experiences dry hydrologic years. We described several elements of reasonable alternatives above. These are the alternatives that should have been presented for the Bureau's draft EA/FONSI on the 2009 DWB to comply with NEPA. 42 U.S.C. § 4332(2)(E).

2. The EA Fails to Disclose and Analyze Adequately the Environmental Impacts of the Proposed Action

The discussion and analysis of environmental impacts contained in the EA is cursory and falls short of NEPA's requirements and stems from having an unclear and poorly described narrative for the proposed 2009 DWB. It obscures realistic chains of cause and effect, which in turn prevent accurate and comprehensive accounting of environmental baselines and measurement of the DWB's potential impacts. NEPA's implementing regulations require that an EA "provide sufficient evidence and analysis for determining whether to prepare an [EIS]." 40 C.F.R. §1508.9(a). For the reasons discussed above, the EA fails to discuss and analyze the environmental effects of the water transfers, crop idling, and groundwater substitution proposed by the 2009 DWB. The Bureau must consider and address the myriad of environmental consequences that are likely to flow from this proposed agency action.

Along with our significant concerns about the adequacy of the proposed monitoring, the draft EA/FONSI also fails to explain what standards will be used to evaluate the monitoring data, and on what basis a decision to modify or terminate the pumping would be made. In light of the document's silence on these crucial issues, the draft EA/FONSI's conclusion that there will not be significant adverse impacts withers quickly under scrutiny.

3. The EA Fails to Analyze Cumulative Impacts Adequately.

The Ninth Circuit Court makes clear that NEPA mandates "a useful analysis of the cumulative impacts of past, present and future projects." *Muckleshoot Indian Tribe v. U.S. Forest Service*, 177 F.3d 800, 810 (9th Cir. 1999). Indeed, "[d]etail is required in describing the cumulative effects of a proposed action with other proposed actions." *Id.* The very cursory cumulative effects discussion contained in the EA plainly fails to meet this standard.

As discussed in Part I.C. above, the proposed DWB does not exist in a vacuum, and is in addition to a broader program to develop regional groundwater resources and a conjunctive use system. The 2009 DWB is also only one of several proposed and existing projects that affect the regional aquifers. The existence of these numerous related projects make an adequate analysis of cumulative impacts especially important.

4. The Bureau Has Failed to Consider the Cumulative Impact of Other Groundwater Development and Surface Water Diversions Affecting the Region

In addition to the improper segmentation evident in the draft EA/FONSI, the assessment of environmental impacts is further deficient because the Bureau has failed to consider the cumulative impacts of the proposed groundwater extraction when taken in conjunction with other projects proposed for the development of groundwater and surface water.

The Bureau and its contractors are party to numerous current and reasonably foreseeable water programs that are related to the water transfers contemplated in the DWB including the following:

- Sacramento Valley Integrated Regional Water Management Plan (2006)
- Sacramento Valley Regional Water Management Plan (January 2006)
- Stony Creek Fan Conjunctive Water Management Program
- Sacramento Valley Water Management Agreement (Phase 8, October 2001)
- Draft Initial Study for 2008-2009 Glenn-Colusa Irrigation District Landowner Groundwater Well Program
- Regional Integration of the Lower Tuscan Groundwater Formation into the Sacramento Valley Surface Water System Through Conjunctive Water Management (June 2005)
- Stony Creek Fan Aquifer Performance Testing Plan for 2008-09
- Lower Tuscan Integrated Planning Program, a program funded by the Bureau that will “integrate the Lower Tuscan formation aquifer system into the management of regional water supplies.”
- Annual forbearance agreements (2008 had an estimated 160,00 acre feet proposed).

We briefly describe some of their key elements here.

<u>Stony Creek Fan Conjunctive Water Management Program.</u> The SCF Aquifer Plan is part of and in furtherance of the Stony Creek Fan Conjunctive Water Management Program (“SCF Program”). This program is being carried out by GCID, Orland-Artois and Orland Unit Water Association.

The long-term objective of the SCF Program is the development of a “regional conjunctive water management program consisting of a direct and in-lieu recharge component, a groundwater production component, and supporting elements.…” (SVWMA: Project 8A Stony Creek Fan Conjunctive Water Management Program
(“SVWMA Project 8A”), at 8A-1). The potential supply from such a program was estimated at 50,000 af per year to 100,000 af per year. *Id.*

The SCF Program has 3 Phases: (1) a feasibility study; (2) a demonstration project; and (3) project implementation. Phase I of the SCF Program has already been completed. The SCF Aquifer Plan described in a draft EA/FONSI is part of Phase II of the larger SCF Program. Phase III of the SCF Program will implement the program’s goal of integrating test and operational production wells into the water supply systems for GCID, Orland-Artois, and Orland Unit Water Association for long-term groundwater production in conjunction with surface water diversions.

The Bureau is well aware of the SCF Program, but declined to analyze the environmental effects of the program as a whole, and not simply considered the effects of an isolated component of the larger program. Indeed, the Bureau recently awarded a grant to GCID to fund the SCF Program. The Bureau’s grant agreement states that the SCF Program “target[s] the Lower Tuscan

Formation and possibly other deep aquifers in the west-central portion of the Sacramento Valley … as the source for all or a portion of the additional groundwater production needed to meet [the SCF Partners'] respective integrated water management objectives." BOR Assistance Agreement No. 06FG202103 at p. 2. The agreement further provides that provides that "[a]dditional test wells and production wells will be installed within the Project Area." *Id.*

Moreover, the Bureau's own description of the reasons for not choosing the "No Action" alternative indicate the Bureau's recognition that the primary goal of the SCF Aquifer Plan is to realize the objectives of the SCF Program – "increas[ing] reliable water supplies through conjunctive management of groundwater and surface water" at a fast pace. *See* EA/FONSI at p. 5. The Bureau was obligated to assess the potentially significant environmental impacts associated with such conjunctive management of groundwater and surface water, and wholly failed to do so.

There are serious concerns raised by the proposal to engage in conjunctive management of groundwater and surface water that are not addressed in the EA. For example, in 1994, following seven years of low annual precipitation, Western Canal Water District and other irrigation districts in Butte, Glenn and Colusa counties exported 105,000 af of water extracted from the Tuscan aquifers to buyers outside of the area. This early experiment in the *conjunctive use* of the groundwater resources – conducted without the benefit of environmental review – caused a significant and immediate adverse impact on the environment. (Msangi 2006). Until the time of the water transfers, groundwater levels had dropped but the aquifers had sustained the normal demands of domestic and agricultural users. The water districts' extractions, however, lowered groundwater levels throughout the Durham and Cherokee areas of eastern Butte County. (Msangi 2006). The water level fell and the water quality deteriorated in the wells serving the City of Durham. (Scalmanini 1995). Irrigation wells failed on several orchards in the Durham area. One farm never recovered from the loss of its crop and later entered into bankruptcy. Residential wells dried up in the upper-gradient areas of the aquifers as far north as Durham (.

<u>The SCF Program is a Component of the Sacramento Valley Water Management Program.</u> The Sacramento Valley Water Management Program (Phase 8) ("SVWMP") also includes the SCF Program as one of its elements. (SVWMA Project 8A at pp. 8A-1 to 8A-13).

The SVWMP recognizes that the SCF Program "has the potential to improve operational flexibility on a regional basis resulting in measurable benefits locally in the form of predictable, sustainable supplies, *and improved reliability for water users' elsewhere in the state*." *Id.* at p. 8A-2 (emphasis added). By piecemealing this program improperly and analyzing only the small component of the SCF Program, the Bureau has failed to assess the environmental impacts associated not just with the anticipated conjunctive use of the groundwater, but also the effect of the anticipated export of water to other regions of the state.

Additionally, approximately five years ago, on August 5, 2003, the Bureau published a notice in the Federal Register announcing its intention to prepare a programmatic EIS to analyze the short-term phase of the SVWMP. 68 Fed. Reg. 46218, 46219 (Aug. 5, 2003). Like the SVWMP, this "Short-term Program" for which the Bureau stated its intent to conduct a programmatic EIS included implementation of the SCF Program. *Id.* at 46219, 46220.

The SCF Program is Also a Component of the Sacramento Valley Integrated Regional Water Management Program. The Bureau has been working with GCID and others to realize the Sacramento Valley Integrated Regional Water Management Program ("SVIRWMP"). SVIRWMP is comprised of a number of sub-regional projects, including the SCF Program. *See* SVIRWMP, Appendix A at A-5; BOR Assistance Agreement No. 06FG202103. Here again, even though the SCF Aquifer Plan is clearly a necessary component of the SCF Program – which is in turn a component of the SVIRWMP – the draft EA/FONSI failed to even acknowledge, let alone assess, the cumulative impacts of these related projects.

Most obviously, the draft EA wholly fails to assess the impact of the Bureau's *Sacramento Valley Regional Water Management Plan (2006)* (SVRWMP) and the forbearance water transfer program that the Bureau and DWR facilitate jointly. As noted above, the Programmatic EIS for the 2002 Sacramento Valley Water Management Agreement or Phase 8 Settlement was initiated, but never completed, so the SVRWMP was the next federal product moving the Phase 8 Settlement forward. The stated purpose of the Phase 8 Settlement and the SVRWMP are to improve water quality standards in the Bay-Delta and local, regional, and statewide water supply reliability. In the 2008 forbearance program, 160,000 af was proposed for transfer to points south of the Delta. To illustrate the ongoing significance of the demand on Sacramento Valley water, we understand that GCID alone entered into "forbearance agreements" to provide 65,000 af of water to the San Luis and Delta Mendota Water Association in 2008, 80,000 af to State Water Project contractors in 2005, and 60,000 af to the Metropolitan Water District of Southern California in 2003.

> Less obvious, but certainly available to the Bureau, are the numerous implementation projects that Phase 8 signatories are pursuing, such as Glenn Colusa Irrigation District's (GCID) proposed to divert groundwater pumped from private wells to agricultural interests in the District. *See* Attach. (GCID Proposed Negative Declaration, GCID Landowner Groundwater Well Program for 2008-09). Additionally, the draft EA does not consider the cumulative effect of the Lower Tuscan Integrated Planning Program, a program funded by the Bureau that will "integrate the Lower Tuscan formation aquifer system into the management of regional water supplies." Grant Agreement at 4. This program, as described by the Bureau, will culminate in the presentation of a proposed water management program for the Lower Tuscan Formation for approval and implementation by the appropriate authorities. Clearly, the cumulative impact of this program and the 2009 DWB's proposed groundwater extraction should have been assessed.

Finally, with the myriad projects and programs that are ignored in the EA and have never been analyzed cumulatively, the EA finally discloses that there could be a devastating impact to groundwater: "The recent reduction in recharge (due to the decrease in precipitation and runoff) in addition to the increase in groundwater transfers would lower groundwater levels. Multi-year groundwater acquisition for other programs in areas that have repeatedly transferred groundwater may also be more susceptible to adverse effects. In these areas groundwater levels may not fully recover following a transfer and may experience a substantial net decline in groundwater levels over several years." (EA at p. 94) While the honesty is refreshing, the lack of comprehensive monitoring, mitigation, and project cessation mechanisms is starling. This alone warrants the preparation of an EIS.

Here again, the document does not discuss or analyze these potential impacts, their potential scope or severity, or potential mitigation efforts. Instead, it relies on the existence of local ordinances, plans, and oversight with the monitoring and mitigation efforts of individual "willing sellers" to cope with any adverse environmental effects. However, as we have shown above, for example, the Glenn County management plan is untested and does not provide adequate protection and monitoring of the region's important groundwater resources. To further clarify the inadequacy of relying on local plans and ordinances, Butte County's Basin Management Objectives have no enforcement mechanism and Chapter 33 requires CEQA review for transfers that include groundwater in Butte County. As one can see, there is very limited local protection for groundwater and no authority to influence pumping that is occurring in a different county.

5. The 2009 DWB is likely to serve as precedent for future actions with significant environmental effects.

As set forth above, this Project is part of a broader effort by the Bureau and DWR to develop groundwater resources and to integrate GCID's water into the state system. For these reasons, the 2009 DWB is likely to "establish a precedent for future actions with significant effects or represents a decision in principle about a future consideration" (40 C.F.R. §1508.27(b)(6)), and should be analyzed in an EIS.

6. The 2009 DWB has potential adverse impacts for a threatened species.

As the Bureau of Reclamation is well aware, the purpose of the ESA is to conserve the ecosystems on which endangered and threatened species depend and to conserve and recover those species so that they no longer require the protections of the Act. 16 U.S.C. § 1531(b), ESA § 2(b); 16 U.S.C. § 1532(3), ESA §3(3) (defining "conservation" as "the use of all methods and procedures which are necessary to bring any endangered species or threatened species to the point at which the measures provided pursuant to this chapter are no longer necessary"). "[T]he ESA was enacted not merely to forestall the extinction of species (i.e., promote species survival), but to allow a species to recover to the point where it may be delisted." *Gifford Pinchot Task Force v. U.S. Fish & Wildlife Service*, 378 F3d 1059, 1069 (9th Cir. 2004). To ensure that the statutory purpose will be carried out, the ESA imposes both substantive and procedural requirements on all federal agencies to carry out programs for the conservation of listed species and to insure that their actions are not likely to jeopardize the continued existence of any listed species or result in the destruction or adverse modification of critical habitat. 16 U.S.C. § 1536. *See NRDC v. Houston*, 146 F.3d 1118, 1127 (9th Cir. 1998) (action agencies have an "affirmative duty" to ensure that their actions do not jeopardize listed species and "independent obligations" to ensure that proposed actions are not likely to adversely affect listed species). To accomplish this goal, agencies must consult with the Fish and Wildlife Service whenever their actions "may affect" a listed species. 16 U.S.C. § 1536(a)(2); 50 C.F.R. § 402.14(a). Section 7 consultation is required for "any action [that] may affect listed species or critical habitat." 50 C.F.R. § 402.14. Agency "action" is defined in the ESA's implementing regulations to "mean all activities or programs of any kind authorized, funded, or carried out, in whole or in part, by Federal agencies in the United States." 50 C.F.R. § 402.02.

The giant garter snake ("GGS") is an endemic species to Central Valley California wetlands. (Draft Recovery Plan for the Giant Garter Snake ("DRP") 1). The giant garter snake, as its name suggests, is the largest of all garter snake species, not to mention one of North America's largest native snakes, reaching a length of up to 64 inches. Female GGS tend to be larger than males. GGS vary in color, especially depending on the region, from brown to olive, with white, yellow, or orange stripes. The GGS can be distinguished from the common garter snake by its lack of red markings and its larger size. GGS feed primarily on aquatic fish and specialize in ambushing small fish underwater, making aquatic habitat essential to their survival. Females give birth to live young from late July to early September, and brood size can vary from 10 to up to 46 young. Some studies have suggested that the GGS is sensitive to habitat change in that it prefers areas that are familiar and will not typically travel far distances. The EA discloses that one GGS study in Colusa County revealed the "longest average movement distances of 0.62 miles, with the longest being 1.7 miles, for sixteen snakes in 2006, and an average of 0.32 miles, with the longest being 0.6 miles for eight snakes in 2007. However, in response to droughts and other changes in water availability, the GGS has been known to travel up to 5 miles in only a few days, but the impacts on GGS survival and reproduction from such extreme conditions are unknown due to the deficiency in data and analysis.

Flooded rice fields, irrigation canals, and wetlands in the Sacramento Valley can be used by the giant garter snake for foraging, cover and dispersal purposes. The draft EA fails to comprehensively analyze the movements and habitat requirements for the federal and state-threatened giant garter snake and yet again defers responsibility to a future time. The Biological Assessment acknowledges the failure of Bureau and DWR to complete the Conservation Strategy that was a requirement of the 2004 Biological Opinion. (BA at p. 19-20) [The BA appears to have no page numbers] What possible excuse delayed this essential planning effort?

The 2009 DWB also proposes to delete or modify other mitigation measures previously adopted as a result of the EWA EIR process to substantially reduce significant impacts, but without showing they are infeasible. For example, the Bureau and DWR propose to delete the 160 acre maximum for "idled block sizes" for rice fields left fallow rather than flooded and to substitute for it a 320 acre maximum. (See 2003 Draft EWA EIS/EIR, p. 10-55; 2004 Final EWA EIS/EIR, Appendix B, p. 18, Conservation Measure # 4.) There is no evidence to support this change. In light of the agencies failure to complete the required Conservation Strategy mentioned above and the data gathered in the Colusa County study, how can the EA suggest that doubling the fallowing acreage is in any way biologically defensible? The agencies additionally propose to delete the mitigation measure excluding Yolo County east of Highway 113 from the areas where rice fields may be left fallow rather than flooded, except in three specific areas. (See 2004 Final EWA EIS/EIR, Appendix B, p. 18, Conservation Measure # 2.) What is the explanation for this change? What are the impacts from this change?

Deleting these mitigation measures required by the EWA approval would violate NEPA and CEQA's requirements that govern whether, when, and how agencies may eliminate mitigation measures previously adopted under NEPA and CEQA. (See *Napa Citizens for Honest Government v. Napa County Board.*

The 2009 DWB fails to include sufficient safeguards to protect the giant garter snake and its habitat. In order to avoid potentially significant adverse impacts for the snake, additional surveys should be conducted prior to any alteration in water regime or landscape. (Addendum March 4, 2009 at p. 8)

It is conspicuously noticeable that there isn't a claim of a less-than-significant impact for the Giant Garter Snake (*Thamnophis gigas*), in the EA and the BA. There is really no conclusion reached due to the fundamental absence of science for the species. The Bureau should also prepare an EIS because the 2009 DWB will likely have significant environmental effects on the Giant Garter Snake, a listed threatened species under the federal Endangered Species Act and California Endangered Species Act. 40 C.F.R. §1508.27(b)(9).

II. Purpose and Need Issues of the 2009 Drought Water Bank

A. The Purpose and Need Section of the EA/FONSI fails to specify the policy framework upon which the 2009 Drought Water Bank is based.

Exemption of the 2009 DWB from the requirements of the California Environmental Quality Act (CEQA) does not reflect the actual environmental effects of the proposal—which are similar to the proposed 1994 Drought Water Banks and for which a final Program Environmental Impact Report was completed in November 1993. In 2000, the Governor's Advisory Drought Planning Panel report, *Critical Water Shortage Contingency Plan* promised a program EIR on a drought-response water transfer program, but was never undertaken. Twice in recent history, the state readily acknowledged that CEQA review for a major drought water banking program was appropriate. So, this Notice of Exemption reflects an end-run around established water law through the use of water transfers, and is therefore vulnerable to legal challenge under the California Environmental Quality Act.

We question the merits of and need for the 2009 DWB itself. The existence of drought conditions at this point in time is highly questionable and reflects the state's abandonment of a sensible water policy framework given our state and national economic recession and tattered public budgets. Our organizations believe the Governor's drought emergency declaration goes too far to help a few junior water right holders, and that at bottom the 2009 Drought Water Bank is not needed. The DWB is to directly benefit the areas of California whose water supplies are the least reliable by operation of state water law. Though their unreliable supplies have long been public knowledge, local, state, and federal agencies in these areas have failed to stop blatantly wasteful uses and diversions of water and to pursue aggressive planning for regional water self-sufficiency.

The EA/FONSI's statement of purpose and need states specifically that "the purpose of the proposed action is to help facilitate the transfer of water throughout the State from willing sellers of CVP water upstream of the Delta to buyers that are at risk of experiencing water shortage in 2009." This paragraph omits coherent discussion of need. The purpose and need should also state that this transfer program would be subject to specific criteria for prioritizing transfers, as described on page 6: "It is anticipated that water made available to [potential buyers] from the DWB would be prioritized as flows: existing health and safety domestic needs, municipal supply subject to water shortage contingency plan measures, and agricultural irrigation for existing crops and livestock subject to water shortage contingency plan measures."

The EA/FONSI makes no attempt to place the 2009 Drought Water Bank into the context of the 2005 California Water Plan that the state recently completed. It appears to us that this plan is largely on the shelf now, perhaps because of the state's dire fiscal problems. It does contain many good recommendations concerning increasing regional water self-sufficiency. However, our review of the 2005 California Water Plan reveals no mention of the 2000 Critical Water Shortage Reduction Marketing Program or any overarching drought response plan that the state could have planned for in 2005, but did not. We sadly conclude that the state of California has no meaningful adopted drought response policy, save for gubernatorial emergency declarations to suspend protective environmental regulations. This is not a sustainable water policy for California.

The purpose and need section of the EA/FONSI *and the Governor's own drought emergency declaration* cry out for placing the 2009 Drought Water Bank into a policy framework. What is the state doing otherwise to facilitate regional water self-sufficiency for these areas with the least reliable water rights? How does the 2009 DWB fit into the state and federal government's water and drought policy framework? Instead, the state and federal response to this third consecutive dry year falls back on simply the Drought Water Bank model that ran into environmental and water users' opposition in 1991 and 1992. Is anybody home at our water agencies?

B. The 2009 Drought Water Bank is not needed because the state's current allocation system—in which the federal Bureau of Reclamation participates—wastes water profligately.

The incentive from the state's lax system of regulation of California's State Water Project and Central Valley projects is to deliver the water now, and worry about tomorrow later. Indeed, the State Water Resources Control Board (SWRCB) has been AWOL for decades. In response to inquiries from the Governor's Delta Vision Task Force last fall, the SWRCB acknowledged that while average runoff in the Delta watershed between 1921 and 2003 was 29 million acre-feet annually, the 6,300 active water right permits issued by the SWRCB is approximately 245 million acre-feet. In other words, **water rights on paper are 8.4 times greater than the real water in California streams diverted to supply those rights on an average annual basis.** *And the SWRCB acknowledges that this "water bubble" does not even take account of the higher priority rights to divert held by pre-1914 appropriators and riparian water right holders, of which there are another 10,110 disclosed right holders.* Many more remain undisclosed.

Like federal financial regulators failing to regulate the shadow financial sector, subprime mortgages, Ponzi schemes, and toxic assets of our recent economic history, the state of California has been derelict in its management of scarce water resources here. This in no way justifies suspension of environmental and water quality regulations, for which the Governor's drought emergency declaration calls. We supplement our comments on this matter of wasteful use and diversion of water by incorporating by reference the joint complaint to the State Water Resources Control Board of the California Water Impact Network and the California Sportfishing Protection Alliance on public trust, waste and unreasonable use and method of diversion as additional evidence of a systematic failure of governance by the State Water Resources Control Board, the Department of Water Resources and the U.S. Bureau of Reclamation, filed with the Board on March 18, 2008 (attached).

We question the Governor's contention of continued dry conditions, since the storms of early March have greatly increased reservoir levels throughout California. The Climate Prediction Center of the National Oceanographic and Atmospheric Administration believes the drought will ease by May 2009. Non-state and non-federal reservoirs indicate conditions fast approaching normal for their facilities: Bullard's Bar in Yuba County is at 107 percent of the 15-year average for this time of year, EBMUD's Pardee Lake is at 98 percent of normal, San Francisco's Hetch Hetchy Reservoir on the Tuolumne River is at 169 percent of normal, while Don Pedro Reservoir on the same river is at 90 percent. The CVP's Millerton (101 percent of normal) and Folsom reservoirs (112 percent) exceed the normal storage for this time of year. These two reservoirs must provide water to the agricultural San Joaquin River Exchange Contractors, and who have among the most senior rights on that river. Rice growers in the Sacramento Valley are generally expecting close to full deliveries from the CVP and Yuba River water supplies. The CVP's own New Melones Reservoir on the Stanislaus River, which contributes to Delta water quality as well as to meeting eastern San Joaquin Valley irrigation demands, is at 87 percent of normal for this time of year.

Moreover, the SWP's terminal reservoirs at Pyramid (102 percent of average) and Castaic (99 percent of average) Lakes are right at about normal storage levels for this time of year, presumably because DWR has been releasing water from Oroville for delivery to these reservoirs.

The fact that reservoirs of the CVP with more senior responsibilities in the water rights hierarchy do well with storage for this time of year suggests that at worst this will be a year of below normal runoff in 2009—hardly a drought scenario. Low storage levels at Oroville, Shasta and San Luis may easily be attributed to redirected releases to terminal reservoirs or groundwater banks in the San Joaquin Valley and Tulare Lake Basin—these latter storage venues and their current performance are not disclosed on DWR’s Daily Reservoir Storage levels web site. Still, given what is known, from what these reservoir levels indicate many major cities and most Central Valley farmers are very likely will have enough water for this year.

The ones expecting to receive little water this year do so because of the normal functioning of their water rights—their imported surface supplies are therefore less reliable in dry times. It is the normal and appropriate functioning of California’s system of water rights law that makes it so. Among those with more junior water rights, the Metropolitan Water District and the Santa Clara Valley Water District are the wealthiest regions and the agencies most capable of undertaking aggressive regional water self-sufficiency actions. They should be further encouraged and assisted to do so through coherently formulated state and federal water policies and programs.

On the agricultural side, the drought emergency declaration appears to benefit mainly the few western San Joaquin Valley farmers whose contractual surface water rights have always been less reliable than most—and whose lands are the most problematic for irrigation. In excess of 1 million acres of irrigated land in the San Joaquin Valley and the Tulare Lake Basin are contaminated with salts and trace metals like selenium, boron, arsenic, and mercury. These lands should be retired from irrigation to stop wasteful use of precious fresh water resources. This water drains back—after leaching from these soils the salts and trace metals—into sloughs and wetlands and the San Joaquin River carrying along these pollutants. Retirement of these lands from irrigation usage would help stem further bioaccumulation of these toxins that have settled in the sediments of these water bodies.

The 2009 DWB would exacerbate pumping of fresh water from the Delta, which has already suffered from excessive pumping in earlier years of this decade. Pumped exports cause reverse flows to occur in Old and Middle Rivers and can result in entrainment of fish and other organisms in the pumps. Our organizations share the widely held view that operation of the Delta export pumps is the major factor causing the Pelagic Organism Decline (POD) and in the deteriorating populations of fall-run Chinook salmon. 2009 will be the second consecutive year where no commercial fishing of fall-run Chinook fish will be allowed because of this species’ population decline. Operation of the DWB at a time when others refrain from taking these fish and other organisms strikes us as a consummate unwillingness on the part of the State of California and the U.S. Bureau of Reclamation to share in the sacrifices needed to help aquatic ecosystems and anadromous fisheries of the Bay-Delta Estuary recover.

New capital facilities should be avoided to save on costly, unreliable, and destructive water supplies that new dams and canals represent. Moreover, these facilities would need new water rights; yet the most reliable rights in California are always the ones that already exist—and of those, they are the ones that predate the California State Water Project and the federal Central Valley Project. We should be applying our current rights far more efficiently—and realistically—than we do now. California should instead pursue a “no-regrets” policy incorporating aggressive water conservation strategies, careful accounting of water use, research and technological innovation, and pro-active investments.[5]

III. Conclusion

The Bureau’s EA/FONSI states on page 9:

> *California laws contain numerous protections that apply to water transfers. However, there are three fundamental principles that apply: no injury to other legal users of water, no unreasonable effects to fish, wildlife, or other instream beneficial uses of water, and no unreasonable effects on the overall economy or the environment in the counties from which the water is transferred.*

We unreservedly state to you that the draft EA/FONSI on the proposed 2009 Drought Water Bank appears to describe a project that would fail all three of these tests as currently described. The 2009 Drought Water Bank clearly has the potential to affect the human and natural environments, both within the Sacramento Valley as well as in the areas of conveyance and delivery. It is entirely likely that injuries to other legal users of water, including those entirely dependent on groundwater in the Sacramento Valley, will occur if this project is approved. Groundwater, fishery and wildlife resources are likely also to suffer harm as instream users of water in the Sacramento Valley. And the economic effects of the proposed DWB are at best poorly understood through the EA/FONSI. To its credit, at least the Bureau studied the proposed project, while DWR, with the Governor’s assistance, went the route of exempting it from CEQA, thereby enabling the agency to ignore these potential effects.

Taken together, the Bureau and DWR treat these serious issues carelessly in the EA/FONSI, and in DWR’s specious reliance for environmental compliance on an emergency exemption and the Environmental Water Account EIS/R of 2003 and 2007. In so doing, they deprive decision makers and the public of their ability to evaluate the potential environmental effects of this Project, and violate the full-disclosure purposes and methods of both the National Environmental Policy Act and the California Environmental Quality Act.

RE: Comment Letter No. 1: Bay Delta Conservation Plan and Associated EIR/EIS Related to Habitat Restoration and Conservation Measures

Dear Mr. Wulff,

The California Sportfishing Protection Alliance (CSPA) has reviewed the proposed Bay Delta Conservation Plan and associated Environmental Impact Report/Environmental Impact Statement (hereinafter, BDCP) submits the following comments. Comment Letter No. 1 relates to habitat restoration and conservation measures intended to important habitat. This Comment Letter includes an attached report titled *Overview of Delta Habitat Restoration*, which analyzes recent Delta habitat restoration projects and includes an appendix that compares the "Overview" with the habitat assessment in BDCP Appendix 5E and identifies major flaws in the proposed native fish habitat restoration program. We request that both documents be considered and responded to as a single submittal.

CSPA worked closely with the Environmental Water Caucus (EWC) in developing their comments and incorporates by reference into these comments both submittals by the EWC on all issues related to BDCP. We also incorporate by reference the submittal by Michael Jackson on behalf of CSPA, California Water Impact Network and AquAlliance, as well as the individual comments submitted by AquAlliance. We further incorporate by reference the submittals by the County of San Joaquin, South Delta Water Agency, Central Delta Water Agency, Restore the Delta, Earth Law Center and Friends of the River, insofar as they are consistent with these comments.

Summary Overview

As discussed more fully below, the BDCP conservation measures to improve important aquatic communities and habitats in the Delta Plan Area are wholly inadequate to mitigate for the expected effects of the BDCP. BDCP and its associated EIR/EIS fail because they are predicated upon a series of monstrous and demonstrably false premises. Based upon these premises, they serve up a many-thousand page omelet of distortion and half-truth in order to reach their predetermined conclusion.

BDCP peddles a revisionist thesis that the Delta's fisheries collapsed because of the historical loss of the pre-reclamation mosaic of Delta habitat. It asserts that severely degraded fisheries can be significantly improved by simply restoring habitat. It claims that restoration of physical habitat can successfully serve in lieu of flow and does so based upon a conceptual programmatic level document. It asks one to believe that you can deprive an estuary of more than half of its flow, turn its hydrograph on its head and expect that fisheries that evolved over millennia, under the historical flow regime, will prosper. The stark reality is that no estuarine ecosystem in the world has survived such insult.

The facts are: 1) reclamation of Delta islands was completed by the second-to-third decade of the last century; 2) Delta fisheries remained relatively stable until the advent of the state and federal export projects; 3) there is now more habitat in the Delta than existed eighty years ago; 4) physical habitat restoration projects in the Delta have largely failed; and 5) the estuary's ecological collapse and one-to-two magnitude declines in anadromous and pelagic fisheries and lower trophic communities occurred after the projects began exporting millions of acre-feet of water yearly.

Habitat is more than the spatial extent of acreage: an increase in habitat area doesn't ensure increases in habitat quality or functionality. The amount of freshwater inflow to an estuary is a physical and ecological driver that defines the quality and quantity of estuarine habitat. As the U.S. Fish & Wildlife Service testified during the State Water Resources Control Board's 2010 flow hearing, "flow in the Delta is one of the most important components of ecosystem function."

Habitat requires adequate physical (flow, residence time, variability, etc.) and chemical parameters (salinity, temperature, turbidity, chemical constituents, etc.), as well as the nutrients necessary for primary production to support renewable fisheries. The export projects have radically altered the Delta's hydrodynamics, which has resulted in a loss of critical flows, degraded water quality and reduced primary productivity. The yearly export of phytoplankton biomass is equivalent to more than 30% of net primary production. This altered hydrology has allowed myriad invasive non-native species to become entrenched to the detriment of native communities.

BDCP proponents confidently assume that proposed habitat restoration projects will be successful. The fact is the majority of restoration projects in the more than 222,902 acres of existing "conservation lands" scattered throughout the Delta have failed to achieve their forecasted goals. Many of these project areas are now habitat dominated by assemblages of invasive species that compete with and prey upon native species, including those listed pursuant to state and federal endangered species acts. Proposed restoration projects are unlikely to provide anticipated benefits unless the physical and chemical parameters approximating historical levels (i.e., mid-20th Century conditions) necessary for native species are also reestablished.

The consistent flaw of previous restoration efforts in the Delta has been a failure to adequately meet the habit requirements of native fish. The estuary's native species evolved over many thousands of years in response to prevailing habitat conditions. Successful restoration of native species requires restoring the conditions under which they evolved and prospered. This entails increasing outflows, mimicking the natural hydrograph, improving water quality, protecting the critical low salinity zone (LSZ) and reducing export of primary productivity. However, these are the essential elements BDCP cannot and will not provide.

The critical need for significantly increased Delta outflow is beyond scientific doubt. The State Water Resources Control Board, in its legislatively mandated 2010 report on needed Delta flows declared, “the best available science suggests that current flows are insufficient to protect public trust resources.” Substantial increases in Delta outflow were recommended. The California Department of Fish and Wildlife, in a similar legislatively mandated report on necessary biological objectives and flow criteria, found, “recent Delta flows are insufficient to support native Delta fishes in habitats that now exist in the Delta.” The San Francisco Estuary Partnership’s 2011 State of San Francisco Bay report observed, “scientists now consider poor freshwater inflow conditions to be one of the major causes for the ongoing declines of fish populations observed in the upper Estuary.”

Conservation measure CM1 is essentially a water conveyance project masquerading as a conservation measure. It will reduce outflow and exacerbate already poor Delta hydrological habitat that is essential for key fish species and their critical habitats. While presented as a project level analysis, less than ten percent of engineering and even less of the geotechnical investigation has been completed. Yet project proponents brazenly claim that all potential adverse impacts have been identified.

Conservation measures CM 2-21 are only presented and analyzed at a programmatic level, lack assured funding and are highly unlikely to achieve the predicted results. There are no assurances that proposed habitat protections and enhancements will be able to overcome the long-term detrimental effects of excessive Delta water diversions or the proposed new North Delta conveyance facilities with experimental fish screens. Indeed, the programmatic nature of the conservation measures precludes anyone from identifying the number and extent of impacts to biological resources, water quality, and other beneficial uses; let alone determining whether the conservation measures will effectively mitigate impacts.

The conservation measures applicable to securing a take permit for CM-1 (Water facilities and Operation) include: CM-2 (Yolo Bypass Enhancement), CM-3 (Natural Communities Enhancement), CM-4 (Tidal Marsh Creation/Restoration), CM-5 (Seasonal Floodplain Creation/restoration), CM-6 (Channel Margin Enhancement), CM-7 (Riparian Restoration), CM-10 Non-tidal Marsh Restoration), CM-11 (Natural Community Enhancement) and possibly CM-16 (Non-Physical Fish Barriers). Many of these measures were included as Stage 1 Action Items in the 2000 CalFed Record of Decision but were never implemented or were partially and/or unsuccessfully implemented with unintended adverse consequences. Funding is highly speculative, subject to congressional or legislative authorization or bond passage. Implementation can proceed with or without BDCP and these measures should have been required mitigation for adverse impacts created by operation of the present export facilities.

Conservation measure CM-2 (Yolo Bypass Enhancement), and conservation measures CM-12 (Mercury Enhancement), CM-13 (Invasive Vegetation), CM-14 (Stockton Ship Channel O2), CM-15 (Predatory Fish), CM-16 (Non-Physical Fish Barriers), CM-17 (Illegal Harvest Reduction), CM-18 (Hatchery Management), CM-19 (Urban Stormwater), CM-20 (Invasive Species), CM-21 (Non-Project Diversions) are, for the most part, not dependent on BDCP. In varying degrees, these measures have long been necessary, are already underway, being approved, financed and managed by others. They will likely proceed regardless of whether BDCP's conservation measures are approved. BDCP should not be seeking credit for these ongoing activities.

A number of critically important conservation measures are conspicuously absent in BDCP. While CM-1 focuses on experimental fish screens at the north Delta diversions, it ignores requirements in the CalFed Record of Decision to upgrade the existing inadequate 1950s-era fish screens in the south Delta to current screening criteria. The South Delta Fish Facilities Forum ceased development of the new screens in 2005 after the state and federal contractors said they wouldn't pay for them. Between 2000 and 2011, more than 130 million fish were salvaged at project facilities, many of which were lost during collection, handling, trucking and post-release predation, and more than a billion fish were estimated lost due to high predation in and around the export facilities.

There are no conservation measures proposed for San Pablo and San Francisco Bays despite the massive impacts the export projects have had and will have on the Bays. A median of 39% of the estuary's unimpaired runoff is already consumed upstream or diverted. Exports sometimes exceed 50% of inflow. Shifts in the seasonal hydrograph and movement of the low salinity zone (LSZ) upstream have been marked by major declines of native phytoplankton, zooplankton and pelagic fish and huge shifts in biological communities. Construction and operation of CM-1 will intensify these problems. Yet BDCP continues to deny that it has any role in creating or mitigating these impacts.

There are no conservation measures proposed for impacts upstream of the Delta. Despite repeated denials by proponents, construction and operation of CM-1 will necessitate reoperation of upstream reservoirs, with resulting instream impacts. Increased total export capacity, especially in drier years at the north Delta diversion point, opens the door to myriad opportunities to significantly increase water transfers. Water transfers are generally authorized under temporary transfer rules or emergency proclamations and receive little or no environmental analysis. BDCP severs the Delta from the upper and lower segments of the watershed to avoid having to acknowledge or mitigate impacts.

Nor are there any conservation measures proposed for the largest source of pollutant loading to the Delta: discharges from irrigated agriculture. The entire Delta is identified on the 2010 Clean Water Act 303(d) List as impaired and incapable of supporting beneficial uses because of agricultural pollutants. A 2007 Regional Board survey of monitoring data from 313 agricultural sites in the Delta and Central Valley revealed that; toxicity to aquatic life was present at 63% of the sites (50% were toxic to more than one species); pesticides criteria were exceeded at 54% of sites (many for multiple pesticides); metal criteria was violated at 66% of sites; human health standards for bacteria were violated at 87% of sites while more than 87% of the sites exceeded general parameters (dissolved oxygen, pH, salt, TSS, etc.). By reducing inflow of relatively good quality water (i.e., reducing dilution) and increasing the time for pollutants to interact with the ecosystem, CM-1 will exacerbate existing impacts.

Perhaps the most flagrant omission is the fact that proposed conservation measures do not include protection and enhancement of the most important and affected habitat in the Delta: the low salinity zone (LSZ) and freshwater pelagic habitats of the Delta on which many Delta native fishes including Delta Smelt depend. These habitats are unproductive because they are entrained and exported in drier years and summers of most years at the existing south Delta export facilities and thus lack the necessary residence time, nutrients, and water quality to sustain pelagic fish production.

The West Delta Restoration Opportunity Area (ROA) especially lacks measures to protect important tidal marsh, aquatic shoreline (channel margin), riparian and pelagic open water habitats despite its overall importance and sensitivity to Delta exports. There is no Central Delta ROA and this Delta region’s habitat appears to have been largely ignored by BDCP planners for restoration, despite its central location in the area most affected by the North and South Delta exports. Conservation Zone 1 and 2, the center and northern Yolo Bypass, also lack needed measures on non-tidal marsh, riparian, seasonally inundated floodplain and channel margin habitats and are not included in any ROA.

If BDCP proposes to continue massive water supply exports from the Delta, it must propose meaningful measures to replace the millions of acre-feet of pelagic habitat lost each year to the export pumps and prevent native species that depend on that habitat from going extinct. CM1 fails to provide the enhanced outflow that fish agencies, regulators and independent scientists have observed is critical to the restoration of the estuary. Instead BDCP offers less outflow in order to enhance water supply benefits.

Other Summary Points

1. Potential export capacity under CM-1 would increase from the present 11,400 cfs to 15,000 cfs, with the existing array of pumps and the new, “isolated” forebay at Clifton Court. There are no credible measures offered to reduce the millions of acre-feet of pelagic habitat that will be exported from the North and South Delta each year under the BDCP. Increased export of pelagic habitat will exacerbate recent population declines and prevent recovery of pelagic species because of further habitat degradation.
2. CM-1’s north Delta fish screens are experimental and will require variances from present fish screen criteria. Screen design was based on laboratory studies and it is unknown if the laboratory studies are representative. Consequently, a number of studies are required to see if the proposed screen design concept will work, will be protective or if the screens can be legally permitted. Half of these studies are proposed post-construction. BDCP rejected requests by NOAA Fisheries and recommendations by the BDCP Fish Facilities Technical Team that construction be phased to see if the first one works before constructing the rest. Delta smelt are present at the diversion point February through June and no screens can prevent

entrainment of eggs and larval Delta smelt, longfin smelt, splittail, striped bass American shad or smaller lamprey ammocoetes.

3. Tidal wetlands are proposed under CM-4 for five ROAs. Three of the five proposed wetlands are Suisun Marsh ROA, Cosumnes/Mokelumne ROA, and Cache Slough ROA. These wetlands will have marginal benefit to key Delta food webs because of isolation from the LSZ and key pelagic habitats. Invasive overbite clams limit food-web production in Suisun Bay and Marsh. Reductions in North and East Delta inflows from proposed North Delta exports would reduce net transport of water and food web contributors from Cache Slough and East Delta. The Cosumnes/Mokelumne ROA will become more isolated from Delta inflows than under present conditions.
4. Suisun Bay LSZ habitat will further deteriorate, as the LSZ moves into the Delta and becomes less productive due to lower Delta outflows predicted under CM-1, especially in drier years. Delta outflow remains the most critical factor in Suisun Bay and the Delta portions of the LSZ nursery areas that are critical to smelt and other pelagic species.
5. CM2 focuses on the Yolo Bypass, Cache Slough, and Sacramento Ship Canal habitats but offers little potential improvement to existing poor water quality conditions (mainly high water temperature and low dissolved oxygen) in these areas, especially during spring and summer when these areas are important salmon and smelt nursery areas. In drier years, spring-summer habitats will suffer from reduced freshwater inflow to Cache Slough from its primary freshwater sources (Miner, Steamboat and Sutter Sloughs) because of the proposed North Delta exports.
6. CM3 lacks focus and actions on West and Central Delta tidal wetland improvements, as large areas of the West Delta tidal wetlands (i.e., West Sherman Island and Big Break) suffer from extensive invasion of non-native submerged aquatic vegetation and deteriorating channel margin habitat (Figure 3.4-27).
7. There is a general lack of focus on the linear shoreline habitats throughout the Delta. Smelt and salmon rearing are far more concentrated in shoreline and nearby open-water habitats than in tidal marshes. CM-6 proposes to restore less than 2% or only twenty of more than seven hundred miles of channel habitat over a thirty-year period.
8. There is a lack of specific restoration strategies regarding habitats, locations, and timing of habitat improvements relative to the needs of each of the listed and soon-to-be-listed native fishes in the Delta
9. There are no credible measures offered to reduce the millions of acre-feet of pelagic habitat that will be exported from the North and South Delta each year under the BDCP.
10. There is no mention of the detailed habitat improvement actions presented in the smelt, salmon, and steelhead state and federal recovery plans.
11. There are repeated references to adaptive management actions that will adjust habitat improvement actions of the BDCP but virtually no details on how adaptive management will actually be implemented or funded. Adaptive management programs have frequently failed throughout the nation, as have decades of adaptive management actions on dozens of failed habitat mitigation projects that were constructed in the Delta.

12. Many of the proposed habitat actions already exist and/or will likely be implemented in the future without the BDCP. These actions should be considered part of the baseline or no-action alternative in the EIR/EIS and not included in BDCP's portfolio of habitat mitigation measures.
13. The proposed restoration projects are insufficient in amount and quality of aquatic habitat to meet the goals and objectives of the BDCP. There is a high degree of uncertainty they will be able to achieve expected goals. Yet, there is no discussion of historical habitat restoration projects, analysis of the results of implementation or why the proposed habitat projects will have different outcomes.
14. CM-1 proposes to operate pursuant to requirements in D-1641 and existing biological opinions. These standards are seriously inadequate as evidenced by the continuing collapse of Delta fisheries. Additionally, the State Water Resources Control Board has failed to take enforcement action against the state and federal projects for thousands of documented violations of D-1641 standards and the fishery agencies have demonstrated a willingness to weaken requirements in the biological opinions at the request of project operators.

The assumptions and conclusions that buttress the BDCP and EIR/EIS conservation strategy and goals are egregiously flawed and technically invalid. Consequently, the analysis of impacts regarding CM1-22 and likelihood of success of the various conservation mitigation measures are seriously deficient and fail to meet minimum CEQA or NEPA standards for environmental review. BDCP must be returned to the drafting table and a new EIR/EIS should be circulated for public review and comment.

Development of the Broad Conservation Goals, Types of Restoration Action Evaluated and Specific Conservation Measures

The BDCP Introduction, Chapter 1, pages 1-2 and 1-3, identifies the broad conservation goals of BDCP's conservancy strategy. The goals are repeated in Chapter 3, Conservation Strategy (3A-2 and 3A-3), which also describes the strategy as being built upon *scientific tenets that reflects the current state of available science* (3A-2, lines 38, 39). Chapter 3, Appendix 3A, page 3A-13, lines 19-32), describes the types of habitat restoration and enhancement actions that were evaluated for inclusion in the conservation strategy. Based upon the evaluation of the *types of habitat restoration and enhancement actions that were evaluated for inclusion in the conservation strategy* and development of the *broad conservation goals*, BDCP offers 22 specific conservation measures to advance the goal of restoring the Delta's ecological functions (Chapter 3, Part 2, Conservation Strategy, 3.4, pages 40-353).

Below are our specific comments on: A) the *broad conservation goals* of BDCP's conservancy strategy; B) the *types of habitat restoration and enhancement actions that were evaluated for inclusion in the conservation strategy* and C) the specific *conservation measures CM 1-21*.

A. Broad Conservation Goals and Strategy

The Broad Conservation Goals and Strategy are discussed in Chapter 1, pages 1-2 and 1-3; and Appendix 3A, pages 3A-2, lines 38-42 and 3A-3, lines 1-21. Goals 1 through 8 and 11 are applicable to fisheries. They include:

1. ***Increase the quality, availability, spatial diversity, and complexity of aquatic habitat in the Delta.***

   CM1-11, if implemented as proposed, would not lead to increased habitat quality and complexity in a timely manner. The main limitation is the lack of potential improvement to pelagic open water habitat under CM1 and lack of the indirect benefits of the other conservation measures to key LSZ pelagic habitats of the West and Central Delta.

2. ***Create new opportunities to restore the ecological health of the Delta by modifying the water conveyance infrastructure.***

   The potential restore ecological health to the Delta is severely restricted by retention of the south Delta export facilities, especially without upgrading them to state-of-the-art standards and current criteria fish screen criteria. The potential for Delta pelagic and shoreline habitats to improve is restricted by the proposed large fine mesh passive screen intake infrastructure in the North Delta.

3. ***Directly address key ecosystem drivers in addition to freshwater flow patterns rather than manipulation of Delta flow patterns alone.***

   Freshwater flow patterns in the Delta under CM1 remain the critical ecosystem driver in the Delta. Enhanced ecosystem inputs from new margin wetland and floodplain habitats will not be of benefit if they cannot contribute to the pelagic habitats of the West and Central Delta. Under the BDCP proposal both Suisun Marsh and Cache Slough Complex would be more isolated from contributing to the LSZ than under present conditions.

4. ***Improve connectivity among aquatic habitats, facilitate migration and movement of covered fish among habitats, and provide transport flows for the dispersal of planktonic material (organic carbon), phytoplankton, zooplankton, macroinvertebrates, and fish eggs and larvae.***

   The proposed North Delta exports will reduce connectivity and create a serious impediment to migration and movement of salmon, smelt, steelhead, sturgeon, and many other important fish of the Central Valley. The North Delta diversions and continuation of South Delta diversions will entrain vast amounts of biological organisms, nutrients, and other essential elements of Bay-Delta productivity.

5. ***Improve synchrony between environmental cues and conditions and the life history of covered fish and their food resources in the upstream rivers, Delta, and Suisun Bay, including seasonal water temperature gradients, salinity gradients, turbidity, and other environmental cues.***

The proposed North Delta exports and continued significant reliance on South Delta exports will further add to reduced synchrony of natural environmental cues to which native fishes are adapted. Food sources will be reduced, water temperatures will increase, salinities will increase, turbidity will be further reduced, and environmental cues will be further disrupted.

6. ***Reduce sources of mortality, and other stressors, on the covered fish and the aquatic ecosystem in the Delta.***

   Delta smelt have suffered relentlessly from the direct and indirect effects of past and present levels of exports from the Delta. A switch of exports to the North Delta upstream of the main pelagic habitats of the smelt will simply increase the risk of smelt to South Delta exports and further degrade smelt critical habitat in the West, Central, and North Delta, as well as Suisun Bay. The North Delta intakes will add a significant source of mortality to Sacramento Valley listed salmon and steelhead that does not exist today. Continuation of South Delta exports does little to alleviate existing stressors that are related to fish growth, survival, and reproduction. Freshwater Delta inflow from the Sacramento River will decrease and inflow from the San Joaquin River will increase, thus contributing to even warmer water in the Delta from spring through summer and early fall. LSZ pelagic habitat of Delta Smelt would be drawn upstream into the influence of north Delta diversions and screening systems (which do not protect smelt). Pelagic low-salinity cool water Delta habitat would also suffer under new North Delta exports and continuing South Delta exports to the point where at a minimum no benefits would accrue. (Appendix 5B forecasts little if any benefits from reduced entrainment to Delta Smelt from the BDCP.) As for salmon, there will be more opportunity for the populations from the Sacramento River system to interact with the project screen systems than under the present configuration. Finally, continuation of the south Delta exports will maintain most of the present risks to these populations.

7. ***Improve habitat conditions for covered fish in the Delta and downstream in the low salinity zone of the estuary in Suisun Bay through the integration of water operations with physical habitat enhancement and restoration.***

   Major habitat enhancements of the proposed conservation measures are isolated from the LSZ of the estuary. Proposed water operations and infrastructure (including the proposed North Delta export facilities) would further isolate, not integrate, proposed habitat improvements.

11. ***Emphasize natural physical habitat and biological processes to support and maintain species covered by the Plan (i.e., covered species) and their habitat.***

    The biological processes and habitats of the LSZ in the West and Central Delta are virtually ignored in the conservation measures. The natural pelagic habitats so important to Delta fishes are virtually ignored in the BDCP.

B. Types of Habitat Restoration and Enhancement Actions That Were Evaluated for Inclusion in the Conservation Strategy

Appendix 3A, page 3A-13, lines 19-32, identifies the types of habitat restoration and enhancement actions that were evaluated for inclusion in the conservation strategy. They include:

1. ***Restoring intertidal habitat to establish vegetated marshes and associated sloughs to increase habitat diversity and complexity, food production, and in-Delta productivity, and rearing habitat for covered species.***

   Most of the tidal marsh restoration proposed is in Suisun Marsh and Cache Slough/Yolo Bypass. Suisun Marsh restoration will be isolated from the low salinity zone upstream in Delta, and subject to modification by invasive clams found in brackish Bay waters. Much of Suisun Marsh ROA is already restored or in managed freshwater marshes (duck clubs and state wildlife areas). Large areas of the Cache Slough ROA are existing functional pelagic habitats adjoining extensive tidal marshes (e.g., Liberty Island, Little Holland Tract, Prospect Island, Sacramento Ship Channel). The Cache Slough ROA is also largely isolated from the LSZ in the Delta in drier years. Furthermore, tidal marshes contribute little productivity to open water pelagic habitats. Special status fish are far more apt to select shoreline habitats adjacent to pelagic waters than tidal marshes.

2. ***Increasing hydraulic residence time and tidal exchange in the Delta sloughs and channels by changing circulation patterns to increase primary productivity and foodweb support and improve turbidity conditions for delta smelt and longfin smelt.***

   Continued reliance on south Delta exports in drier years and late spring and summer of wetter years will continue stressors on pelagic species and their tidal aquatic habitats. LSZ Any shift in the LSZ upstream toward the North Delta intakes could put added pressures on the smelt populations because the screens will not protect larvae and early juvenile smelt whose habitat includes freshwater tidal pelagic habitats.

3. ***Increasing the amount of functional floodplain habitat to increase the quantity and quality of rearing habitat for salmonids and sturgeon and spawning habitat for Sacramento splittail, and generate food resources for pelagic species.***

   The BDCP holds little promise in providing more floodplain habitats that would be inundated by tidal or flood flows especially in the Yolo Bypass (CM2). More floodplain inundation in the East Delta and Yolo Bypass without improved access in CM2 would not significantly benefit salmon growth, survival, and production from the Delta.

4. ***Providing adequate water quality and quantity within the Delta at appropriate times to help conserve resident native fishes and improve rearing and migration habitats***

for salmon moving through the Delta.

Target water quality objectives in the Delta include cooler waters, keeping the LSZ to the west away from the export facilities in both the North and South Delta, increasing the area of the LSZ, keeping the low-productivity reservoir water out of the Delta, and retention of the higher turbidity, higher productivity, low salinity water within the Delta's pelagic habitat. Retaining a salinity gradient and positive downstream flow through the Delta in winter and spring are necessary to improve salmon survival through the Delta. Such conditions are not provided under CM1 or other conservation measures.

C. Specific BDCP Conservation Measures CM 1-22

The specific BDCP conservation measures are proposed at Chapter 3, Part 2, Conservation Strategy, 3.4, pages 40-353 and include: CM1 (Water Facilities and Operation), CM2 (Yolo Bypass Enhancement), CM3 (Natural Communities Enhancement), CM4 (Tidal Marsh Creation/Restoration), CM5 (Seasonal Floodplain Creation/Restoration), CM-6 (Channel Margin Enhancement), CM7 (Riparian Restoration), CM8 (Grassland Restoration), CM9 (Vernal Pool and Alkali Wetland Restoration), CM10 (Non-Tidal Marsh Restoration), CM11 (Natural Community Enhancement), CM12 (Mercury Enhancement), CM13 (Invasive Vegetation), CM14 (Stockton Ship Channel O2), CM15 (Predatory Fish), CM16 (Non-Physical Fish Barriers), CM17 (Illegal Harvest Reduction), CM18 (Hatchery Management), CM19 (Urban Stormwater), CM20 (Invasive Species), CM21 (Non-Project Diversions), CM22 (Avoidance and Minimization Measures).

General Overview of Conservation Measures

The amount of freshwater inflow to an estuary is a physical and ecological driver that defines the quality and quantity of estuarine habitat (Jassby et al. 1995; Kimmerer 2002; 2004 Feyrer et al. 2008, 2010; Moyle and Bennett, 2008; Moyle et al., 2010).

Before construction of most of the major dams on the estuary's tributary rivers (1930-43) an average of 82% of estimated unimpaired flow reached San Francisco Bay. By the 1980's, the percentage had decreased significantly to 60%. The averaged for the 2000s is 49%.

BDCP conservation measures applicable to securing a take permit for CM1 (Water facilities and Operation) include CM2 (Yolo Bypass Enhancement), CM3 (Natural Communities Enhancement), CM4 (Tidal Marsh Creation/Restoration), CM5 (Seasonal Floodplain Creation/restoration), CM6 (Channel Margin Enhancement), CM7 (Riparian Restoration), CM10 Non-Tidal Marsh Restoration) and CM11 (Natural Community Enhancement).

Salmon, steelhead, sturgeon, splittail, striped bass, and other important native and non-native migratory Central Valley fishes significantly depend on the Delta for spawning, young rearing, or residence during all or parts of their life cycles. Altered habitats and hydrology have greatly hindered native fish communities and favored non-native invasive plants, clams and less nutritional primary producers and predatory and competitive fishes.

Unfortunately, only CM1 has received a project level evaluation and even that evaluation is sadly lacking in specific and necessary details. The lack of project level analysis and disclosure in the other conservation measures effectively piecemeals the project and defers mitigation and assurances in violation of HCP/NCCP permitting requirements. All components should receive the same level of detail.

Of these, CM1 is misleadingly described as a conservation measure. CM1 provides for the construction and operation of new north Delta water conveyance facilities to bring water from the Sacramento River to the existing water export pumping plants in the south Delta, as well as for the operation of the existing south Delta export facilities. Diversion of Sacramento River inflow under the Delta to facilitate the increased export of water cannot be justified as a conservation measure. Nor can it qualify as a HCP or NCCP conservation measure addressing compliance with state and federal endangered species acts.

Further, there is no discussion in either the BDCP or EIR/S as to how conservation measures CM 2-21, which are predicated on uncertain public funding, which may or may not be implemented, which are unlikely to be fully successful and which are only analyzed to a programmatic level of analysis can be employed to mitigate for the impacts of a massive water diversion project that has been analyzed (if inadequately) to a project level of detail. Conservation measures CM 2-21 will need to be analyzed to a project level of detail and funding and implementation will need to be assured in order to qualify for consideration in an HCP or NCCP.

Conservation measures CM 2-21 together comprise a stand-alone publicly funded project to restore the Delta’s ecosystem and is not dependent on CM1. In fact, conservation measure CM2 and conservation measures CM 12-21 are not dependent on BDCP and are already underway and, in varying degrees, being approved, financed and managed by others. They will proceed regardless of whether BDCP is approved or not. BDCP should not be seeking credit for these ongoing activities that are not dependent on BDCP or CM1. That said, it should be noted that historical efforts similar to CM 12-21 have already failed to achieve their envisioned or desired results. For that matter, BDCP should not be seeking credit for conservation measures CM 3-11, which will be funded by the public purse and are also not dependent on BDCP or CM1.

Most importantly, none of the conservation measures CM 2-21 are will be as successful as predicted in the BDCP and EIR/S. For example, historical habitat restoration efforts in the Delta have had questionable benefits and frequently provided habitat for undesirable non-native species, predators and noxious vegetation. Numerous commentators have remarked that excessive diversions of water have changed the hydrology of the estuary into something resembling an Arkansas lake. Creating more “Arkansas lake” habitat will not restore the natural ecological processes that supported myriad native species over millennia. Flow and appropriate salinity levels are major components of pelagic estuarine habitat.

None of the conservation measures address the effects of increased Delta exports on the habitat and aquatic species of San Francisco or San Pablo Bays. This is a glaring omission, as numerous studies have documented the effects of Delta outflow on the circulation, water quality and productivity of San Francisco and San Pablo Bays and further reductions in outflow will exacerbate present adverse impacts caused by excessive upstream diversions.[1] Overall net outflow to San Francisco and San Pablo Bays will decrease under BDCP. The major water supply benefits of the tunnels come in wetter years when freshwater flushes the Bays.

The uncertainty of success of proposed habitat restoration efforts are lavishly documented in comments by the Delta Science Program's Independent Review Panel report on the BDCP Effects Analysis, the Delta Independent Science Board's review of the draft EIR/EIS for BDCP, the Independent Panel Review of BDCP sponsored by American Rivers and the Nature Conservancy, the March 2014 comments submitted by the Pacific Fishery Management Council, the February 2014 comments by the California Advisory Committee on Salmon and Steelhead Trout, as well as numerous earlier comments by the National Research Council on adaptive management and the effects analysis, the red flag and progress comments by the National Marine Fisheries Service, U.S. Fish and Wildlife Service, U.S. EPA, U.S. Corps of Engineers and comments on the EIR/EIS by the State Water Resources Control Board.

The underlying assumptions of habitat restoration are further brought into question by the evaluation of BDCP modeling by MBK Engineers in their presentation before the Delta Stewardship Council, which identified a number of flaws including the use of outdated models, the failure to accurately model climate change, the faulty assumptions of actual reservoir operations, the overrepresentation of outflow and underrepresentation of exports. The failure of BDCP models to accurately reflect anticipated changes in CVP and SWP operations with BDCP bring into serious question the assumptions of habitat restoration.

BDCP modeling demonstrates that, under the proposed alternative, Delta outflow will decrease, exports will increase, X2 will migrate eastward, residence time and pollutant concentration will increase throughout the Delta, salinity levels and violations of present fish and agricultural salinity standards will increase, survival rates of winter-run, spring-run and Sacramento and San Joaquin fall-run salmon smolts will decrease, and concentrations of mercury and selenium in bass and sturgeon will increase.

Comments on Specific Conservation Measures

1. CM1, Water Facilities and Operation, Pages 3.4.1 – 3.4-39.

---

[1] Cloern, J. E., and A. D. Jassby (2012), Drivers of change in estuarine-coastal ecosystems: Discoveries from four

CM1 is essentially a water conveyance project masquerading as a conservation measure. It will reduce outflow and exacerbate already poor Delta hydrological habitat that is essential for key fish species and their critical habitats. By reducing outflow to San Francisco and San Pablo Bays and drawing X2 further eastward, CM-1 will increase the habitat expanse of *Potamocorbula amurensis*, the saltwater clam that invaded the estuary in the 1980s to the detriment of primary and secondary productivity and fish production. Higher salinities and reduced outflow will also expand the habitat of an array of invasive aquatic vegetation that has expanded throughout the Delta and established itself in recent habitat restoration areas. Invasive aquatic vegetation has reduced productivity and provided habitat for an assortment of non-native predatory fish species. CM1 will increase residence time and will exacerbate already poor water quality conditions and significantly increase the frequency of violations of water quality standards established to protect fish and other beneficial uses of water.

Existing water exports from the south Delta have altered Delta hydrology, degraded water quality, expanded the range of invasive species, reduced plankton productivity, exported primary production, decreased suspended sediment and entrained vast numbers of fish. According to the California Department of Fish and Wildlife’s Fall Midwater Trawls, between 1967 (the beginning of SWP exports) and 2013, population abundance indices of striped bass, Delta smelt, longfin smelt, American shad, splittail and threadfin shad have declined 99.6, 95.6, 99.8, 90.9, 98.5 and 97.8%, respectively. During the same period, the Summer Townet Survey reveals that abundance indices for striped bass and Delta smelt declined 98.2 and 94.2%, respectively. Native lower trophic orders and populations of wild winter-run and spring-run Chinook salmon show similar orders of magnitude declines.

The majority of Delta exports will continue to come from the south Delta export facilities. During dry years, south Delta exports will significantly exceed north Delta exports. Yet there is no conservation measure to upgrade the existing 1950s-technology fish screens at south Delta facilities to state-of-the-art screens, as required by the CalFed Record of Decision. It is highly uncertain whether or not the proposed new fish screens in the north Delta will work as envisioned. The new screens will require a variance from present National Marine Fisheries Service (NMFS) and California Department of Fish and Wildlife (DFW) fish screen requirements. BDPC has rejected the recommendations of the NMFS and the Fish Facilities Technical Team to phase in installation of the new screens to see if they work or can be legally permitted.

The assessment models in the CM1 proposed operations include the existing restrictions including operational criteria prescribed in the two OCAP biological opinions and the state’s D-1641 water quality standards. However, these are the same restrictions and operating criteria that contributed to many of the present problems, including the Pelagic Organism Decline (POD).

A fundamental problem with CM1 is that it does not enhance Delta outflow, but rather decreases outflow to enhance exports. Outflow is the common denominator of many intertwined processes and influences distribution, condition and abundance of numerous species.[2] The failure to increase outflow will likely undermine any improvements that may occur with other conservation measures.

BDCP is pregnant with uncertainty, as evidenced by comments by the Delta Science Program's Independent Review Panel report on the BDCP Effects Analysis, the Delta Independent Science Board's review of the draft EIR/EIS for BDCP, the Independent Panel Review of BDCP sponsored by American Rivers and the Nature Conservancy, as well as numerous earlier comments by the National Research Council on adaptive management and the effects analysis, the red flag and progress comments by the National Marine Fisheries Service, U.S. Fish and Wildlife Service, U.S. EPA, U.S. Corps of Engineers and comments on the EIR/EIS by the State Water Resources Control Board.

Failing to acknowledge the enormous uncertainties inherent in CM-1 construction and operation and waiting to address uncertainty until sometime later through a vague undefined decision tree and adaptive management process is unacceptable. If is all the more unacceptable because all four decision tree operational alternatives will lead to reduced outflow in the long-term.

Existing water export operations by BDCP project proponents have frequently violated promulgated water quality and flow standards established to protect fisheries and other beneficial uses. These include, San Joaquin River and south and west Delta salinity objectives protective of agriculture, Delta and Suisun Marsh salinity objectives protective of fish and wildlife, Delta outflow objectives, Sacramento and San Joaquin River flow objectives and objectives limiting exports and establishing inflow/export ratios. The State Water Resources Control Board has never taken enforcement action for thousands of documented violations of these water quality standards. There is no discussion or assurances in BDCP regarding compliance with water quality violations or how or whether CM-1 will comply with water quality standards in the future.

Discharges from irrigated agriculture, the largest source of pollutant loading to the Central Valley, the Delta and critical smelt and salmon habitat areas, are completely ignored. Forty-two years after passage of the federal Clean Water Act and forty-five

---

[2] *"Outflow is thus the common denominator among the multitude of intertwined processes. In recognizing this, the Panel is unified in agreeing that the distribution, condition, or abundance of some estuarine organisms are statistically related to outflow and X2 because these two indicators reflect underlying physical and ecological processes that more directly affect the estuarine organisms. In statistical terminology, a number of important ecological factors "co-vary" with outflow and X2 and are more proximal influences on organism distribution, condition, and abundance. For example, some biotic indices may correlate with X2 because their distributions are driven by properties (for example salinity) that co-vary with X2, or because seasonal trends in X2 happen to coincide with inherent reproductive seasonality."* (Workshop on Delta Outflows and Related Stressors Panel Summary Report, May 2014)

years following enactment of California's Porter-Cologne Water Quality Control Act, the State and Regional Water Boards cannot document any reduction in the total mass loading of pollutants from irrigated agriculture and municipal stormwater discharges. For that matter, they cannot document any reduction in the total mass loading of pollutants from municipal and industrial wastewater facilities.

The entire Delta is identified on the 2010 Clean Water Act 303(d) List as impaired and incapable of supporting beneficial uses because of agricultural pollutants. A 2007 Regional Board survey of monitoring data from 313 agricultural sites in the Delta and Central Valley revealed that; toxicity to aquatic life was present at 63% of the sites (50% were toxic to more than one species); pesticides criteria were exceeded at 54% of sites (many for multiple pesticides); metal criteria was violated at 66% of sites; human health standards for bacteria were violated at 87% of sites and more than 87% of the sites exceeded general parameters (dissolved oxygen, pH, salt, TSS, etc.). By reducing inflow of relatively good quality water (i.e., reducing dilution) and increasing the time for pollutants to interact with the ecosystem, CM-1 will exacerbate existing impacts.

Nothing in BDCP and CM1 and associated conservation measures demonstrates or provides assurances that CM1, in conjunction with continued south Delta exports, will alleviate present downward trends, let alone reverse these trends and begin restoration of the Delta ecosystem to meet the requirements of an HCP or NCCP.

2. CM2 Yolo Bypass Fisheries Enhancement, Pages 3.4-40 – 3.4-66.

CM2 is designed to mitigate a long list of identified problems on the Yolo Bypass and Cache Slough that were, in significant measure, created by flood control system projects. The flood control system should mitigate these problems. In any case, a number of these valuable and important activities are already underway, are being financed and managed by others and can move forward with or without CM-1. BDCP should not be latching on to ongoing projects or taking credit for them.

CM-2 is only analyzed at a programmatic level. Many of the proposed projects are highly speculative, may or may not be implemented and have uncertain likelihood of being funded. They cannot comply with HCP or NCCP requirements unless they can demonstrate adequate assurances of funding and implementation.

There is no ROA for 30 miles of the central tidal Bypass and non-tidal northern Bypass where tidal and non-tidal wetlands and seasonal inundated habitat could be added with benefits to young salmon that would be passing into the Bypass via the Fremont Weir. Nor are there proposals to address the many water diversions in the Bypass that entrain salmon and smelt. Many of the diversions in the south end have unscreened tide gates.

The Ship Channel that runs for over 20 miles along the east side of the lower Bypass and the Tule Canal that runs within the east side of the Bypass are important smelt spawning and early rearing habitats, yet they suffer from poor habitat and water quality conditions. The BDCP fails to address these issues. The entire Bypass, Cache Slough, and the Ship Channel suffer poor water quality from stormwater and agricultural return-flow discharges in winter, spring, and summer that degrade the smelt and salmon habitats. The Bypass also receives significant methylmercury loading that bioconcentrates in fish tissue. These issues have long been known and amply documented but existing regulatory programs have failed to achieve anticipated results. Failure to ensure that these problems are adequately addressed increases the likelihood that many of the CM2 improvements may be wasted or may even be detrimental to overall fish survival and production because fish can be diverted from the Sacramento River into marginal habitat in the ROA.

3. CM3, Natural Communities Protection and Restoration, Pages 3.4-66 – 3.4-115.

CM-3 proposes to provide a mechanism and guidance to establish a reserve system by acquiring lands for protection and restoration to meet biological goals and objectives addressed under the BDCP. However, no specific properties have been identified for acquisition in the BDCP, although Restoration Opportunity Areas (ROAs) have been identified. Goals for establishing habitat include: 27,000 acres of tidal perennial aquatic; 932 acres of tidal mudflat; 6,000 acres of tidal brackish emergent wetland; 24,000 acres of tidal freshwater emergent wetland; 4,300 acres of valley/foothill riparian; 100 acres of non-tidal perennial aquatic; 670 acres of non-tidal freshwater perennial emergent wetland; and unknown acres of other seasonal wetland.

CM-3 is essentially a conceptual wish list. It has only been analyzed to a programmatic level. Specific properties have not been identified and specific plans have not been developed. Potential adverse impacts and possible mitigation measures have not been identified or analyzed. If implementation proceeds, it will lag far behind the construction of CM-1. Funding is not assured and is dependent on future state and federal authorizations. Given the lack of success of numerous previous habitat restoration projects in the Delta, implementation is unlikely to achieve the 100% success rate envisioned by BDCP. Examples of previous restoration projects that failed to meet their objectives include: Decker Island, McCormick Williamson Tract, West Sherman Island, Little Holland Tract, Prospect Island, Kimball Island, Winters Island, Chipps Island, Montezuma Island, Mildred Island, Franks Tract, Big Break, Antioch Point, Donlon Island and Hog Island. Many of these projects are already mitigation sites for Corps dredging and levee projects, DWR water projects (Four Pumps Program, Delta Levees Program, Delta Barriers Program, etc.) or required in the various biological opinions.

Habitat restoration is not simply acres of new terrain or physical structure. Habitat is the quantity and quality of water flowing through terrain. Open water habitat is critically important, especially for pelagic species, but largely ignored in BDCP’s conservation measures. It is highly unlikely that conservation measures CM 2-11 can mitigate for the significant reduction in the inflow of relatively good quality water to the estuary caused by the diversion of Sacramento water through tunnels under the

Delta. As previously noted, BDCP modeling demonstrates that those inflow reductions will: decrease outflow; move X2 and the LSZ's crucial habitat for pelagic species eastward; increase the concentration of pollutants and the residence time for pollutants to interact with the ecosystem; reduce smolt survival rates for winter-run, spring-run and Sacramento and San Joaquin fall-run salmon and increase the bioconcentration of mercury and selenium in fish tissue.

Statements of Overriding Consideration for Significant and Adverse Impacts may be approved by a lead agency, pursuant to CEQA. However, such overriding considerations have no place in a Section 7 consultation for an HCP or NCCP, especially when they would not occur in the absence of the project and where adverse impacts affect listed species.

The West Delta ROA contains virtually all the dry year spring-summer-fall critical habitats of the Delta Smelt and much of the winter-spring habitat of rearing salmon in the Delta. These large pelagic habitat units and many miles of shorelines and shoals of the West Delta are critical to the success of these species as well as the BDCP. BDCP documents describe the West Delta as an integral part of the "North Delta Arc of Native Fishes" (Figure 1). Yet, inexplicably, the West Delta ROA is virtually ignored in CM3 and other conservation measures. Over 50 miles of shoreline, half of which is un-leveed and "natural," are completely ignored, as are thousands of acres of important pelagic open-water habitat of the West Delta. These are critical areas heavily used by salmon and smelt in the Delta, especially in dry years when populations are highly stressed by low Delta outflow. In these drier years, the West Delta is especially critical habitat, given the high salinities of Suisun Marsh and the Bay and the fact that the Cache Slough complex in the north Delta is subject to lethal temperatures. At such times the LSZ lies almost entirely within the West Delta. The remaining LSZ habitat is completely ignored, as it is in the Central Delta and does not have an ROA.

The LSZ is supposed to be the most productive and prolific area of an estuary. However, as BDCP acknowledges in Chapter 5 Effects Analysis, primary production in the West Delta ROA is currently the second lowest of the ROAs. BDCP models predict that production will increase but will remain lower than the average of the other ROAs. The BDCP states: "*Tidal habitat restoration in the West Delta ROA could increase local food production for rearing salmonids and splittail*," but virtually no tidal habitat restoration is proposed here. Of course, tidal habitat is already extensive in the western Delta, as virtually the entire area is tidal habitat. Primary productivity does not suffer from lack of tidal habitat. Poor productivity or primary production is a result of the radically altered hydrodynamics, low quality inputs and the export of phytoplankton biomass equivalent to 30% of Delta primary production (Cloern and Jassby, 2012) by the state and federal projects.

Excessive Delta exports literally vacuum the critical LSZ pelagic habitat to the central and south Delta for export to southern California. This important habitat area needs more nutrients, longer residence times, more productive inputs from adjacent ROAs, and, most critically, less export of its primary production to southern California. High inflows of unproductive “blue” reservoir water during the summer from the Sacramento River, coupled with negative flows in the lower San Joaquin River, draw critical habitat toward the South Delta export facilities. This reduces residence time for primary production and exports critical pelagic habitat. Summer temperatures frequently exceed levels lethal to Delta smelt. Pelagic habitat remaining in the western Delta, during the summer, is largely comprised of unproductive reservoir water feeding the exports.

The new North Delta export facility in CM1 will exacerbate these hydrodynamic problems by reducing lower Sacramento River inflows, increasing reverse flow above Georgiana Slough, altering DCC operations and providing another, closer outlet for LSZ export. Enhancing the pelagic habitat and plankton community of the West Delta ROA would require managing and restoring natural Delta hydrodynamics. Because it fails to manage and restore Delta hydrodynamics, CM-3 cannot mitigate the adverse impacts of CM-1.

4. CM4, Tidal Natural Communities Restoration, Pages 3.4-116 – 3.4-144.

Open water or pelagic habitat is largely missing from the tidal habitat discussion in CM4, as it is in CM3. Open water habitat in the Delta is the key habitat of smelt and other pelagic fishes and clearly part of the Tidal Perennial Aquatic Habitat Community. But CM4 ignores open water habitat and primarily focuses on emergent wetland restoration in the Suisun Marsh and Cache Slough areas. It essentially ignores the potential habitat in the west and central Delta that is critical for salmon and pelagic species in drier years, when threats to salmon and smelt are most severe. In these drier years, the Suisun Marsh and Cache Slough ROAs are less important because the LSZ moves into the west Delta away from Suisun Marsh, while high temperatures and low inflow impact Cache Slough. Implementation of CM1 will exacerbate these impacts.

As one example of misplaced priorities, the entire six miles of shoreline along the north shore of the lower Sacramento River from Collinsville to Rio Vista is un-leveed and bordered by major smelt spawning shoal habitats. Salmon, smelt, splittail and other native fishes often dominate fish catches in this area and smelt surveys have their highest catches in these areas. Unfortunately, adjacent pastures, non-native Arundo riparian shoreline communities and dredging are adversely impacting this area.

Other locations identified in the west Delta ROA for restoration include relatively small acreage in Seventeen Mile Slough, Decker Island, areas around Three-Mile Slough and Big Break. However, potential benefits are undermined by continuation of south Delta exports, which draw water from these areas.

CM4 should serve as a cautionary tale concerning expectations of habitat restoration. This area abounds in failed habitat projects including Decker Island, Big Break, Kimble Island, PG&E mitigation project near Collinsville, Chips Island, Winter Island and areas of Sherman Island. These areas have become prime habitat for invasive species, noxious weeds and predators. As previously observed, restoring habitat is more than merely acquiring acreage: it requires meeting the physical and chemical parameters under which native species evolved for millennia.

Implementation of CM1 will likely adversely impact the time and space array of quality pelagic habitat in the Delta. In other words, it will likely decrease the amount of quality Delta smelt habitat.

For climate change and sea-level rise comment, please see ISB comments B-52

5. **CM5, Seasonally Inundated Floodplain Restoration, 3.4-145 – 3.4-154.**

There are several references to seasonal habitat in the Conservation Strategy, Part 1 and 2 of Chapter 3. Other than the potential opportunities for creation and restoration of habitat in the Yolo Bypass/Cache Slough area provide in CM-2, most of which will proceed regardless of CM-1: and in the south Delta, where seasonal floodplain could be incorporated in a bypass on the San Joaquin, there is limited opportunity to enhance floodplain habitat that would seasonally inundate during high flows in most of the Delta. Conceptually, areas such as east-side floodplains and margins of the Delta could provide habitat for salmon rearing and potentially increase Delta productivity. However, with the continued winter-spring closure of the Delta Cross Channel, benefits from the east Delta would likely be minimal, as this water moves directly to the South Delta export pumps when the DCC is closed.

6. **CM6, Channel Margin Enhancement, 3.4-155 – 3.4-161.**

Channel margin enhancement is the poster-child of BDCP's public relations efforts. Parts 1 & 2 of the Conservation Strategy, as well as the Executive Summary, effusively discuss the virtues of channel margin enhancement to benefit a wide variety of species. Indeed, there are hundreds of miles of channel margin habitat that could be enhanced to the benefit of all Delta native fishes including salmon and smelt. While salmon sometimes use tidal marshes for rearing, salmon, smelt, and other native fishes predominantly use the channel shorelines and shoals adjacent to Delta pelagic habitats.

However, under CM6 only twenty miles of channel margin habitat restoration will occur over thirty-year period. Fifteen miles of restoration will be split between the Sacramento River, Steamboat Slough and Sutter Slough and five miles on the San Joaquin River. The west Delta ROA is ignored, although it would greatly benefit from channel margin enhancement. Of course, like all of the proposed habitat restoration proposals in BDCP, channel margin enhancement is a conceptual wish list: there has been no project level analysis. No specific properties have been identified, no specific plans have been developed, no specific mitigation has been proposed and no assured funding has been identified.

7. CM7, Riparian Natural Community Restoration, 3.4-162 – 3.4-175.

In addition to the riparian habitat of CM6 channel margins, there is also a need to restore large-block riparian communities especially in areas subject to seasonal inundation. The best opportunities for these are in the Yolo Bypass, the Cosumnes/Mokelumne floodplain, and the lower San Joaquin floodplains. The BDCP goes far to state that the Yolo Bypass and Cache Slough complexes are precluded from such restoration by flood control needs. However, it was little more than a decade ago that these areas were in agricultural production protected by levees (e.g., Liberty, Little Holland, Prospect, etc.). Riparian floodplain habitats are simply not a threat to the flood control capacity of these areas that were recently not part of the floodplain at all except possibly in very large floods. Riparian floodplain forest habitats were once a major component of the regional Delta habitat array used by native fishes, especially salmon, and should be restored as much as possible.

10. CM-10, Nontidal Marsh Restoration, 3.4-193 – 3.4-201.

Nontidal marsh restoration is primarily for the benefit of the giant garter snake and greater sandhill crane. Nontidal marsh restoration could also be of benefit to salmon and other native fishes in areas upstream of the Delta such as the upper Yolo Bypass. However, fish are virtually ignored in CM10. Such marshes could also potentially contribute to Delta productivity through the transfer of organic carbon in the form of live and dead organisms and detritus, as well as inorganic nutrients and sediment.

Over 20 miles of the upper Yolo Bypass are not included in the proposed BDCP habitat restoration mosaic. Despite providing for annual streamflow and passage at the Fremont Weir, there is no provision for habitat in the entire upper Bypass that could take advantage of inundation with the new flow. It has been clearly demonstrated that such habitat greatly increase the growth and survival of salmon compared to the adjacent leveed Sacramento River. As compared to open agricultural fields, marshes in such nontidal areas offer significant habitat advantages for native fish spawning, rearing, and migrating. These advantages include increased cover from currents and predatory birds. The same potential occurs upstream of the Delta on other Delta tributaries including the San Joaquin River and its tributaries; this potential is not covered in the CM-10.

11. CM11, Natural Community Enhancement and Management, 3.4-202 – 3.4-256.

CM11 is essentially a conceptual hodgepodge of how the conceptual programmatic habitat restoration projects will be managed in accordance to achieve natural community goals and objectives. What is missing is a serious discussion of why previous restoration projects and management of habitat have utterly failed to reverse the downward spiral of native species in the estuary. Nor, is there any discussion of how the implementation of BDCP conservation measures will be different: why BDCP results are likely to be more successful. If the reviewer of these comments disagrees with this observation, he or she should provide specific replies on how these proposed efforts will be different from historical or present programs and why a different outcome can be expected.

12. CM12, Methylmercury Management, 3.4-257 – 3.4-264.

The section on Methylmercury Management was completely rewritten following the November 2010 preliminary administrative draft, because the 2010 draft lacked a lacked a clear statement of the problem and specific actions that would help to alleviate it. Those items remain lacking in substance in the current draft. The section leaves out extensive past and present work of the USGS and universities on methylmercury in the Delta and in upstream watershed habitats and ongoing source control programs. The risks from methylmercury in tidal wetlands by ROA are not assessed in the HCP. Instead CM12, as in other CMs with high uncertainty, only offers adaptive management and monitoring to account for the complexities of the system "to ensure that measures implemented at the project scale through CM12 do not conflict with goals for restoration site ecological function." (P. 3.4-264).

13. CM13, Invasive Aquatic Vegetation Control, 3.4-266 – 3.4-284.

The measure is focused on ongoing and emerging risks posed by invasive aquatic vegetation throughout the Plan Area and builds heavily on the existing state program, managed by the California Department of Boating and Waterways, to continue aquatic vegetation control using chemical methods. Despite the recognized "major concern with the use of herbicides over large areas and the potential for toxic effects" (p. 3.4-273), the program focuses on this costly and ecologically degrading process instead of the root problem. The root of IAV problems are species-and-location specific but have an over-riding theme of disturbed physical habitats and lack of flow.

The huge areas of the West and Central Delta infested with Egeria including Franks Tract, Big Break, and West Sherman are large breached formerly-reclaimed islands that lack circulation and turbidity that normally limit such rooted invasive plants. All the shallow margins of these areas are infested (see Figures 3.4-27, 28) and their adjoining vast pelagic habitats suffer terribly. Rooted invasives like Egeria collect suspended plankton and sediment thus reducing turbidity, and compete for nutrients with pelagic phytoplankton.

The root cause of the predominance of invasive vegetation in these critical areas is lack of primary plankton productivity in the pelagic foodweb; this in turn is caused by exports and high inflows of reservoir water to meet export demand, in combination with the unnatural physical state of deep breached former leveed agricultural islands. Another example of a disturbed habitat is Seventeen Mile Slough (connecting to the San Joaquin River and Three Mile Slough in the Central Delta). It is infested with water hyacinth because its circulation was cut off by a road-crossing blockage at its east end. Boating and Waterway treatments result in seventeen miles of channel clogged with dead water hyacinth (and dead habitat). The appropriate treatment is restoration of tidal circulation by removing the barrier at the east end of the slough and the removal of dead hyacinth. Control of extensive IAV infestations of backwater habitat also requires a reduction in water depth so that native tules can recover.

14. CM14, Stockton Ship Channel Dissolved Oxygen Levels, 3.4-285 – 3.4-292.

Comments regarding CM-14 can be found in CSPA's Comment Letter No. 2: Bay Delta Conservation Plan and Associated EIR/EIS Related to Water Quality and in the technical comments prepared by Dr. G. Fred Lee that are attached to those comments.

15. CM15, Localized Reduction of Predatory Fishes, 3.4-293 – 3.4-312.

Like many of the CMs, CM15 Localized Reduction of Predatory Fishes was completely rewritten following the November 2010 preliminary administrative draft. The current version of this measure claims to have been developed with extensive input from fish agency staff and claims to be focused on research and adaptive management to better understand the role of fish predation as a driver of covered fish species distribution, behavior, survival/abundance, and population status in the Plan Area.

Despite the staff effort to improve this measure, BDCP again proposes to rely on research and monitoring to address this long-standing problem brought about by the associated habitat effects of exports and the high Delta inflows of reservoir water to meet export demand. The real problem is that the state and federal exports have created habitat conditions that favor non-native predators over native species. The Delta is, in many respects, like an "Arkansas lake" full of "Arkansas" predator fish; such as largemouth bass, bluegill, crappie, and channel catfish.

The only control of this problem is to restore and replicate the natural Delta habitats under which native species evolved over thousands years and to remove, alter, or isolate habitats that favor non-native predators. No measure of predator removal will resolve this problem.

The measure proposes a limited suite of initial implementation actions with substantial investments in research prior to developing a full field implementation of the measure. In reality, Delta scientists already know why these species occur and how to control them. Predator removal at "hotspots" has been on-going for decades. However, fishermen and scientists have noted the futility of this approach as a predator removal action.

16. CM-16, Nonphysical Fish Barriers, 3.4-313 – 3.4-317.

The Nonphysical Fish Barriers program is still in the experimental stage after several decades of research, monitoring, and adaptive management. It remains focused on increasing the survival of juvenile covered fishes (primarily salmonids) by discouraging them from entering channels known to result in higher mortality than other viable migration routes. The efforts have focused on prime cross-Delta channels that carry juvenile salmon to South Delta export fish salvage facilities.

Such efforts recognize the serious nature of such non-natural migratory behavior, but ignore the real cause of the problem and past/present lack of treatment. First, exports and associated altered Delta hydrology cause the problem. Ineffective salvage facilities in the South Delta fail to treat the problem. Closure of barriers such as the Delta Cross Channel and Head of Old River Barrier simple make the problem worse. Research has shown such barriers (e.g., bubble "screens") are ineffective and may even attract predators. Even if they were effective, there are presently no accurate methods to quantify improved survival.

17. CM-17, Illegal Harvest Reduction, 3.4-318 – 3.4-321.

CM17 Illegal Harvest Reduction is focused on increasing the enforcement of fishing regulations in the Delta and bays with the goal of reducing illegal harvest of covered salmonids and sturgeon (and non-native predatory sportfish). The CM focuses on the lack of game wardens to "police" the problem. Such harvest is "illegal" under state laws and adequate enforcement should be the responsibility of the State not the BDCP. Furthermore the BDCP should not take credit for any effort for the State policing its problem. There is nothing in the EIR/EIS to indicate that this CM will be different than present programs or be more effective in addressing the issue.

18. CM-18, Conservation Hatcheries, 3.4-322 – 3.4-325.

CM18 Conservation Hatcheries was completely rewritten following the November 2010 preliminary administrative draft. The current version of this measure was developed with extensive input from USFWS staff familiar with the existing and proposed Delta and longfin smelt conservation hatchery programs. The CM is focused on providing refugial hatchery populations and fish suitable for use in research actions. The Delta smelt population is noted as continuing to decline and at high risk of extinction in its present population state, and thus would seem to benefit from a conservation hatchery funded by BDCP. This whole conservation hatchery seems to come from a sense of desperation, yet the BDCP offers no real actions that would improve the plight of the wild Delta smelt population or its critical habitats.

The BDCP admits entrainment and salvage losses would not decline, and that the habitat improvements proposed would provide minimal if any benefit to the smelt population. The BDCP fails to focus on specific improvements to crucial LSZ habitat area and the proposed new North Delta diversion is likely to move it further upstream into more unsuitable areas. What is the point of stocking hatchery smelt if BDCP provides less favorable habitat conditions for them.

The history of trying to maintain or restore salmonid populations with hatcheries is fraught with problems that exemplify problems likely to confront a similar approach to smelt or other species. Stocking smelt not accustomed to natural habitat and predators may cause more predators to seek out wild smelt. Wild smelt may inbreed with inferior hatchery smelt. Key genetic information could be altered or even lost in the wild population from breeding with hatchery smelt. Collecting wild smelt for the conservation hatchery has its own effects. Simply breeding the captive population could have serious consequence to the genetic state of the captive stock that could be a threat to the wild population.

19. CM-19, Urban Stormwater Treatment, 3.4-326 – 3.4-332.

Nearly the entire Delta aquatic habitat array is surrounded by agricultural and urban basins protected by levees. All of these basins route storm and/or agricultural return water back to Delta waters via hundreds of large and small pumping plants. Damage to the water quality of Delta habitats from this process is immense. The Cache Slough, Yolo Bypass, and Ship Channel habitats of the Cache Slough ROA are especially influenced by such blatant water pollution. An argument could be made that some pollution is good and contributes to productivity and high turbidity so much welcomed in the Delta pelagic habitats, but too much pollution is pollution. Many of these “stormwater” inputs are “allowed” under state waiver programs for small stormwater and agricultural systems, and violations of Basin Standards occur. High water temperature, low dissolved oxygen, and excessive salts and chemicals degrade many important rearing habitats including nearly 40 miles of the Tule Canal in the Yolo Bypass and 20 miles of the Ship Channel, areas heavily used by smelt for spawning and early rearing. Warning signs not to eat the fish are found throughout these areas. Heavy spring inputs of such pollution threaten the survival of salmon, smelt, and other Delta native fishes. Water quality protection and enhancement should be an important part of the BDCP habitat restoration program.

21. CM-21, Non-project Diversions, 3.4-339 – 3.4-344.

In fall 2011, DWR directed that the BDCP include screening of non-project water diversions as a conservation measure. There are literally thousands of such diversions in the Delta, with many in prime rearing habitats of Delta smelt. The largest would include Delta power plants owned by Mirant and built by PG&E located at Antioch and Pittsburg right in the heart of the smelt distribution range. (Note: the BDCP attempts to include these plants in the BDCP HCP, despite the projects having their own approved HCP.)

Though technically screened, the screens on these fossil fuel burning plants' cooling water intakes have a mesh too large to keep out larval smelt. Larger smelt are at great risk to screen impingement mortality if caught by inflows. "Remediation of these non-project diversions could eliminate or reduce this entrainment or impingement, and improve Delta ecosystem health by reducing the diversion of plankton and other nutritional resources, thereby benefiting all covered fishes" (p.

3.4-339). (Note: unlike project diversions these power plant diversions are not consumptive and pass water, albeit too warm for smelt, back to the Delta.)

Thousands of smaller agricultural and duck club intakes are unscreened in Suisun Marsh, Delta, and Yolo Bypass. Total Delta unscreened diversion volume likely equals several thousand cfs and potentially causes entrainment and impingement losses. While the CM21 focuses on screening remediation at diversion intakes it includes, "[e]liminating those non-project diversions with the greatest risk of entrainment to delta smelt." This would involve extremely costly land and/or water purchases/leases and involve the loss of high-valued, productive agricultural lands. Such an approach ignores the "…diversions with the greatest risk of entrainment to delta smelt:" the state and federal project pumps.

22. CM-22. Avoidance and Minimization Measures, 3.4-345 – 3.4-353.

CM22 Avoidance and Minimization Measures was not previously identified as a potential conservation measure, but was designated to recognize that there are many avoidance and minimization measures to reduce the risk of incidental take that must be implemented in the course of implementing conservation actions, including construction of water facilities and construction of natural community restoration sites. Of special note is the inclusion of the effects of water facilities (tunnel intakes) and Adaptive Management and Monitoring in this conservation measure. Within the BDCP process these two subjects are far too important to be buried in CM22. These are fundamental elements of the BDCP process that should be assessed and described in detail in their own stand alone sections of the BDCP.

The BDCP conservation measures are essentially the proposed mitigation for the tunnels, continued operation of South Delta exports, and their associated effects on Bay-Delta hydrology. There is little mention in the BDCP plan or EIR/EIS of Avoidance and Minimization Measures for the proposed North Delta tunnel intakes or for the continued operation of South Delta intakes, or for their effects on Bay-Delta hydrology under operating criteria limits of D-1641 water quality standards or present biological opinions. One of the most critical topics that must be addressed is how the two diversions would avoid and minimize effects on Delta smelt in dry and critical years.

Concluding Observations

The Public Policy Institute of California published a June 2012 report titled, *Where the Wild Things Aren't, Making the Delta a Better Place for Native Species.* The report[3] promotes a "*Reconciled Delta - a coherent, robust, and dynamic portfolio of habitats and flows that support desired ecosystem functions and conditions.*"

Despite a relatively negative prognosis for the future of the Delta, these authors state,

---

[3] http://www.ppic.org/main/publication.asp?i=1053

> “*physical habitats and flows can be managed, where possible, to provide conditions that native estuarine species need at different stages in their lives…. In our vision for a reconciled Delta ecosystem, habitats in different parts of the Delta would be specialized to foster improved conditions for native fishes. All forms of habitat cannot be at all locations, so we propose a strategy in which different habitat types are available and connected to support each desirable species at the appropriate season, taking advantage of existing ecological differences among different regions of the Delta. Area specialization can provide the ecosystem diversity and variability that native fishes (and other organisms) need, while supporting continued human uses of Delta land and waters.*”

These statements portray the basic problem with the BDCP: it lacks specifics as to habitats, flows, and timing to meet the needs of the target native fishes in the Delta. Specifically BDCP needs to identify the critical areas in the Delta for anadromous and pelagic species and then analyze and discuss the problems with these habitat areas. Only then, can it develop and propose specific, effective and implementable measures to improve habitats and fish populations.

The complete lack of discussion of pelagic habitat and the LSZ of the Delta estuary is an illustrative example of what is missing from BDCP. It is as if BDCP forgot the purpose of habitat conservation plans and why its proponents are proposing one. The purpose of HCPs should be to increase the likelihood that listed species will survive recovery, consistent with the purposes of state and federal endangered species acts.

If BDCP proposes to continue massive water supply exports from the Delta, it must propose meaningful measures to replace the millions of acre-feet of pelagic habitat lost each year to the export pumps and prevent native species that depend on that habitat from going extinct. CM1 fails to provide the enhanced outflow that fish agencies, regulators and independent scientists have observed is critical to the restoration of the estuary. Instead BDCP offers less outflow in order to enhance water supply benefits.

If we have learned one thing, over the past several decades in the Bay-Delta, it is that regime shifts and population crashes occur in drier years. Yet we continue to relax standards in dry years and focus protection in wetter years. The smelt population has yet to recover from 1981. Striped bass have yet to recover from 1987-1992. We killed modest smelt recoveries in 2001-2002, 2007-2009, and 2012-2014. BDCP will increase problems in dry years because the plan retains large south Delta exports during these years. A start toward recovery of Delta smelt would be a realistic plan to save what little habitat occurs in dry years when the LSZ pelagic habitat lies within the west and central Delta. That measure should be addressed in CM1 and not reside in conceptual and uncertain programmatic measures to be implemented sometime in the future. Determining how the system should work after the infrastructure is constructed and operating is a recipe for further disaster.

BDCP highlights the importance of Cache Slough ROA to target species especially delta smelt. It fails to mention the importance of tidal freshwater inputs from the areas major freshwater sources: Sutter and Steamboat sloughs. It fails to mention key stressors like warm water, agricultural diversions and waste discharges, North Bay Aqueduct exports, and lack of dry year flows (importance of Fremont Weir notch), etc. Likewise, it fails to discuss key stressors in the Sacramento Ship Channel, such as, propeller entrainment from cargo ships and how the channel gets its freshwater inflow. The gates at the upper entry to the Sacramento Ship Channel are rusted shut. Consequently, a high percentage of freshwater inflow comes from West Sacramento’s storm-sewer system and local agricultural drainage.

BDCP fails to recognize the importance of outflow in maintaining location, productivity, and water quality of the LSZ, especially through the summer. It retains the illusion, expressed in the USFWS biological opinions that smelt are not in the Delta during summer because they, X2 and the LSZ are in Suisun Bay. The fact is that, under modern hydrodynamic conditions in the Delta, the LSZ and X2 are in the Delta most summers, especially in drier years.

BDCP equally fails to realistically discuss Suisun Marsh and its main channel, Montezuma Slough. Little discussion is provided regarding the role, or potential use, of the Salinity Control Structure at the upper end of Montezuma Slough, how important maintaining freshwater inflow and low salinity is to the ecology of the slough and marsh, or how important this area is, or could be, to the production of nearly all the native Bay-Delta fish. Lack of Delta outflow in spring and summer of drier years results in the loss of this important nursery and the production of many of its native fishes each year. This critical habitat loss, following expansion of Delta exports in the 1970's, was a major factor in the decline of many native and non-native Bay-Delta fish. Coupled with the massive degradation of Delta pelagic habitats, there is little fish production capacity left in the Bay-Delta’s open waters.

BDCP not only fails to address these fundamental problems, it actually proposes to exacerbate these problems with additional outflow reductions, introduction of a massive new diversion on the lower Sacramento River, higher exports, and further degradation of the LSZ pelagic habitats.

In the final analysis, BDCP is not a program intended to restore habitat and fisheries: it is simply a project to maximize the export of water from the Delta. More insidiously, it proposes to do so by diverting 2.5 MAF of freshwater inflow via tunnels under a Delta that is already grievously suffering from a lack of freshwater flow. The other conservation measures are simply window dressing: conceptual in nature, lacking in specific details, analyzed at a programmatic level, facing uncertain public funding, and highly unlikely to achieve the unrealistically predicted results. BDCP is not restoration; it is a death sentence for an estuary.

The assumptions and conclusions that buttress the BDCP and EIR/EIS conservation strategy and goals are egregiously flawed and technically invalid. Consequently, the analysis of impacts regarding CM1-22 and likelihood of success of the various conservation mitigation measures are deficient and fail to meet minimum CEQA or NEPA standards for environmental review. BDCP must be returned to the drafting table and a new EIR/EIS should be circulated for public review and comment.

Thank you for considering these comments. If you have questions or require clarification, please don’t hesitate to contact us.

Sincerely,

Bill Jennings

RE: Comment Letter No. 2: Bay Delta Conservation Plan and Associated EIR/EIS Related to Water Quality

Dear Mr. Wulff,

The California Sportfishing Protection Alliance (CSPA) has reviewed the proposed Bay Delta Conservation Plan and associated Environmental Impact Report/Environmental Impact Statement (hereinafter, BDCP or EIR/EIS) and submits the following comments related to water quality. Our comments include the attached review from Dr. G. Fred Lee and Dr. Anne Jones-Lee and we request that both documents be considered and responded to as a single submittal.

CSPA worked closely with the Environmental Water Caucus (EWC) in developing their comments and incorporates by reference into these comments both submittals by the EWC on all issues related to BDCP. We also incorporate by reference the submittal by Michael Jackson on behalf of CSPA, California Water Impact Network and AquAlliance, as well as the individual comments submitted by AquAlliance. We further incorporate by reference the submittals by the County of San Joaquin, South Delta Water Agency, Central Delta Water Agency, Restore the Delta, Earth Law Center and Friends of the River.

CSPA asked Dr. Lee and Dr. Jones-Lee to review Chapter 8 and Chapter 25 of the EIR/EIS and evaluate whether the approach in analyzing potential impacts to water quality and public health was technically valid and reliable. Their assessment of Chapter 8 is that,

> *"The approach used does not adequately or reliably consider the range of water quality impacts caused by the wide variety of potential pollutants present in the various Delta channels, that can be expected to result from the removal of large amounts of high-quality Sacramento River water from the Delta by this project."* and *"As it stands now Chapter 8 of this EIR/EIS does not reliably inform the public or decision-makers about the magnitude of the errors in estimates and conclusions inherent in the BDCP analysis of the impact of the diversions on Delta water quality/beneficial uses."*

Drs. Lee and Jones-Lee's assessment of the technical validity of Chapter 25 is that the,

> *"…approach is not technically valid for identifying all the constituents that need to be considered in evaluating potential water quality and public health impacts of the proposed BDCP."*

Table 31-1, page 31-9, Summary of Significant and Unavoidable Adverse Impacts, identifies six impacts to surface water quality. Three (concentrations of bromide, chloride and electrical conductivity) result from facilities operations and maintenance (CM1) and three (concentrations of mercury, organic carbon and pesticides) result from implementation of CM2-CM22. Perhaps, nothing more graphically illustrates the fundamental inadequacy of the EIR/EIS than the fact that it only identifies three water quality adverse impacts resulting from the diversion of another 2.5 million acre feet of water from an estuary already grievously suffering from lack of flow.

Our specific concerns are enumerated below followed by our comments.

1. A Word of Caution

We offer a word of caution. The Delta is an incredibly complex estuarine ecosystem and only in our hubris do we believe we understand the intricacies of its hydrological, chemical and biological tapestry. Virtually every previous environmental document prepared for hydro-modification projects in this estuary have promised benign or beneficial results. All exacerbated existing conditions. Almost every significant physical change of the environment by humankind has been accompanied by unintended consequences. Adaptive management must be an integral component of any Delta Plan. But, adaptive management is difficult to implement. As the National Research Council put it:[1]

> *"Numerous attempts have been made to develop and implement adaptive management strategies in environmental management, but many of them have not been successful, for a variety of reasons, including lack of resources; unwillingness of decision makers to admit to and embrace uncertainty; institutional, legal, and political preferences for known and predictable outcomes; the inherent uncertainty and variability of natural systems; the high cost of implementation; and the lack of clear mechanisms for incorporating scientific findings into decision making."*

Adaptive management has a long and checkered history in this estuary. Taken together, the suite of water quality control plans and water rights decisions by the State Water Resources Control Board (SWRCB or State Water Board) from D-990 (1961) through D-1641 (2000) to the adoption of the present Water Quality Control Plan for the San Francisco Bay/Sacramento-San Joaquin Delta Estuary (2006) constitutes adaptive management. The array of biological opinions issued over the years by the U.S. Fish and Wildlife Service and National Marine Fisheries Service comprises adaptive management. CalFed was an elaborate structured water planning and adaptive management program, as is the Long-Term Operational Criteria and Plan (OCAP) for coordination of the State Water Project and Central Valley Project, with its Water Operations Management Team (WOMT) and various technical working groups.

All of the reasons identified by the National Research Council, as to why adaptive management frequently fails, presently exist in this estuary. Managers and decision makers have routinely rejected the "adaptive" recommendations made by scientists, biologists and technical review teams. Resource and regulatory agencies have failed to adopt and implement recommended criteria and failed to enforce existing criteria. Financial resources have been lacking. Adaptive management has not only failed to reverse the downward spiral of native species in the estuary, it has chaperoned them to the brink of extinction. For adaptive management to play a meaningful role, scientists must have the authority to "adapt."

We can find nothing in the thousands of pages of BDCP's plan or EIR/EIS that provides any evidence that adaptive management is likely to succeed. Adaptive management remains subject to political pressure and the approval of the state and federal contractors. If the reviewer of these

---

[1] National Research Council, *A Review of the Use of Science and Adaptive Management in California's Draft Bay Delta Conservation Plan*, 2011, p. 6.

comments has a different opinion, please provide some support for the view that “adaptive management” will be different this time.

Over mere decades, construction and operation of the Central Valley and State Water Projects have deprived the Delta estuary of half its flow; turned the natural hydrograph on its head, reduced temporal and spatial variability; eliminated crucial habitat, complexity and diversity and deprived the estuary of dilution necessary to assimilate increased pollutant mass loading. It is not surprising that an ecosystem that developed and prospered under a state of nature has been brought to the brink of destruction. No estuarine ecosystem in the world has survived this level of abuse. If the reviewer can identify an estuary somewhere in the world that is suffering from lack of freshwater flow and that has been restored by depriving it of additional millions of acre-feet of flow, please provide the information to us.

Water quality and quantity are flip sides of the same coin; changes in flow change assimilative capacity, residence time and the fate and transport of contaminants. Hydrologic changes modify constituent concentration and bioavailability, which in turn can adversely impact the aquatic ecosystem and other beneficial uses.

Water from the Sacramento River is significantly less polluted than water flowing into the estuary from other tributaries, especially the San Joaquin River. Sacramento River water drawn across the Delta to the export pumps is a major reason water quality in the South Delta is better than it would otherwise be. Diversion of approximately 2.5 million acre feet (MAF) of this relatively good quality water around the Delta will increase the concentration of existing constituents in the surface water remaining in the Delta. It will also increase the residence time of water in the Delta, thereby enhancing the opportunity for bioaccumulation and oxygen depletion to occur. This is exacerbated in tidal environments where pollutants tend to move back and forth with the tides. The EIR/EIS and Delta Plan fail to contain a technically defensible analysis and discussion of the likelihood and extent of degradation and adverse impacts to Delta water quality caused by alternative conveyance or increased exports.

Previous efforts to evaluate potential water quality impacts from proposed projects to modify the hydrology of the Delta have either ignored water quality, with the exception of salt, or relied upon models that track “particles” to evaluate water quality. However, the majority of pollutants identified as impairing the estuary are non-conservative dissolved forms of pesticides, mercury, nutrients or oxygen demand constituents. Conservative constituents like salt are unacceptable surrogates for the universe of chemical constituents and pathogens degrading and impairing Delta waters.

CalSim II and various particle-tracking models, like DSM2, are unable to model potential impacts to water quality from non-conservative constituents. Different constituents respond differently to changes in flow and residence time. Consequently, any credible environmental review should evaluate the impacts of potential hydrologic modifications on a pollutant-by-pollutant basis. Unfortunately, BDCP fails to avail itself of the many water quality models that are routinely employed in NPDES permitting and expressly designed to address the fate and transport of chemical constituents in the environment.

The pollutants identified as causing impairments on the 303(d) list are only the tip of the iceberg. There are water quality impairments in the Delta attributable to total organic carbon, nutrients and other contaminants for which there are no federal or state water quality criteria. In addition to a lack of promulgated water quality criteria for many common water pollutants, there are situations in which the current water quality criteria/standards are well recognized as not being protective of aquatic life resources. For example, the water quality criterion for selenium in the SJR and Delta is not protective of some aquatic life.[2]

Furthermore, existing water criteria fails to address many issues that must be considered in considering impacts on aquatic life. For example:

- Existing criteria fails to consider additive and synergistic properties of regulated chemicals that occur in concentration below criteria. For example, Delta water frequently contains a cocktail of as many as 15 pesticides, many of which interact additively or synergistically.
- Adverse impacts to sensitive species, such as zooplankton, were not included in the development of many criteria.
- There is limited information on chronic exposure to sublethal impacts of chemicals and mixtures of chemicals. Numerous studies in the scientific literature demonstrate adverse effects of chemical exposure well below water quality criterion.
- Water quality criterion fail to address the chronic effects of multiple stressors acting on an already weakened aquatic ecosystem.
- Chemical degradants (or products of chemical breakdown in the environment) are little understood but frequently are highly toxic.
- Water quality criteria have been developed for only a small subset of the chemicals found in these waters. Of the approximately 100,000 chemicals registered for use in the United States, only about 200 are regulated with respect to water quality. The Priority Pollutant List is an artifact of a legal settlement several decades ago, has never been peer-reviewed and is an inadequate surrogate for the maelstrom of chemicals found in waterways today. These include pharmaceuticals and personal care products, industrial chemicals and other potentially hazardous constituents that have been identified as carcinogens, reproductive toxins, endocrine disruptors and immune suppressors, etc.
- Criteria are frequently insufficiently protective for pollutants that bioconcentrate and/or bioaccumulate in tissue.
- Many drinking water criteria are economically based and not health risk based.

As noted above, relocation of export facilities to the Sacramento River will increase residence time in the Delta. This increased residence time may encourage the growth of toxic blue-green algae, which has become a serious problem in recent years. Bioaccumulating constituents like selenium and methyl-mercury or pollutants like DDT and dioxin will have more opportunity to work their way up the food chain. Increases in the concentration of mercury in fish tissue would

---

[2] US EPA, as part of endangered species consultations for the California Toxics Rule, agreed to have the US Geological Survey model the fate and transport of selenium in the Bay-Delta Estuary and the information would serve as the basis for revised water quality criteria. USGS completed the study in December 2010 and it indicated that the Bay-Delta standards should be lowered from 5 ug/l to 1 ug/l or less, depending on the residence time of selenium. The study can be found at: www.epa.gov/region9/water/ctr

further threaten the health of the Delta's large subsistence fishing community. Longer residence times will increase the timeframe for oxygen demanding constituents to reduce oxygen levels in channels already identified as impaired because of low dissolved oxygen.

An alternative conveyance facility and reduction in Sacramento inflow will impact dissolved oxygen levels in the Mokelumne River and Stockton Deep-Water Ship Channel. Presently, flow from the Sacramento is diverted through the cross-channel into the Mokelumne and San Joaquin River as it is drawn to the south Delta pumping facilities. The presence of better quality Sacramento River water in the central Delta and the reverse flows in the San Joaquin at Stockton served to somewhat ameliorate oxygen depletion in the reach below Stockton.

Presently, some part of the pollutant load in the San Joaquin River is drawn to the pumps via Old River, Middle River, Turner Cut and Columbia Cut and exported or "siphoned" south. Any reduction of this "siphon" mechanism would also affect nutrients and numerous other pollutants in the eastern and southeastern Delta. It would likely increase the spatial distribution of water quality impacts into the Central Delta. For example, it could increase nutrient loading to the ship channel exacerbating dissolved oxygen problems. Selenium concentrations might increase in the Delta to levels comparable to those found in wildlife in Suisun Bay. EC impairment might expand into the eastern Delta.

Alternative conveyance and reduction of dilution and outflow will significantly increase the concentration of salt in channels further impacting the yield of Delta agriculture. It will also reduce salinity variability and encourage the spread of certain undesirable invasive species. BDCP has been referred to as a habitat expansion plan for the overbite clam *Potamocorbula amurensis.*

To summarize, the Delta and its tributary streams are formally identified as impaired by a broad suite of pollutants. Water quality criteria have been developed for only a very small subset of the chemicals found in these waters. These criteria fail to adequately consider additive/synergistic, bioaccumulative and chronic/sublethal effects or multiple stressors acting on an already weakened aquatic ecosystem. Increased diversion or routing of good quality dilution flows around the estuary will result in increased concentration and residence time of pollutants. Increased residence time exacerbates the effects of toxic and bioaccumulative pollutants. Reduced diversion and increased Delta flow enhances flushing of pollutants and decreases pollutant concentration.

The BDCP and its EIR/EIS fail to comprehensively analyze and address potential impacts to fish, wildlife and human health from reduced water quality caused by loss of dilution, increased residence time and modified channel hydrology. They also fail to include a comprehensive antidegradation analysis required by the federal Clean Water Act and California's Porter-Cologne Water Quality Control Act.

2. BDCP's Analysis of Water Quality is Technically Invalid and Inconsistent with Prevailing Standards.

"All Models are Wrong, Some are Useful." Statistician E. P. Box

The approach to identifying impacts to water quality is fundamentally and technically flawed. Properly calibrated and verified, comparative models are useful in distinguishing relative differences between alternatives. However, comparative models like CalSim II or DSM2 are not designed and are unable to make credible short-term predictions. There are a number of predictive water quality models that have been designed, peer-reviewed and approved for assessing water quality – but these readily available models were not used.

The BDCP misuses tiered comparative models in an attempt to evaluate potential exceedances of one-hour and four-day water quality criteria that are based upon a not-to-be-exceeded more than once-in-three years standard. More frequent occurrences could, in and of themselves, lead to 303(d) listings of impairment that would be significant impacts. This misuse of modeling appears to be an ill-disguised attempt to minimize and deflect attention from the obvious impacts of diverting 2.5 MAF of freshwater around a severely polluted Delta that is already suffering from a chronic lack of flow. As such, it seriously understates the number and magnitude of adverse impacts.

Models are complex simulations that, at their best, only represent an idealization of actual field conditions. Models can be a black box with a “trust us” outcome. They must be used with extreme caution to ensure that the underlying model assumptions hold for the site-specific situations being modeled. Subtle changes in coefficients, assumptions or input data can dramatically alter output. It is crucial that models be properly calibrated and verified. The design parameters, assumptions, input data, calibration and validation must be transparent in order to be able to meaningfully evaluate the ability to accurately project values.

A critical problem arises when decision makers attribute more precision to modeling results than is warranted and where a model’s output is misused to make definitive comparisons and predictions. While models can be employed to inform analysis, they cannot provide near-certain conclusions that significant environmental effects will or will not occur or will or will not be mitigated, especially where common sense and existing knowledge indicate otherwise.

The EIR/EIS, Table 4-1. Overview of BDCP EIR/EIS Modeling Tools, shows that several models were used to simulate water quality projections for the various project alternatives:

- *Artificial Neural Network (ANN) for CALSIM II An ANN has been developed for CALSIM II that attempts to mimic the flow-salinity relationships in the Delta, as simulated in DSM2. The ANN attempts to statistically correlate the salinity results from a particular DSM2 model run to the various peripheral flows (Delta inflows, exports and diversions), gate operations and an indicator of tidal energy.*
- *CALSIM II simulates operations of the SWP, CVP and areas tributary to the Sacramento-San Joaquin Delta. The model, based on inputted priorities and constraints, determines monthly river flows and diversions, Delta flows and exports, reservoir storage, deliveries to project and non-project users, and controls on project operations. CALSIM II results are used to determine water quality, hydrodynamics, and particle tracking in the DSM2 model.*

- *Delta Simulation Model II (DSM2) DSM2 is a one-dimensional mathematical model that simulates hydrodynamics, water quality, and particle tracking throughout the Delta based on flow data generated from CALSIM II outputs. It describes the existing conditions in the Delta as well as performs simulations for the assessment of incremental environmental effects caused by facilities and operations. The model can be used to calculate stages, flows, velocities, mass transport processes for conservative constituents, and transport of individual particles. HYDRO provides the flow input for QUAL and PTM. QUAL simulates one-dimensional fate and transport of conservative water quality constituents given a flow field simulated by HYDRO. PTM simulates pseudo three-dimensional transport of neutrally buoyant particles based on the flow field simulated by HYDRO.*
- *Particle Tracking Model (PTM) PTM simulates fate and transport of conservative and non-conservative water quality constituents throughout the Sacramento-San Joaquin Delta given a flow field simulated by HYDRO. The model uses velocity, flow, and stage output from DSM2-HYDRO. Outputs are used to estimate the effects of hydrodynamic changes on the fate and transport of larval fish, other covered species, and toxics through the Delta, as well as entrainment of larval fish at various locations. It allows assessment of particle fate, transport, and movement rate from numerous starting points to numerous end points. It provides information on movement of planktonic larval fish, such as delta and longfin smelt, in a tidal environment and is used extensively in Central Valley fishery assessments.*
- *DSM2-HYDRO is a one-dimensional hydraulic model used to predict flow rate, stage, and water velocity in the Delta and Suisun Marsh at a 15-minute timestep.*
- *DSM2-QUAL simulates multiple conservative and non-conservative constituents including dissolved oxygen, carbonaceous BOD, phytoplankton, organic nitrogen, ammonia nitrogen, nitrate nitrogen, organic phosphorus, dissolved phosphorus, TDS and temperature. The model is used to predict water temperature, dissolved oxygen, and salinity in the Delta and Suisun Marsh at a 15-minute timestep.*

All of the DSM2 models require data provided by CalSim II.

The Review of the Draft BDCP EIR/EIS and Draft BDCP conducted by the Delta Independent Science Board (15 May 2014) observed,

> *"As noted for other chapters in the DEIR/DEIS, a concise and informative summary of the chapter would be extremely useful to readers and reviewers. This chapter, covering water quality impacts of the different Alternatives, is not very informative because of its reliance on a few modeling approaches, most notably CALSIM and DSM2, without an explanation of the limitations of these models. There is a noted lack of emphasis on validating model outputs with observational data, as well as a lack of any presentation or discussion of the uncertainties associated with the models."* Page B-22.
>
> *As stated above, there is an over-reliance on model outputs, both to describe existing conditions as well as to project the effects of Alternatives on water*

> *quality constituents. There do not seem to be either a) attempts to compare model outputs for existing conditions to existing water quality data, or b) calls for monitoring of future conditions in order to inform adaptive management of Draft BDCP implementation. Because models will always be incorrect, such observational data are obviously required. Moreover, models were run for only certain constituents and not others; this needs to be clarified and the reasons for selective applications of models should be explained.* Page B-23.

3. BDCP's Inappropriate Use of CalSim II.

CalSim II is like Aladdin's Lamp; it grants wishes to whoever rubs it. CalSim II can be manipulated to produce desired results. Even properly operated it is only as accurate as the data and assumptions that are plugged into the model. It has previously been used to project a false certainty that impacts will be minor. For example, it has been used to show that salmonid mortality will increase by a specific percentage and discussion of possible error or of ranges of possible outcomes has been entirely absent. The model cannot possibly produce such certainty. At best it can predict, given a certain set of data and assumptions, a range of possible outcomes, with some outcomes potentially more probable than other, and with all predictions limited by both known and unknown sources of error.

CalSim II is a highly complex simulation model of a complex system that requires significant expertise to run and understand. Consequently, only a few individuals concentrated in the Department of Water Resources, U.S. Bureau of Reclamation and several consulting firms understand the details and capabilities of the model. State Water Resources Control Board (SWRCB) staff cannot run the model. To the extent CalSim II is relied upon, the EIR/EIS must be transparent and clearly explain and justify all assumptions made in model runs. It must explicitly state when findings are based on post processing and when findings are based on direct model results. And results must include error bars to account for uncertainty and margin of safety.

As an optimization model, CalSim II is hardwired to assume perfect supply and perfect demand. The notion of perfect supply is predicated on the erroneous assumption that groundwater can always be obtained to augment upstream supply. However, the state and federal projects have no right to groundwater in the unadjudicated Sacramento River basin. Operating under this assumption risks causing impacts to ecosystems dependent upon groundwater basins in the areas of origin. The notion of perfect demand is also problematic, as it cannot account for the myriad of flow, habitat and water quality requirements mandated by state and federal statutes. Perfect demand assumes water deliveries constrained only by environmental constraints included in the code. In other words, CalSim II never truly measures environmental harm beyond simply projecting how to maximize deliveries without violating the incorporated environmental constraints.

As a monthly time-step model, CalSim II cannot determine weekly, daily or instantaneous effects; i.e., it cannot accurately simulate actual instantaneous or even weekly flows. It follows that CalSim II cannot identify real-time impacts to objectives or requirements. Indeed, DWR admits, "CalSim II modeling should only be used in 'comparative mode,' that is when comparing the results of alternate CalSim II model runs and that 'great caution should be taken when comparing actual data to modeled data.'"[3] Since CalSim II results are employed as boundary conditions by subsequent water quality models, like DSM2, those limitations undermine efforts by subsequent models to accurately evaluate specific exceedances of water quality criteria or impacts to water quality.

CalSim II assumes foresight and compliance by project operators. However, this cannot satisfy CEQA/NEPA's mandates to analyze and disclose the full spectrum of potential environmental impacts caused by a project vis-à-vis a no-project and other alternatives. A report produced by the National Heritage Institute summarizes this flaw by "call[ing] into question the use of CalSim II as a tool for environmental impact assessment, since it is changes in the environment associated with specific projects and the satisfaction of arbitrary constraints which is the critical focus of environmental review."[4]

A formal peer-review of CalSim II was highly critical and detailed numerous inadequacies in the model. Among these was the opinion that CalSim II "has not yet been calibrated or validated for making absolute prediction values."[5]

The Department of Civil Engineering University of California at Davis conducted a comprehensive survey of members of California's technical and policy-oriented water management community regarding the use and development of CalSim II in California. Detailed interviews were conducted with individuals from California's water community, including staff from both DWR and USBR (the agencies that created, own, and manage the model) and individuals affiliated with consulting firms, water districts, environmental groups, and universities.[6]

The results of the survey, which was funded by the CalFed Science Program and peer-reviewed, should serve as a cautionary note to those who make decisions based on CalSim II. The report cites that in interviewing DWR and USBR management and modeling technical staff: "*Many interviewees acknowledge that <u>using CALSIM II in a predictive manner is risky and/or inappropriate</u>, but without any other agency-supported alternative they have no other option.*" The report continues that: "All users agree that CalSim II needs better documentation of the model, data, inputs, and results. CalSim II is data-driven, and so it requires numerous input files, many of which lack documentation," and "There is considerable debate about the current and desirable state of CalSim II's calibration and verification," and "Its representation of the SWP and CVP includes many simplifications that raise concerns regarding the accuracy of results." It

[5] Close, A, et al. 2003. A Strategic Review of CALSIM II and its Use for Water Planning, Management, and Operations in Central California, Submitted to the California Bay Delta Authority Science Program, Association of Bay Governments, Oakland, California. 4 December 2003. Page 9.

[6] Ferreira, Ines C., et al. 2005. Musings on a Model: CalSim II in California's Water Community, published in San Francisco Estuary & Watershed Science. March 2005. 13 Pages.

reported, “Many interviewees are concerned that CalSim II’s monthly time step cannot capture hydrologic variability adequately and thus does not compute water exports and export capacity accurately, both of which are significant factors in system operations,” and, “The model’s inability to capture within-month variations sometimes results in overestimates of the volume of water the projects can export from the Sacramento- San Joaquin Bay-Delta and makes it seem easier to meet environmental standards than it is in real operations.” The study concluded by observing, “CalSim II is being used, and will continue to be used, for many other types of analyses for which it may be ill-suited, including in absolute mode.”

More recently, Walter Bourez of MBK Engineers made a presentation on BDCP operations modeling at the 17 January 2014 meeting of the Delta Independent Science Board.[7] The presentation concluded:

- *Incorporation of climate change contains errors and does not incorporate adaptation measures.*
- *BDCP’s “High Outflow Scenario” is not sufficiently defined for analysis.*
- *BDCPs simulated operation of the dual conveyance, coordinating proposed North Delta diversion facilities with existing South Delta diversion facilities, is inconsistent with the project description.*
- *BDCP models do not accurately reflect anticipated changes in CVP and SWP operations with BDCP.*
- *Independent modeling of the BDCP revealed differences in CVP and SWP operations and water deliveries from the analysis disclosed for the Draft EIR/EIS. Total exports would increase about 200 TAF and Delta outflow would decrease approximately 200 TAF while the North Delta intake would divert 680 TAF more and the South Delta intakes would divert 460 TAF less than projected in BDCP modeling.*

A reduction of Delta outflow coupled with an even larger reduction in the inflow of better quality Sacramento River water into the Central Delta would exacerbate water quality problems. This reduction on outflow and increase in exports, plus the failure to accurately model climate change and CVP and SWP operations, undermines DSM2’s assessment of water quality conditions and resulting impacts from operation of BDCP, since DSM2 relies on modeling results generated by CalSim II.

A consortium of water agencies including Contra Costa Water District, East Bay Municipal Utility District, Friant Water Authority, Northern California Water Association, North Delta Water Agency, San Joaquin River Exchange Contractors Water Authority, San Joaquin Tributaries Authority and Tehama Colusa Canal Authority asked MBK Engineers to review the CalSim II modeling studies performed as part of the BDCP. A 29-page report, supported by a 72 page technical appendix, summarized their analysis of the BDCP model. MBK Engineers found that:

---

[7] Can be found at, http://deltacouncil.ca.gov/sites/default/files/documents/files/BDCP_Review_ISB_2014_01_17Final_sent.pdf

> *"There are three basic reasons why the BDCP Model cannot be used to determine the effects of the BDCP: 1) the no action alternatives do not depict reasonable operations due to climate change assumptions, 2) operating criteria used in the BDCP Alternative 4 result in unrealistic operations, and 3) updates to CalSim II since the BDCP modeling was performed almost 4 years ago alter model results."* (P. 3)
>
> *"The CalSim II model is the foundational model for analysis of the BDCP, including the effects analysis in the Draft BDCP and the impacts evaluation in the Draft EIR/EIS. Results from CalSim II are used to examine how water supply and reservoir operations are modified by the BDCP, and the results are also used by subsequent models to determine physical and biological effects, such as water quality, water levels, temperature, Delta flows, and fish response. Any errors and inconsistencies identified in the underlying CalSim II model are therefore present in subsequent models and adversely affect the results of later analyses based on those subsequent models."* (P. 10)
>
> *"Hydrologic modeling of BDCP alternatives using CalSim II has not been refined enough to understand how BDCP may affect CVP and SWP operations and changes in Delta flow dynamics. Better defined operating criteria for project alternatives is needed along with adequate modeling rules to analyze how BDCP may affect water operations."* (P. 27)

Flow Science Inc., at the request of the Sacramento Regional County Sanitation District, reviewed documents and model results associated with the BDCP environmental review process in order to determine how the proposed BDCP alternatives might impact Sacramento River temperatures at Freeport. In a 23 April 2014 Technical Memorandum, they stated:

> *"As noted above, the corrections to the DSM2 temperature boundary conditions have a substantial effect on the temperatures at Freeport. In additions, the methodology for determining the temperature boundary conditions (for both the original and corrected boundary conditions) is questionable because the same set of temperature boundary conditions are used for all BDCP alternatives. Changes in boundary conditions between scenarios reflect only climate change effects and not different BDCP or upstream reservoir operations. That is, all ELT simulations used the same temperature boundary conditions for all BDCP alternatives, and all the LLT simulations used the same temperature boundary conditions for all BDCP alternatives. Clearly, with this approach the modeling will predict no (or minimal) impacts of the BDCP on the temperature at Freeport, since Freeport is located close to the boundary. However, the various BDCP alternatives are likely to result in substantially different river flows at different times of the year (e.g., whether or not Fall X2 is implemented may cause substantially different reservoir releases and river flows)."* (P. 2)

Flow Science recommended, *"that SRCSD comment the EIR does not contain information - and the modeling data upon the EIR is based are insufficient – to support any conclusions about how*

Sacramento River temperatures at Freeport may change in the future." (P. 7) The same flaws identified by Flow Science would extend to evaluating the potential impacts resulting from various BDCP temperature scenarios on water quality constituents and fisheries.

The Review of the Draft BDCP EIR/EIS and Draft BDCP conducted by the Delta Independent Science Board (15 May 2014) observed,

> *"The major analytical problem is the gap between CALSIM-II modeling of the water-supply system and actual operations. The State Water Project and Central Valley Project account for only a part of the water management decisions and impacts in this vast system. DWR and USBR modeling has improved considerably in recent decades but remains centered on the SWP and CVP. This limited modeling therefore largely ignores or oversimplifies most water management decisions in California, which are those taken by local and regional governments and water users. The limited modeling thus seems inadequate for impact analysis of a system governed largely by local agencies."* Page A-24.

4. BDCP's Inappropriate Use of DSM2

As described in the BDCP EIR/EIS (5A-A34), DSM2 is a one-dimensional hydrodynamics, water quality and particle tracking simulation model used to simulate hydrodynamics, water quality, and particle tracking in the Sacramento-San Joaquin Delta. It is a data-intensive DWR model that runs for a limited period (only 16 years) and has never been peer-reviewed. Several of its modules have only received limited validation and calibration. For example, its particle tracking module has been severely criticized.[8] The EIR/EIS describes its limitations, at 5A-A49-50, as:

> *DSM2 is a 1D model with inherent limitations in simulating hydrodynamic and transport processes in a complex estuarine environment such as the Sacramento – San Joaquin Delta. DSM2 assumes that velocity in a channel can be adequately represented by a single average velocity over the channel cross-section, meaning that variations both across the width of the channel and through the water column are negligible. DSM2 does not have the ability to model short-circuiting of flow through a reach, where a majority of the flow in a cross-section is confined to a small portion of the cross-section. DSM2 does not conserve momentum at the channel junctions and does not model the secondary currents in a channel. DSM2 also does not explicitly account for dispersion due to flow accelerating through channel bends. It cannot model the vertical salinity stratification in the channels.*
>
> *It has inherent limitations in simulating the hydrodynamics related to the open water areas. Since a reservoir surface area is constant in DSM2, it impacts the stage in the reservoir and thereby impacting the flow exchange with the adjoining channel. Due to the inability to change the cross-sectional area of the reservoir*

---

[8] Panel Review of the CA Department of Fish and Game's Quantifiable Biological Objectives and Flow Criteria for Aquatic and Terrestrial Species of Concern Dependent on the Delta, A2: Discussion of the DSM2 PTM, 2010, P. 17 - 19.

> *inlets with changing water surface elevation, the final entrance and exit coefficients were fine tuned to match a median flow range. This causes errors in the flow exchange at breaches during the extreme spring and neap tides. Using an arbitrary bottom elevation value for the reservoirs representing the proposed marsh areas to get around the wetting-drying limitation of DSM2 may increase the dilution of salinity in the reservoirs. Accurate representation of RMA's tidal marsh areas, bottom elevations, location of breaches, breach widths, cross-sections, and boundary conditions in DSM2 is critical to the agreement of corroboration results.*
>
> *For open water bodies DSM2 assumes uniform and instantaneous mixing over entire open water area. Thus it does not account for the any salinity gradients that may exist within the open water bodies. Significant uncertainty exists in flow and EC input data related to in-Delta agriculture, which leads to uncertainty in the simulated EC values. Caution needs to be exercised when using EC outputs on a sub-monthly scale. Water quality results inside the water bodies representing the tidal marsh areas were not validated specifically and because of the bottom elevation assumptions, preferably do not use it for analysis.*

The Review of the Draft BDCP EIR/EIS and Draft BDCP conducted by the Delta Independent Science Board (15 May 2014) observed,

> *"DSM2 used for salinity-flow analysis is a one-dimensional model having inherent limitations in simulating open water areas, flow in bends and small channel, inlet/outlets and three-dimensional turbulent mixing, particularly with sea level decimeters higher than today's."* Page A-12

In other words, in an exceedingly complex Delta with myriad meandering small channels and constantly changing flows, DSM2 modeling output inadequately accounts for varying velocities and secondary currents, channel junctions and open waters, stratification, fluctuating channel beds, turbulent mixing, surface waves, sediment resuspension and agricultural inputs and diversions. And, as previously discussed, DSM2 is dependent on flawed CalSim II output data regarding flows and boundary conditions.

For example, fluctuating channel beds directly affect water quality. In the renewal of the NPDES permit for Sacramento Regional County Sanitation District's NPDES permit, it was found that the bed of the Sacramento River fluctuates as much as six feet near the outfall diffuser. Modeling revealed that bottom contours had a direct effect on whether constituent plumes from the diffuser exceeded water quality standards. Discharges from the Stockton Wastewater Treatment facility experienced a somewhat different problem. Because of an abrupt turn in the river below the outfall, pollutants tended to concentrate along one bank and had the potential to exceed water quality standards. Consequently, Stockton was unable to qualify for a mixing zone. Another example is the relatively recent sediment buildup blocking flow into the head of Steamboat Slough, which has reduced the depth of the entrance from approximately nineteen feet to ten feet. While not hindering boating navigation, the underwater barrier certainly affects fish migration, flow and potentially water quality. Sediment buildup and scouring in channels is a constant in the Delta. The failure to continually update information on channel bathymetry undermines DSM2's ability to accurately model hydrology and water quality.

While the EIR/EIS discusses the limitations of DSM2, it fails to account for and disclose the uncertainty of model results There are few, if any, error bars attached to predictions and comparisons to indicate to makers and the general public the relative confidence level in the results. The EIR/EIS is deficient without discussion of the degree of uncertainty in results.

Whatever the merits of DSM2 for comparative analysis, it is fundamentally unable to model or identify specific violations of water quality criteria or other impacts to water quality. The EIR/EIS acknowledges that the North Delta diversion facility will increase the percentage of more polluted San Joaquin River water in the Delta. It also acknowledges that BDCP will increase the residence time of water in the East, South, West and North Delta over existing conditions (Table 5C.5.4-14, p. 5C.5.4-84, BDCP). The diversion of two and a half MAF of Sacramento River water will inevitably change the constituent composition and hydrology of the estuary. Changes in hydrology affect the fate and transport of contaminants, which in turn, affect beneficial uses.

As previously discussed, water quality criteria for aquatic life are established on a one-hour or four-day basis not to be exceeded more than once in three years. Exceedances of these criteria cause direct adverse impacts to listed species and other aquatic life. Exceedances of human health criteria can have direct adverse impacts to people. Exceedances of criteria protecting other identified beneficial uses of water will adversely impact those who rely on the beneficial use. For example, multiple exceedances of a pollutant within a waterway would qualify the waterway for listing as an impaired waterbody on the CWA 303(d) list. Such a listing would have enormous financial implications for the municipalities and business discharging wastewater and stormwater into the Delta. NPDES permits and Waste Discharge Permit requirements would become more stringent entailing expensive facility upgrades and enhanced management practices.

The data and models relied upon by BDCP in this EIR/EIS are incapable of evaluating and predicting the potential adverse impacts by the project on water quality. They may confirm common sense: that the removal of 2.5 MAF of freshwater from the Delta will inevitably increase the concentration and residence time of salinity and a number of conservative constituents in the Delta. However, they cannot credibly predict or quantify exceedances of specific water quality criteria for the universe of constituents, especially non-conservative constituents, which exist and interact in the estuary. Consequently, they are unsuitable for analyzing and unable to make the effects determinations described in Chapter 8, Section 8.4.2.3, pp. 8-75 & 8-76. A vast discretionary project with potential to cause great harm that will certainly have major unintended consequences should not proceed until the significant impacts of that project on water quality can be conclusively identified and addressed.

5. BDCP's Inappropriate Use of "Best" Professional Judgment.

Professional judgment is frequently employed but not defined in the EIR/EIS. Chapter 8, Section 8.4.2.1, Screening Analysis and Results, page 8-173, states:

> *This water quality analysis assessed the potential effects of implementing the various alternatives on 182 constituents (or classes of constituents). The initial analysis of water quality effects, referred to as the "screening analysis" in the Methods of Analysis section (above) resulted in the following findings. Of the 182 constituents, 110 were determined to have no potential to be adversely affected by the alternatives to an extent to which adverse environmental effects would be expected. Historical data for these constituents showed no exceedances of water quality objectives/criteria in the major Delta source waters, were not on the State's 303(d) list in the affected environment, were not of concern* ***based on professional judgment*** *or scoping comments, and had no potential for substantial long-term water quality degradation. Consequently, no further analyses were performed for these 110 constituents. Conversely, further analysis was determined to be necessary for 72 constituents. Of these, 15 are addressed further in the Screening Analysis itself in Appendix 8C because they did not warrant alternative-specific analyses, and 1 - temperature - is addressed in Chapter 11, Fish and Aquatic Resources. The remaining 56 constituents are addressed in the Environmental Consequences section, and are contained in the sections noted in Table 8-61.*

Through every step in the screening and evaluative process, professional judgment was used in determining whether a constituent had the potential to exceed thresholds of significance, should be carried forward for further assessment, was a 'constituent of concern,' whether it should be addressed qualitatively or quantitatively and whether the project could result in significant impacts to specific constituents. Of the 182 constituents that were analyzed, detailed assessments were performed on 24 and of those, 8 were assessed quantitatively (modeling, ratios) and 16 were assessed qualitatively (professional judgment).

Unfortunately, the EIR/EIS does not indicate whether professional judgment followed a rigorous step-by-step formal process, if an Ouija board, crystal ball or fortune-teller was involved or if conclusions were simply pulled from someone's arse. It fails to adequately discuss the methodology, science, criteria or analysis used to add, remove or modify constituent inclusion in the screening analysis or to determine the degree of impact significance. There is no discussion of why limited data sets were relied upon or why the more extensive data sets from regulatory programs were ignored. Inadequate data limits professional judgments. There is no discussion justifying the reliance on boundary water quality conditions and the exclusion of the extensive pollutant loading that occurs in the Delta in reaching conclusions. There is no discussion on the use of average or median constituent concentrations or the 95th or average percentile for assessing the potential to violate one-hour or four-day criteria that should not be violated more than once in three years. There is no discussion or attempted quantification regarding the uncertainty of conclusions. Nor is there any discussion of how heavily criticized comparative models, used outside their temporal, spatial and resolution limits, may or may not be sufficient for making explicit determinations regarding the potential effects of BDCP on constituents and impacts to water quality standards caused by a modified hydrology, reduced dilution and increased residence time.

It is the responsibility of those who rely on professional judgment, in the absence of conclusive information, to hold paramount the safety, health and welfare of the public and the environment. Professional judgment must the predicated on ethics and conformance with the respective codes or standards of professional conduct. Professional judgment requires information sufficient to achieve an acceptable degree of accuracy, a working knowledge of the science and criteria, and a degree of synthesis and depth of knowledge necessary to make sound judgment without harm to the environment. An intelligent evaluation of the criteria and a thorough engineering analysis is critical to professional judgment. Professional judgment cannot reside in a black box, but has a responsibility to the public's trust. Professional judgment cannot serve as a substitute for the failure to collect and evaluate adequate data. Professional judgment must disclose a transparent process where explanation of the factors involved, how conclusions were arrived at and the uncertainty of those conclusions is weighed or evaluated. There must be an attempt to quantify uncertainty with error bars or detailed discussion. Whatever professional judgment is, the abject and pervasive failure in the EIR/EIS to acknowledge, quantify and discuss the uncertainty of conclusions is not professional judgment: it is an appalling display of amateurism.

Neither the plan nor EIR/EIS comport with prevailing standards for technical analysis, which is why BDCP's documents are inappropriate, technically invalid and fail to meet the fair disclosure requirements of CEQA and NEPA.

6. Reliance Upon a Truncated and Inadequate Data Set to Screen, Evaluate and Predict Impacts to Water Quality is Technically Indefensible.

Appendix 8C describes the screening analysis. Section 8C.1.1, P. page C-1, Data Sources, states,

> *"This section describes sources for data used in the screening analysis. Water quality data in the Delta has been collected by a myriad of public and private organizations. However, for consistency and due to data availability concerns, the input data for the screening analysis was limited to two data sets that were publically available via the web and managed by a public agency (i.e., data from the DWR Water Data Library and the Bay Delta and Tributaries Project [BDAT])."*

Both data sets are extremely limited. The Bay Delta and Tributaries Project (BDAT) data set is relatively old and is not even presently available on the DWR web site. The DWR data set ignores an enormous quantity of data collected, pursuant to stringent protocols, by other agencies, as evidenced by the extremely few samples of numerous constituents collected. A number of priority pollutants were never sampled or sampled only a few times.

The selection of sites arbitrarily limited the amount and kinds of ambient data that was collected and excluded numerous toxic constituents identified as carcinogens, reproductive toxins, endocrine disruptors and immune suppressors. One, of many, examples is Bis(2-

ethylhexyl)phthalate (DEHP), frequently known as Di(2-ethylhexy)phthalate. Bis(2-ethylhexyl)phthalate is discussed below under its own heading. Regulatory sampling in the Central Valley reveals its presence in both ambient waters and wastewater effluent at concentrations exceeding water quality criteria.

Section 8C.1.1.1, Table SA-1, page 8C-2, identifies the source water locations where data was collected on the upstream Sacramento River, upstream San Joaquin River and Chipps -Mallard – Suisun areas representing the Delta west boundary. It states,

> *"Interior Delta sites were not considered, because modeling performed in support of the Environmental Consequences impact assessments assumed no new sources of water quality constituents and, therefore, water quality concerns are assumed to arise primarily through altered mixing of Delta source waters."*

The assumption that there are "no new sources of water quality constituents" in the Delta illustrates the inadequacies of BDCP modeling or the determination of proponents to only accept facts that support their desired outcome. There are enormous sources of water quality constituents within the Delta. These sources include: municipal wastewater and stormwater discharges from Lodi, Stockton, Manteca, Lathrop, Tracy, Mountain House, Discovery Bay, Brentwood, Iron House Sanitary District, Rio Vista, Isleton and unincorporated areas; industrial and construction stormwater discharges; enormous return flows from irrigated agriculture and dairy operations; discharges from marinas and on-the-water recreational activities; illegal dumping; pesticide drift from aerial spray operations for agriculture and vector control, as well as extensive application of pesticides to control aquatic weeds; and ballast discharges from shipping and spills from bulk loading operations at the ports, among others. Indeed, the permitted waste discharge limits of municipal wastewater treatment plants within the Delta (excluding Sacramento), is over 100 MGD and is almost a third more flow than is flowing in the San Joaquin River at Vernalis, as of this writing.

Failure to consider and analyze the extensive mass loading of an astonishing array of contaminants within the Delta not only renders the screening analysis technically insufficient, it renders all of the subsequent assessments of water quality impacts technically invalid.

Table SA-6, pages 8C-22-27, identifies all constituents (182) measured at the boundary stations, number of times analyzed and detected, and minimum and maximum values reported in the data set.

Because of the extremely limited data set, many of the priority pollutants were not sampled or sampled infrequently. For example, aluminum was not sampled, although the NPDES permit for Sacramento Regional Wastewater Treatment Plant reveals that ambient aluminum in the Sacramento River exceeds the acute water quality criteria for freshwater aquatic life more than tenfold. Cadmium has only one data point on the San Joaquin and 25 (12 dissolved, 13 total) on the Sacramento. The average cadmium concentration on both rivers exceeds the acute and 4-day criteria for aquatic life, adjusted for hardness. The arbitrary selection of screening sampling sites eliminated extensive NPDES and other data sets that would have permitted a more defensible and accurate assessment of potential adverse impacts.

Table SA-11, Step 6 Water quality constituents (totaling 72) for which detailed assessment were performed, page BC-39, identifies which constituents were carried forward for further analysis and which assessments were conducted quantitatively and which were assessed qualitatively. Nine constituents were addressed quantitatively (i.e., modeling) and 63 were assessed qualitatively (i.e., best professional judgment). However, there is virtually no discussion in Appendix 8C or Chapter 8 of what constitutes a quantitative evaluation, the methodology employed, threshold levels and how conclusions were reached. The lack of transparency fails to comply with minimal professional standards for an EIR/EIS for a major water development project.

Chapter 8, Water Quality, Section 8.2.2.1, page 8.27, describes water quality monitoring program and sources of data. Noticeable absent are the vast data sets of the Regional Water Board's NPDES permitting program and Irrigated Lands Program.

Table 8-6, page 8-31, Locations Selected to Represent Existing Water Quality in the Delta, includes only three sites in the interior Delta: San Joaquin River at Buckley Cove, Franks Tract at Russo's Landing and Old River at Rancho del Rio. The data sources were identified as BDAT, again an old data set not currently available on the web. The use of only three sites to represent potential impacts to water quality in an 841 square mile Delta containing 700 miles of meandering waterways is technically indefensible and renders any assessment of impacts to water quality invalid.

Table 8-33, Median Metal Concentrations for Selected Sites, May 1988-September 1993, page 8-105, shows the total and dissolved concentration of the priority pollutants arsenic, cadmium, copper, lead and zinc at San Joaquin River at Buckley Cove, Sacramento River at Green's Landing, Sacramento River above Point Sacramento, San Joaquin River at Antioch Ship Channel, Old River at Rancho Del Rio, Suisun Bay at Bulls Head, Franks Tract and the San Joaquin River at Vernalis. Of these, Buckley Cove, Franks Tract and Old River are within the central Delta. All of the metals are hardness dependent but no hardness data was presented.

Taking the San Joaquin River at Buckley Cove as an example, we found that the lowest ambient hardness in the San Joaquin below the Stockton Wastewater Treatment Plant was 30 mg/l. Buckley Cove is only a few miles downriver from the Stockton Treatment Plant outfall. Table 8-33, shows that the mean ambient concentrations for copper, cadmium and lead (expressed as both dissolved and total recoverable) are 5 ug/l. Adjusting for hardness, per US EPA and SWRCB requirements, the concentrations of all three metals at Buckley Cove are potentially toxic to aquatic life. The hardness adjusted median dissolved or total concentrations of all three metals exceed the acute one-hour and chronic four-day toxicity criteria. As these metal concentrations are median values, the highest recorded concentrations of these metal would potentially be more toxic. The San Joaquin River in the Delta is already listed as impaired for unknown toxicity. Other examples could have been used, as we found relatively low hardness values elsewhere in the Delta; e.g., 36 & 39 mg/l at the Delta pumping plant headworks at Banks.

This issue is discussed more fully in comments on hardness dependent metals below, but it illustrates that the EIR/EIS is deficient in not analyzing the potential adverse impacts caused by the diversion of 2.5 MAF of Sacramento River water and the resulting loss of dilution and increased residence time on water quality and beneficial uses in the eastern Delta. Loss of dilution and increase in residence are recipes for water quality degradation. The EIR/EIS's claims are counterintuitive and without a detailed explanation of how conclusions were arrived at or inclusion of sufficient data to verify conclusions, the EIR/EIS is technically invalid and legally inadequate.

7. The Failure to Evaluate Numerous Toxic Constituents is Unacceptable.

As discussed above, failure to evaluate toxic chemicals because the arbitrarily selected data sets omitted analysis of those chemicals is unacceptable. Bis(2-ethylhexyl)phthalate (DEHP) is an example of a number of chemicals that are known to be highly toxic and for which monitoring data exists. Yet, because these constituents were not included in the very limited data sets used in evaluating impacts for BDCP, there is no analysis of the project's impacts for these constituents.

On 30 December 2009 the US EPA issued a press release announcing an *Action Plan* (a series of actions) on four chemicals raising serious health or environmental concerns, including phthalates. The Action Plan was to address the manufacturing, processing, distribution, and use of these chemicals. One of the phthalates listed is bis(2-ethylhexyl)phthalate, also commonly called di-(2-ethylhexyl)phthalate and abbreviated DEHP. Bis(2-ethylhexyl)phthalate is an organic compound and is produced on a massive scale by many companies. Phthalates were detected in greater than 75% of approximately 2,540 urinary samples collected from participants of the National Health and Nutrition Examination Survey (NHANES). Exposure in the United States to diethyl phthalate, dibutyl phthalate or diisobutylphthalate, benzyl butyl phthalate, and di-(2-ethylhexyl)phthalate is widespread.

Water quality standards for bis(2-ethylhexyl)phthalate were first established in California under the December 1992 National Toxics Rule (NTR), which was amended in 1999. On 18 May 2000, US EPA adopted the California Toxics Rule (CTR). The CTR promulgated new toxics criteria for California and, in addition, incorporated the previously adopted NTR criteria that were applicable in the state. Despite the current regulation under the CTR, US EPA has revised their recommended Ambient Criteria for bis(2-ethylhexyl)phthalate to a significantly lower number. This new lower criteria for bis(2-ethylhexyl)phthalate would result in more wastewater discharges being regulated to keep this plasticizer out of California's waterways.

EPA's existing regulation of bis(2-ethylhexyl)phthalate is based on human consumption of water and fish. EPA has also issued new information regarding the impacts to aquatic life:

> *"Of the 8 phthalates, BBP, DEHP, and DBP elicit the most toxicity to terrestrial organisms, fish, and aquatic invertebrates (EC, 2008a, Staples et al. 1997). Ecotoxicity studies with these phthalates showed adverse effects to aquatic organisms with a broad range of endpoints and at concentrations that coincide with measured environmental concentrations. Toxic effects were observed at*

> *environmentally relevant exposures in the low ng/L to µg/L range (Oehlmann et al. 2008).”*

Sacramento Regional Wastewater Treatment Plant NPDES Permit includes the statement:

> “*The CTR includes a criterion of 1.8 µg/L for bis(2-ethylhexyl)phthalate for the protection of human health for waters from which both water and organisms are consumed… The maximum effluent concentration (MEC) for bis(2-ethylhexyl) phthalate was 8.1 µg/L out of 87 samples while the maximum observed upstream receiving water concentration was 0.58 µg/L out of 55 samples.*”

A CSPA review of phthalates in the Central Valley revealed that 27 wastewater treatment plants had levels of bis(2-ethylhexyl)phthalate in the discharge that presented a reasonable potential to exceed criteria. Receiving water levels in a number of tributaries to the Delta also exceeded criteria, including: Clear Creek (7 ug/l); Yolo Bypass (9 ug/l); Upper Sacramento near Red Bluff (10 ug/l); Deer Creek, tributary to the Yuba River (4 ug/l); Yuba River near Yuba City (10 ug/l); and the San Joaquin River near Turlock (12.3 ug/l) and near Stockton (8.1 ug/l).

Despite the concern by US EPA in issuing an Action Plan for bis(2-ethylhexyl)phthalate, widespread human exposure, the fact that bis(2-ethylhexyl)phthalate has been regulated in California since 1992, sampling is required as a condition of NPDES permits and bis(2-ethylhexyl)phthalate has been detected at levels exceeding criteria in both wastewater discharges and receiving waters that are tributary to the Delta; the EIR/EIS simply concludes that bis(2-ethylhexyl)phthalate is not of concern, is only found in low concentrations and analytical tools have only recently been developed.

The EIR/EIS Chapter 8, page 8-58, states that:

> “*In 2006, CCWD participated in a study to examine the toxicological relevance of EDCs and PPCPs in both raw source and treated water (Contra Costa Water District 2009). Of the 62 compounds analyzed, only five were detected in the treated water: sulfamethoxazole (pharmaceutical), meprobamate (pharmaceutical), atrazine (herbicide—endocrine disruptor), triclosan (pharmaceutical), and dioctyl phthalate (used to make plastics—endocrine disruptor). The study concluded that detection occurred at low concentrations and should not pose any health threats.*” (Emphasis added)

And Appendix 8C, page 15, states that:

> “*Examples of EDCs include natural plant and animal steroid hormones, metals (e.g., arsenic, cadmium, lead, and mercury), dioxins, PAHs, pesticides, pharmaceuticals and personal care products (PPCPs), and PCBs. Sources of anthropogenic EDCs include wastewater treatment plants, private septic systems, urban stormwater runoff, industrial effluents, landfill leachates, discharges from fish hatcheries and dairy facilities, runoff from agricultural fields and livestock enclosures, and land amended with biosolids or manure. Constituents of emerging*

> *concern (CECs) include the following classes of chemicals: perfluoranated compounds (e.g., PFOS, PFOA), polybrominated diphenyl ethers (PBDEs), PPCPs, and phthalates. These chemicals are generally found in such low concentrations in the environment that only recently have analytical tools been developed to detect and quantify these concentrations*." (Emphasis added)

However, the EIR/EIS, in discussing the 2006 Contra Costa Water District Report, failed to consider other significant factors that may have biased the conclusions. Chapter 8, page 8-57, also observes:

> *"In 2001 and 2002, a survey of raw and treated drinking water from four water filtration plants in San Diego County showed the occurrence of several PPCPs including phthalate esters, sunscreens, clofibrate, clofibric acid, ibuprofen, triclosan, and DEET (Loraine and Pettigrove 2006). This is important because on average, roughly a third of the water in San Diego County originates from the Delta via conveyances of the SWP. According to the study, occurrence and concentrations of these compounds were highly seasonally dependent, and reached maximums when the flow of the San Joaquin River was low and the quantity of imported water was high. The maximum concentrations of the PPCPs measured in the raw water were correlated with low-flow conditions in the Delta that feed the SWP."*

For example, 2006 was an extremely wet year in both the Sacramento and San Joaquin river basins, while the preceding year (2005) was above normal in the Sacramento basin and wet in the San Joaquin basin. Had the CCWD study occurred during a drought, results might have been very different. The San Diego County study demonstrates that dry years and reduced dilution are correlated with constituent concentration. The EIR/EIS is deficient for failing to address phthalates and the array of other constituents that were excluded from analysis because of the data set selected.

8. Failure to Adequately Account for Changes in Dilution Undermines Water Quality Impact Analyses.

The EIR/EIS acknowledges that the SWP/CVP water diversions "…reduce the amount of water available for dilution and assimilation of contaminant inputs…" Chapter 8, page 8-14, lines 14-17) Table 8-38, Summary of Methodologies Used for Water Quality Impact Analyses, page 8-14 of Chapter 8, identifies the methodologies and tools employed for impact analyses. CalSim2 served as input to the DSM2 model. DSM2 addressed EC and DOC concentrations and flow fractions. Mass Balance, using flow fractions and constituents addressed the other constituents quantitatively, other than EC and DOC (apparently 6 constituents). Qualitative analysis addressed the remaining parameters (apparently 16 constituents) through a varied approach based on constituent and location but "attempted to estimate concentration changes attributable to the Alternatives."

CalSim II is a heavily criticized large-scale comparative model that runs in 30-day time steps. DSM2 is a heavily criticized, comparative, never-peer-reviewed model that takes CalSim II output and attempts to track particles, representing conservative constituents, through the myriad twisted channels of the Delta. Neither model is sufficient for addressing constituents that are toxic in low micrograms or nanograms with respect to one-hour and four-day criteria that are predicated upon a standard not to be exceeded more than once in three years. Professional judgment, as used in this document, embraces black-box conclusions based on extremely limited data sets collected from few locations and that ignores constituent loading in a heavily polluted estuary. This is not a recipe for making technically valid conclusions regarding available dilution or changes in dilution.

It is an undeniable fact that concentrations of constituents in the Sacramento River are considerably lower than concentrations of equivalent constituents in the San Joaquin River. It is an undeniable fact that removing 2.5 MAF of Sacramento River water decreases dilution and assimilative capacity and increases the residence time for constituents to interact with the environment in the Delta. It is an undeniable fact that many constituents in the Delta exceed applicable water quality criteria and numerous other constituents are extremely close to exceeding criteria. It is an undeniable fact that the Delta is part of a tidal estuary where constituents slosh back and forth with incoming and ebbing tides. It is an undeniable fact that the loss of dilution and increase in residence time in a tidal environment will increase the concentration of constituents. It is an uncontestable fact that this will increase degradation and violations of water quality standards. Yet, through sheer sophistry, magical modeling and black-box conclusions, the EIR/EIS blatantly proclaims that there will be no adverse impacts from the maelstrom of toxic pollutants that currently plague the Delta.

In the previous section on limited data sets, we discussed the San Diego County water filtration plant study that showed that occurrence of PPCP increased during periods when the plants received increased water supplies from the Delta. Chapter 8, page 8-57. It noted that,

> *According to the study, occurrence and concentrations of these compounds were highly seasonally dependent, and reached maximums when the flow of the San Joaquin River was low and the quantity of imported water was high. The maximum concentrations of the PPCPs measured in the raw water were correlated with low-flow conditions in the Delta that feed the SWP."*

Droughts are a normal condition in California. According to DWR, there have been 10 multi-year droughts of large-scale extent in the last 100 years, spanning 40 years or 40% of the time. The increase of an average of 2.5 MAF of water diverted under the Delta will, in effect, create more drought conditions experienced in the Delta regardless of actual weather occurring. It will exacerbate the impacts of drought on water quality. As global warming reduces Delta inflow, the project impacts will be substantially greater because of the tunnels.

The EIR/EIS, Chapter 8, page 8-449, lines 19-31, states in addressing nitrate that,

> *"When dilution is necessary in order for the discharge to be in compliance with the Basin Plans (which incorporate the 10 mg/L-N MCL by reference), not all of the assimilative capacity of the receiving water is granted to the discharger. Thus, limited decreases in flows are not anticipated to result in systemic exceedances of*

> *the MCLs by these POTWs. Furthermore, NPDES permits are renewed on a 5-year basis, and thus, if under changes in flows, dilution was no longer sufficient to maintain nitrate below the MCL in the receiving water, the NPDES permit renewal process would address such cases."*

This statement confirms a basic lack of understanding of the NPDES permitting process in the Central Valley by the EIR/EIS. The Central Valley Regional Board has granted dischargers the entire assimilative capacity of a stream on a number of occasions. For example, the September 2006 NPDES Permit for Linda County Water District Wastewater Treatment Plant (NPDES No. CA0079651) granted the full assimilative capacity of the Feather River for EC to Linda County. Further, the Regional Board frequently issues NPDES permits without requiring an antidegradation analysis that would identify how much authorized but presently unused assimilative capacity has been granted and how much assimilative capacity remains for future allocation. Additionally, the Regional Board never requires watershed wide or basin wide antidegradation analyses. Consequently, there are a number of watersheds where more assimilative capacity has been authorized than remains and other waterways where assimilative capacity is presently exceeded but have not yet been placed on the 303(d) list. The suggestion that lack of assimilative would be addressed in subsequent NPDES renewal processes relies on a regulatory requirement that is not followed or enforced in practice.

9. The Assessment of Hardness Dependent Metals is Wrong and Leads to Significant Errors of Analysis.

The EIR/EIS's analysis of the family of hardness dependent metals is technically wrong. The discussion below is focused on copper but the comments are equally applicable to cadmium, lead, silver and zinc. In fact, even with the extremely limited data set, use of the proper methodology reveals that the San Joaquin River at Vernalis has the potential to exceed both the acute and chronic criteria for copper, cadmium, lead, zinc. The Sacramento River has the potential to exceed both the acute and chronic criteria for copper, cadmium and the chronic criteria for lead. Even using average concentrations and the 5th percentile of hardness reveals potential to exceed some criteria. Silver was not sampled in the data sets provided.

Table 8N.1, Appendix 8N, Trace Metals, page 8N-1, Table 1, Concentration of dissolved copper in primary source waters to Delta, shows the maximum dissolved copper concentrations in the Sacramento River (9.5 ug/l), San Joaquin River, (8.0 ug/l) and San Francisco Bay (2.6 ug/l).

Chapter 8, Water Quality, page 8-170, Table 8-58, Water Quality Criteria and Objectives for Trace Metals (µg/L), presents the dissolved water quality standards for copper as 13 ug/l (acute, 1-hour average) and 9 ug/l (chronic, 4-day average).

Chapter 8, page 8-169, lines17-18, states, "*Criteria were calculated based on each source waters average and 5th percentile hardness.*" The toxicity of hardness dependent metals was based on average (58 mg/l) and the 5th percentile hardness (39 mg/l, Sacramento River, appendix 8N6, table 11) rather than the lowest observed hardness (16 mg/l). Hardness dependent metals exhibit greater toxicity at lower hardness. Ambient criteria for acute values are applicable to short periods of time, acute 1-hour average concentrations and chronic 4-day average concentrations.

The Water-Quality Assessment of the Sacramento River Basin, California Water-Quality, Sediment and Tissue Chemistry, and Biological Data, 1995-1998 (Open-File Report 2000- 91) by the United States Geological Survey found the hardness of the Sacramento River at Freeport to be 19 mg/l as CaCO3, on 6 January 1997.[9] The USGS is a reliable source of information and there is no reason not to use the lowest reported hardness of 19 mg/l.

Page F-65 of Central Valley Regional Board Order No. R5-2010-0114-01, NPDES NO. CA0077682, for the Sacramento Regional Wastewater Treatment Plant states: "For the receiving water, the applicable copper chronic criterion is 3.0 μg/L and the applicable acute criterion is 4.0 μg/L, as total recoverable, based on a hardness of 26 mg/L (as CaCO3), using USEPA default translators. The maximum observed upstream total copper concentration was 20.4 μg/L, based on data from 1992-2008."

The rationale in the EIR/EIS for using the average and 5th percentile data points rather than the simple worst-case hardness is not presented. There is certainly no indication that a four-day average would be properly represented by an average of data points collected over a 24 year period. The worst-case conditions and the worst-case potential for toxicity have not been evaluated for hardness dependent metals. As can be seen from the Sacramento Regional NPDES permit, the regulatory agency responsible for water quality in most of the Delta, the Central Valley Regional Water Quality Control Board, assessed the applicable receiving water criteria using the lowest observed hardness of 26 mg/l. The permit was appealed because of its use of an elevated hardness value, among other things.

The procedures described in US EPA's *Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses* indicate that, except possibly where a locally important species is very sensitive, (freshwater or saltwater) aquatic organisms and their uses should not be affected unacceptably if the four-day average concentration of (name of material) does not exceed (the Criterion Continuous Concentration) μg/L more than once every three years on the average and if the one-hour average concentration does not exceed (the Criterion Maximum Concentration) μg/L more than once every three years on the average. The use of an average or 95th percentile hardness would potentially allow the criteria for hardness dependent metals to exceed the water quality criteria each time a hardness higher than the lowest recorded hardness is used to calculate the hardness. This in turn allows for exceedance of the criteria more than once in three years, the level EPA suggests would unacceptably affect aquatic life.

US EPA adopted new copper criteria in 2007 based on the biotic ligand model (BLM) which is a metal bioavailability model based on recent information about the chemical behavior and physiological effects of metals in aquatic environments. The EIR/EIS, page 8-171, explains that:

> "*The BLM criteria account for the aggregate effect of several different water quality parameters on copper toxicity in addition to hardness (e.g., dissolved organic carbon, pH, and various salt concentrations), with the protective*

---

[9] http://ca.water.usgs.gov/sac_nawqa/Publications/ofr_2000-391/data_sw/Freeport/freefld.html

> *criterion being sensitive to DOC concentrations in water. When calculated based on the average of all necessary parameters and the 5th percentile DOC, copper BLM-based criteria were higher (i.e., less sensitive) than the corresponding non WER-adjusted copper criteria presented in Table 8-59. Therefore, the calculated hardness-based CTR copper criteria are found to be adequately protective of fish olfaction.*"

However, the EIR/EIS again uses average and 95th percentile values for the input values into the BLM model resulting in the situation where water quality is not protected during periods when low hardness occurs.

Using a hardness of 25 mg/l results in dissolved copper criteria of 2.7 ug/l (4-day average) and 3.6 ug/l (1-hour average) which is significantly more protective than the 9 ug/l and 13 ug/l, respectively, developed and used in the EIR/EIS. Using the worst-case hardness of 19 mg/l, as measured by the USGS results in even more restrictive criteria than that required by the Central Valley Regional Board. The EIR/EIS's conclusion on page 8-171 that "*the calculated hardness-based CTR copper criteria are found to be adequately protective of fish olfaction"* is simply misleading, wrong, non-protective and technically deficient.

10. The Analysis of Aluminum is Deficient.

Aluminum is identified as a water quality constituent for which a detailed assessment is performed (Table 8-61, p. 8-174), identified as a constituent carried forward in the screening analysis (Table SA-9, p. 8C-37) and subjected to qualitative analysis (Table SA-11, p. 8C-40). However, water quality data for aluminum is not included in the detailed table of constituents measured at boundary stations (Table SA-6, p. 8C-22) and there is no discussion of aluminum in Chapter 8.

The Sacramento River maximum aluminum concentrations are over 8,000 μg/L (Sacramento Regional Wastewater Treatment Plant NPDES Permit, page F-43, Order No. R5-2010-0114-021). The US EPA water quality criteria for the protection of freshwater aquatic life are four-day average (chronic) and one-hour average (acute) for aluminum are 87 ug/*l* and 750 ug/*l*, respectively. The drinking water standard (maximum contaminant level (MCL)), both state and federal, for aluminum is 200 ug/l. The draft EIR/EIS (8-764, Trace Metals) is quite simply wrong in stating that the primary source of aluminum in the Delta is due to wastewater discharges. As is stated above the background concentration of aluminum in the Delta, above the Sacramento Regional WWTP, was almost 92 times higher than EPA's chronic criteria for aluminum and more than ten times above the acute criteria which is necessary to protect aquatic life. This measured concentration of aluminum in the Delta also exceeds the drinking water standard by 40 times.

The failure to address aluminum in the Water Quality section is a serious omission causing the EIR/EIS to be incomplete and not in compliance with CEQA and/or NEPA.

11. Impacts on Existing Mixing Zones are Ignored.

The Central Valley Regional Water Quality Control Board has issued numerous NPDES permits that allow for mixing zones for numerous constituents in ambient waters. Mixing zones are controversial and only allowed following detailed analysis and modeling that defines the specific dimensions of a zone of initial dilution. Mixing zones are especially difficult in tidal areas as incoming and outgoing tides cause constituents to slosh back and forth: this tidal-action essentially re-doses the area. There must always be a zone of passage, because a mixing zone cannot legally prevent passage of aquatic life. The EIR/EIS does not identify, discuss or provide maps of existing mixing zones in the Delta.

Altering the flow regime in a waterbody would impact the hydraulic and perhaps the constituent assimilative capacity available for mixing zones. Failure to reevaluate and modify mixing zones within the Delta could have significant adverse impacts to the beneficial uses of receiving waters. Mixing zones were also issued based in part on the economic impact to wastewater dischargers to fully treat their wastestream to meet end-of-pipe limitations. The impacts of Alternative 4 to mixing zones, beneficial uses, the associated economics and a requirement for reissuing NPDES permits that contain mixing zones should be evaluated and discussed.

12. Additive and Synergistic Impacts are Not Considered.

The EIR/EIS identifies the Delta as being listed as impaired by numerous pollutants including unknown toxicity. It is reasonable to assume that additive or synergistic effects of the many listed constituents could be contributing to toxicity within the Delta. It is more than reasonable to believe that a massive hydrologic project that proposes to deprive an estuary of more than 2.5 MAF of freshwater, thereby altering the existing flow regime, increasing residence time and affecting the fate and transport of pollutants in a highly degraded Delta, will likely have an impact on additive and synergistic toxicological interactions. However, in reviewing the EIR/EIS, we could only find one sentence mentioning additive or synergistic effects in the 791 pages of Chapter 8, Water Quality, no mention in Appendix 8C, Screening Analysis and only one passing sentence in the 3,055 pages of Chapter 11, Fish and Aquatic Resources, Parts 1 & 2.

If two or more constituents are present together in water, they may exert a combined effect to aquatic life, which can be additive, antagonistic or synergistic. For example: zinc and cadmium are additive in toxicity; copper is more than additive with chlorine, zinc, cadmium and mercury, while it decreases the toxicity of cyanide. The toxicity to mayflies of phenol and ammonia at low concentrations is additive, but at higher concentrations is more than additive. Organophosphate pesticide mixtures frequently exhibit additive or synergistic effects, as do pyrethroid and organophosphate mixtures. Temperature, pH, hardness, salinity and dissolved oxygen levels can exacerbate toxic effects. Acute toxicity to aquatic life can occur even when none of the individual constituents in a mixture exceed a water quality standard. Loss of dilution or increases in residence time enhances toxicity. As many as fifteen different pesticides have been identified in a single sample of Delta waters.

US EPA and the Environmental Research Laboratory published a study of acute and chronic toxicity tests that were conducted to determine the effects of metals combined as mixtures at proposed water quality criteria concentrations and at multiples of the LC50 and obtained from tests on six metals with three aquatic species. Arsenic, cadmium, chromium, copper, mercury and lead caused nearly 100% mortality in rainbow trout and daphnids (*C dubia*) during acute exposure. These results point out the need for additional studies to determine the type and degree of interaction of toxicants because single chemical water quality criteria may not sufficiently protect some species when other toxicants are present concurrently. (http://nepis.epa.gov/Exe/ZyPURL.cgi?Dockey=91005B2N.txt)

The Central Valley Basin Plan,[10] *Implementation, Policy for Application of Water Quality Objectives* requires that:

> *"Where multiple toxic pollutants exist together in water, the potential for toxicologic interactions exists. On a case by case basis, the Regional Water Board will evaluate available receiving water and effluent data to determine whether there is a reasonable potential for interactive toxicity. Pollutants which are carcinogens or which manifest their toxic effects on the same organ systems or through similar mechanisms will generally be considered to have potentially additive toxicity."* Implementation, page IV-17.00-18.00.

The section provides the specific methodology to be followed to determine additive toxicity.

The EIR/EIS is grievously deficient in failing to acknowledge or adequately address how the project's hydrological modifications and resulting changes in flow, residence time, dilution and the fate, transport and mixing of pollutants will affect aquatic species.

13. Analysis of Potential Impacts Related to pH is Deficient.

Appendix 8C, Section 8C.1.5.7, pH, Page 8C-19, states, in part, the following with regard to pH:

> "*Because pH is a fundamental property of water, it affects the chemistry of numerous other constituents within the water, and thus, in addition to having potential direct effects on beneficial uses (such as municipal and domestic water supply and aquatic organisms), can also affect beneficial uses indirectly by altering the chemistry and toxicity of other constituents in the water.*
>
> *Within the affected environment, pH is typically between 6.5 and 8.5. The pH within the affected environment is controlled primarily by natural factors, such as alkalinity from natural weathering of minerals and carbon dioxide concentrations controlled by algae and bacterial respiration. Figure 8C- 1 shows exceedance probabilities of historical pH data from 1975 to 2009 in the Sacramento River at Freeport/Greene's Landing, the San Joaquin River at Vernalis, and San Francisco Bay at Martinez. The data indicate that the Sacramento River and San*

---

[10] http://www.waterboards.ca.gov/centralvalley/water_issues/basin_plans/index.shtml

> *Francisco Bay are within the Basin Plan objective range of 6.5 to 8.5 >95% of the time, while the San Joaquin River is between the limits >90% of the time. As water moves from these locations to areas within the Delta, pH changes as a result of natural factors, and therefore the pH at any given location within the Delta may have no correlation to the source waters that contribute water to that location. Given this, and given that the alternatives do not include components that would directly depress or elevate pH, it is not expected that pH would change substantially upstream of the Delta, within the Delta, or in the SWP and CVP Service Area under the alternatives, relative to Existing Conditions and (for Alternatives 1A–9) the No Action Alternative. Any negligible changes in pH that may occur in the water bodies of the affected environment would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regards to pH.*"

The quote graphically illustrates the inadequacies of the EIR/EIS's method of assessing pH. It only considers pH loading from tributary rivers to the exclusion of in Delta inputs. Review of the annual monitoring reports from the San Joaquin County and Delta Irrigated Lands Coalition reveals numerous exceedances of pH criteria, as do the annual reports submitted pursuant to the General Industrial and Construction Stormwater Permit program. There are many other sources including illegal dumping (the Delta is a favorite place to dump old batteries) and spills from bulk loading of petroleum coke, sulfur and other fertilizers at the Port of Stockton. The EIR/EIS fails to address how hydrologic modification and increased residence time in Delta channels affects pH impacts on water quality.

For drinking water, pH levels are important due to corrosive effects and adverse impacts to water treatment processes. For aquatic life, the pH range from 6.5 to 9 is considered nontoxic, however the toxicity of many constituents can be affected by changes in pH. Where pH levels are outside the 6.5 to 9.0 range, fish suffer adverse physiological effects increasing in severity until lethal levels are reached. The degree of dissociation of weak acids or bases is affected by changes in pH, which is important since the toxicity of several compounds is affected by the degree of dissociation. US EPA criteria recommend that rapid pH fluctuations should be avoided. The Central Valley Basin Plan water quality objective for pH limits shifts to no more than 0.5 pH units outside the 6.5 to 8.5 range.

The final page of Appendix 8C is Figure 8C-1, Probability of Exceedance for pH for Sacramento River at Freeport/Greene's Landing, San Joaquin River at Vernalis, and San Francisco Bay at Martinez for 1975-2009, shows that the Sacramento River and San Francisco Bay are below the 6.5 objective approximately 5% of the time and the San Joaquin River is below the pH objective almost 10% of the time. The EIR/EIS speaks as if this is a good record of compliance. It is not when one considers the potentially toxic impacts to aquatic life. US EPA Water Quality Criteria procedures are described in *Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses* and indicate that, except possibly where a locally important species is very sensitive, (freshwater or saltwater) aquatic organisms and their uses should not be affected unacceptably if the four-day average concentration of (name of material) does not exceed (the Criterion Continuous Concentration) µg/L more than once every three years on the average and if the one-hour average concentration does not exceed (the Criterion Maximum Concentration) µg/L more than once every three years on the average. While pH is not measured as a concentration, surely exceeding the objective 5 or 10% of the time is not an acceptable compliance record when other potentially toxic constituents are present.

The EIR/EIS states that “natural factors” will alter pH levels and any changes in pH would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies. However, there is no information in the EIR/EIS supporting this claim. To the contrary, any exceedance of a water quality objective should be considered serious. As water is withdrawn from the Delta, water from the San Joaquin River would have a proportionally greater impact on the Delta waters under all scenarios of Alternative 4. This could lead to an increase in overall pH violations of the water quality objective for pH. The EIR/EIS fails to discuss pH shifts, which have the potential to increase toxicity and violate the Basin Plan objective for pH.

14. The Assessment of Pesticides Fails to Meet Minimal Requirements for a Disclosure Document.

The impacts of CM1 on pesticides is addressed at: Pesticides (Impact WQ-21: Effects on Pesticide Concentrations Resulting from Facilities Operations and Maintenance (CM1), pp. 8-463 – 8-467. The assessment of pesticide impacts is a largely qualitative analysis based upon best professional judgment. We could find no discussion of the analysis that would justify the subjective conclusion that, “These modeled changes in source water fractions are not of sufficient magnitude to substantially alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses of the Delta.” (P. 8-465, lines 30-33)

BDCP Appendix 8D, Source Water Fingerprinting Results, reveals that the distribution and mixing of Delta source water would significantly change. Modeling shows that for Alternative 4 H4, relative to the Existing Conditions Alternative, the source water fraction of San Joaquin River water at Rock Slough would increase 15-22% during September through March (11-15% during drought periods). At Contra Costa PP No. 1, the fraction would increase 15-23% during September through March (11-15% during October and November of droughts). At Franks Tract, the San Joaquin fraction would increase 11-16% during October through April and February through June. At Buckley Cove, the fraction would increase 11% in July and 16% in August during droughts. The other scenarios resulted in different fractions, as did comparisons with the No Action Alternative. For example, relative to the No Acton Alternative, the fraction of San Joaquin water at Buckley Cove would increase 16-17% in July (31-34% in drought conditions) and 24-25% in August (47-49% during droughts). Delta agricultural fractions are also projected to increase up to 8%, depending on location.

Not only will the San Joaquin River comprise a greater percentage of volume in eastern and southern Delta channels but the increase in residence time ensures that the suite of pesticides and other pollutants flowing down the river will have a longer period in which to mix with local municipal, industrial and agricultural inputs of pesticides and other pollutants and to interact with the environment.

We could find no credible discussion of the suite of pesticides present in these waters. It appears that limited data sets were used that ignored much of the pesticide monitoring data that has been acquired in recent years, especially monitoring by municipalities and agricultural coalitions. We could find no credible discussion regarding the potential effects of increased residence time on pesticide concentration and potential for bioaccumulative effects in the Delta. Despite the San Joaquin River and Delta being listed as impaired by various pesticides and unknown toxicity, we could find no discussion of the concentration, frequency and synergistic and additive effects of the universe of pesticides found in local waters.

For example, diazinon and chlorpyrifos are additive in toxicity, as are diazinon and esfenvalerate. Carbamate and organophosphate insecticides interact synergistically. There is an expansive literature on the toxicity and sublethal effects of pesticide mixtures.

Addressing pesticides, the Delta Independent Science Board in their Review of the Draft BDCP EIR/EIS and Draft BDCP (15 May 2014) observed,

> "Despite the acknowledged difficulty in predicting water quality impacts of the project, caused by lack of observational field data, as far as we could see there was no call for enhanced monitoring of pesticides in the Delta. As stated above, reliance on model outputs without their validation by comparison to observational data is a flawed approach, especially for assessing the effects of water quality constituents with high levels of uncertainty surrounding them, such as pesticides. In the section on pesticides, it was also remarkable that there was no mention of recent investigations showing very significant synergism between carbamate and organophosphate insecticides." Page B-24.

Apparently, source waters plus local inputs plus increased residence time plus additive/synergistic effects were not modeled or assessed. CM13 herbicide application was found to have significant and unavoidable impacts but we could not find a discussion where the impacts of CM13 were integrated into consideration of potential impacts of CM1. There is no antidegradation analysis that quantifies the degree of degradation, even if degradation fails to exceed a water quality standard. How much degradation or how many toxic events must occur in order to meet a "sufficient magnitude" threshold?

15. The Evaluation of Salinity and Electrical Conductivity is Deficient.

The SWRCB's 2010 Integrated Report, Clean Water Act Section 303(d) List/305(b) Report identifies vast areas of the Delta as impaired and incapable of supporting identified beneficial uses because of electrical conductivity (EC). The EIR/EIS states:

> "*The Region 5 Basin Plan specifies EC objectives for the Sacramento River, Feather River, and San Joaquin River; it also contains EC objectives for the Delta, which have been superseded by the 2006 Bay-Delta WQCP… impairment by elevated EC levels, as follows: (a) southern, northwestern, and western channels in the Delta; (b) Delta export area; (c) Grasslands drainage area, Mud Slough, and Salt Slough in the San Joaquin River valley; (d) San Joaquin River*

> *from Bear Creek to Delta boundary; and (e) Suisun Marsh (State Water Resources Control Board 2011).*" (P. 8-55)

The EIR/EIS acknowledges that:

> *"In the Plan Area, Alternative 4, Scenarios H1-H4, would result in an increase in the frequency with which Bay-Delta WQCP EC objectives are exceeded for the entire period modeled (1976–1991): in the Sacramento River at Emmaton (agricultural objective; 17–19% increase) in the western Delta, and in the San Joaquin River at San Andreas Landing (agricultural objective; 2–3% increase) and Prisoners Point (fish and wildlife objective; 14–25% increase), both in the interior Delta; and in Old River near Middle River and at Tracy Bridge (agricultural objectives; up to 2% increase), both in the southern Delta. Average EC levels at Emmaton would increase by <1–14% for the entire period modeled and 8–13% during the drought period modeled. Average EC levels at San Andreas Landing would increase by 0–9% during for the entire period modeled and 7–13% during the drought period modeled."* (P. 8-440)

Consequently, operation of CM1 results in a significant adverse impact (P. 8-440). Since, the effectiveness of mitigation measures is uncertain, the impacts are termed significant and unavoidable.

With respect to the potential impacts on EC from implementation of CM2-22, the EIR/EIS acknowledges the CM4 would increase the magnitude of daily tidal water exchange and alter other hydrodynamic conditions in adjacent Delta channels. However, the DSM2 modeling included "assumptions regarding possible locations of tidal habitat restoration areas, and how restoration would affect Delta hydrodynamic conditions and thus the effects of this restoration measure on Delta EC were included in the assessment of CM1 facilities operations and maintenance." (P. 8-442, lines 27-30) Consequently, implementation "would not be expected to adversely affect EC levels in the affected environment" and the effects are determined, "to not be adverse." (P. 8-442, lines 31-34) Please explain how CM4 could be evaluated with CM1, which was found to have significant and unavoidable impacts, but that CM4 will not be expected to have adverse effects, especially, as CM4 is only evaluated at a programmatic level. The CEQA conclusion of no adverse impacts is equally baffling. It assumes that the substitution of agricultural lands with habitat will offset any increased tidal effects and, consequently, there will be no adverse impacts and no mitigation is required. (P. 8-442, lines 35-43; P. 8-443, lines 1-2) Since the specific extent and location of habitat has not been determined, on what basis and methodology does the EIR/EIS conclude that CM2-CM22 would not cause significant impacts and that no mitigation will be required?

The EIR/EIS Section 8.2.3.7 Salinity and Electrical Conductivity, beginning on page 8-52 states:

> "*Concern about salinity involves three main issues: drinking water, crop irrigation, and biota/habitat… In addition, industrial processes that require low-salinity water can be negatively affected. Salt removal during the water purification process (for either drinking or process water) is presently very expensive.*"

> "*When salinity concentrations in irrigation water are too high, yields for salt-sensitive crops may be reduced.*" (Page 8-53)
>
> "*Incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, Environmental Commitments, a separate, non-environmental commitment to address the potential increased water treatment costs that could result from EC concentration effects on municipal, industrial and agricultural water purveyor operations.*"

Agricultural crop yields reductions will occur as salinity in the irrigation water increases, not just for salt sensitive crops but also for more tolerant plant species. (Irrigation with Reclaimed Municipal Wastewater, a Guidance Manual, SWRCB Report No. 84-1 wr, Chapter 3 and Table 3-1) The anticipated reduction in crop yield as EC levels increase is not presented. A methodology for determining crop yield reductions is not presented. The proposed commitment to address "increased water treatment costs" does not address crop yield reductions and the associated lower profits earned since it is unlikely that irrigation water would be treated. In any case, the project does not fully protect the identified beneficial use of irrigated agriculture.

Industrial uses of water can be the most limiting water quality objectives for salinity as shown in Water Quality Criteria (McKee and Wolf, SWRCB 1963) Chapter 5. It is currently not uncommon for industries to use reverse osmosis (RO) system to remove salts prior to use in cooling towers and boiler systems. The EIR/EIS should document how many systems are in place for industrial uses to account for elevated salt levels within the use area. How many additional salt treatment and removal systems will need to be installed to account for the increased EC levels projected by the project? The existing and future costs associated with the EIR/EIS alternatives have not been accounted for. In any case, the project fails to full protect the identified beneficial use of municipal and industrial supply.

The Delta currently exceeds the water quality standard for EC and Alternative 4 will exacerbate this situation. The EIR/EIS essentially states that we will "look at it later" and attempt to mitigate by reimbursing for losses. There is no assessment of the current crop yield losses or those expected to occur due to implementation of the various options. There is no assessment of the current and anticipated impacts to industry or other from increased salinity and modified hydrology. There is no quantification of the actual costs to agriculture, industry, local communities or individuals that may occur due to increasing salinity levels. Mitigation must be feasible: have funds been committed to repay those who experience losses? It's easy to say there will be a commitment to offset the costs when those costs have not been assessed and a mechanism for injured parties to file claims to recover those costs has not been developed. However, this should be analyzed as a part of the EIR/EIS.

The EIR/EIS makes several conclusory, unsupported statements concerning increased EC loading in the future, including:

> *There could be increased discharges of EC-elevating parameters in the future in water bodies upstream of the Delta as a result of urban growth and increased runoff and wastewater discharges. The state has begun to aggressively regulate*

> *point-source discharge effects on Delta salinity-elevating parameters, capping dischargers at existing levels, and is expected to further regulate EC and related parameters upstream of and within the Delta in the future as salt management plans are developed. Based on these considerations, EC levels (highs, lows, typical conditions) in the Sacramento River and its tributaries, the eastside tributaries, or their associated reservoirs upstream of the Delta would not be expected to be outside the ranges occurring under Existing Conditions or the No Action Alternative.* (8-436, lines 9-17)
>
> *However, with the implementation of the adopted TMDL for the San Joaquin River at Vernalis and the ongoing development of the TMDL for the San Joaquin River upstream of Vernalis and its implementation, it is expected that long-term EC levels will improve. Based on these considerations, substantial changes in EC levels in the San Joaquin River relative to Existing Conditions or the No Action Alternative would not be expected of sufficient magnitude and geographic extent that would result in adverse effects on any beneficial uses, or substantially degrade the quality of these water bodies, with regard to EC.* (8-436, lines 29-35)

CSPA routinely reviews municipal and industrial NPDES permits and has filed numerous appeals with the SWRCB over the Regional Board's failure to comply with CWA regulations regarding EC loading. Several of the Regional Board-issued permits have been or are in litigation. CSPA recently submitted comments on the renewal of Waste Discharge Requirements (WDRs) for the Grasslands Bypass Project. We were involved in the development of TMDLs and have unsuccessfully sought to persuade the Regional Board to comply with SWRCB direction to move the salinity compliance point upstream from Vernalis. We authored the legislation that sunset the original agricultural waiver of Waste Discharge Requirements (WDRs), were deeply involved in the development of the replacement conditional waivers and litigated each one of them. We currently have appeals pending before the SWRCB of the recently adopted agricultural WDRs for the Eastside and Westside San Joaquin Valley, San Joaquin County/Delta and the Sacramento Valley. CSPA maintains a rotating docket of 30-35 enforcement cases against industrial violators of the General Industrial Stormwater Permit. We have no evidence and do not believe there is any documented, quantifiable evidence that the mass loading of EC has stabilized, been reduced or that there is significant likelihood of reductions in the near future. If the authors of EIR/EIS believe otherwise, they should provide the documented quantifiable evidence. If not, they should eliminate or modify the unsupported conclusions referenced above.

The SWRCB has refused to enforce water quality standards it adopted in 1995 and incorporated into water rights permits in 2000. For example, between April of 2007 and December 2013, there were 868 documented days of noncompliance with the D-1641 EC standards at the Old River near Tracy Boulevard Bridge compliance point. In 2013 EC standards at Emmaton were ignored, as the SWRCB informed DWR and USBR that it would not seek enforcement. This year, the SWRCB simply waived existing standards. Based on past enforcement history, there is no reasonable basis to assume that EC standards will be enforced in the future. Consequently, the EIR/EIS conclusions that salinity levels are likely to be consistent with levels projected in the EIR/EIS are in error. If the authors of the EIR/EIS have reason to believe that future enforcement or compliance will be substantially different that it has been in the past, please provide it.

As previously noted, the EIR/EIS completely ignores the federally promulgated salinity standards at 40 CFR 131.37. Those standards include estuarine habitat criteria for salinity at Chipps Island, Roe Island and Suisun Marsh plus a criteria of 0.44 micro-mhos between 1 April and 31 May for striped bass and splittail spawning and migration on the San Joaquin River at Jersey Point, San Andreas Landing, Prisoners Point, Buckley Cove, Rough and Ready Island, Brandt Bridge, Mossdale and Vernalis when the San Joaquin Index is greater than 2.5 MAF and at Jersey Point, San Andreas landing and Prisoners Point when the San Joaquin Index is less than 205 MAF. The EIR/EIS must discuss, analyze and address the project's impacts and compliance with currently applicable USEPA federally promulgated criteria for the Delta.

Chapter 8 (Water Quality) and Chapter 11 (Fish and Aquatic Resources, Parts 1 & 2) largely ignore the water quality and habitat needs of striped bass and splittail in the eastern Delta and lower San Joaquin River. The studies US EPA relied upon in establishing salinity criteria protective of the migration and spawning beneficial uses of striped bass and splittail are still applicable.[11]

Neither, Chapter 8 (Water Quality) and Chapter 11 (Fish and Aquatic Resources, Parts 1 & 2) adequately surveys, analyzes or discusses the impacts of EC and other contaminants, or the impacts of modified hydrology and increased residence time on freshwater invertebrates (especially their egg and sensitive stages) in the eastern and southern Delta and lower San Joaquin River. Zooplankton is a critical source of food to numerous fish species. Different zooplankton species tend to inhabit freshwater, low salinity zones or high salinity zones. Native Copepod and Mysid species have plummeted. The same applies to the phytoplankton community.

With respect to native aquatic and adjacent riparian plant species, the EIR/EIS acknowledges that field surveys were limited by continuing legal challenges to efforts to obtain entry permits. In reviewing Chapter 8, we could find little discussion or analysis on the potential salinity and other water quality impacts to aquatic and riparian plants, with the exception of assessments on the effects of CM2-22 herbicide and pesticide use. The problem here is not an inadequate analysis

---

[11] Turner, J.L., Striped Bass Spawning in the Sacramento and San Joaquin Rivers in Central California from 1963 to 1972. Calif. Fish and Game, 62(2):106-118, 1972: Turner, J.L. and Harold K Chadwick, Distribution and Abundance of Young-of-the-Year Striped Bass, Morone saxatilis, in Relation to River Flow in the Sacramento-San Joaquin Estuary. Anadromous Fisheries Branch, CDFG, 1972: Fraley, T.C., Striped bass, Roccus Saxatilis, Spawning in the Sacramento-San Joaquin Rivers During 1963 and 1964, 1966: Radtke, L.D. and Jerry L. Turner, High Concentrations of Total Dissolved Solids Block Spawning Migration of Striped Bass, Roccus saxatilis, in the San Joaquin River, California. Transactions of the American Fisheries Society. 96:4, 405-407, 1967: Radtke, L.D., Distribution of Adult and Subadult Striped Bass, Roccus Saxatilis, in the Sacramento-San Joaquin Delta, 1966: Turner J.L and Timothy C. Farley, Effects of Temperature, Salinity, and Dissolved Oxygen on the Survival of Striped Bass Eggs and Larvae. Calif. Fish and Game 57(4):268-273. 1971: See also, SWRCB, Draft Water Quality Control Plan for Salinity, San Francisco Bay/Sacramento-San Joaquin Delta Estuary, 1988 and SWRCB, Water Quality Control Plan for Salinity, San Francisco Bay/Sacramento-San Joaquin Delta Estuary, 1991.

of the impacts of salinity and other contaminants to riparian and channel vegetation communities in the South Delta or San Joaquin River, but that there is virtually no analysis.

The Delta was historically dominated by freshwater and the estuary was where the mixing of fresh and salt waters occurred. There are several natural divisions within the Delta and lower San Joaquin River system. Historically, the Southern and Eastern Delta was dominated by freshwater conditions and once supported myriad native freshwater species. A few of these species include common tules (*Scirpus acutus, S. californicus*), cattails (*Typha spp.)*, common reed (*Phragmites communis*), swamp knotweed (*Polygonum coccineum*), marsh bindweed (*Calystegia sepium*), bur-reed (*Sparganium eurycarpum*), cinquefoil (*Potentilla anserina*), twinberry (*Lonicera involucrata*), dogwood (*Cornus stolonifera*), buttonwillow (*Cephalanthus occidentale*), and willows (*Salix lasiolepis, S. lucida*). This wetland community was once very common and remnants of these communities still can be found on numerous channel islands and along the waterside of levees. Others grow in the water itself. A number of these species, like twinberry (*Lonicera involucrate*), are extremely sensitive to salt. The EIR/EIS must examine potential impacts of increased salinity levels and residence time to native aquatic and riparian plants.

16. The Discussion of the Narrative Toxicity Objective and the Potential for Emerging or Legacy Pollutants to Violate Criteria and Beneficial Uses is Inadequate.

The EIR/EIS Table 8.5, Receptors Affected by Water Quality-Characterized by the Designated Beneficial Uses of the Study Area (p.8-29) identifies emerging pollutants (ECs/PPCPs) as having the potential to affect water quality. The Central Valley Regional Board Basin Plan contains a narrative toxicity objective that prohibits: ***"**Toxic substances to be present, individually or in combination, in concentrations that produce detrimental physiological responses in human, plant, animal, or aquatic life."*

Constituents of Emerging Concern (CECs) clearly have potential to violate the Basin Plan's narrative toxicity objective. There is an extensive and rapidly expanding body of scientific literature discussing emerging pollutants.

> The increasing production and use of pharmaceuticals and personal care products (PPCPs) – some of which may be endocrine disrupting compounds (EDCs) – have led to a growing concern about the occurrence of these compounds in the environment. Recent studies have reported the occurrence worldwide of EDCs, PPCPs, and other organic wastewater contaminants (OWCs) – collectively referred to as "constituents of emerging concern" (CECs) or "emerging constituents" (ECs) – in wastewater treatment plant (WWTP) effluents, surface waters used as drinking water supplies, and in some cases, finished drinking waters. Of the 126 samples analyzed for the project, one sample (American River at Fairbairn drinking water treatment plant [DWTP] intake collected in April 2008) had no detectable levels of any EDCs, PPCPs, or OWCs. All other samples had one or more analytes detected at or above the corresponding MRLs. The five most frequently detected PPCPs were caffeine, carbamazepine, primidone, sulfamethoxazole, and tri(2-chloroethyl) phosphate (TCEP). At the sample sites upstream of WWTP discharges in all three watersheds, the concentrations of selected PPCPs, except for

caffeine, were low (i.e., ≤ 13 ng/L), pointing to WWTP discharges as the main source of most PPCPs and OWCs in the environment. (Source, Fate, and Transport of Endocrine disruptors, Pharmaceuticals, and Personal Care Products in Drinking Water Sources in California, National Water Research Institute Fountain Valley, California, May 2010)

Over the last 10 years, reports of feminized wildlife have fueled chilling headlines. Most of these reports have focused on the many ways that estrogen in sewage effluent can distort normal male development. Now a new study reveals one way that the hormone pollutant can affect females: Too much estrogen causes subtle changes in female fish's courting behavior, which could alter a population's genetic makeup (Environ. Sci. Technol., DOI: 10.1021/es101185b).

Increase in intersex fish downstream from WWTP possibly associated with endocrine-active contaminants. (Boulder Colorado, Colorado University, 2008)

Skewed sex ratio downstream from WWTP possibly associated with endocrine-active contaminants. (Boulder Colorado, Colorado University, 2006)

Fluoxetine (FLX), Sertraline (SER) and their degradants NFLX, and NSER were the primary antidepressants in brain tissue samples. Little or no venlafaxine (VEN), the dominant antidepressant in both water and bed sediment, was present. Degradates were measured at higher concentrations in brain samples than parent compounds. (Boulder Creek, Colorado & Fourmile Creek, Iowa, the College of Wooster, 2010)

SAR sites (with WWTP or urban runoff influent) males had significantly lower Testosterone (T) than the reference site males. Males from SAR sites had significantly higher17β-estradiol (E2) than reference site. Females from SAR sites had significantly lower E2 than the reference site females. (USGS, Santa Ana River (SAR) SAR sites, 2009)

“Several recent studies have documented endocrine disruption in Delta fish. One of the biomarkers of EDCs is intersex fish, fish with both male and female reproductive organs. A recent histopathological evaluation of delta smelt for the Pelagic Organism Decline found 9 of 144 maturing delta smelt (6%) collected in the fall were intersex males. This study provides evidence that delta smelt are being exposed to EDCs. Brander and Cherr (2008) observed choriogenin induction in male silversides from Suisun Marsh. Riordan and Adam (2008) reported endocrine disruption in male fathead minnows following in-situ exposures below the Sacramento Regional Treatment Plant. Lavado, et al. (in press) conducted studies in 2006 and 2007 to evaluate the occurrence and potential sources of EDCs in Central Valley waterways. In their study, estrogenic activity was repeatedly observed at 6 of 16 locations in the Bay-Delta watershed, including in water from the Lower Napa River and Lower Sacramento River in the Delta. Further studies are needed to identify the compounds responsible for the observed estrogenic activity and their sources.” (Alameda County Water District, Alameda County Flood Control and Water Conservation District, Zone 7, Metropolitan Water District of Southern California, San Luis

& Delta-Mendota Water Authority, Santa Clara Valley Water District, State Water Contractors, June 1, 2010)

A 2008 study of the maternal transfer of xenobiotics and effects on larval fish in the estuary documented that offspring of fish caught in the Delta had undeveloped brains, inadequate energy supplies and dysfunctional livers. An array of compounds known to cause myriad problems in both young and adult fish, including skeletal and organ deformities and dysfunction; changes in hormone function and behavior were identified in fish tissue. A two-year DWR funded study of sublethal factors that might be contributing to the decline of pelagic fish in the Bay-Delta assessed the health status of larval, juvenile and adult female striped bass collected in the Delta using morphometric, histopathological, otolith and biochemical metrics. It concluded that a wide-array of contaminants were significant stressors on the vast majority of juvenile striped bass causing severe physiological stress, morbidity and likely compromised immune systems. Findings of abnormal disease and parasitism were found in juvenile fish in all years studied and were considered to have a significant impact on the health of the fish and the population. In addition, the data suggested that adult striped bass are also likely adverse affected by the bioaccumulation of contaminants, such as PBDE’s, and that such contaminant effects need to be considered a significant stressor that is affecting the decline of striped bass and are likely causing population level effects in early life stages. Both studies can be found accessed at https://sites.google.com/site/drdavidostrach/about-david-ostrach.

A recent study by the Toxic Substances Hydrology Program of the U.S. Geological Survey (USGS) shows that a broad range of chemicals found in residential, industrial, and agricultural wastewaters commonly occurs in mixtures at low concentrations downstream from areas of intense urbanization and animal production. The chemicals include human and veterinary drugs (including antibiotics), natural and synthetic hormones, detergent metabolites, plasticizers, insecticides, and fire retardants. One or more of these chemicals were found in 80 percent of the streams sampled. Half of the streams contained 7 or more of these chemicals, and about one-third of the streams contained 10 or more of these chemicals. This study is the first national-scale examination of these organic wastewater contaminants in streams and supports the USGS mission to assess the quantity and quality of the Nation's water resources. A more complete analysis of these and other emerging water-quality issues is ongoing. Knowledge of the potential human and environmental health effects of these 95 chemicals is highly varied; drinking-water standards or other human or ecological health criteria have been established for 14. Measured concentrations rarely exceeded any of the standards or criteria. Thirty-three are known or suspected to be hormonally active; 46 are pharmaceutically active. Little is known about the potential health effects to humans or aquatic organisms exposed to the low levels of most of these chemicals or the mixtures commonly found in this study. ("Pharmaceuticals, hormones, and other organic wastewater contaminants in U.S. streams, 1999-2000: A national reconnaissance," an article published in the March 15, 2002 issue of Environmental Science & Technology, v. 36, no. 6, pages 1202-1211. Data are presented in a companion USGS report, "Water-quality data for pharmaceuticals, hormones, and other organic wastewater contaminants

> in U.S. streams, 1999-2000" (USGS Open-File Report 02-94). These and other reports, data, and maps can be accessed on the Internet at http://toxics.usgs.gov.)
>
> PPCPs are found where people or animals are treated with drugs and people use personal care products. PPCPs are found in any water body influenced by raw or treated sewage, including rivers, streams, ground water, coastal marine environments, and many drinking water sources. PPCPs have been identified in most places sampled. The U.S. Geological Survey (USGS) implemented a national reconnaissance to provide baseline information on the environmental occurrence of PPCPs in water resources. You can find more information about this project from the USGS's What's in Our Wastewaters and Where Does it Go? (http://toxics.usgs.gov/highlights/whatsin.html). PPCPs in the environment are frequently found in aquatic environments because PPCPs dissolve easily and don't evaporate at normal temperature and pressures. Practices such as the use of sewage sludge ("biosolids") and reclaimed water for irrigation brings PPCPs into contact with the soil. (http://www.epa.gov/ppcp/faq.html#iftherearei ndeed)

From the recent scientific investigations and literature, it is reasonable to conclude that CECs are present in the Delta at levels that cause toxicity in violation of the narrative toxicity objective. It is also reasonable to conclude that wastewater discharges into the Delta contain CECs in concentrations that at a minimum threaten to violate the Receiving Water Limitation for toxicity, which prohibits toxic substances to be present in concentrations that produce detrimental physiological responses in human or aquatic life.

US EPA has compiled a database; *Treating Contaminants of Emerging Concern A Literature Review Database* (August 2010). Local wastewater treatment system design engineers have also been testing treatment system capabilities for removing CECs. There appear to be treatment technologies that are capable of removing significant levels of CECs.

With respect to CEC’s, the Delta Independent Science Board in their Review of the Draft BDCP EIR/EIS and Draft BDCP (15 May 2014) observed,

> *“Very optimistic descriptions of CECs and their removal from wastewater by WWTPs are given, but no acknowledgment is made of many other CECs that are shown to be highly recalcitrant to such removals. Such demonstrations of unfamiliarity with the subjects covered do not engender confidence in the analysis.”* Page B-22.

With respect to pollutants that bioaccumulate, the Delta Independent Science Board observed,

> *“Also, in regard to bioaccumulation, mercury and selenium appear to be the only constituents that were evaluated for their bioaccumulative properties. A range of organic contaminants (e.g., PAHs, dioxins, some endocrine disrupting compounds) also bioaccumulate, but this was not acknowledged or addressed in the DEIR/DEIS document.”* Page B-24.

The EIR/EIS does not sufficiently assess the current state of water quality within the Delta or compliance with the narrative toxicity objective. The Delta is 303d listed as impaired for unknown toxicity. CECs, legacy and bioaccumulating pollutants present more than a reasonable potential to be causing and/or contributing to this toxicity.

17. There is no Defensible Antidegradation Analysis.

There is a fundamental flaw in the EIR/EIS in the analysis regarding Water Quality. Individual constituents were analyzed and discussed based on the potential for exceedance of federal water quality criteria or state water quality objectives or if the constituent was on the state's Clean Water Act Section 303(d) list. A cornerstone of the State Water Board and Regional Water Board's regulatory authority is the Antidegradation Policy (Resolution 68-16), which is included in the Basin Plans as an appendix. However, the EIR/EIS fails to discuss or analyze constituents which will "degrade" water quality unless they pose a threat to exceed a water quality standard.

Section 101(a) of the Clean Water Act (CWA), the basis for the antidegradation policy, states that the objective of the Act is to "restore and maintain the chemical, biological and physical integrity of the nation's waters." Section 303(d)(4) of the CWA carries this further, referring explicitly to the need for states to satisfy the antidegradation regulations at 40 CFR § 131.12 before taking action to lower water quality. These regulations (40 CFR § 131.12(a)) describe the federal antidegradation policy and dictate that states must adopt both a policy at least as stringent as the federal policy as well as implementing procedures.

The CWA requires the **full** protection of identified beneficial uses. The Federal Antidegradation Policy, as required in 40 CFR 131.12 states, "The antidegradation policy and implementation methods shall, at a minimum, be consistent with the following: (1) Existing instream water uses and the level of water quality necessary to protect the existing uses shall be maintained and protected." EPA Region 9's guidance on implementing antidegradation policy states, "All actions that could lower water quality in Tier II waters require a determination that existing uses will be fully maintained and protected." (EPA, Region 9, Guidance on Implementing the Antidegradation Provisions of 40 CFR 131.12, page 7) The Delta is classified as a Tier II, "high quality," waterbody by US EPA and the SWRCB.

California's Antidegradation Policy is composed of both the federal antidegradation policy and the State Board's Resolution 68-16 (State Water Resources Control Board, Water Quality Order 86-17, p. 20 (1986) ("Order 86-17); Memorandum from Chief Counsel William Attwater, SWRCB to Regional Board Executive Officers, "Federal Antidegradation Policy," pp. 2, 18 (Oct. 7, 1987) ("State Antidegradation Guidance")). As a state policy, with inclusion in the Water Quality Control Plan (Basin Plan), the antidegradation policy is binding on all of the Regional Boards (Water Quality Order 86-17, pp. 17-18).

The BDCP will require a number of waste discharge permits from the SWRCB or Regional Water Quality Control Board for construction and operation of the project. It will require a CWA Section 401 Water Quality Certification, which is necessary for any "federal license or permit to conduct and activity…[that] may result in any discharge into navigable waters." (33 U.S.C. § 1341(a)(1).) In order to obtain a 401 certification, a project must meet CWA requirements to meet water quality requirements CWA Section 303 (33 U.S.C. § 1341(d)) BDCP will require a CWA Section 404 permit from the U.S Army Corps of Engineers, which will trigger the 401 certification process. The state cannot issue a Section 401 certification if there is no reasonable assurance that the project will meet water quality standards. As confirmed by the U.S. Supreme Court, CWA Section 401 certification considers the impacts of the entire activity and not simply the impacts of a particular discharge that triggers Section 401. (*PUD No. 1 of Jefferson County v. Washington Department of Ecology*, 511 U.S. 700 (1994)) Since water quality standards consist of both the water quality criteria and the designated uses of the navigable waters involved, an antidegradation analysis is required to ensure that the "existing instream water uses and the level of water quality necessary to protect the existing uses shall be maintained and protected." (40 CFR 131.12)

California's Antidegradation Policy (Resolution 68-16) requires that:

- Existing high quality water will be maintained until it has been demonstrated that any change will be with the maximum benefit to the people of the State.
- The change will not unreasonably affect present and anticipated beneficial uses.
- The change will not result in water quality less than prescribed in the policies.
- Any activity which produces a waste or increased volume or concentration will be required to meet waste discharge requirements which will result in the best practicable treatment or control of the discharge necessary to assure that a pollution or nuisance will not occur and the highest water quality with maximum benefit to the people of the state will be maintained.

Implementation of the state's antidegradation policy is guided by the State Antidegradation Guidance, SWRCB Administrative Procedures Update 90-004, 2 July 1990 ("APU 90-004") and USEPA Region IX, "Guidance on Implementing the Antidegradation Provisions of 40 CFR 131.12" (3 June 1987) (" Region IX Guidance"), as well as Water Quality Order 86-17.
The Regional Board must apply the antidegradation policy whenever it takes an action that will lower water quality (State Antidegradation Guidance, pp. 3, 5, 18, and Region IX Guidance, p. 1). Application of the policy does not depend on whether the action will actually impair beneficial uses (State Antidegradation Guidance, p. 6). The proposed project, as defined by the alternatives described in the EIR/EIS, will result in reduced flows and lower water quality in the Delta for some constituents.

The State Board's APU 90-004 specifies guidance to the Regional Boards for implementing the state and federal antidegradation policies and guidance. The guidance establishes a two-tiered process for addressing these policies and sets forth two levels of analysis: a simple analysis and a complete analysis. A simple analysis may be employed where a Regional Board determines that: 1) a reduction in water quality will be spatially localized or limited with respect to the waterbody, e.g. confined to the mixing zone; 2) a reduction in water quality is temporally limited; 3) a proposed action will produce minor effects which will not result in a significant reduction of water quality; and 4) a proposed activity has been approved in a General Plan and has been adequately subjected to the environmental and economic analysis required in an EIR.
A complete antidegradation analysis is required if discharges would result in: 1) a substantial increase in mass emissions of a constituent; or 2) significant mortality, growth impairment, or

reproductive impairment of resident species. Regional Boards are advised to apply stricter scrutiny to non-threshold constituents, i.e., carcinogens and other constituents that are deemed to present a risk of source magnitude at all non-zero concentrations. If a Regional Board cannot find that the above determinations can be reached, a complete analysis is required.

Even a minimal antidegradation analysis would require an examination of: 1) existing applicable water quality standards; 2) ambient conditions in receiving waters compared to standards; 3) incremental changes in constituent loading, both concentration and mass; 4) treatability; 5) best practicable treatment and control (BPTC); 6) comparison of the proposed increased loadings relative to other sources; 7) an assessment of the significance of changes in ambient water quality and 8) whether the waterbody was a ONRW. A minimal antidegradation analysis must also analyze whether: 1) such degradation is consistent with the maximum benefit to the people of the state; 2) the activity is necessary to accommodate important economic or social development in the area; 3) the highest statutory and regulatory requirements and best management practices for pollution control are achieved; and 4) resulting water quality is adequate to protect and maintain existing beneficial uses.

The EIR/EIS, page 8-408 states in part that:

> "*Effects of the Alternative on Delta Hydrodynamics Under the No Action Alternative and Alternatives 1–9, the following two primary factors can substantially affect water quality within the Delta:*
>
> - *Within the south, west, and interior Delta, a decrease in the percentage of Sacramento River sourced water and a concurrent increase in San Joaquin River-sourced water can increase the concentrations of numerous constituents (e.g., boron, bromide, chloride, electrical conductivity, nitrate, organic carbon, some pesticides, selenium). This source water replacement is caused by decreased exports of San Joaquin River water (due to increased Sacramento River water exports), or effects of climate change on timing of flows in the rivers. Changes in channel flows also can affect water residence time and many related physical, chemical, and biological variables.*
> - *Particularly in the west Delta, sea water intrusion as a result of sea level rise or decreased Delta outflow can increase the concentration of salts (bromide, chloride) and levels of electrical conductivity. Conversely, increased Delta outflow (e.g., as a result of Fall X2 operations in wet and above normal water years) will decrease levels of these constituents, particularly in the west Delta.*"

BDCP will reduce flows and result in lower water quality for a number of constituents, including boron, bromide, chloride, electrical conductivity, nitrate, organic carbon, some pesticides and selenium. The Delta is currently impaired for many of the constituents that will increase under the proposed alternative. While California's Antidegradation Policy requires that, "[t]he change will not unreasonably affect present and anticipated beneficial uses and the change will not result in water quality less than prescribed in the policies," the Federal Antidegradation Policy requires a "determination that existing uses will be fully maintained and protected." EPA, Region 9, Guidance on Implementing the Antidegradation Provisions of 40 CFR 131.12, page 7.

The proposed project will result in a substantial increase in mass emissions of constituents that already exceed water quality standards. This does not comply with the Policies set forth in the Basin Plan. Massively exceeding a water quality standard – any water quality standard - does not fully protect present and anticipated beneficial uses. Impacts to the existing impaired water for unknown toxicity and specifically mortality, growth and reproduction of resident species have not been thoroughly discussed or analyzed for toxic constituents. Nor have impacts to native zooplankton and phytoplankton communities that comprise the base of the food chain web been analyzed.

A complete Antidegradation analysis must be conducted to determine: incremental changes in constituent loading, both concentration and mass; the significance of changes in ambient water quality; whether such degradation is consistent with the maximum benefit to the people of the state; whether the activity is necessary to accommodate important economic or social development in the area; and whether the resulting water quality is adequate to fully protect and maintain existing beneficial uses.

18. The Analysis and Discussion of Pathogens is Fundamentally Flawed.

The EIR/EIS (8.2.3.12) identifies the beneficial uses impacted by pathogens as municipal and domestic supply, water contact recreation, shellfish harvesting, and commercial and sport fishing. Missing from this list is irrigated agriculture. Pathogens have not been evaluated for Agricultural Supply water. California Code of Regulations, Title 22, is mentioned in the EIR/EIS specifically with regard to pathogens and protecting Contact Recreational beneficial uses. However, Title 22 equally addresses agricultural irrigation and the acceptable levels of pathogens. From a regulatory point of view, Title 22 requirements are only directly applicable to reclaimed water; however, the science used to determine a protective level for pathogens is directly applicable for protecting irrigated agriculture and recreational activities. The potential impacts to irrigated agriculture and the ingestion of food crops irrigated with water exceeding the recommended levels for pathogens presents at least the same level of concern as does recreational activity in that same water. The impacts to Irrigated Agriculture from pathogens, nitrates, constituents of emerging concern (CECs) and phthalates have not been assessed. The EIR/EIS is therefore incomplete.

This Section of the EIR/EIS, page 8-80 states that: "*Viruses also can be removed effectively through chlorine or ozone oxidation.*" This statement is incorrect; while chlorination may be effective at rendering some limited number of viruses inactive, it removes none. For the most part, viruses and protozoa have a moderate to high tolerance to chlorine. (CDC, Effect of Chlorination on Inactivating Selected Pathogens, 21 March 2012) It is also fairly well documented in Civil Engineering texts that viruses and parasites are best removed by filtration and chlorination is generally accepted as ineffective. Going back to the requirements contained in CCR Title 22, filtration is required to remove pathogens, and one will note that disinfection with chlorine is not a requirement. Tertiary treatment, consisting of chemical coagulation, sedimentation, and filtration, has been found to remove approximately 99.5% of viruses. Filtration is an effective means of reducing viruses and parasites from the waste stream, not disinfection with chlorine.

The EIR/EIS is also incorrect in stating that pathogens experience rapid die off in the natural environment. The latest science shows that pathogens can survive for lengthy time periods and the indicator tests used to identify pathogens may not be reliable:

> A. *“Previous research had raised questions about whether E. coli O157:H7 outlasts indicator bacteria in the environment. So Michael Jenkins and his colleagues at the U.S. Department of Agriculture's Agricultural Research Service decided to test the reliability of the EPA's method by measuring the survival rates of E. coli O157:H7 and four species of indicator bacteria. In one experiment, they injected the E. coli strain and the indicator bacteria into small, porous chambers and then suspended the chambers in test ponds in northeast Georgia. By varying the chambers' depth in the water, the scientists could monitor the microbe's survival rate under different levels of solar radiation. In another experiment, they placed inoculated pond water in bottles in an outdoor laboratory. The researchers then measured bacteria levels at regular intervals. Both experiments exposed the bacteria to predation by other microorganisms—a common fate of microbes in the environment.*
>
> *They found that in both experiments, the indicator bacteria died off significantly more quickly than E. coli O157:H7 did. For example, in the outdoor lab experiments, most cells of fecal Enterococcus—an indicator species—died in less than five days. But it took between seven and 18 days for most of the E. coli O157:H7 to die. The virulent strain appeared to be more resistant than indicator bacteria to solar radiation and to predation by other microorganisms. The findings suggest that the dangerous E. coli could be present in water even when tests for fecal indicator bacteria are negative, Jenkins says. "We need to develop methods that are going to be able to quantify the pathogens themselves," he says.” (*Chemical & Engineering News, ISSN 0009-2347)
>
> B. *“In general, many different kinds of viruses can persist in and on environmental media, including liquid and solid media and in the airborne state, with half-lives of hours, days, weeks or even months. The extent of persistence depends on the type of virus, it physical state (dispersed, aggregated, cell-associated, membrane-bound, adsorb to other solids, etc.), the medium in which it is present (faeces, respiratory secretions, tissues, other liquids or solids, air, etc. and prevailing environmental conditions that influence virus survival. The environmental conditions influencing virus survival generally include: temperature; pH and other physical and chemical properties of the medium in which the viruses are present, such as moisture content, organic matter, particulates, salt concentration, protective ions, and antiviral chemicals such as proteolytic enzymes; antiviral microbial activity, and light. On environmental surfaces and in aerosols additional environmental factors also influence virus survival, such as relative humidity and physico-chemical forces at air-water and air-water-solid interfaces.”* (WHO Virus Survival Report, Virus Survival in the Environment with Special Attention to Survival in Sewage Droplets and Other Environmental Media of Fecal or Respiratory Origin, August 21, 2003)
>
> C. *“Three enteroviruses — polioviruses, echoviruses and coxsackieviruses — were used to contaminate soil and vegetables; their survival times, under various storage*

> *conditions, were then recorded (2). The concentration of the viruses employed varied from 1 x 104-5 to 1 x 105-5 CCID50/ml. Depending on soil type, moisture content, pH and temperature, the viruses survived for 150 to 170 days in soil. When added to uncooked vegetables and stored under household conditions, the viruses survived for as long as 15 days."* (Rev. sci. tech. Off. int. Epiz., 1991, 10 (3), 733-748, Virus survival in the environment)

Pathogens and their longevity are important in the context of multiple beneficial uses. Below, we describe how many of these uses affect and are affected by pathogens, and how these effects, of and on, these uses should have been analyzed

Recreational Waters Criteria and Beach Closures

In most areas of California, the current water quality criterion for bacteria in recreational waters is based on fecal coliform organisms:

- In waters designated for contact recreation (REC-1), the fecal coliform concentration based on a minimum of not less than five samples for any 30-day period shall not exceed a geometric mean of 200/100 ml, nor shall more than ten percent of the total number of samples taken during any 30-day period exceed 400/100 ml.

US EPA's evaluation of the bacteriological data indicated that using the fecal coliform indicator group at the maximum geometric mean of 200/100 ml would cause an estimated 8 illnesses per 1,000 swimmers at marine beaches (*Ambient Water Quality Criteria for Bacteria – 1986)*. US EPA now recommends the addition of criteria for E. coli (126/100 ml) and enterococci (33/100 ml) based on the same "acceptable" illness rate of 8 illnesses per 1,000 swimmers at marine beaches.

Even at the "acceptable" illness rate of 8 out of every 1,000 swimmers; the National Resources Defense Council (NRDC) in 2008 issued a press release interpreting EPA's data that beach closures were at their highest level in 18 years. In 2002, the Centers for Disease Control and Prevention (CDC) concluded that the incidence of waterborne infections from recreational water use has steadily increased over the last several decades. Despite the beach closures and the increase in reported sewage-related illnesses, in a healthy population, most of the illnesses resulting from exposure to inadequately treated sewage are relatively minor (respiratory illness; ear, nose, or throat irritation; and especially gastroenteritis) and go unreported. Even if such illnesses are reported to doctors, there is seldom an attempt to find or track an environmental source.

Another complicating issue is inadequate data on the occurrence of sewer spills or overflows. The State Water Board has only begun requiring reporting of sewer spills into its new sanitary sewer overflow (SSO) database and reporting compliance rates are mixed. The lack of data regarding sewer spills and the under-reporting of illnesses makes it difficult to definitively estimate the incidence of diseases caused by exposure to sewage-contaminated waters. The number of reported cases is a small subset of the actual number of illnesses caused by sewage exposure or waterborne pathogens.

The Delta is a recreational magnet, attracting many thousands of water enthusiasts, including boaters, swimmers, water-skiers, windsurfers, fishermen and others who routinely come into contact with the water. The Delta is also home to thousands of people who permanently live on boats, many of which do not always follow proper sanitation protocols. During warmer weather, many people anchor boats for extended periods of time in attractive anchorages, without always returning to pump-out facilities empty marine sanitation devices. A large homeless population lives in the Delta and along urban tributary streams and lack even rudimentary sanitation facilities.

CSPA staff and members have spent thousands and thousands of days on Delta waters and are acutely aware of the numerous cases of gastrointestinal illnesses and seriously infected cuts experienced by individuals following exposure to the water. Few of these illnesses are formally report to health authorities. We are aware that urban stormwater monitoring reveals that, following rainfall, stormwater discharges and local receiving waters far exceed water quality standards for pathogens.

The EIR/EIS fails to identify how many exceedances of bacteria standards were recorded during the period analyzed, discuss or estimate the number of illnesses typically occurring or that are projected to occur or identify recreational closures.

Beneficial Uses of the Receiving Water

By memorandum, dated September 28th 2000, Jeff Stone, California Department of Health Services (DHS), Office of Drinking Water, Recycled Water Unit, to Regional and District Engineers wrote that: "Federal Standards for water quality where recreational bathing may occur were developed for freshwaters which are not directly influenced by sewage discharges (treated or untreated)." The memorandum goes on to state that the Department does not believe that the federal criteria are protective if the source of water is domestic wastewater and cites the "Uniform Guidelines" prepared by the Department.

Irrigated Agriculture

Although the discussion of pathogens has largely been limited to recreational uses, Irrigated Agriculture is a designated beneficial use of most inland waters. Outbreaks of bacteria-contaminated food have made headlines over the past few years. California Department of Public Health, Regulations, CCR Title 22, Section 60303, require that for the irrigation of Food Crops, including edible root crops, reclaimed water be tertiary treated water disinfected to 2.2 MPN/100 ml (total coliform organisms). Obviously, 2.2 MPN total coliform is significantly less than the 200 MPN fecal coliform bacteria criteria established for recreational waters.

Undiluted surface water can be and is used to irrigate food crops. The science used to develop the bacteria limitation in the Title 22 Reclamation Criteria for the irrigation of food crops is applicable to surface waters even though the Title 22 regulatory requirements do not apply. By Memorandum to Regional Water Boards, dated August 18, 1992, the then Department of Health Services, Office of Drinking Water, issued the *Uniform Guidelines for the Disinfection of*

Wastewater (Uniform Guidelines). The Uniform Guidelines recommend that for agricultural uses where there is less than a twenty-to-one dilution of wastewater within the receiving stream, that a tertiary level of treatment be required with a 2.2 MPN/100 ml limitation for total coliform organisms. A footnote for this situation states that where there is no dilution, the water reclamation criteria shall apply. The Uniform Guidelines further recommend that: when there is dilution available in the receiving stream of at least 20-to-1 the wastewater be treated to a secondary level and disinfected to a 23 MPN/100 ml; and when there is dilution available of at least 100-to-1 the wastewater be treated to a secondary level and disinfected to a 240 MPN/100 ml.

Municipal (Drinking) and Domestic

The Uniform Guidelines recommend that for drinking water uses where there is less than a twenty to one dilution of wastewater within the receiving stream, no domestic wastewater discharges be allowed. Tertiary treated, 2.2 MPN/100 ml, wastewater could only be allowed to a receiving stream with a drinking water beneficial use if greater than a twenty-to-one dilution reliably exists.

Contact Recreation

The Uniform Guidelines and the Reclamation Criteria of CCR Title 22 require that for unrestricted recreational uses that wastewater be tertiary treated and disinfected to 2.2 MPN/100 ml (total coliform organisms), unless a 20 to 1 in stream dilution exists then the wastewater may be secondary treated and disinfected to 23 MPN/100 ml. This recommendation for contact recreational uses is directly comparable to the US EPA recommended bacteria criteria.

Domestic Wastewater Treatment

As stated above, the California Department of Public Health, formerly the Department of Health Services, does not support the Federal Criteria as being protective if the source of water in the receiving stream is domestic wastewater (treated or untreated).

Domestic wastewater discharges are regulated under Federal NPDES permits issued by the State and Regional Boards. The federal Clean Water Act, Section 101(a)(2), states: “it is the national goal that wherever attainable, an interim goal of water quality which provides for the protection and propagation of fish, shellfish, and wildlife, and for recreation in and on the water be achieved by July 1, 1983.” Federal Regulations, developed to implement the requirements of the Clean Water Act, create a rebuttable presumption that all waters be designated as fishable and swimmable. Federal Regulations, 40 CFR Sections 131.2 and 131.10, require that all waters of the State regulated to protect the beneficial uses of public water supply, protection and propagation of fish, shell fish and wildlife, recreation in and on the water, agricultural, industrial and other purposes including navigation.

The diversion of approximately 2.5 MAF of relatively good dilution flow from the estuary will increase the relative percentage of water from the San Joaquin River in the eastern and southern Delta. This will inevitably increase the relative concentration of human and agricultural wastes in these waters, including dairy and livestock wastes that have been identified as sources of pathogens. It will also increase the residence time of pathogens and increase the potential to impact those who come in contact with the water. It will increase the opportunity for pathogens to affect irrigated food crops and domestic water supplies. The EIR/EIS is deficient because it fails to adequately and accurately consider the potential adverse effects of pathogens on human health

19. The Analysis of Water Temperature is Deficient.

The Water Quality section of the EIR/EIS states that: "*Because the primary concern of water temperature is effects on fish and aquatic organisms, temperature is addressed in Chapter 11, Fish and Aquatic Resources.*" Any discussion of Water Quality is incomplete without including temperature. There are water quality objectives for temperature in the Basin Plan; Water Quality Objectives (Page III-8.00, Sacramento and San Joaquin Basins), and the Water Quality Control Plan for Temperature (Thermal Plan, an appendix to the Basin Plan). Elevated temperature is a pollutant and compliance with objectives is a relevant discussion with regard to water quality. Also, temperature directly affects the toxicity of other constituents such as ammonia. Temperature also impacts dissolved oxygen concentrations and may impact compliance with the DO objective. Strictly in terms of compliance with objectives and the impacts to other constituents, a thorough discussion of temperature must be included in the Water Quality section of the EIR/EIS. The Water Quality section must be amended to discuss temperature, compliance with limitations, protection of beneficial uses and the impacts from the various alternatives described in the EIR/EIS.

The temperature objectives in the Basin Plan and the Thermal Plan are principally based on antidegradation (changes in temperature) and not necessarily on the direct protection of beneficial uses of receiving water or the Delta. The Delta is home to numerous species of Coldwater fish and all life stages. Maximum temperatures for the protection of Coldwater fish species are well documented; and the Central Valley Regional Board has included specific temperature regimes in NPDES permits, such as for the Cities of Lincoln and Placerville. Any discussion of temperatures must not be limited to regulatory compliance with objectives but must also discuss the temperatures necessary to assure a productive population of Coldwater aquatic life.

20. Color is Inadequately Addressed.

CCR Title 22, Chapter 15, Article 16, Secondary Water Standards, Section 64449, states, in part, that: "The secondary MCLs shown in Tables 64449-A and 64449-B shall not exceed in the water supplied to the public by community water systems." Table 64449-A contains a MCL for color of 15 units.

Drinking water MCLs are included in the Central Valley Basin Plan by direct reference under the Chemical Constituents Objective; therefore the MCLs are applicable water quality standards.

The EIR/EIS (Section 8C.1.5.2) incorrectly states that: "*Color in water has a secondary MCL of 15 color units. Secondary MCLs are established <u>only as guidelines</u> to assist public water systems* *in managing their drinking water for aesthetic considerations*." In California the secondary MCL for color is a regulatory requirement and an applicable water quality standard.

The EIR/EIS (Section 8C.1.5.2) continues:

> "*To the degree that color itself is a concern from an aesthetic standpoint, conventional drinking water treatment removes many of the constituents that cause high color levels in water. <u>Coagulation/flocculation and filtration remove metals like iron, manganese and zinc</u>. <u>Aeration removes iron and manganese</u>. <u>Granular activated carbon removes most of the contaminants which cause color</u> (U.S. EPA 2012b). Color in the three major source waters to the Delta does not vary considerably (see Step 1, Table SA-6). The average in the Sacramento River at Freeport/Greene's Landing is approximately <u>22 units</u>, while San Francisco Bay at Martinez and San Joaquin River at Vernalis average approximately <u>30 units</u>. The standard deviations at these locations are 22–37 units, indicating that substantial variability exists at all three locations, and no specific source waters is consistently highest in color. <u>The Delta is not 303(d) listed for color and thus no beneficial use impairment due to its current levels is occurring</u>.*"

The total portions of iron, manganese and zinc may be removed by coagulation, flocculation and filtration; however, the dissolved segment will likely pass through such treatment systems. The EIR/EIS does not present any information regarding the total and/or dissolved speciation of these metals.

It makes no engineering sense that aeration would remove iron and manganese from a water column. Aeration is a process where air is added to a treatment process; this may remove volatile constituents to the atmosphere, but not metals.

The EIR/EIS clearly shows that color exceeds the water quality standard throughout the Delta where the average levels of 22 units and 30 units clearly exceed the 15 unit standard. The fact that the 303(d) list has not been modified to include color does not indicate that the water quality standard is not being exceeded.

The State Water Resources Control Board's Policy, Resolution No. 88-63, "Sources of Drinking Water" states that All surface and ground waters of the State are considered to be suitable, or potentially suitable, for municipal or domestic water supply and should be so designated by the Regional Boards…" Drinking water quality must be maintained within the waters of the State not just following extraction and treatment.

The drinking water beneficial use is impaired by color within the Delta; the EIR/EIS clearly documents this case by showing average color levels, which exceed the drinking water MCL. The EIR/EIS is not only deficient with regard to the discussion of color, but it is misleading and simply incorrect.

In closing, the EIR/EIS is seriously misleading, grossly inadequate, technically deficient and fails, in multiple ways, to meet the minimal CEQA and NEPA requirements for an environmental review document.

Thank you for considering these comments. If you have questions or require clarification, please don’t hesitate to contact us.

Sincerely,

Bill Jennings

July 25, 2014

The following comments are offered in response to the request for public comment on the Bay Delta Conservation Plan (BDCP) Draft Environmental Impact Report/Environmental Impact Statement (EIR/EIS) (http://baydeltaconservationplan.com/PublicReview.aspx). According to published information (http://baydeltaconservationplan.com/Libraries/Dynamic_Document_Library/Highlights_of_the_Draft_EIR-EIS_12-9-13.sflb.ashx),

> *"The proposed Bay Delta Conservation Plan (BDCP) is a comprehensive conservation strategy that intends to address the critical issues in the Delta using an ecosystem-based approach. The Plan would help to restore fish and wildlife species in the Delta and to improve reliability of water supplies, while minimizing impacts on Delta communities and farms."*
>
> *"The Draft EIR/EIS is intended to analyze and disclose the potential impacts on the human environment from the proposed action and alternatives."*

These comments address Chapter 8 of the draft EIR/EIS, which is devoted to Delta Water Quality as impacted by the preferred alternative plan described thus: (http://baydeltaconservationplan.com/Libraries/Dynamic_Document_Library/Draft_BDCP_Highlights_12-9-13.sflb.ashx):

> *"The proposed BDCP project includes three new intakes along the Sacramento River in the north Delta and twin underground main tunnels through the Delta, approximately 30 miles long, to carry water under the Delta to the CVP* [Central Valley Project] *and SWP* [State Water Project] *pumping plants. A forebay would be needed near the intakes to collect water diverted from the river, then gravity flow would move water supplies through the tunnels."*
>
> *"The twin tunnels would be lined with concrete segments and capable of moving a maximum of 9,000 cubic feet per second (cfs). The gravity-flow system requires two 40-foot-diameter tunnels to convey the needed flows and overcome friction losses to keep water moving through the system."*

These comments also address additional aspects of public health impacts of the proposed project as included in Chapter 25 of the draft EIR/EIS, which is described thus (Chapter 25 page 1):

> *"This chapter focuses on issues related to human health and safety that could potentially be affected by implementation of the BDCP alternatives, particularly with respect to water quality, the potential to cause or worsen water borne illness, the potential to create habitat for vectors that may carry diseases; and to address potential health related concerns from additional electric transmission lines needed under most of the alternatives."*

Overall Assessment

Overall, the draft BDCP EIR/EIS and approaches used in its development are inadequate in scope and reliability for evaluating the potential impacts of diverting substantial amounts of Sacramento River water around or through the Delta on chemical constituents and water quality in Delta channels. The draft EIR/EIS basically used model output of expected changes in the concentrations of a few water quality parameters that have not been found to exceed a water quality objective at a few selected locations in the Delta as was done for this draft EIR/EIS. The approach used does not adequately or reliably consider the range of water quality impacts caused by the wide variety of potential pollutants present in the various Delta channels, that can be expected to result from the removal of large amounts of high-quality Sacramento River water from the Delta by this project.

As discussed herein the existing database on chemical contaminants contributed to the Delta, the impacts of sources of flow and changes in those sources on contaminant concentration, distribution, and impact within the Delta, and Delta channel water quality overall is too limited to make a sufficiently reliable assessment of the impacts of a project as extensive, expensive, and far-reaching as that proposed. Further, the level of uncertainty inherent in the existing modeling of Delta channel flows, and the Sacramento River component of those flows, renders it insufficiently reliable to adequately estimate the change in channel flow and character that will be expected to result from the massive diversion of Sacramento River flow around or through the Delta as proposed, much less the influence on those flow alterations on the concentrations, distribution, and impacts of chemical contaminants in the Delta.

As discussed in these comments there are a number of issues that should have been, but were not adequately, considered in assessing the water quality impacts of the existing Sacramento River flow into the Delta as well as the impacts of significantly reducing that flow. An area of the Delta of importance and with which Dr. Lee is particularly familiar is the Central Delta where the Sacramento River mixes with the San Joaquin River below Columbia Cut. As found in his studies of that area, and discussed in his reports that are on Drs. Lee and Jones-Lee's website, [www.gfredlee.com in the San Joaquin River Delta section at http://www.gfredlee.com/psjriv2.html] the amount of Sacramento River in the San Joaquin River channel is dependent on the amount of south Delta water that is pumped from the Delta by the CVP and SWP; the Sacramento River is drawn through the Delta by and toward the export pumps While the export pumps for those two projects will continue to draw south Delta water from the Southern Delta with half of total exports will coming from the north Delta facilities and, in the long-term alternative 4 will lead to increased exports and reduced outflow. These issues as well as others discussed herein need to be defined and evaluated before further consideration is given to the proposed BDCP diversion project.

A properly developed EIR/EIS would have included a detained analysis of potential errors in predicting constituent concentrations in the various Delta channels and in predicting the changes in flow and associated impacts on constituent concentrations, distribution, and effects. As it stands now Chapter 8 of this EIR/EIS does not reliably inform the public or decision-makers about the magnitude of the errors in estimates and conclusions inherent in the BDCP analysis of the impact of the diversions on Delta water quality/beneficial uses.

Background to Comments

Dr. G. Fred Lee has been involved and pioneered in graduate-level teaching, research, laboratory direction, consulting, and professional service in a myriad aspects of sources, fate, transport, and public health and environmental quality impacts of chemicals in natural waters (including lakes, reservoirs, rivers, estuaries, and nearshore marine waters) since the early 1960s; he has published nearly 1000 professional papers and reports on his work. Information on Drs. Lee and Jones-Lee's experience in these areas and publications are available on their website, www.gfredlee.com; their involvement in, and publications concerning, the Sacramento San Joaquin River Delta specifically are addressed at http://www.gfredlee.com/psjriv2.html.

Drs. Lee and Jones-Lee began working on Delta water quality issues in the summer of 1989 when he was a Distinguished Professor and she was Associate Professor of Engineering at the New Jersey Institute of Technology. At that time they were contracted by Delta Wetlands, a proposed private project to develop water supply reservoirs in the Delta, to evaluate the expected water quality in the proposed reservoirs based on their more than 25 years of work on reservoir water quality in the USA and many other areas of the world. Their project involved collecting and reviewing existing Delta water quality and related data and assessing the anticipated water quality in the proposed Delta reservoirs for water supply and other beneficial uses, since it was to be Delta water that would be used to fill the proposed reservoirs.

Beginning in 2002 Drs. Lee and Jones-Lee became technical advisors to the San Joaquin River Deep Water Ship Channel (DWSC) Low-DO (dissolved oxygen) TMDL Steering Committee. That involvement led to their being appointed principal investigators (PIs) for a $2-million CalFed project to investigate the causes of the low-DO problems in the DWSC. As project PIs they coordinated the studies of 12 investigators and developed synthesis reports for the project. In addition, they published additional papers and reports discussing the study findings and their significance and implications for water quality in Delta. Appendix A to these comments provides a brief description and citations with URLs for many of those writings; additional papers and reports on Delta water quality issues are available in the San Joaquin River & Delta section of their website (http://www.gfredlee.com/psjriv2.html). The SJR DWSC low DO TMDL project led to the development of,

> Lee. G. F., and Jones-Lee, A., "Synthesis and Discussion of Findings on the Causes and Factors Influencing Low DO in the San Joaquin River Deep Water Ship Channel near Stockton, CA: Including 2002 Data," Report Submitted to SJR DO TMDL Steering Committee/Technical Advisory Committee and CALFED Bay-Delta Program, G. Fred Lee & Associates, El Macero, CA, March (2003). http://www.gfredlee.com/SJR-Delta/SynthesisRpt3-21-03.pdf
>
> Lee, G. F. and Jones-Lee, A., "Supplement to Synthesis Report on the Low-DO Problem in the SJR DWSC," Report of G. Fred Lee & Associates, El Macero, CA, June (2004). http://www.gfredlee.com/SJR-Delta/SynthRptSupp.pdf

and a number of other papers and reports on these studies. Further information on these studies is presented below.

Following the completion of the SJR DWSC DO TMDL synthesis report developed, Lee, G. F. and Jones-Lee, A., "Overview of Sacramento-San Joaquin River Delta Water Quality Issues," Report of G. Fred Lee & Associates, El Macero, CA (2004). http://www.gfredlee.com/SJR-Delta/Delta-WQ-IssuesRpt.pdf

Lee, G. F., and Jones-Lee, A., "Overview—Sacramento/San Joaquin Delta Water Quality," Presented at CA/NV AWWA Fall Conference, Sacramento, CA, PowerPoint Slides, G. Fred Lee & Associates, El Macero, CA, October (2007). http://www.gfredlee.com/SJR-Delta/DeltaWQCANVAWWAOct07.pdf

The Lee and Jones-Lee (2004) Delta water quality report was the first comprehensive report on Delta water quality issues that examined the water quality implications of violations of water quality objectives in the Delta channels.

A major finding discussed therein was that the flow through the Delta channels impacted the location and magnitude of violations of water quality objectives in a Delta channel. While the importance of channel flow was impacting water quality/beneficial uses of the channel, it was pointed out that there was very little concrete understanding of how altering the channel flow impacted the water quality.

Of particular note with respect to addressing issues of the draft EIR/EIS Chapter 25 is Dr. Lee's BA and MSPH degrees in public health and his PhD in environmental engineering with a minor with public health. Much of his work during his five-decades-long profession career has been in water quality research and consulting activities that address public health and water quality aspects of chemical and biological contaminants in the environment and drinking water.

In summary these comments on the adequacy of the BDCP draft EIR EIS to adequately and reliably present information on the impact of proposed diversion of 9,000 cfs of Sacramento River around the Delta began in 1989. Since then we have been active in review of Delta water quality issues including developing over 90 reports/papers on these issues. Further information on this experience is in

Lee, G. F., and Jones-Lee, A., "Experience in Reviewing Delta Water Quality Issues," G. Fred Lee & Associates, El Macero, CA, April 3 (2011). http://www.gfredlee.com/SJR-Delta/GFLAJL-Delta-EXP-REV.pdf

Specific Comments on Draft EIR/EIS BDCP "Chapter 8 Water Quality"

"8.1 Readers' Guide

Chapter 8, Water Quality, describes the environmental setting and potential impacts of the BDCP on water quality in and upstream of the Sacramento-San Joaquin Delta. The chapter provides the results of the evaluation of the effects of implementing the BDCP conservation measures on water quality constituents under a no action alternative and 15 different project alternatives."

Pages 8-15&16 Table 8-1 lists the beneficial uses of the Delta. An issue that needs to be acknowledged and understood is that Sacramento River flow into and through the Delta plays an important part in reducing the water quality impacts of regulated and unrecognized/unregulated pollutants added to Delta water, both by its dilution of pollutant concentration and by decreasing the pollutant residence times in the Delta. The reduction in Sacramento River flow into and through the Delta that will result from the proposed plan will be expected to increase the water quality and public health significance of unrecognized/unregulated pollutants in the Delta waters. These issues were discussed in the following presentations and writings:

> Lee, G. F., and Jones-Lee, A., "Enhanced Delta Flows Needed to Help Control Water Quality Impacts of Delta Pollutants," Testimony for CA State Water Resources Control Board Public Workshop: Comprehensive (Phase 2) Review & Update to Bay-Delta Plan Workshop 1: Ecosystem Changes and the Low Salinity Zone, Sacramento, CA, September 5, 2012, Report of G. Fred Lee & Associates, El Macero, CA, August 17 (2012).
> http://www.gfredlee.com/SJR-Delta/Lee_Testimony_BayDelta_Workshop_1.pdf
>
> Lee, G. F., and Jones-Lee, A., “Discussion of Water Quality Issues That Should Be Considered in Evaluating the Potential Impact of Delta Water Diversions/Manipulations on Chemical Pollutants on Aquatic Life Resources of the Delta,” Report of G. Fred Lee & Associates, El Macero, CA, February 11 (2010).
> http://www.gfredlee.com/SJR-Delta/Impact_Diversions.pdf
>
> Lee, G. F., and Jones-Lee, A., “Comments on Water Quality Issues Associated with SWRCB’s Developing Flow Criteria for Protection of the Public Trust Aquatic Life Resources of the Delta,” Submitted to CA State Water Resources Control Board as part of Public Trust Delta Flow Criteria Development, by G. Fred Lee & Associates, El Macero, CA, February 11 (2010).
> http://www.gfredlee.com/SJR-Delta/Public_Trust_WQ.pdf

The proposed BDCP diversion of Sacramento River water around the Delta rather than continuing to allow river water to flow through the Delta to the CVP and SWP diversions will be detrimental to Delta water quality.

Section 8.2.1.8 beginning on Page 8-25 presents a review of “water quality constituents of concern,” and makes mention of some of the unrecognized pollutants. That section, however, does not adequately address this issue. There are many more unregulated and unrecognized potential pollutants that could be impacting Delta water quality beneficial uses; these issues are reviewed in:

> Lee, G. F., and Jones-Lee, A., “Unrecognized Environmental Pollutants,” Water Encyclopedia: Surface and Agricultural Water, Wiley, Hoboken, NJ pp 371-373 (2005).
> http://www.gfredlee.com/SurfaceWQ/WileyUnrecognizedPollutants.pdf
>
> Volume 13 Number 1, January 12, 2010 - Topics: Impacts of unmonitored, unregulated, and unrecognized chemicals in the aquatic systems.
> www.gfredlee.com/Newsletter/swnewsV13N1.pdf

As noted, above the proposed BDCP diversion of Sacramento River water around the Delta will be adverse to beneficial uses of the Delta due by enhancing the water quality impacts of unregulated and unregulated potential pollutants.

Page 8-26 lines 16-17 states, *“Excess nutrients can cause blooms of nuisance algae and aquatic* *vegetation, and their decay can result in depleted DO."* The draft does not adequately address the at least equally, and in some areas, more significant impacts of aquatic macrophytes on aquatic life (fish) habitat and recreational use (boating) in the Delta.

Page 8-36 lines 20-22 state, *"Nutrient concentrations currently in the Delta are high enough that they are probably not a true limiting factor for overall algal growth, and therefore increases in ammonia generally will not lead to an increase in algal growth (Jassby et al. 2002:1)."* It should be noted that the Central Valley Regional Water Quality Control Board (CVRWQCB) recently established a limit on the release of ammonia in city of Stockton wastewater discharges to the SJR on the belief that that ammonia is significant in stimulating the growth of algae in Southern California water supply reservoirs, causing tastes and odors in the water supply.

Page 8-47 presents a discussion of PCB-pollution of the Delta. That discussion is highly deficient in that it fails to mention the large amount of work that has been done on PCB accumulation in fish in the Delta and Delta tributaries. In 2002 Dr. Lee reviewed the extensive data on PCBs in fish of the Central Valley on behalf of the State Water Resources Control Board (SWRCB)/CVRWQCB. From that work, Lee and Jones-Lee developed the following reports:

> Lee, G. F. and Jones-Lee, A., "Organochlorine Pesticide, PCB and Dioxin/Furan Excessive Bioaccumulation Management Guidance," California Water Institute Report TP 02-06 to the California Water Resources Control Board/Central Valley Regional Water Quality Control Board, 170 pp, California State University Fresno, Fresno, CA, December (2002).
> http://www.gfredlee.com/SurfaceWQ/OClTMDLRpt12-11-02.pdf
>
> Lee, G. F., and Jones-Lee, A., "Update of Organochlorine (OCl) 'Legacy' Pesticide and PCB Concentrations in Delta and Central Valley Fish," Report of G. Fred Lee & Associates, El Macero, CA, September 10 (2007).
> http://gfredlee.com/SurfaceWQ/UpdateLegacyPestCVFish.pdf

As discussed in those reports, the PCB-pollution of Delta and Delta tributary fish is a major water quality issue in the Central Valley waterways, sufficient to render the consumption of some large game fish such as largemouth bass hazardous to human health. While the California Office of Environmental Health Hazard Assessment (OHHEA) has reported that the levels of legacy chlorinated hydrocarbon pesticides such as DDT/DDE in fish tissue has been decreasing, the PCB content of Central Valley fish has not decreased.

Pages 8-51&52 present some information on the low-DO situation in the SJR DWSC. That discussion is deficient, however, in that it fails to discuss how manipulation of SJR DWSC flow has been, and still can be, a major factor in causing low-DO conditions in the DWSC. As discussed in reports cited in the Background section of these comments and Appendix A, the export of Delta waters by the CVP and SWP is a major contributor to low DO in the DWSC. The draft EIR/EIS fails to adequately discuss the current situation concerning the low DO in DWSC. As written, it misleads a reader to believe that the installation and operation an aeration system will control the low-DO situation in the DWSC. It also fails to discuss that there are no funds available to operate an aeration system in a manner to control the low DO that can result from the residual oxygen demand contributed from agricultural sources. Agricultural sources contribute algal nutrients to the upstream SJR waters; those nutrients support the growth of algae that cause significant oxygen demand in the DWSC especially under low-flow conditions in the SJR DWSC. The loss of Sacramento River water in the ship channel will potentially expand the downstream range of dissolved oxygen problems. Information on the current low-DO situation in the SJR DWSC is available in the following reports:

> Lee, G. F., Comments on SJR DWSC Low-DO issues discussed at March 28, 2012 BDCP meeting. Comments submitted to J. Grindstaff, Executive Officer, Delta Stewardship Council, by G. Fred Lee & Associates, El Macero, CA, April 28 (2012). http://www.gfredlee.com/SJR-Delta/Comments_SJR_DO_Issues_DSC.pdf
>
> Lee, G. F., and Jones-Lee, A., "Background Information on SJR Upstream Oxygen Demand Control Issues," Prepared for San Joaquin River Technical Work Group, Report of G. Fred Lee & Associates, El Macero, CA, July 11 (2010). http://www.gfredlee.com/SJR-Delta/Bkgrnd-SJR-DO.pdf
>
> Lee, G. F., and Jones-Lee, A., "Issues in Controlling the Residual Oxygen Demand in the SJR DWSC That Leads to DO WQO Violations," Report of G. Fred Lee & Associates, El Macero, CA, November 3, 2010; updated February 6 (2011). http://www.gfredlee.com/SJR-Delta/Residual-Ox-Demand-DWSC.pdf

As discussed in those reports, algal nutrients discharged by irrigated agriculture in the Grasslands Project area needs to be controlled in order to control algal growth in the SJR that contributes to the residual oxygen demand in the DWSC that can lead to low-DO conditions. The control of that source is especially important under the proposed plan that would divert Sacramento River water around the Delta, in order to mitigate the impact of the loss of Sacramento River on the low-DO situation in the SJR DWSC. The control of algal nutrients upstream in the SJR could greatly reduce, if not eliminate, the need for an aeration system.

Page 8-52 lines 36-37 states, *"EC and TDS values tend to be highly correlated because the majority of chemicals that contribute to TDS are charged particles that impart conductance of water."* It is incorrect to describe ions that contribute to electrical conductivity as "charge particles." The ions are not particles.

Pages 8-69 through 8-74 are devoted to "Nitrate/Nitrite and Phosphorus" in the Delta. That discussion is significantly deficient as it does not adequately discuss problems with the Gilbert discussion of N/P ratios as factor in influencing fish populations in the Delta. While those issues were discussed in an earlier section of the draft EIR/EIS, they are not discussed in the section that focuses on these issues on pages 8-70 and 8-71. When Gilbert first proposed to rely on N/P ratios, we developed the paper cited below to address the unreliability of that approach.

> Lee, G. F., and Jones-Lee, A., "Comments on the Adequacy of C. Dahm's Discussion of Delta Eutrophication Issues & Delta N/P Rations as a Cause of Adverse Impact on Delta Fish," Comments to Delta Stewardship Council, Report of G. Fred Lee &Associates, El Macero, CA, November 17 (2011). http://www.gfredlee.com/SJR-Delta/DSC-Comments-Dahm-Eutroph.pdf

> Lee, G. F., and Jones-Lee, A., "Comments on P. Glibert Defense of N/P Ratios as Major Influence on Aquatic Ecosystems Composition in Delta," Report of G. Fred Lee & Associates, El Macro, CA, September 17 (2012).
> http://www.gfredlee.com/SJR-Delta/Comments_Glibert_NPRatio.pdf

The BDCP draft EIR/EIs Water Quality Chapter 8 should have discussed the findings presented in Dr. Erwin van Nieuwenhuyse's professional workshop presentation and publication concerning the response in average summer chlorophyll concentration in the Delta to an abrupt and sustained reduction in phosphorus discharge from the Sacramento Regional Wastewater Treatment Plant. His presentation slides are available at http://www.cwemf.org/workshops/DeltaNutrientsWrkshp/VanNieuwenhuyse.pdf and his published paper is:

> vanNieuwenhuyse, E., "Response of Summer Chlorophyll Concentration to Reduced Total Phosphorus Concentration in the Rhine River (Netherlands) and the Sacramento– San Joaquin Delta (California, USA)," Can. J. Fish. Aquatic, Sci. 64(11):1529-1542 (2007).
> [http://www.ingentaconnect.com/content/nrc/cjfas/2007/00000064/00000011/art00006]

His presentation and paper provided important information on the impact of phosphorus discharges from that facility on planktonic algae in the Delta. He found that the changes in the fish production and ecosystem in Delta that occurred was more likely a result of the decrease in phosphorus discharged rather than of a change in N/P ratios.

Another issue that was not properly addressed in the draft EIR/EIS is that particulate inorganic phosphorus is largely not available to support algal growth. This issue has been reviewed in a number of publications including:

> Lee, G. F., "A Proposal for Assessing Algal-Available Phosphorus Loads in Runoff from Irrigated Agriculture in the Central Valley of California," Report of G. Fred Lee & Associates, El Macero, CA, November (2006).
> http://www.gfredlee.com/Nutrients/AlgalAssayAvailP.pdf
>
> Lee, G. F., "Assessing Algal Available Phosphorus," Submitted for Inclusion in the Proceedings of US EPA Science Symposium: "Sources, Transport, and Fate of Nutrients in the Mississippi River and Atchafalaya River Basins," Minneapolis, MN, November 7-9 (2006).
> http://www.gfredlee.com/Nutrients/AvailPEPASymp06.pdf
>
> Lee, G. F., and Jones-Lee, A., "Assessing the Water Quality Significance of N & P Compound Concentrations in Agricultural Runoff," Invited Paper Presented at Agrochemical Division, American Chemical Society National Meeting, San Francisco, CA, September (2006).
> http://www.gfredlee.com/Nutrients/N-PRunoffACS.pdf

It is the algal-available P load to the Delta –soluble ortho P as well as algal-cell phosphorus – that needs to be the focus of phosphorus control programs to control excessive algal growth in Delta waters.

Pages 8-162 & 8-163 present a discussion of organic carbon. That discussion should include the findings reported in:

> Lee, G. F., "Synopsis of G. Fred Lee and Anne Jones-Lee's Work on Domestic Water Supply Water Quality, and TOC Issues in the Sacramento/San Joaquin River Delta," Report of G. Fred Lee & Associates, El Macero, CA (2004).
> http://www.gfredlee.com/SJR-Delta/GFL-DeltaTOCWork.pdf
>
> Lee, G. F. and Jones-Lee, A., "Issues that Need to Be Considered in Evaluating the Sources and Potential Control of TOC that Leads to THMs for Water Utilities that Use Delta Water as a Water Supply Source," Report of G. Fred Lee & Associates, El Macero, CA, May (2003).
> http://www.gfredlee.com/SJR-Delta/TOC_update.pdf

Pages 8-164 devoted to pesticides fails to mention the comprehensive review of the organochlorine legacy pesticides such as DDT that are still present in Delta tributary soils and sediments and contribute to the presence of some of these pesticides in some fish in the Delta and Delta tributaries in concentrations that represent a threat to human health. These issues are reviewed in:

> Lee, G. F. and Jones-Lee, A., "Organochlorine Pesticide, PCB and Dioxin/Furan Excessive Bioaccumulation Management Guidance," California Water Institute Report TP 02-06 to the California Water Resources Control Board/Central Valley Regional Water Quality Control Board, 170 pp, California State University Fresno, Fresno, CA, December (2002).
> http://www.gfredlee.com/SurfaceWQ/OClTMDLRpt12-11-02.pdf
>
> Lee, G. F., and Jones-Lee, A., “Update of Organochlorine (OCl) ‘Legacy’ Pesticide and PCB Concentrations in Delta and Central Valley Fish,” Report of G. Fred Lee & Associates, El Macero, CA, September 10 (2007).
> http://gfredlee.com/SurfaceWQ/UpdateLegacyPestCVFish.pdf

While OEHHA has been finding that DDT concentrations in Central Valley fish are decreasing they remain sufficiently high in some fish to be of human health concern.

> Lee, G. F. and Jones-Lee, A., "Organochlorine Pesticide, PCB and Dioxin/Furan Excessive Bioaccumulation Management Guidance," California Water Institute Report TP 02-06 to the California Water Resources Control Board/Central Valley Regional Water Quality Control Board, 170 pp, California State University Fresno, Fresno, CA, December (2002).
> http://www.gfredlee.com/SurfaceWQ/OClTMDLRpt12-11-02.pdf
>
> Lee, G. F., and Jones-Lee, A., “Update of Organochlorine (OCl) ‘Legacy’ Pesticide and PCB Concentrations in Delta and Central Valley Fish,” Report of G. Fred Lee & Associates, El Macero, CA, September 10 (2007).
> http://gfredlee.com/SurfaceWQ/UpdateLegacyPestCVFish.pdf

Page 8-166 devoted to phosphorus fails to discuss key issues concerning the importance of phosphorus in impacting Delta water quality discussed above. Of particular importance is the work of vanNieuwenhuyse (2007) that found that when the phosphorus load to the Delta was decreased, the phytoplankton concentrations also decreased.

Page 8-173 begins Section 8.4.2 Determination of Effects. The comments presented below concerning this section focus on the BDCP's assessment of the impacts of the proposed BDCP diversion of Sacramento River water around the Delta on Delta water quality as presented in 8.4.3.9 Alternative 4 – Dual Conveyance with Modified Pipeline/Tunnel and Intakes 2, 3, and 5 (9,000 cfs; Operational Scenario H) that begins on page 8-407. These comments are also applicable to the other identified alternatives identified in the document.

Page 8-173Section 8.4.2.1 Screening Analysis and Results beginning on line 16 states:
"This water quality analysis assessed the potential effects of implementing the various alternatives on 182 constituents (or classes of constituents). The initial analysis of water quality effects, referred to as the "screening analysis" in the Methods of Analysis section (above) resulted in the following findings. Of the 182 constituents, 110 were determined to have no potential to be adversely affected by the alternatives to an extent to which adverse environmental effects would be expected. Historical data for these constituents showed no exceedances of water quality objectives/criteria in the major Delta source waters, were not on the State's 303(d) list in the affected environment, were not of concern based on professional judgment or scoping comments, and had no potential for substantial long-term water quality degradation. Consequently, no further analyses were performed for these 110 constituents."

The approach described for excusing particular constituents from further consideration of impact was imprudent. Such disregard may well result in not considering water quality parameters that are present in one or more of the Delta channels at concentrations just under current water quality criteria/standards/objectives and may well be of concern once the Sacramento River flow is reduced as proposed, and under future revisions of the US EPA water quality criteria, state of California water quality objectives, and regional boards' basin plan objectives. Further it is well-recognized that some of the current water quality criteria, state standards, and Basin Plan objectives are not protective of the beneficial uses of water. Also the BDCP approach for selecting the chemical constituents for analysis of impacts of diverting Sacramento River flow ignores the well established facts of additive and syngistic impacts of chemical where two or more chemicals that exist at less than toxic concentrations can be combined to cause toxicity.

As summarized in writings referenced in Appendix A, Dr. Lee has extensive experience in developing water quality criteria and state standards, and in their implementation in discharge limits for the protection of beneficial uses of waterbodies. On numerous occasions he has been asked to serve as an independent technical peer-reviewer of federal and state water quality criteria and standards. He and Dr. Jones-Lee have published several papers and reports on their work and findings in these areas including:

> Lee, G. F., and Jones-Lee, A., "Clean Water Act, Water Quality Criteria/Standards, TMDLs, and Weight-of-Evidence Approach for Regulating Water Quality," Water Encyclopedia: Water Law and Economics, Wiley, Hoboken, NJ, pp 598-604 (2005).
> http://www.gfredlee.com/SurfaceWQ/WileyCleanWaterAct.pdf
>
> Lee, G. F. and Jones-Lee, A., "Appropriate Use of Numeric Chemical Water Quality Criteria," Health and Ecological Risk Assessment, 1:5-11 (1995).
> http://www.gfredlee.com/SurfaceWQ/chemcri.pdf

Lee, G. F., Jones, A., and Newbry, B., "Water Quality Standards and Water Quality," Journ. Water Pollut. Control Fed. 54(7):1131-1138 (1982). http://www.gfredlee.com/SurfaceWQ/WQStds-WaterQuality.pdf

The draft BDCP EIR/EIS discussion of anticipated water quality impacts of the proposed plan did not appropriately or adequately address the fact that the concentrations and distribution/locations of regulated and unregulated/inadequately regulated chemicals, whether or not they have or are presently known to exceed regulatory limits, will be expected to be altered by the diversion of large amounts of Sacramento River water around the Delta. This will be expected to affect the water quality impacts of regulated and unregulated/inadequately regulated chemicals in Delta waters. The BDCP's dismissing from further analysis of potential water quality effects, constituents that it concluded based on inadequate evaluation and without appropriate attention to the impact of the loss of Sacramento River water to the system, had not exceeded water quality objectives/criteria in the major Delta source waters, were not on the State's 303(d) list in the affected environment, or were not of concern, renders the draft EIR/EIS fundamentally flawed. That flaw alone is sufficiently significant to merit the denial of certification of this draft EIR/EIS.

As discussed in our review of the Delta Water Quality report cited below, as part of SWRCB water rights decision D-1641, several agencies, through the Interagency Ecological Program (IEP), conduct an Environmental Monitoring Program (EMP) that is supposed to provide information on the impacts of Delta water exports to central and Southern California on Delta resources and water quality.

Lee, G. F. and Jones-Lee, A., "Overview of Sacramento-San Joaquin River Delta Water Quality Issues," Report of G. Fred Lee & Associates, El Macero, CA (2004). http://www.gfredlee.com/SJR-Delta/Delta-WQ-IssuesRpt.pdf

A critical review of the IEP EMP, however, shows that it falls short of adequately defining the full range of water quality impacts of the export of Delta water by the federal project (Central Valley Project – CVP) and state project (State Water Project – SWP). In 2004 Dr. Lee was a member of the peer-review panel that reviewed the adequacy of the IEP water quality monitoring program. In that forum he pointed out that that program was highly deficient in providing the information needed to evaluate the impacts of the SWP diversions on Delta water quality. His comments were ignored, and even today large amounts of money continue to be spent on Delta monitoring but are not directed to the stated purpose of the D-1641 water rights decision that allowed the SWP to divert large amounts of water from the Delta.

The CVRWQCB and SWRCB have been trying for several years, without success, to develop a comprehensive Delta water quality monitoring program. The basic problem is a lack of funding for such a program. If the BDCP-proposed Delta diversion project is allowed to be implemented, those benefiting from the project should be required to fund a comprehensive water quality monitoring program to adequately define the impacts of that diversion on Delta water quality.

Page 8-407 begins the discussion of Section 8.4.3.9, Alternative 4 – Dual Conveyance with Modified Pipeline/Tunnel and Intakes 2, 3, and 5 (9,000 cfs; Operational Scenario H). This section states, "Alternative 4 would comprise physical/structural components similar to those under Alternative 1A, however, there are notable differences. Alternative 4 would convey up to 9,000 cfs of water from the north Delta to the south Delta and that Alternative 4 would include an operable barrier at the head of Old River. Diverted water would be conveyed through pipelines/tunnels from three screened intakes (i.e., Intakes 2, 3 and 5) located on the east bank of the Sacramento River between Clarksburg and Courtland. Alternative 4 would include a 245 acre intermediate forebay at Glannvale Tract. Clifton Court Forebay would be dredged and expanded by approximately 690 acres to the southeast of the existing forebay. Water supply and conveyance operations would follow the guidelines described as Scenario H1, H2, H3, or H4, which variously include or exclude implementation of fall X2 and/or enhanced spring outflow. Conservation Measures 2–22 would be implemented under this alternative, and would be the same as those under Alternative 1A."

The subsection, "Effects of the Alternative on Delta Hydrodynamics," begins on page 408 with: *"Under the No Action Alternative and Alternatives 1–9, the following two primary factors can substantially affect water quality within the Delta:*

- *Within the south, west, and interior Delta, a decrease in the percentage of Sacramento River-sourced water and a concurrent increase in San Joaquin River-sourced water can increase the concentrations of numerous constituents (e.g., boron, bromide, chloride, electrical conductivity, nitrate, organic carbon, some pesticides, selenium). This source water replacement is caused by decreased exports of San Joaquin River water (due to increased Sacramento River water exports), or effects of climate change on timing of flows in the rivers. Changes in channel flows also can affect water residence time and many related physical, chemical, and biological variables.*

- *Particularly in the west Delta, sea water intrusion as a result of sea level rise or decreased Delta outflow can increase the concentration of salts (bromide, chloride) and levels of electrical conductivity. Conversely, increased Delta outflow (e.g., as a result of Fall X2 operations in wet and above normal water years) will decrease levels of these constituents, particularly in the west Delta."*

As discussed in these comments, not only would the concentrations of the mentioned constituents increase with increases in the proportion of San Joaquin River water but also the concentrations of many other known pollutants as well as unregulated, unrecognized and inadequately regulated pollutants be increased. For some constituents the concentrations would be expected to increase in some Delta channels to levels in excess of water quality objectives and in some cases significantly impact Delta water quality. The draft EIR/EIS is deficient in that it fails to address this issue. Also, decreases in the amount of Sacramento River water in the Delta will result in changes in the areas in which adverse impacts on Delta channel water quality occur.

The draft EIR EIS fails to mention that increasing the concentrations of pollutants that are already causing water quality objectives is a violation of SWRCB/CVRWQCB antigradation issues that preclude degrading existing water quality of causing a degradation of water quality that causes and water quality objective violation.

Page 8-432 lines 39-43 and page 8-433 lines 1-2 state, *“Amounts of oxygen demanding substances present (e.g., ammonia, organics) in the reservoirs and rivers upstream of the Delta, rates of photosynthesis (which is influenced by nutrient levels/loading), and respiration and decomposition of aquatic life is not expected to change sufficiently under Alternative 4 to substantially alter DO levels relative to Existing Conditions or the No Action Alternative. Any minor reductions in DO levels that may occur under this alternative would not be expected to be of sufficient frequency, magnitude and geographic extent to adversely affect beneficial uses, or substantially degrade the quality of these water bodies, with regard to DO.”*

That assessment ignores the importance of Sacramento River water currently drawn into the Delta by the current export projects, CVP and SWP, in the existing DO levels in the Delta, and the effect on DO that the reduction of that flow as proposed would have. As discussed in the synthesis report cited below, the flow of the Sacramento River water through the Delta limits the downstream extent of the low-DO conditions in the SJR DWSC to Turner Cut. With the reduced Sacramento River flow into the Central Delta as proposed, the lower SJR DWSC could experience low-DO conditions.

> Lee. G. F., and Jones-Lee, A., "Synthesis and Discussion of Findings on the Causes and Factors Influencing Low DO in the San Joaquin River Deep Water Ship Channel near Stockton, CA: Including 2002 Data," Report Submitted to SJR DO TMDL Steering Committee/Technical Advisory Committee and CALFED Bay-Delta Program, G. Fred Lee & Associates, El Macero, CA, March (2003). http://www.gfredlee.com/SJR-Delta/SynthesisRpt3-21-03.pdf

As discussed in our reports the current operation of the CVP and SWP draws SJR water that enters the DWSC to the export pumps at Turner Cut. This has important implications for the homing of Chinook Salmon to SJR watershed spawning waters since there is no homing signal as the fish enter San Francisco Bay/Delta to guide them to their home stream waters. We have discussed this issue in,

> Lee, G. F., and Jones-Lee, A., “Need for SJR Watershed Water to Reach San Francisco Bay,” Comments submitted to Delta Stewardship Council, Sacramento, CA by G. Fred Lee & Associates, El Macero, CA, May 22 (2011).
> http://www.gfredlee.com/SJR-Delta/NeedSJRtoSFBay.pdf

Page 8-433 lines 13 through 21 state,
Under all operational scenarios of Alternative 4, minor DO level changes could occur due to nutrient loading to the Delta relative to Existing Conditions and the No Action Alternative (see WQ-1, WQ-15, WQ-23). The state has begun to aggressively regulate point-source discharge effects on Delta nutrients, and is expected to further regulate nutrients upstream of and in the Delta in the future. Although population increased in the affected environment between 1983 and 2001, average monthly DO levels during this period of record show no trend in decline in the presence of presumed increases in anthropogenic sources of nutrients (see Table 4.4-15 in the ES/AE section). Based on these considerations, excessive nutrients that would cause low DO levels would not be expected to occur under any operational scenario of Alternative 4.

Based on Dr. Lee’s more than five decades of experience assessing the impacts of nutrients on DO in waterbodies throughout the world and his 25 years of experience in investigating nutrient

sources and impacts in the Delta watershed and within the Delta, it is misleading to characterize the current SWRCB efforts in developing nutrient objectives as having *“begun to aggressively regulate”* nutrient discharges. It will be many years before reliable and workable nutrient objectives will be available that can be used to regulate nutrient discharges from agricultural sources in the Delta watershed. As discussed above the major cause of the residual oxygen demand and low-DO in the SJR DWSC is nutrient input from upstream agricultural sources that stimulates the growth of algae in the DWSC which because of the flow-related residence time, are able to decompose in the DWSC where their bacterial decomposition exerts greater oxygen demand than can be assimilated.
We have developed several paper/reports on the impact of and controlling nutrients in SJR watershed including.

> Lee, G. F., and Jones-Lee, A., “Potential Water Quality Impacts of Agriculture Runoff/Discharges in the Central Valley of California,” Presented at Central Coast Agricultural Water Quality Coalition’s 2007 National Conference on Agriculture & the Environment, Monterey, CA, PowerPoint Slides, G. > http://www.gfredlee.com/SJR-Delta/CWEMF_Workshop_Agenda.pdf

An issue that needs to be addressed by the SWP is the low-DO situation that occurs in the southern-most part of Old River channel in the South Delta in the vicinity of the Tracy Boulevard Bridge. The SWP export pumping of South Delta water resulted in major flow problems in the South Delta. The temporary barriers constructed to try maintain the water levels in the South Delta channels to enable agriculture to continue to pump irrigation water from the channel have restriced the flow in the southern-most part of Old River channel sufficiently to allow large-scale algal growth and die-off leading to low DO in the channel. As part of an extension of the SJR DWSC Low-DO TMDL project, we organized a boat tour of the South Delta channels on August 5, 2004. The DeltaKeeper (Bill Jennings) made available a DK boat and crew that enabled several members of the CVWQCB and CalFed staff to accompany Lee on this tour. During the tour the evidence of a large fish kill that had occurred the evening before was observed near the Tracy Blvd Bridge; hundreds of dead fish were observed floating on the surface of the water. The DWR maintains a DO monitoring station in the region of the fish kill, which showed that the previous night the DO in the channel dropped to near-zero. A report on that tour and the fish kill is presented in,

> Lee, G. F.; Jones-Lee, A. and Burr, K., "Results of the August 5, 2003,Tour of the South Delta Channels," Report of G. Fred Lee & Associates, El Macero, CA, February (2004).

http://www.gfredlee.com/SJR-Delta/South-Delta-Tour.pdf

Lee, G. F., "Comments on SWRCB Review of South Delta Channel Water Quality," Report of G. Fred Lee & Associates, El Macero, CA, January 15 (2011). http://www.gfredlee.com/SJR-Delta/SoDeltaWQ1-11.pdf

Review of the data from the DWR monitoring station at that location shows frequent DO water quality objective violations occurred in this channel. That situation has been occurring for many years. It is clear that DWR as part of the SWP should be required to eliminate the low-DO problems that occur in the South Delta as a result of the operation of the SWP.

The low DO in the Old River channel is the result of high nutrient and algal lows in SJR that enters Old River at the Head of Old River and the lack of adequate flow of the channel due to the barrier constructed to maintain water levels in the Old River Channel.

Page 8-435 lines 17-20 states with regard to NEPA Effects:
"CM2–CM22 would not be expected to contribute to adverse DO levels in the Delta. The increased habitat provided by CM2–CM11 could contribute to an increased biochemical or sediment demand, through contribution of organic carbon and the action of plants decaying. However, similar habitat exists currently in the Delta and is not identified as contributing to adverse DO conditions."

Dr. Lee has considerable experience in examining the character of water discharged from wetlands; he conducted some of the first work done on the impacts of wetlands on water quality, which was discussed in the following paper:

Lee, G. F., Bentley, E., and Amundson, R., "Effects of Marshes on Water Quality," IN: Ecological Studies 10, Coupling of Land and Water Systems, Springer-Verlag, New York, pp. 105-127 (1975). http://www.gfredlee.com/SurfaceWQ/MarshesBentleyAmundson.pdf

Based on the monitoring programs and studies that have been conducted in the Delta, it is inappropriate to use the range of DO found in low-flow channels that receive predominately tidal flow from wetlands. The development of wetlands as part of establishing addition shallow habitat as part of the proposed BDCP Delta improvement.

Page 8-435 lines 25-27 states:
"CM14, an oxygen aeration facility in the Stockton Deep Water Ship Channel to meet TMDL objectives established by the Central Valley Water Board, would maintain DO levels above those that impair fish species when covered species are present."

As discussed elsewhere in these comments, the implementation of an aeration facility in the SJR DWSC to eliminate DO water quality objectives since the funding for construction and operation is not available. Further there is significant questions about whether the proposed aeration facility can prevent DO depletions below the water quality objective especially in the near bottom waters of the DWSC so that there are no more than one violation of the DO objective in any amount more than once every three years.

Page 8-440 lines 44-45 and page 8-441 lines 1-3 states:
"In addition to and to supplement Mitigation Measure WQ-11, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, Environmental Commitments, a separate, non-environmental commitment to address the potential increased water treatment costs that could result from EC concentration effects on municipal, industrial and agricultural water purveyor operations."

While it may be possible to pay water utilities and agricultural interests as compensation for impact of increased salinity due to the diversion of Sacramento River around the Delta, an issue that needs to be considered is the impact of increased salinity in domestic waters on the recharge of domestic wastewaters. An increase in the salinity in a municipality's water supply can lead to restrictions on the recharge of its domestic wastewaters as part of groundwater replenishment projects. This is already an issue in the use of Delta waters as a water supply for some Southern California municipalities. It can be very expensive to treat a domestic wastewater to achieve groundwater recharge limits.

Page 8-447-261. The section on the Effects of Nitrate Concentrations Resulting from Facilities Operations and Maintenance (CM1) that begins on line 13 needs to be expanded to include the impact of the CVRWQCB's recent adoption of reduced nitrate loads to the SJR and Delta from the Stockton waste water treatment plant.

Page 8-407 line 32 begins the presentation of Section 8.4.3.9 Alternative 4 – Dual Conveyance with Modified Pipeline/Tunnel and Intakes 2, 3, and 5 (9,000 cfs; Operational Scenario H). Many of the issues discussed above in reference to Alternative 4 are applicable to all of the alternatives involved in diversion of Sacramento River water around the Delta. While the relative reduction in the amount of diversion could be expected to lessen or increase the magnitude of some of the impacts, those impacts would still need to be better defined.

Page 8-700 line 28 begins the discussion of 8.4.3.16 Alternative 9—Through Delta/Separate Corridors (15,000 cfs; Operational Scenario G). The diversion of Sacramento River water through the Delta via isolated facilities would lead to many of the same adverse impacts noted above for diversion of Sacramento River water around the Delta via tunnels and or canals.

Page 8-771 line 15 begins a list of references for this draft EIR/EIS. While the list of references is voluminous, as noted in these comments there are a number of key, pertinent papers and reports not included in this list that should have been reviewed, discussed, and referenced in a certifiable EIR/EIS for the proposed BDCP project. The exclusion of those sources contributed to the deficiencies discussed in these comments.

Additional Comments

The limitations of the ability of DWR to provide reliable information on flow of water in Delta channels occurred when we were trying to understand the flow of Sacramento River and the San Joaquin River through the Central Delta as part of our work on SJR DWSC Low-DO TMDL project. We were unable to obtain from DWR modeling staff the respect flows in the Central Delta channels as a function of SJR, Sacramento River, Old River flows and export pumping by the CVP SWP. This situation still exists today. This is the type of information that is needed to begin to reliably evaluate the impact of diversion of Sacramento River flow around or through the Delta.

MBK Engineers conducted a detailed review of BDCP modeling; Walter Bourez of MBK Engineers presented to the DISB his findings on one of the models used in the BDCP draft EIR/EIS which differed from those presented by BDCP. (He used a 2013 version of the model, rather than the 2009 model BDCP used.)

MBK Engineers concluded in its presentation to the Delta Independent Science Board (2014), *"An initial review led the Reviewers to conclude that the BDCP Model, which serves as the basis for the environmental analysis contained in the BDCP Environmental Impact Report/Statement (EIR/S), provides very limited useful information to understand the effects of the BDCP. The BDCP Model contains erroneous assumptions, errors, and outdated tools, which result in impractical or unrealistic Central Valley Project (CVP) and State Water Project (SWP) operations. The unrealistic operations, in turn, do not accurately depict the effects of the BDCP."*
MBK Engineers presentation to Delta Independent Science Board (2014)

The Delta Independent Science Board (DISB) is required by the Delta Reform Act of 2009 to review the BDCP draft EIR/EIS and to submit its comments to the Delta Stewardship Council and the Department of Fish and Game. In its May 15, 2014 cover letter transmitting its comments pursuant to that requirement [http://deltacouncil.ca.gov/sites/default/files/documents/files/Attachment-1-Final-BDCP-comments.pdf], the DISB acknowledged the monumental task faced by the preparers of the draft EIR/EIS but expressed the following conclusion:
"We find, however, that the science in this BDCP effort falls short of what the project requires. We highlight our concerns in the attached report. The report, in turn, draws on our detailed responses to charge questions from the Delta Stewardship Council (Appendix A) and on our reviews of individual chapters in the DEIR/DEIS (Appendix B). Our concerns raise issues that, if not addressed, may undermine the contributions of BDCP to meeting the co-equal goals for the Delta."

The DISB report transmitted by that letter, cited below, begins with the following summary:

"Summary of Major Concerns
Does the Bay Delta Conservation Plan (BDCP) Draft EIR/EIS (DEIR/DEIS) use the best available science in analyzing project alternatives and their effects? That is, do the analyses use science that is good enough, and use it well enough, for a project that is so large, complex, expensive, long-lasting, and important?

We find that the DEIR/DEIS currently falls short of meeting this "good enough" scientific standard. In particular:
1. Many of the impact assessments hinge on overly optimistic expectations about the feasibility, effectiveness, or timing of the proposed conservation actions, especially habitat restoration.
2. The project is encumbered by uncertainties that are considered inconsistently and incompletely; modeling has not been used effectively to bracket a range of uncertainties or to

explore how uncertainties may propagate.
3. The potential effects of climate change and sea-level rise on the implementation and outcomes of BDCP actions are not adequately evaluated.
4. Insufficient attention is given to linkages and interactions among species, landscapes, and the proposed actions themselves.
5. The analyses largely neglect the influences of downstream effects on San Francisco Bay, levee failures, and environmental effects of increased water availability for agriculture and its environmental impacts in the San Joaquin Valley and downstream.
6. Details of how adaptive management will be implemented are left to a future management team without explicit prior consideration of (a) situations where adaptive management may be inappropriate or impossible to use, (b) contingency plans in case things do not work as planned, or (c) specific thresholds for action.
7. Available tools of risk assessment and decision support have not been used to assess the individual and combined risks associated with BDCP actions.
8. The presentation, despite clear writing and an abundance of information and analyses, makes it difficult to compare alternatives and evaluate the critical underlying assumptions."

> Delta Independent Science Board, "Review of the Draft EIR/EIS and Draft BDCP," Report to the Delta Stewardship Council and California Department of Fish and Wildlife, May 15 (2014).

Comments made to the Delta Stewardship Council by Dr. Alex Parker of the California Maritime Academy and a member of the independent science review panel of the BDCP's Effects Analysis established at the request of the Department of Water Resources and the Bureau of Reclamation concerning the technical aspects of the plan were quoted in a June 3, 2014 posting on: http://mavensnotebook.com/2014/06/03/reviewing-the-science-of-the-bay-delta-conservation-plan/. That posting stated:
"Dr. Parker said he would just provide the highlights of their analysis and the major themes that emerged as a result of their review. 'We are heartened to see that the Delta Independent Science Board review of the draft BDCP and the EIR/EIS echoed a lot of our concerns, and I think that probably highlights for folks the areas where attention needs to be paid.'

He said there were four themes that emerged for the panel: [two of which are quoted here:]

- *The first is a real disconnect between the assessments of scientific certainty or uncertainty that is reflected in the Effects Analysis chapter versus what is in technical appendices, he said. 'This was a concern to us because we know that with a set of documents this vast, most people are going to read the Effects Analysis and not the technical appendices. There's a real concern that the effects analysis doesn't adequately address that level of uncertainty around virtually all of the conclusions that are made.'*
- *The implementation of the BDCP and its effects are highly uncertain, so the way to address this is through adaptive management, he said. 'It is part of the plan; however the Effects Analysis needs to really clearly articulate the uncertainty in order to have an effective adaptive management process and at present, that simply doesn't exist within the main document.'"*

"Another place where this [a lack of a whole ecosystem approach in the BDCP effects analysis] is clear to us is with respect to hydrodynamics modeling, Dr. Parker said. 'Hydrodynamics is

basically the movement of water, and this is a master variable in the system,' he said. 'If we want to have any conversation about circulation patterns, temperatures, submerged aquatic vegetation, contaminants, nutrients – we need to have reasonable modeling of the hydrodynamic system, and because we don't know where the restoration opportunity areas are necessarily defined in all cases – these are places where major conservation and restoration activities will take place – they were limited in what they could model in terms of hydrodynamics. That wasn't adequately acknowledged throughout, and again, raises high level of uncertainty in the ultimate analysis.' He also noted there were some counterintuitive results from some of the hydrodynamic modeling that was done there, but there wasn't sufficient information to really understand where those results came from."

Those conclusions concerning the lack of a reliable database and Delta flow information to develop a credible EIR/EIS for the BDCP for assessing the impacts of the diversion of Sacramento River water around or through the Delta, are in keeping with a number of the specific comments made by us independently above.

Comments on Chapter 25 – Public Health

Page 25-1 line 3 states, *"This chapter focuses on issues related to human health and safety that could potentially be affected by implementation of the BDCP alternatives, particularly with respect to water quality, the potential to cause or worsen water borne illness, the potential to create habitat for vectors that may carry diseases; and to address potential health related concerns from additional electric transmission lines needed under most of the alternatives."*

Page 25-1 lines 20-22 states, *"This chapter does not duplicate the information provided in other sections of the EIR/EIS, but rather focuses the discussion on potential impacts on human health of implementing the BDCP action alternatives."* Our comments on those bioaccumulating constituents in Chapter 8 are also applicable to the same constituents covered in Chapter 25.

Page 25-4 lines 9-11 states, *"Please see Chapter 8, Water Quality, Section 8.1.3.13, Pesticides and Herbicides, for a detailed discussion on the prior use of legacy pesticides in the Plan Area."* As discussed in our comments on those sections of Chapter 8, the BDCP draft EIS EIR is deficient as it fails to adequately discuss the readily available compilation data of organochlorine pesticides and PCBs in Delta and Central Valley water and fish developed and discussed by Lee and Jones-Lee.

Page 25-6 presents information on some of the sources of mercury in the Delta watershed. In addition to those mentioned, another tributary source of mercury is the Putah Creek. The findings of Lee and Jones-Lee's study of the current situation regarding mercury in Putah Creek have been published as,

> Lee, G. F., and Jones-Lee, A, "LEHR Superfund Stormwater Runoff and Putah Creek Mercury Issues," *Journal Remediation*, **19(2)**:123-134, Spring (2009). http://www.gfredlee.com/SJR-Delta/LEHRrunoffHgRemediation.pdf
>
> Lee, G. F., and Jones-Lee, A., "Summary of Slides – Putah Creek Mercury Water Quality Issues," Report of G. Fred Lee & Associates, El Macero, CA, Presented to Delta Tributaries Mercury Council, December 2 (2008).

http://www.gfredlee.com/SJR-Delta/PutahHgMineSummary.pdf

Lee, G. F., and Jones-Lee, A., "Runoff of Mercury from UCD/DOE LEHR Superfund Site – Putah Creek Mercury Issues," PowerPoint Slides for Presentation to Delta Mercury Tributaries Council, Sacramento River Watershed Program [http://www.sacriver.org/issues/mercury/dtmc/], December 2 (2008). http://www.gfredlee.com/SJR-Delta/PutahHgMinesli.pdf

As discussed in those papers and reports, soils along Putah Creek are polluted with mercury that accumulates in fish tissue. The source of that mercury is mercury mines in the creek's watershed. Before the Lake Berryessa dam was constructed, stormwater runoff from the Putah Creek watershed transported mercury from former mercury mines to the Putah Creek flood plain. It will be very difficult to remediate the mercury-polluted soils along Putah Creek, and thus difficult to reduce the Putah Creek as source of mercury for the Delta.

Page 25-7 section on PCBs makes reference to deVlaming (2008). More reliable sources of information on PCBs in Delta tributaries and Delta water and fish are those included in the reports:

Lee, G. F., and Jones-Lee, A., "Update of Organochlorine (OCl) 'Legacy' Pesticide and PCB Concentrations in Delta and Central Valley Fish," Report of G. Fred Lee & Associates, El Macero, CA, September 10 (2007). http://gfredlee.com/SurfaceWQ/UpdateLegacyPestCVFish.pdf

Lee, G. F., "Need for Funding to Support Studies to Control Excessive Bioaccumulation of Organochlorine 'Legacy' Pesticides, PCBs and Dioxins in Edible Fish in the Central Valley of California," Report of G. Fred Lee & Associates, El Macero, CA, July (2003). http://www.gfredlee.com/Runoff/OCl_Support.pdf

Lee, G.F, and Jones-Lee, A., "Developing TMDLs for Organochlorine Pesticides and PCBs," Presented at the American Chemical Society Environmental Chemistry Division national meeting in San Diego, California, April (2001). http://www.gfredlee.com/Runoff/sandiego_030801.pdf

Lee, G. F. and Jones-Lee, A., "Excessive Bioaccumulation of Organochlorine Legacy Pesticides & PCBs in CA Central Valley Fish," PowerPoint Slides made available at US EPA National Fish Contaminant Forum, San Diego, CA, January (2004). http://www.gfredlee.com/Runoff/OCl-slides-SanDiego.pdf

Page 25-7 devoted to Legacy Pesticides failed to reference the reports of Lee's comprehensive review of legacy pesticides in Delta and Central Valley fish on behalf of the SWRCB and CVRWQCB; those reports were referenced in the comments above on draft EIR/EIS Chapter 8.

Page 25-8 lines 17-21 states, *"In March 2004, the U.S. Food and Drug Administration (FDA) issued recommendations for the consumption of fish or shellfish for women who might become pregnant, women who are pregnant or nursing, and young children (no other sensitive receptors were identified). While FDA states fish and shellfish are an important part of a healthy diet,* *nearly all fish and shellfish contain trace amounts of mercury (U.S. Food and Drug Administration 2011). However, some species contain higher amounts of the toxicant, and thus it is not recommended that women who might become pregnant, women who are pregnant or nursing, or young children eat shark, swordfish, king mackerel, or tilefish. None of these species are commonly found in the Delta. Further, local advisories should be checked for the safety of locally caught fish and if these advisories are unavailable, the weekly consumption of fish or shellfish species should be limited."* As discussed in US EPA guidance referenced below, it is highly inappropriate to compare Delta or other waterbody fish tissue concentration to FDA tissue limits for the purpose of assessing the health hazard associated with consuming those fish.

> US EPA, "Guidance for Assessing Chemical Contaminant Data for Use in Fish Advisories, Volume 1 Fish Sampling and Analysis, Third Edition," EPA 823-B-00-007, US EPA Office of Water, Washington, DC, November (2000).
> USEPA_2000_Guidance_Document_volume2.pdf

As stated in the above-referenced US EPA guidance,
"EPA and FDA have agreed that the use of FDA Action Levels for the purpose of making local advisory determinations is inappropriate. in letters to all states, guidance documents, and annual conferences, this practice has been discouraged by EPA and FDA in favor of EPA's risk-based approach to derive local fish consumption advisories."

"FDA action levels and tolerances are indicators of chemical residue levels in fish and shellfish that should not be exceeded for the general population who consume fish and shellfish typically purchased in supermarkets or fish markets that sell products that are harvested from a wide geographic area, including imported fish and shellfish products. However, the underlying assumptions used in the FDA methodology were never intended to be protective of recreational, tribal, ethnic, and subsistence fishers who typically consume larger quantities of fish than the general population and often harvest the fish and shellfish they consume from the same local waterbodies repeatedly over many years."

The US EPA guidelines or the California Office of Environmental Health Hazard Assessment (OEHHA) fish consumption advisory values should be used to determine the potential public health hazards associated with consumption of contaminated fish.

Page 25-24 lines 33-34 states, *"The CWA sets water quality standards for all contaminants in surface waters. In California, such responsibility has been delegated to the State, which administers the CWA through the Porter-Cologne [Water Quality Control] Act (Water Code, Section 13000 et seq.)."* As discussed in reviews cited below, the Clean Water Act establishes the approach for establishing water quality criteria that can be developed into state water quality standards. Contrary to the BDCP's statement quoted above, the CWA does not "set water quality standards for all contaminants."

> http://www.gfredlee.com/exp/wqexp.htm
>
> Lee, G. F., and Jones-Lee, A., "Clean Water Act, Water Quality Criteria/Standards, TMDLs, and Weight-of-Evidence Approach for Regulating Water Quality," Water Encyclopedia:

Water Law and Economics, Wiley, Hoboken, NJ, pp 598-604 (2005).
http://www.gfredlee.com/SurfaceWQ/WileyCleanWaterAct.pdf

Page 25-36 lines 6-8 states, discussed in Chapter 8, Water Quality (Section 8.1.1.6), numerical water quality objectives and standards have been established to protect beneficial uses, and therefore represent concentrations or values that should not be exceeded. “That statement is not accurate in that water quality objectives and standards can be exceeded once every three years.

Page 25-36 Section 25.3.1.3 Constituents of Concern and Water Quality again describes the approach used for the draft BDCP EIR/EIS to identify the constituents of concern, that is limiting the constituents considered to those that have been found to be present in concentrations above a water quality object or other standard. As discussed in our comments on Chapter 8 above, this approach is not technically valid for identifying all the constituents that need to be considered in evaluating potential water quality and public health impacts of the proposed BDCP.

As discussed above in the overall assessment, there is insufficient valid information to reliably evaluate the impact of diverting Sacramento River around or through the Delta on water quality/beneficial uses of the Delta.

Appendix A

The following professional papers, reports, and presentations provide examples of Drs. Lee and Jones-Lee's experience in reviewing Delta water quality issues.

RE: Comment Letter No. 3: Bay Delta Conservation Plan and Associated EIR/EIS Related to Delta Smelt and Summer Outflow Protection

Dear Mr. Wulff,

The California Sportfishing Protection Alliance (CSPA) has reviewed the proposed Bay Delta Conservation Plan and associated Environmental Impact Report/Environmental Impact Statement (hereinafter, BDCP) submits the following comments. Comment Letter No. 3 relates to Delta smelt and summer outflow protection and includes a report, included below, titled *Delta Smelt on the Scaffold*, and an attached report titled, *The Summer of 2013, The demise of Delta smelt under D-1641 Delta Water Quality Standards.* The three documents constitute our comments on juvenile Delta smelt and we request that all three be considered and responded to as a single submittal.

CSPA worked closely with the Environmental Water Caucus (EWC) in developing their comments and incorporates by reference into these comments both submittals by the EWC on all issues related to BDCP. We also incorporate by reference the submittal by Michael Jackson on behalf of CSPA, California Water Impact Network and AquAlliance, as well as the individual comments submitted by AquAlliance. We further incorporate by reference the submittals by the County of San Joaquin, South Delta Water Agency, Central Delta Water Agency, Restore the Delta, Earth Law Center and Friends of the River.

The BDCP and the EIR/EIS inexplicable fail to acknowledge, analyze or discuss the presence of juvenile Delta smelt in the western Delta during summer and fail to acknowledge, analyze or discuss the preferred Alternative's potential adverse impacts on juvenile Delta smelt in July and August. Consequently, the BDCP and EIR/EIS are deficient and fail to comply with minimum CEQA and NEPA requirements for an environmental review document.

Since the start of Delta export pumping by the State Water Project in 1967, California Department of Fish and Wildlife (CDFW) Fall Midwater Trawl abundance indices for Delta smelt, striped bass, longfin smelt, American shad and threadfin shad have declined 95.6, 99.6, 99.8, 90.9, 98.5, 97.8 percent, respectively. The five-year abundances between 1967-1971 and

2009-2013 for Delta smelt, striped bass, longfin smelt, American shad and threadfin shad have declined 89.8, 98.8, 99.4, 87.7 and 98.1 percent, respectively. The abundance indices of CDFW's Summer Townet Survey for Delta smelt and striped bass declined 94.2 and 98.2 percent, respectively, between 1967 and 2013 and the five year average decline between 1967-1971 and 2009-2013 for Delta smelt and striped bass was 93.8 and 98.1 percent, respectively.

Of these pelagic species, Delta smelt are likely at serious risk of short-term extinction. Last year the Fall Midwater Trawl abundance index for Delta smelt was the second lowest in history, indistinguishable from the lowest. This year CDFW's 20-mm Survey 9 collected the fewest Delta smelt in history. Inexplicably, the BDCP and EIR/EIS virtually ignore the critical juvenile life-stage of Delta smelt in the summer months.

While there is extensive discussion of the impacts of entrainment (understating risks to eggs and sensitive life stages and impingement), predation (ignoring the project's creation of habitat favoring predators) and habitat area (based upon flawed optimistic projections of expanded habitat acreage) we could find no discussion regarding the significant impacts of near-lethal or lethal July-August temperatures and low June-August Delta outflows, with respect to juvenile life stages of Delta smelt. We also could not find substantial discussion of effects of low outflow during drier years and how low outflow, coupled with water exports, draws the low salinity zone (LSZ) into the western Delta. This omission is apparently based on the assumption that, since habitat conditions in the western Delta during the summer are not good for Delta smelt, they aren't there. Almost twenty years of 20-mm surveys demonstrate that this is simply not true. Low outflow conditions, coupled with exports, draw the LSZ and Delta smelt into the western Delta. At times, the majority of juvenile Delta smelt is in the western Delta in late June and early July.

The EIR/EIS acknowledges that outflow will decrease in summer months. Chapter 11, Fish and Aquatic Resources, Section 11.0.2.8, Alternative 4-Summary of Effects, states,

> *"SWP and CVP exports in summer months would increase and result in lower outflow under all four scenarios compared to No Action Alternative."* Page 11-52, lines 23-25.

The four evaluated operating scenarios of the preferred alternative included or excluded enhanced flows in spring or fall. Protective summer outflows were essentially ignored.

The Chapter 11, beginning on page 11-1289 describes the differences between the four scenarios of Alternative 4 as:

> *"Scenario H1 – Does not include enhanced spring outflow or Fall X2 requirements.*
>
> *Scenario H2 – includes enhanced spring outflow, but not Fall X2 requirements. This scenario lies within the range of the other scenarios.*

> *Scenario H3 – Does not include enhanced spring outflow, but includes Fall X2 requirements 16 (similar to Alternative 2A). This scenario lies within the range of the H1 and H4 scenarios.*
>
> *Scenario H4 – Includes both enhanced spring outflow requirements, and Fall X2 requirements."*
> Page 11-1290, Lines 13-18.

In discussing Impact AQUA-4: Effects of Water Operations on Spawning and Egg Incubation Habitat for Delta Smelt, the EIR/EIS states,

> *"**CEQA Conclusion**: As described above, operations under Alternative 4 would not reduce abiotic spawning habitat availability or change water temperatures for spawning delta smelt under any of the proposed flow scenarios. Consequently, the impact would be less than significant, and no mitigation is required."* Page 11-1295, lines 29-32

However, we could find no discussion regarding summer juvenile rearing impacts, except for a brief mention in the EIR/EIS's discussion of Impact AQUA-5; Effects of Water Operation on Rearing Habitat for Delta Smelt, which states,

> *"They also concluded that water temperature was not a predictor of delta smelt presence in the fall, although it has been shown to be important during summer months (Nobriga et al. 2008)."* Page 11-1296, Lines 11-13.

Chapter 5 of BDCP Effects Analysis seems to imply that Delta smelt cannot by found in areas of the Delta where key habitat attributes are not met. It states;

> *"During summer, water temperatures can reach stressful if not lethal levels in parts of the estuary (Nobriga et al. 2008), a trend that is anticipated to worsen given projected climate warming (Brown et al. 2013). Further, the interaction of water temperature and prey density is a widely agreed-upon constraint on delta smelt (Kimmerer 2008; Mac Nally et al. 2010; Maunder and Deriso 2011; Miller et al. 2012; Rose et al. 2013a, 2013b). However, low water salinity and transparency contribute to delta smelt's occurrence at Liberty Island and the adjacent reach of the Sacramento Deep Water Shipping Channel in the Cache Slough subregion (e.g., Nobriga et al. 2005).* ***In addition, the trawl survey sampling grids are large enough to have robustly documented that delta smelt cannot be expected to occur in large numbers where the key abiotic habitat attributes (low salinity/low turbidity, and low water temperature in the summer) are not met*** *(Feyrer et al. 2007; Nobriga et al. 2008; Kimmerer et al. 2009; Feyrer et al. 2011; Sommer and Mejia 2013)."* Page 5.5.1-19, lines 14-24.

The assumption that significant numbers of Delta smelt are not expected to be in waters that potentially jeopardizes their existence apparently is the basis for the U.S. Fish and Wildlife (USFWS) Biological Opinion that provides no protection for Delta smelt in July and August and why the State Water Resources Control Board (SWRCB), with the concurrence of state and federal agencies, reduced Delta outflow requirements in July of this year and allowed the salinity compliance point at Emmaton to be moved upstream to Three Mile Slough. Unfortunately, as we document below, it's simply not accurate.

This belief is apparently why the U.S. Fish and Wildlife (USFWS) Biological Opinion provides no protection for Delta smelt in July and August and why the State Water Resources Control Board (SWRCB), with the concurrence of state and federal agencies, reduced Delta outflow requirements in July of this year and allowed the salinity compliance point at Emmaton to be moved upstream to Three Mile Slough. This belief is apparently why BDCP and the EIR/EIS virtually ignored and failed to discuss juvenile Delta smelt and the impacts of lethal temperatures and low outflow during summer periods and failed to consider protective outflows in summer.

Given the decades-long collapse of smelt populations amid the astonishing array of biological opinions, water quality control plans, water rights decisions and adaptive management programs and habitat restoration projects; no professional deference can be accorded to the agencies involved in the planning, management, analysis or approval of BDCP. These agencies have literally escorted Delta smelt to the brink of extinction. And no deference or benefit-of-doubt can be accorded to the speculative claims and assurances that habitat restoration projects and adaptive management efforts will be more successful and result in different outcomes this time around. Especially, given agency's historical track record of failure.

Contrary to the assumptions of BDCP and the EIR/EIS, large percentages of Delta smelt juveniles are in the western Delta in late June and early July and probably August, especially in drier years. In fact, 100% of the Delta smelt identified in the recently completed Survey 9 of the 20-mm survey, are at the southern end of Sherman Island and not in Suisun Bay where the BDCP and the EIR/EIS seem to assume they are. In 2013, more than 60% of Delta smelt juveniles were in the western Delta.

Over centuries, Delta smelt evolved within salinity parameters for various life stages. They can't magically change their habitat needs simply because it inconveniences water exporters. Low Delta outflow, coupled with excessive water exports, shifts the low salinity zone (LSZ) and juvenile Delta smelt eastward into the western Delta where smelt are exposed to near-lethal and lethal water temperatures during heat waves similar to what occurred in July 2013 and is occurring in July 2014.

The attached CSPA report titled *The Summer of 2013, the demise of Delta smelt under D-1641 Delta Water Quality Standards*, chronicles conditions in 2013 when Delta outflow was suddenly reduced and water exports by the state and federal project facilities dramatically increased. The LSZ and juvenile Delta smelt were drawn into the western Delta where they encountered lethal water temperatures. As predicted, the 2013 Fall Midwater Trawl Delta smelt Index plunged to its second lowest on record, statistically indistinguishable from the lowest.

Delta Smelt on the Scaffold, included below, contains;

- CSPA developed indexes that reveal that, based on CDFW 20-mm survey data, abundances of juvenile Delta smelt reached their lowest level in history in late June and early July 2014. Survey 9, of the 20-mm Survey collected only two Delta smelt in 141 separate trawls at 40 locations stretching from Cache Slough to San Pablo Bay.

- Examination of the startling difference between the calculated Net Delta Outflow Index (NDOI), relied upon by the SWRCB, USBR, DWR to measure compliance with D-1641 outflow requirements, and the actual tidally filtered data collected by the U.S. Geological Survey's (USGS) stations at Rio Vista, Three Mile Slough, San Joaquin River at Jersey Point and Dutch Slough. The USGS gaged results of Delta outflow better correlate with salinity intrusion that the NDOI.

- Late June and early July 20-mm surveys for Delta smelt between 1998 and 2014.

Together, they establish, contrary to conclusions in the BDCP and the EIR/EIS, that juvenile Delta smelt are in the western Delta during June, July and potentially August, where they are at risk from lethal temperatures. They also establish that the NDOI relied upon to determine compliance with water quality and flow standards established by the SWRCB are flawed and overestimate actual outflow.

Consequently, any assumptions, analyses, conclusions or determinations contained in the BDCP or the EIR/EIS that rely on the NDOI as representing actual Delta outflow are inaccurate. Likewise, any assumptions, analyses or conclusions that compliance with D-1641's flow and water quality standards are protective of identified beneficial uses are similarly flawed.

BDCP and the EIR/EIS are inadequate and violate CEQA and NEPA by failing to disclose these facts and analyze the project's potential adverse impacts to juvenile Delta smelt in summer.

Thank you for considering these comments. If you have questions or require clarification, please don't hesitate to contact us.

Sincerely,

Bill Jennings

Bill Jennings, Executive Director

Delta Smelt on The Scaffold

Juvenile Delta Smelt Abundance Levels at All-Time Low

Thomas Cannon
Bill Jennings

California Sportfishing Protection Alliance

July 2014

During the summer of 2013, reductions in outflow, coupled with increased water exports, drew the low salinity zone (LSZ) and Delta smelt eastward into the western Delta where smelt encountered lethal water temperatures. That situation was chronicled in a California Sportfishing Protection Alliance (CSPA) report titled *The Summer of 2013, the demise of Delta smelt under D-1641 Delta Water Quality Standards*, which predicted that the smelt population would plunge.[1] As we predicted, the following Fall Midwater Trawl's Delta smelt abundance index was the second lowest level on record, statistically indistinguishable from the absolute lowest.

In 2014, the State Water Resources Control Board has significantly relaxed flow and water quality standards protecting the estuary. Delta outflow is below levels in recent memory. Exports and water transfers are being approved with little environmental review because state and federal agencies claim that Delta smelt are not in the Delta in late June and July. As we show below, this is simply not true. Low outflows have drawn Delta smelt into the Delta where they're at risk from lethal temperatures. Further, outflows are significantly less than being reported by the agencies. Delta smelt populations are headed for new record lows. The point of no return, i.e., the level where the population cannot recover, is unknown. But, that point is likely approaching.

The California Department of Fish and Wildlife (DFW) conducts four primary surveys of Delta smelt in the Bay-Delta: Smelt Larval Survey, 20-mm Survey, Summer Townet and Fall Midwater Trawl. Each survey provides an annual index of abundance for specific life stages of Delta smelt. The 20-mm survey monitors post-larval-juvenile Delta smelt and comprises nine separate surveys. However the 20-mm index is based on initial surveys in March/April and do not reflect conditions in late June and early July, as smelt are drawn into the Delta by low outflow and export pumping and exposed to high temperatures. DFW's Smelt larval & 20-mm survey indices are not published.

Because DFW's 20-mm index doesn't reflect what happens to Delta smelt in June and July, CSPA took DFW's 20-mm survey data and developed indices for early June, late June and early July between 1996-2014. Our method simply stacks average densities from survey areas for each survey on a bar graph to derive an index. Our index demonstrates changes over the three survey periods and the relative contribution of the six different Delta regions. It is not weighted by the area or volume of the regions and includes the northern population of smelt and includes stations in Cache Slough and the Sacramento Deep Water Ship Channel that were added to the 710s group in the past decade.

The two methods provide similar indices and patterns of indices over the years. The early June smelt index was the second lowest in history but the late June and early July indexes were, by a significant margin, the lowest in history. Astonishingly, DFW's early July 2014 20-mm survey managed to capture only 2 smelt in 147 separate trawls. The early July index pattern over the years is also similar to the Fall Midwater Trawl Indices, which is an alarming indication of likely results from this fall's upcoming FMWT index.

Following are the CSPA Delta smelt indexes for June and July 2014, DFW's June/July 2014 survey results, a discussion concerning the inadequacies of DWR, USBR Delta outflow calculations and the DFW 20-mm surveys between 1996 and 2014.

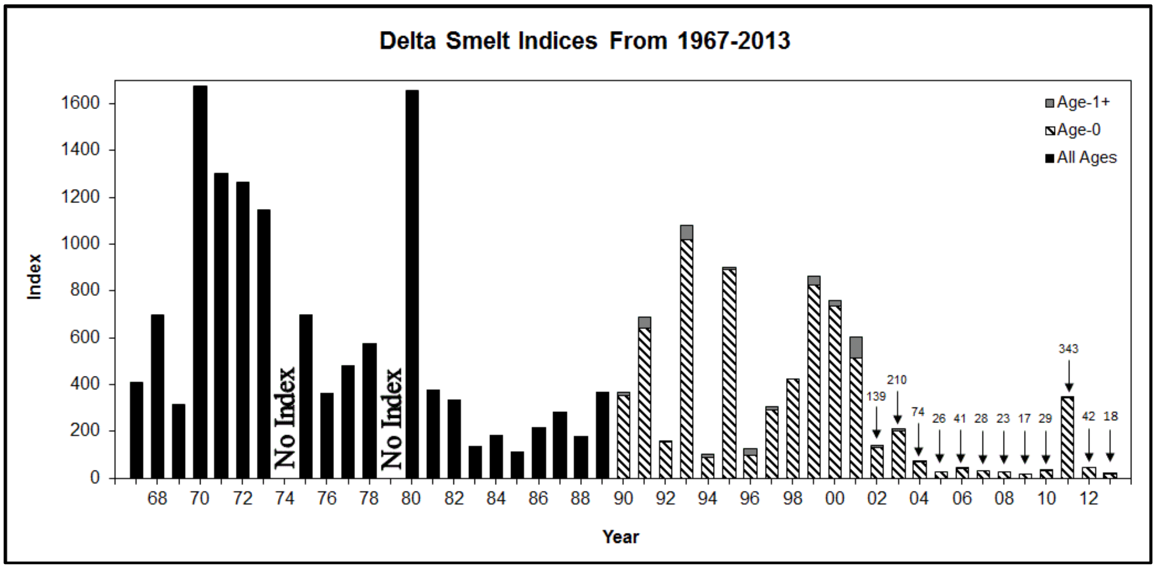
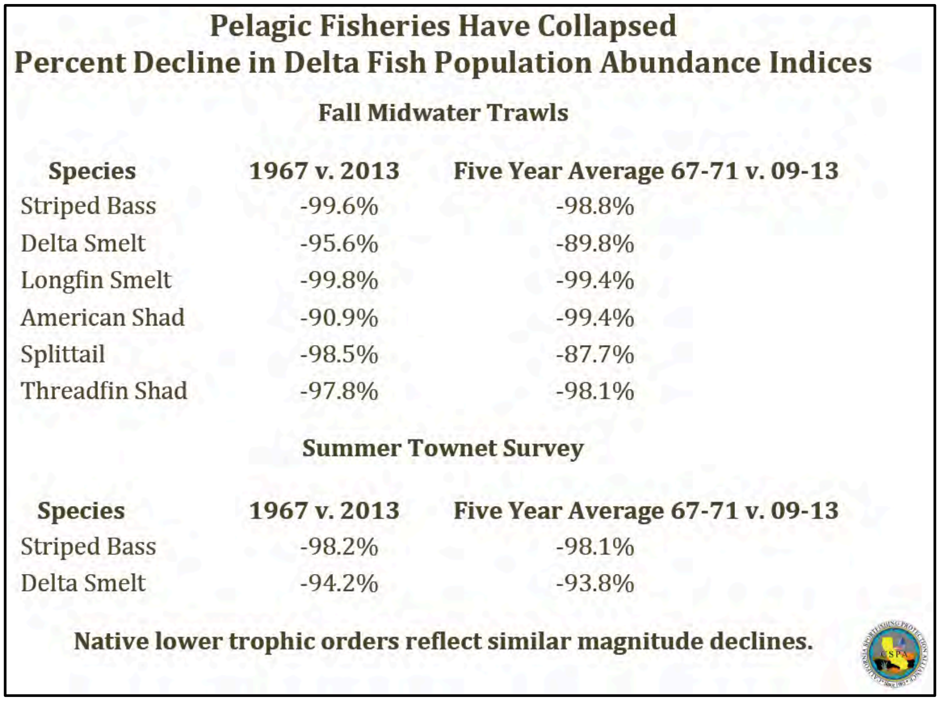
This pattern is replicated in the annual abundance indices of the Fall Midwater Trawl, which illustrates the continued decline of Delta smelt since the State Water Project began exporting water in 1967.



California Department of Fish and Wildlife: Delta Smelt Fall Midwater Trawl Indices 1967-2013.[5]

The decline of Delta fisheries is not limited to Delta smelt but encompasses the entire range of pelagic species.[6]



Pelagic Fisheries Have Collapsed
Percent Decline in Delta Fish Population Abundance Indices

Fall Midwater Trawls

Species	1967 v. 2013	Five Year Average 67-71 v. 09-13
Striped Bass	-99.6%	-98.8%
Delta Smelt	-95.6%	-89.8%
Longfin Smelt	-99.8%	-99.4%
American Shad	-90.9%	-99.4%
Splittail	-98.5%	-87.7%
Threadfin Shad	-97.8%	-98.1%

Summer Townet Survey

Species	1967 v. 2013	Five Year Average 67-71 v. 09-13
Striped Bass	-98.2%	-98.1%
Delta Smelt	-94.2%	-93.8%

Native lower trophic orders reflect similar magnitude declines.

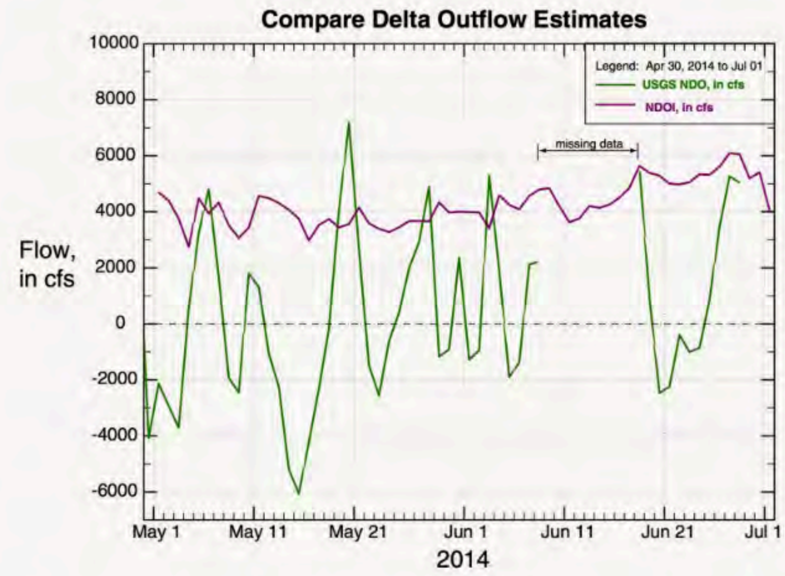
[6] http://calsport.org/news/wp-content/uploads/St-Bd-Drought-Wkshp1.pdf

The problem has been exacerbated in recent years by excessive water exports from the Delta coupled with extremely low outflow to the Bay and relaxed or ignored flow and water quality standards. This combination low flow and exports draws the crucial low salinity zone (LSZ) into the Delta where pelagic species are subjected to entrainment in the massive export pumps and lethal summer water temperatures. Last year was bad as a combination of low outflows and high exports hammered Delta smelt.[7] This year is likely to be much worse and Delta smelt are literally on the brink of extinction.

The Estimates of Delta Outflow by USBR and DWR are Simply Wrong!

U.S. Bureau of Reclamation (USBR) and California Department of Water Resources (DWR) claim that net Delta outflow (NDOI) averaged 3170 cubic feet per second (cfs) between I July and 11 July 2014.[8] However, the NDOI, which is a complicated computation that guesses at net Delta channel depletion, is simply wrong.

The U.S. Geological Survey (USGS) maintains four state-of-the-art UVM flow gages on the Sacramento and San Joaquin Rivers and Three-mile and Dutch Sloughs that, cumulatively, record total Net Delta Outflow (NDO). Examination of tidally filtered outflow data from these gages reveals that the outflows reported by USBR and DWR are seriously inflated in low water conditions.



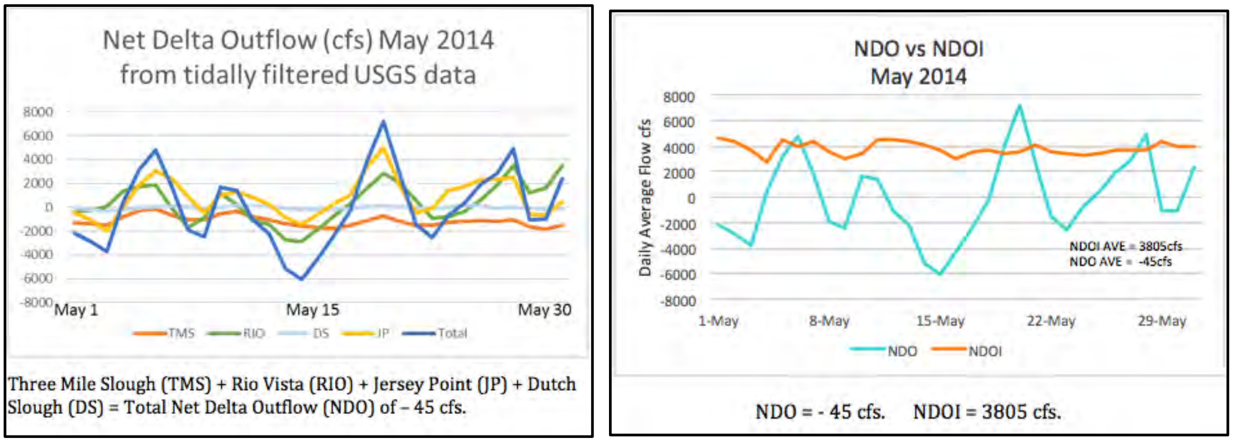
By official estimates, fresh water outflow from the Delta is about 4,000 cfs; USGS monitors show that outflow to the Bay vacillated between minus 6,000 cfs and plus 6,000 but the average for May and June was close to zero.
Graph by Pete Smith

Retired USGS Engineer, Pete Smith, prepared the above comparison of NDO versus NDOI that was recently reported in the California Spigot.[9]

---

[7] http://calsport.org/news/wp-content/uploads/CSPA-Cannon-Summer-2013-6.pdf
[8] http://www.usbr.gov/mp/cvo/vungvari/doutdly.pdf
[9] http://www.californiaspigot.blogspot.com

CSPA fishery consultant and biostatistician, Thomas Cannon, also prepared an assessment for CSPA that analyzed the NDOI index and discovered that it seriously overestimates actual Delta outflow. Mr. Cannon calculated that the actual Delta outflow in May 2014 was a minus 45 cfs, instead of the positive 3805 cfs claimed by USBR and DWR. He also discovered that DWR had long aware been of the discrepancy.[10]

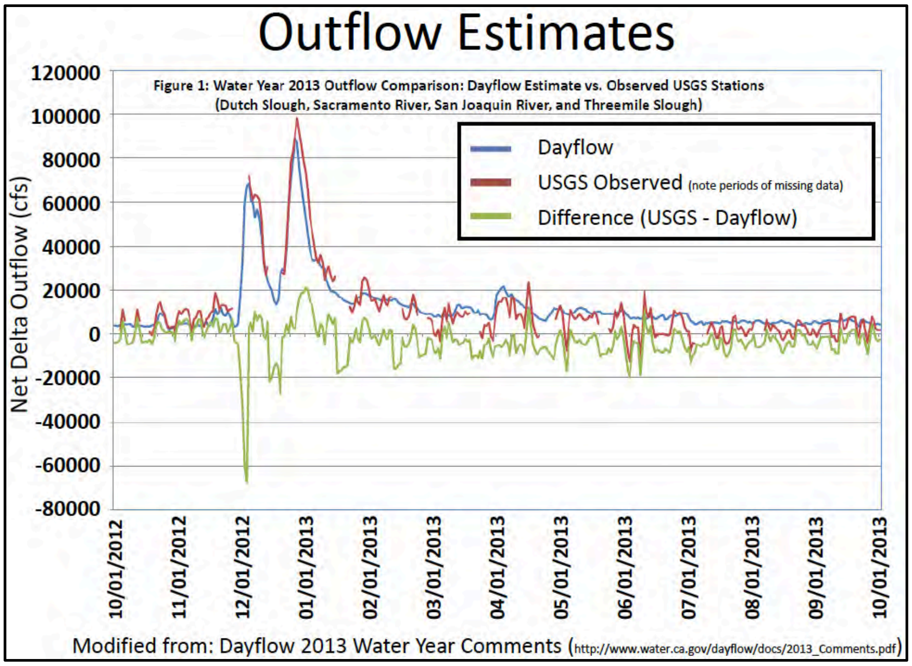


Three Mile Slough (TMS) + Rio Vista (RIO) + Jersey Point (JP) + Dutch Slough (DS) = Total Net Delta Outflow (NDO) of – 45 cfs.

NDO = - 45 cfs. NDOI = 3805 cfs.

Thomas Cannon: Net Delta Outflow in May 2014 and NDO vs. NDOI.

Dr. Michael L. MacWilliams, of Delta Modeling Associates, in a presentation to the Delta Science Program's workshop on Delta outflows and related stressors, observed that NDOI estimates during the fall of 2013 were more than double the USGS measured outflows.



Modified from: Dayflow 2013 Water Year Comments (http://www.water.ca.gov/dayflow/docs/2013_Comments.pdf)

---

[10] http://calsport.org/news/wp-content/uploads/CSPA-NDO-v-NDOI-2.pdf

Dr. MacWilliams testified that, based on measured data for salinity intrusion and X2, the NDOI estimates appeared to be clearly incorrect.[11]

During the first ten days of July 2014, the NDOI was reported as a positive outflow averaging 3170 cfs. However, examination of the four USGS tidally filtered stations at Rio Vista, Threemile Slough, Jersey Point and Dutch Slough reveals that outflow had become negative, beginning around 4/5 July. Inflow from the Bay approached 7000 cfs by 8 July. This was reflected in sharply increasing salinity (EC) levels in the Delta, which could not have occurred under a positive NDOI outflow.

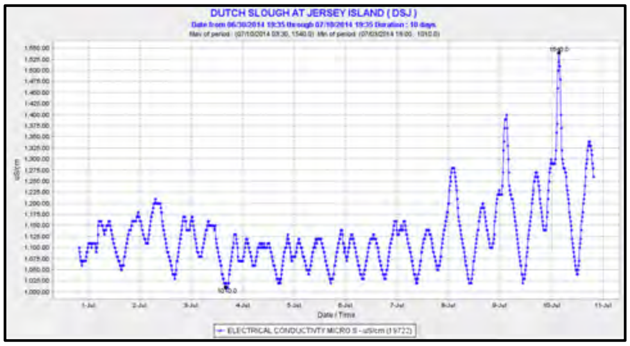
USGS Dutch Slough Flow (11313433)



CDEC Dutch Slough EC (DSJ)

Real time data from the USGS[12] and California Data Exchange Center (CDEC)[13] can be accessed online.

The final report of the expert panel observed that, "Although a precise estimate of the accuracy of the measured outflow is not known, the measured values should be more accurate than the NDOI as long as the four monitoring stations used in the calculations are operating properly." The panel asked, "why the measured outflows (rather than NDOI) aren't used for the specific outflow standards during the July-to-January period, and also why they aren't used as the alternative flow compliance option in the springtime X2 standard."[14]

The California Spigot quoted State Water Resources Control Board engineer, Rick Satkowski, as saying, in light of these findings, the State Board will be looking at, "possible changes in determining outflow.

[13] http://cdec.water.ca.gov/staMeta.html

[14] http://deltacouncil.ca.gov/sites/default/files/documents/files/Delta-Outflows-Report-Final-2014-05-05.pdf

USBR and DWR have long known of the difference between measured net delta outflow and the calculated net delta outflow index. They have long known that they do not have reliable data on in Delta channel depletions. They have long known that not all inflow into the Delta from tributary streams is accurately gaged. But they are also aware that if NDO, instead of the NDOI, is used as the standard of net delta outflow, more water will have to be directed to outflow and less to exports, especially in dry years.

USBR and DWR are committed to maximizing water deliveries to contractors, even if it sends the Delta smelt, once the most abundant fish in the Delta, toward extinction. That is unacceptable!

Contrary to USBR and DWR Claims, Delta Smelt are in the Delta in June, July and August

The USFWS Biological Opinion for Delta smelt provides no protection in July and August because the service claims that there are no Delta smelt in the Delta during those months. On that basis, USBR and DWR, with USFWS concurrence, provided no protection for smelt during water transfers. Earlier this year, the State Water Board, again with USFWS concurrence, lowered the Delta outflow criteria, contained in D-1641, from 4000 cfs to 3000 cfs during the months of May and July. However, they are simply wrong!

Last year, as chronicled in CSPA's report titled *The Summer of 2013, the demise of Delta smelt under D-1641 Delta Water Quality Standards*,[15] reductions in outflow, coupled with increased water exports, drew Delta smelt into the western Delta where they encountered lethal water temperatures. Abundance levels plunged.

Delta smelt are in the Delta. They shouldn't be. During late June and July, Delta smelt should be in the LSZ in Suisun Bay, protected from the lethal 76-77 degrees water temperatures frequently found in the Delta during summer. However, a combination of low outflow and excessive exports draws the LSZ and Delta smelt into the Delta during drier years.

There is also a small population of smelt that spawn in the Cache Slough-Sacramento Ship Channel area. However, they become trapped and unable to migrate back to the LSZ and seek to survive in the stratified waters of the deep water in the ship channel. Extended heat waves pose a severe threat to that population, as the coldwater pool will ultimately dissipate. In 2009, the California Department of Fish and Wildlife (CDFW) conducted supplemental monitoring at six sites in the ship channel and found that smelt populations decreased through July and virtually disappeared by August. The USFWS's 2008 Biological Opinion does not suggest that the Cache Slough-Sacramento Ship Channel area provides a viable temperature refuge for Delta smelt when their only recognized habitat – the LSZ in the Delta – has been rendered unsuitable for survival.

Below are the CDFW's late June and early July 20mm Delta smelt surveys from 1996 to 2014. The 20mm surveys are comprised of three separate trawls conducted at 40 sites in the Delta. They demonstrate that in all but the wettest years, Delta smelt are in the Delta during late June and early

July. In drier years, a significant percentage of Delta smelt, perhaps the majority of juveniles, are in the Delta.

Delta Smelt on the Scaffold

To summarize: during the summer of 2013, reductions in outflow, coupled with increased water exports, drew the LSZ and Delta smelt eastward into the Delta where smelt encountered lethal water temperatures. That situation was chronicled in a CSPA report titled *The Summer of 2013, the demise of Delta smelt under D-1641 Delta Water Quality Standards*, which predicted that the smelt population would plunge.[17] As predicted, the following Fall Midwater Trawl's Delta smelt abundance index was the second lowest level on record, statistically indistinguishable from the absolute lowest.

DFW conducts a series of 20-mm Delta smelt trawls monitoring post-larval-juvenile smelt. DFW does not publish their 20-mm Delta smelt indices, which are based on the initial surveys that begin in March of each year. CSPA took DFW 20-mm data and developed a series of indexes focused on the critical late June early July, when Delta smelt are drawn into the Delta be a combination of low outflow and export pumping. Those smelt are at risk of encountering lethal water temperatures. In 2014, juvenile Delta smelt were hammered by a combination of critically low outflow, water exports and lethal water temperature, as they were in 2013. The CSPA Delta

The previous low in 2009 was followed by a slightly better water year (below normal on the Sacramento and above normal on the San Joaquin) and smelt populations experienced a small rebound. This year, Delta smelt are being subjected to another year of critically dry conditions on both rivers. And this year, the State Water Board seriously weakened Delta flow and water quality standards. Delta outflow is below levels in recent memory and Delta smelt populations are at historic lows. Yet exports continue and water transfers are being approved with little environmental review.

The next Fall Midwater Trawl will almost surely find Delta smelt populations at new record lows. Population abundance levels over the last few years make the numbers of Delta smelt during the Pelagic Organism Decline (POD) in the early 2000s look robust. The POD years generated an enormous outcry. Myriad meeting were conducted, numerous studies funded and an array of programs launched. Today, the agencies that were so concerned about the POD are silent and have embraced measures they know will be disastrous for the species.

The point of no return, i.e., the level where the population cannot recover, is unknown. But, that point is likely approaching. A species that existed in this estuary for thousands of years and was the most abundant fish in the Delta is on the scaffold. Perhaps, the greatest tragedy is that our trustee agencies charged with the protection of Delta smelt; the USFWS, CDFW and the State Water Board have escorted it there.

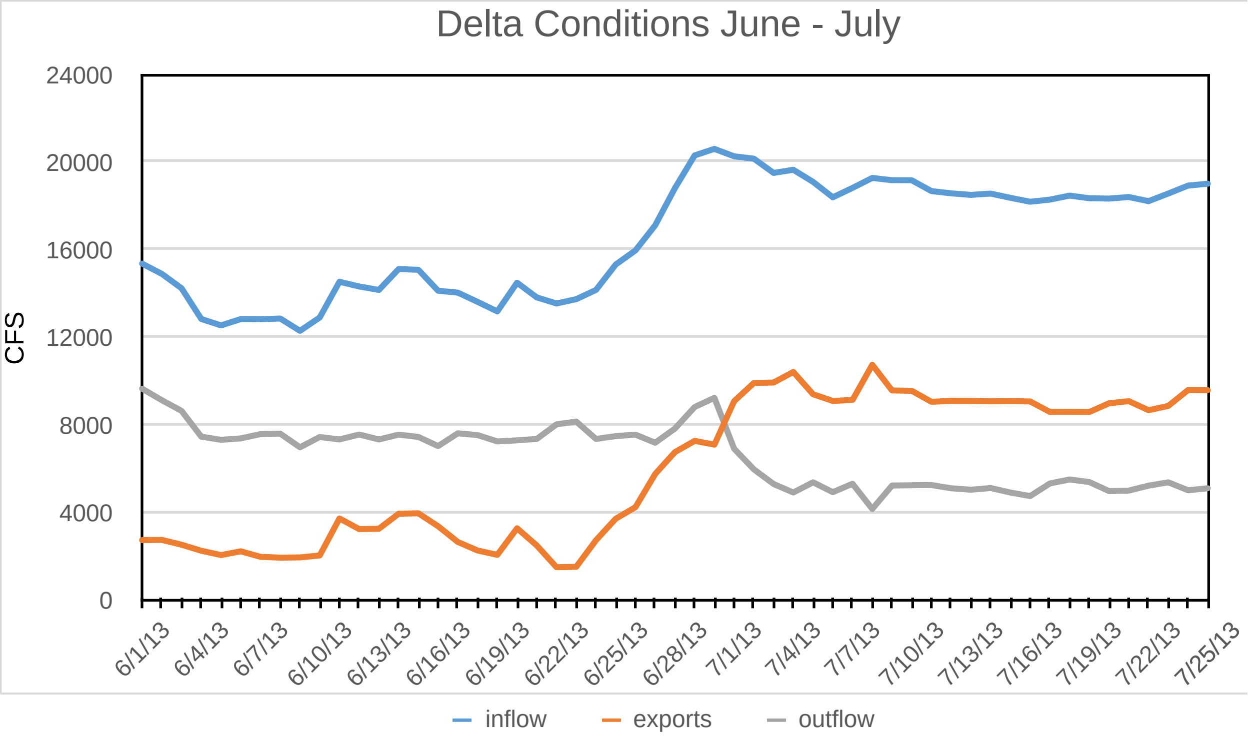
August 2013

Summer 2013



Dry Year Standards Relaxed?

Despite near record low precipitation in the Central Valley in the spring of 2013, the water year remained classified as "dry," pursuant to D-1641. The "dry year" standards for EC at Emmaton were violated in April, May and June and the EC standard at Jersey Point was violated in June. These standards were established to protect agricultural beneficial uses in the Delta.

The Department of Water Resources and the Bureau of Reclamation, fearing that water exports from the State and Federal Water Projects (Projects) would lead to violations of Delta outflow and western Delta EC standards and depletion of cold water storage in Shasta Reservoir, asked the State Water Resources Control Board on 24 May to reclassify the water year to "critically dry" and requested permission to move the temperature compliance point on the Sacramento River upstream from Red Bluff to Anderson to save the cold-water pool supply in Shasta Reservoir. The Department of Fish and Wildlife, NOAA Fisheries and US Fish and Wildlife Service submitted letters supporting the request.

While the State Board had no authority to arbitrary change a water year classification, it informed the agencies that it "will not object or take any action if the Bureau and Department operate to meet critically dry year salinity objectives for Western and interior Delta."

On or about June 22, the Projects began substantially increasing exports and Delta inflows, and shortly thereafter significantly reducing Delta outflow per the Delta Standards.

The D-1641 standards for a dry year (Figure 1) already allowed salinity to encroach into the West Delta at Emmaton and Jersey Point. Earlier violations of those standards in the spring had already exacerbated conditions by summer (it should also be noted that South Delta EC standards were also violated in June and July through August 15).

This report reviews conditions in the summer of 2013, the inadequacy of D-1641 dry year standards and the adverse impacts to Delta smelt caused by violation of those already inadequate standards.

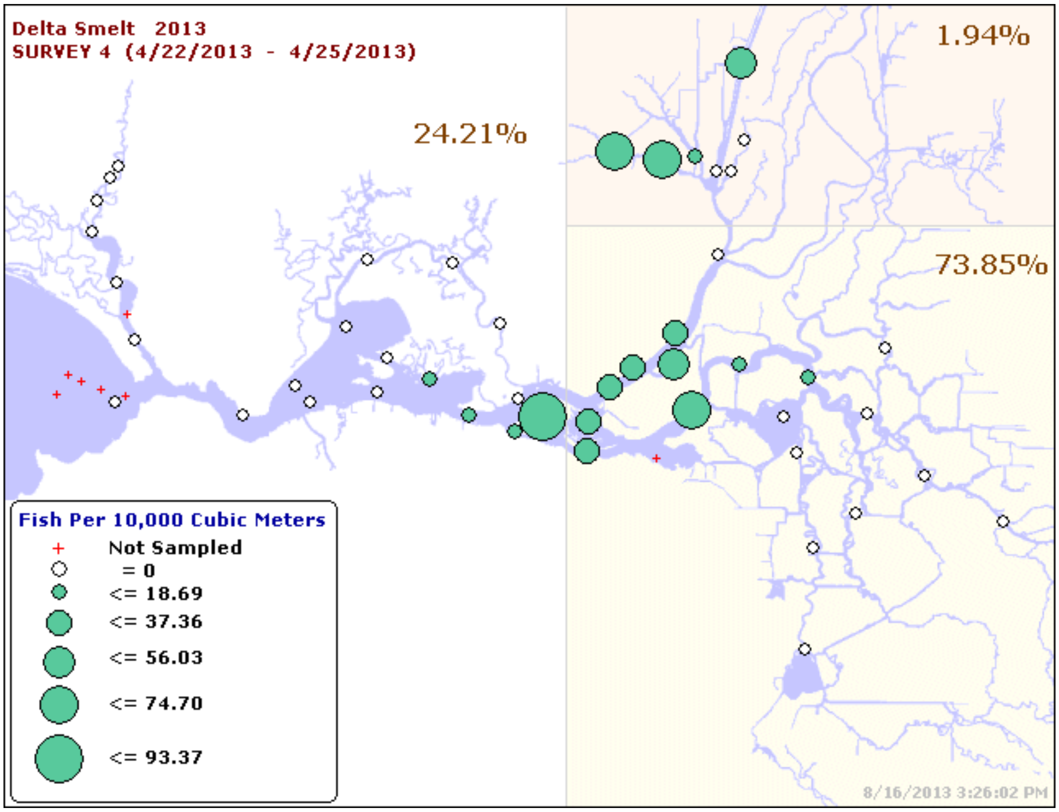

Figure 2. Late-April 2013, 20-mm Smelt Survey results. (Source: http://www.dfg.ca.gov/delta/data/20mm/)

Delta Smelt in April

Although not the subject of this report, spring conditions set the stage for summer. April 2013 was a tough time for smelt. Sacramento River inflow to the Delta dropped to only 6,000 cfs, San Joaquin inflows were 1500-3000 cfs, exports were up to 2,500-3,000 cfs, and outflow was as low as 6,000 cfs. Old and Middle River OMR flows were -1000 to -4000 cfs. The Delta Cross Channel was closed.

Over the past 20 years, the late April – early May period had been under the protection of VAMP (Vernalis Adaptive Management Program) experiment, but these protections ended in 2010. This year, without these protections, late April exports climbed to 2,500-3,000 cfs reaching 4,000 cfs in early May (from 1500 cfs cap under VAMP). This increase in exports without the VAMP export cap occurred under lower inflows, outflows, and negative OMR flows. Nearly three quarters of the Delta smelt population was in the Central and Western Delta (20-mm survey, Fig. 2) and thus subject to being exported (especially with negative OMRs with the DCC closed). Most of the smelt were not of salvageable size (they were only 10-25 mm), so they were entrained in the export water likely in large numbers (hundreds of thousands per day were moving into Old River toward pumps).

Despite these horrible conditions many still survived in the western Delta under the modest outflows and thus became subject to summer conditions.

Delta Smelt in Mid June

In mid June 2013 the small remnant population of delta smelt surviving in the San Francisco Bay-Delta after the below-normal water year of 2012 and poor spring conditions described above were spread through their usual dry-year habitats in the western Delta, eastern Suisun Bay, Montezuma Slough, and the Cache Slough/Bypass/Ship Channel complex in the north Delta (Figure 3).

Other than the north Delta group, most of the smelt were in their summer low-salinity zone (LSZ) home where salinities are low (0.5-5 ppt) and water temperature optimal (about 20C). With the protective dry-year EC standard of 0.45 through June 15, the LSZ was in eastern Suisun Bay west of the Delta.

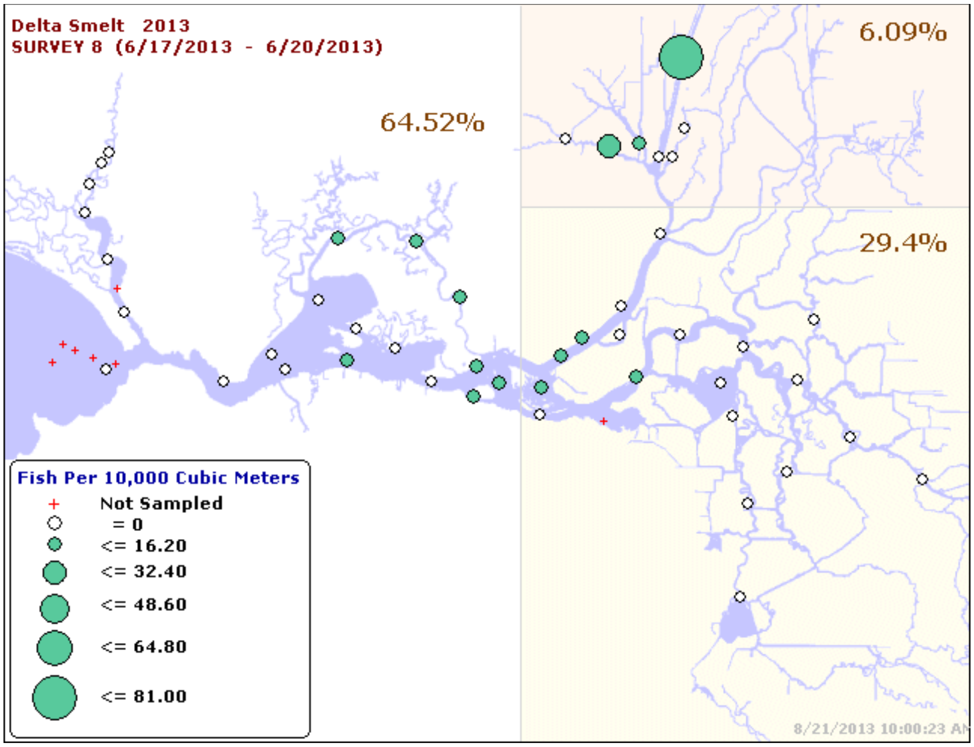

Figure 3. Mid-June 2013, 20-mm Smelt Survey results. (Source: http://www.dfg.ca.gov/delta/data/20mm/)

Summer Flow and Salinity Conditions

Beginning in the third week in June, inflow increase from the 12,000-14,000 cfs level to 20,000 cfs and exports increased from 2,000 to 10,000 cfs (Figure 4). A week later Delta outflow was reduced to 5,000 cfs.

West Delta

The effect is seen in the EC patterns at Emmaton and Jersey Point in the west Delta (Figures 5a and 5b). As outflow declines, salinities (EC) increase. The LSZ with its 500-6000 EC signature moved upstream into the West Delta with each incoming tide. In contrast, in wet year 2011, outflow was maintained at 8000 cfs and the LSZ did not move upstream into the Delta (Figure 5c).

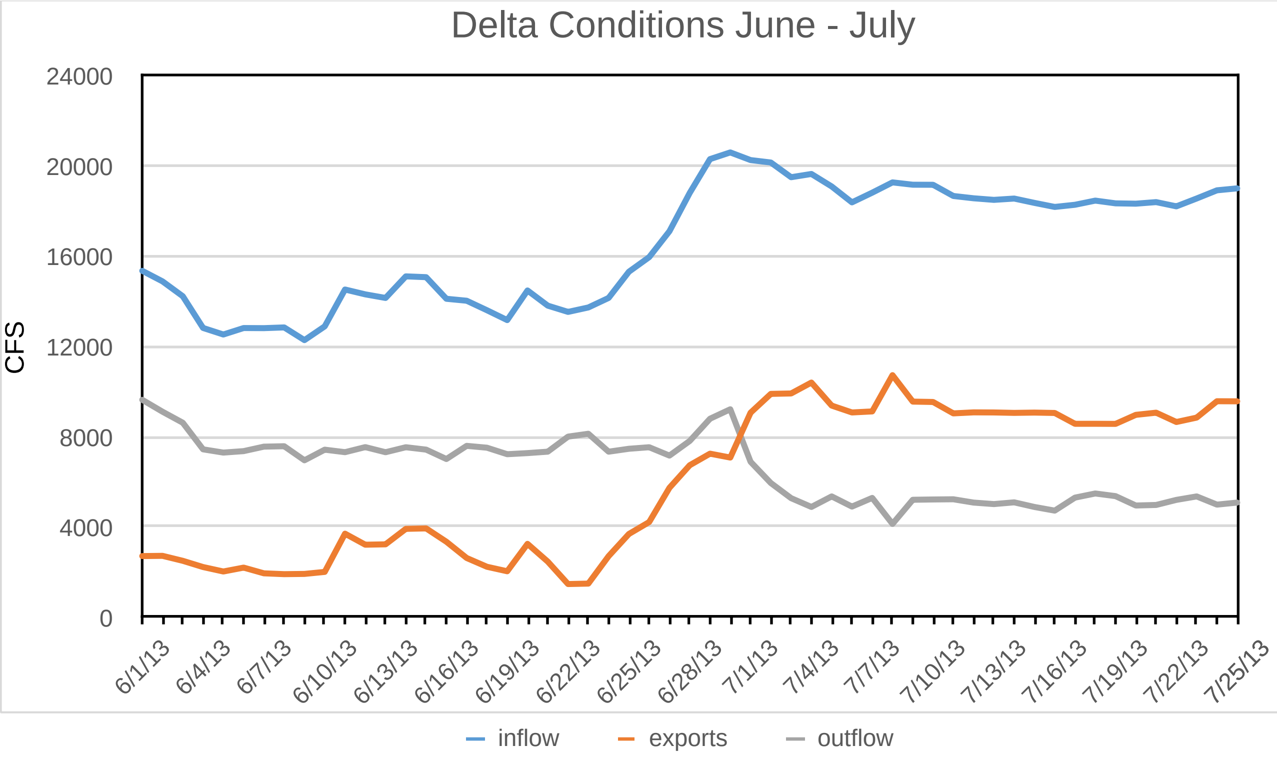

Figure 4. June through July 2013 Delta inflow, outflow, and exports. Summer EC standards kick in after mid June.

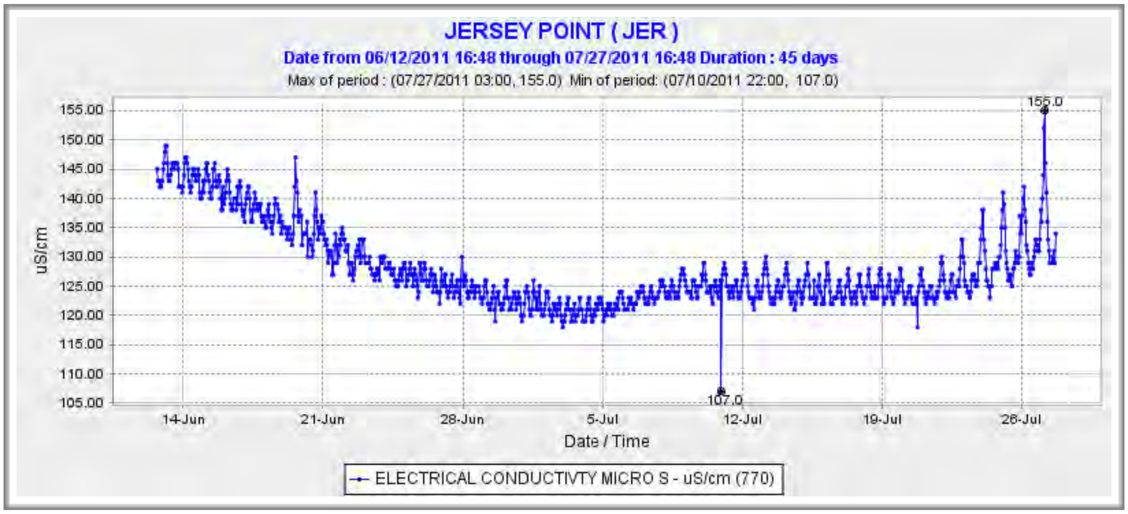

Figure 5c. Conductivity (EC) at Jersey Point on lower San Joaquin River in West Delta after mid June 2011. (Source: CDEC)

Eastern Suisun Bay

Salinity (EC) in Eastern Suisun Bay at Collinsville on the north and Pittsburg on the south also increased at the beginning of July with the decrease in outflow (Figures 6 and 7). At high tide the LSZ was well upstream of the two locations by early July. The lower end of the LSZ did extend downstream to these locations during low tides through July.

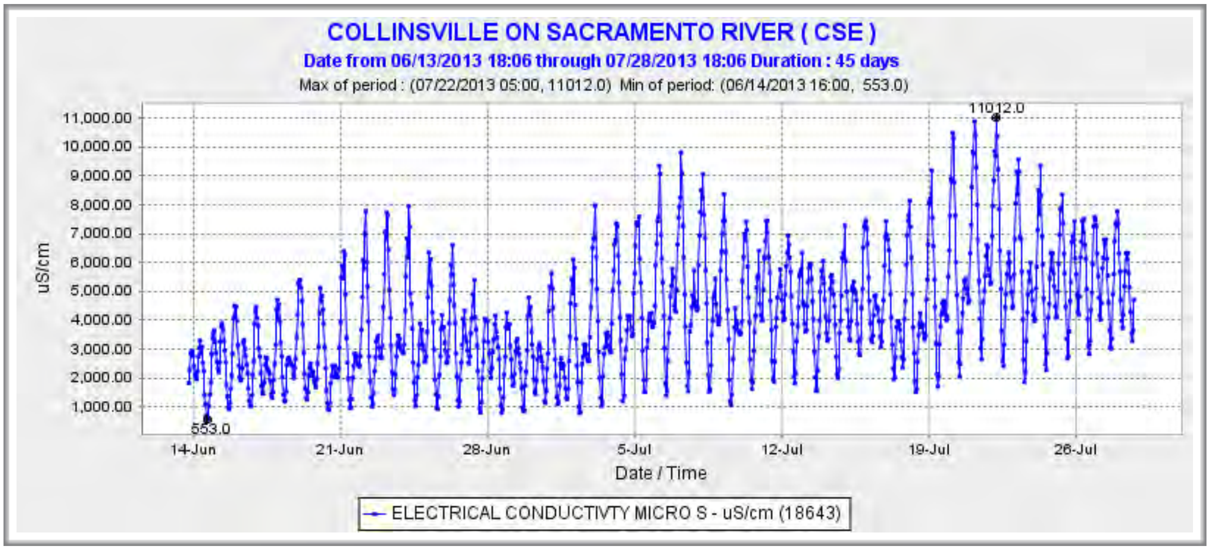

Figure 6. Conductivity (EC) at Collinsville in Eastern Suisun Bay after mid June 2013. (Source: CDEC)

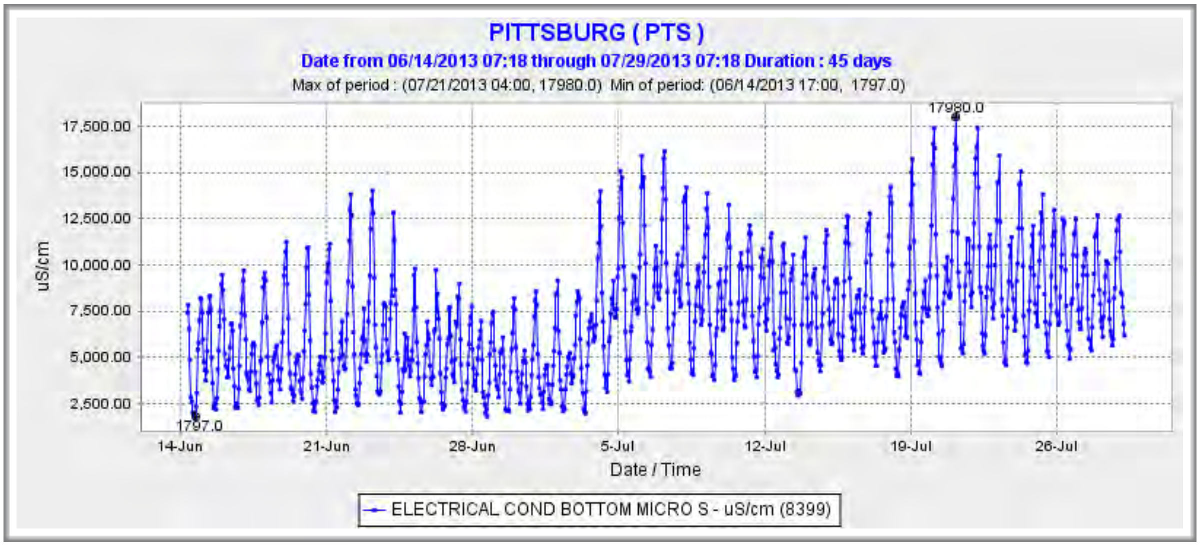

Figure 7. Conductivity (EC) at Pittsburg in Eastern Suisun Bay after mid June 2013. (Source: CDEC)

Central Delta

Central Delta EC as measured Threemile Slough on the San Joaquin River (Figure 8) and False River (Figure 9) also shows the movement of the LSZ upstream coincident with the reduction in Delta outflow at the beginning of July.

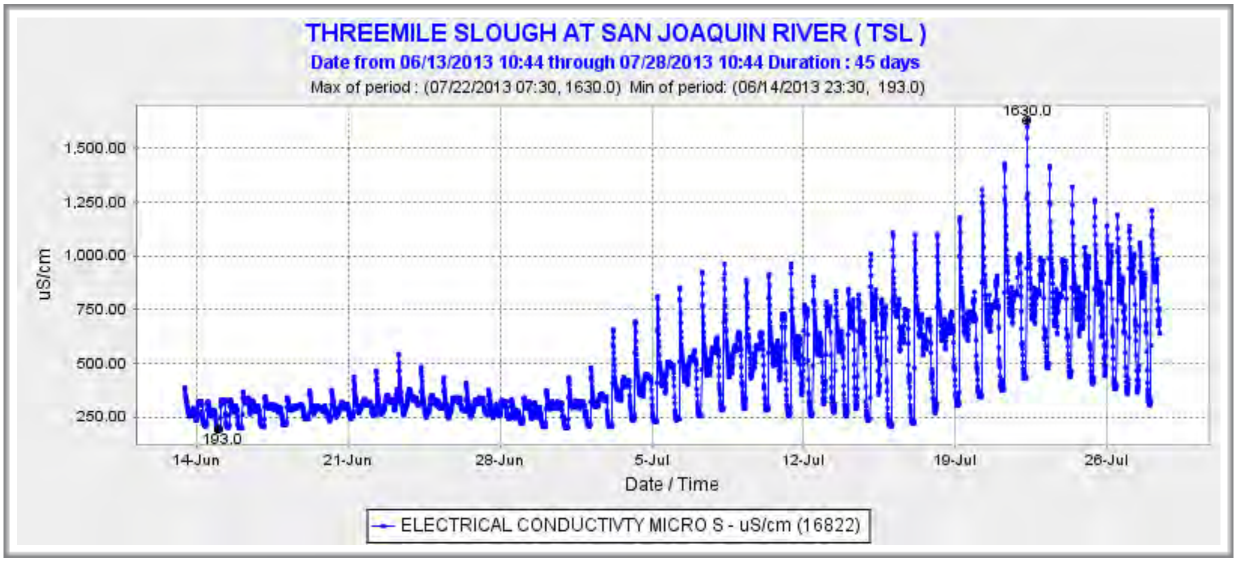

Figure 8. Conductivity (EC) at Threemile Slough in the Central Delta after mid June 2013. (Source: CDEC)

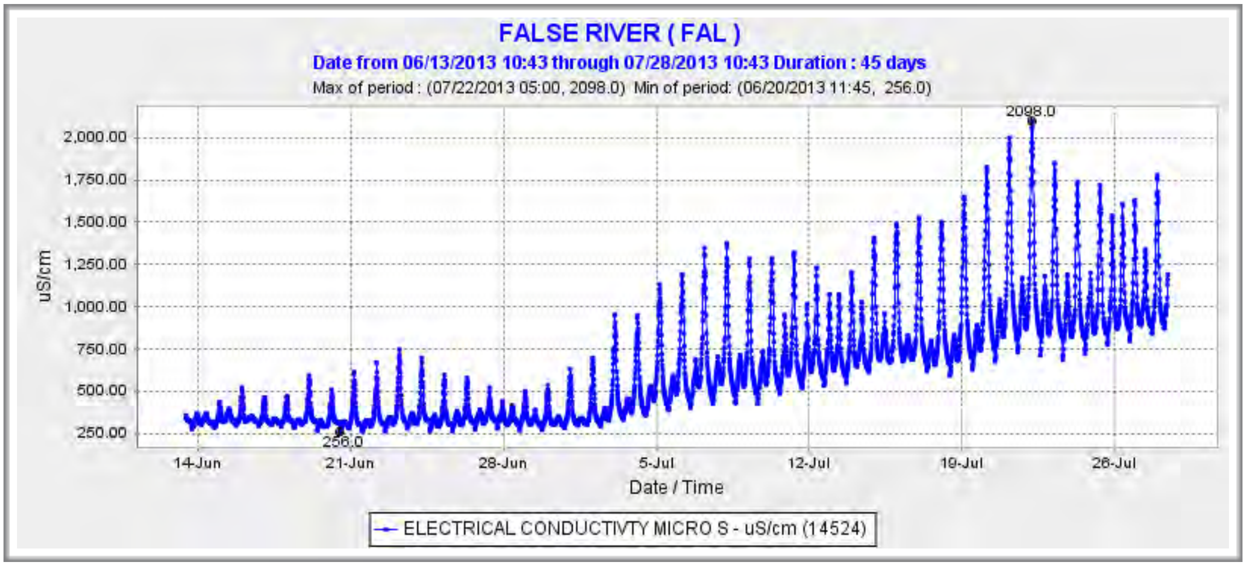

Figure 9. Conductivity (EC) at False River in the Central Delta at Franks Tract after mid June 2013. (Source: CDEC)

South Delta

South Delta EC also increased as the upper portion of the LSZ was mixed with cross Delta moving freshwater Sacramento River on the way to the export pumps. Salinity gradually increased in Old River as the head of the LSZ actually moved into the South Delta toward the export pumps (Figure 10).

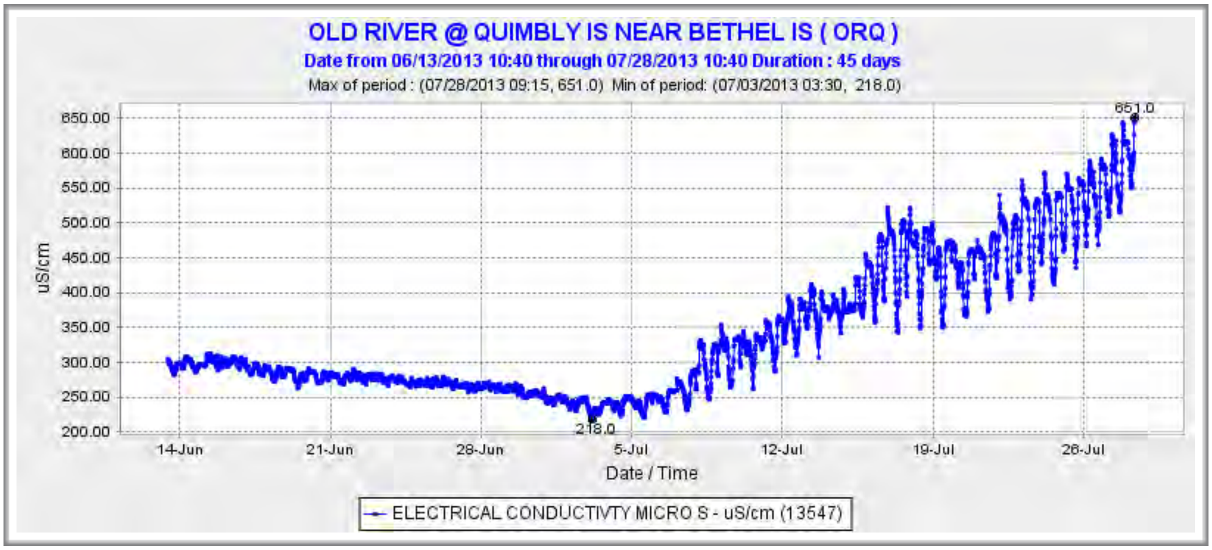

Figure 10. Conductivity (EC) in Old River in the Central Delta near Bethel Is after mid June 2013. (Source: CDEC)

Salinity in Clifton Court Forebay was slightly less as Forebay water is a mixture of Old River, Middle River, and East Delta waters of lower salinity (Figure11).

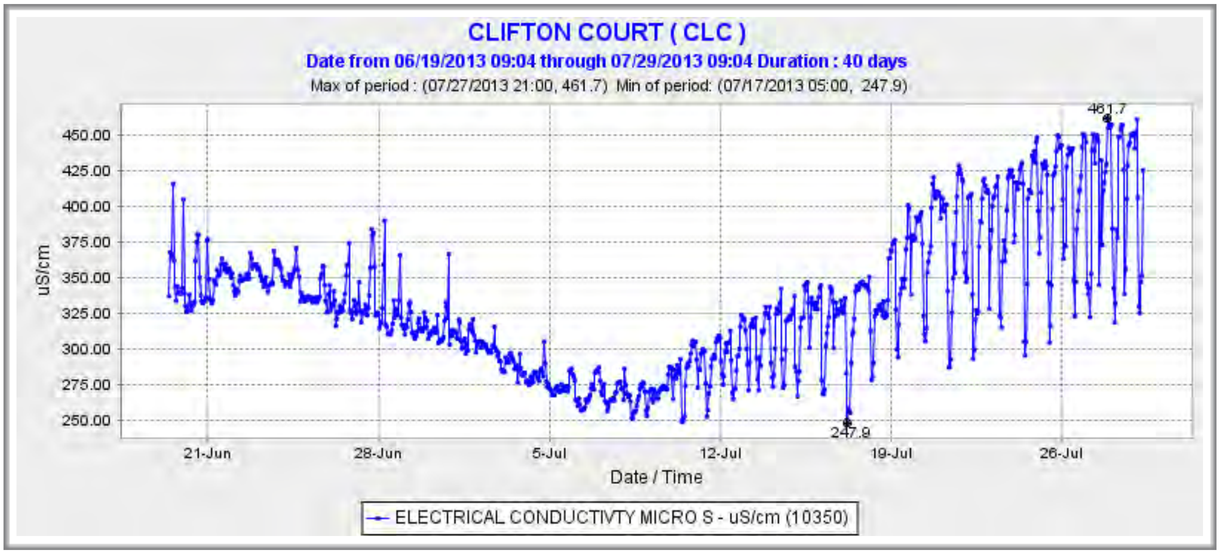

Figure 11. Conductivity (EC) in Clifton Court Forebay after mid June 2013. (Source: CDEC)

Summer Water Temperatures

Western Delta

Water temperatures reached near lethal levels for smelt (75-77F) in the western Delta by the beginning of July (Figures 12-14). Water temperatures rose sharply in late June due to the combination of warm air temperatures and sharply higher Delta inflows. Water temperatures declined thereafter through mid July with lower air temperatures, lower Delta inflows, and cooler waters moving upstream from Suisun Bay with lower outflows.

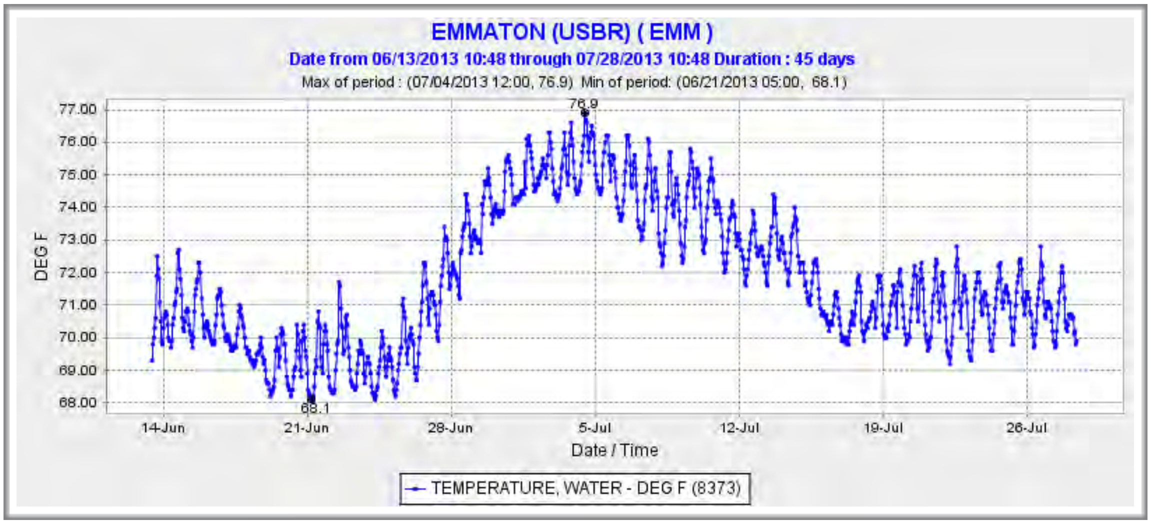

Figure 12. Water temperature at Emmaton mid June through July 2013. (Source: CDEC)

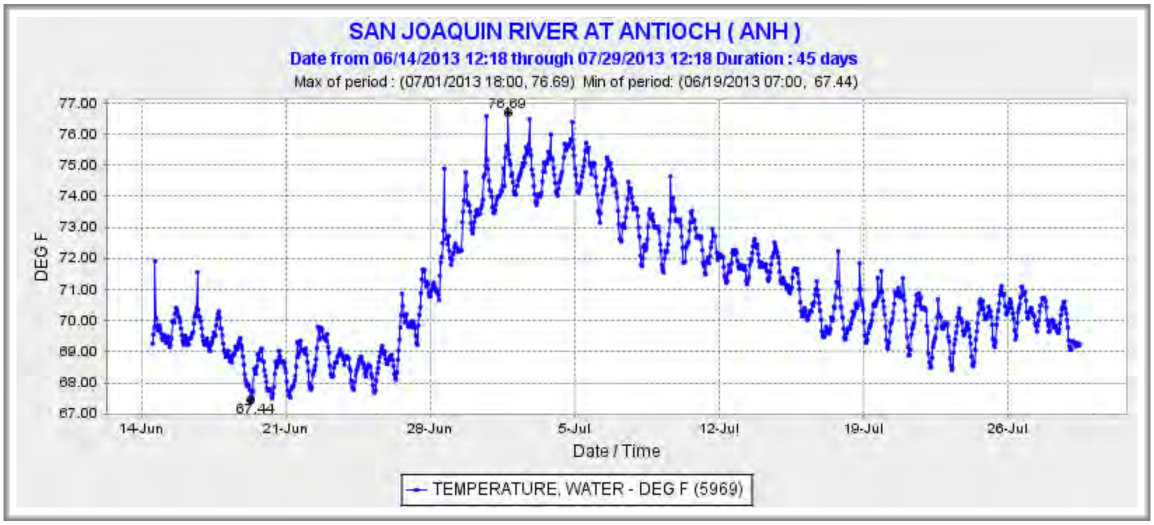

Figure 13. Water temperature at Antioch mid June through July 2013. (Source: CDEC)

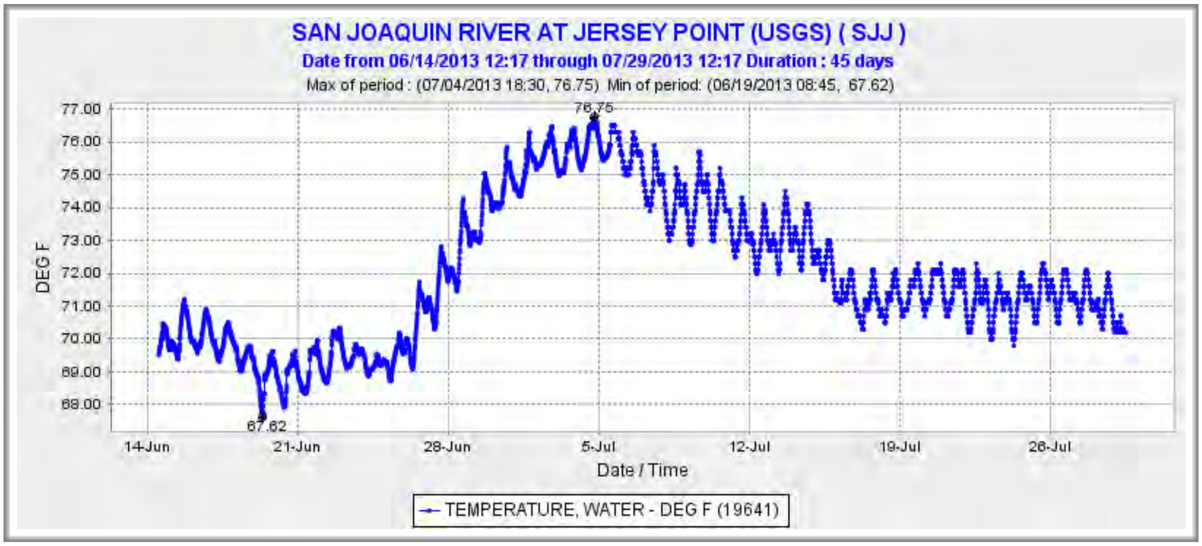

Figure 14. Water temperature at Jersey Point mid June through July 2013. (Source: CDEC)

Central Delta

Water temperatures reached near lethal levels for smelt (75-77F) in the Central Delta by the beginning of July (Figures 15 and 16). Water temperatures rose sharply in late June due to the combination of warm air temperatures and sharply higher Delta inflows. Water temperatures declined thereafter through mid July with lower air temperatures, lower Delta inflows, and cooler waters moving upstream from The West Delta with lower outflows.

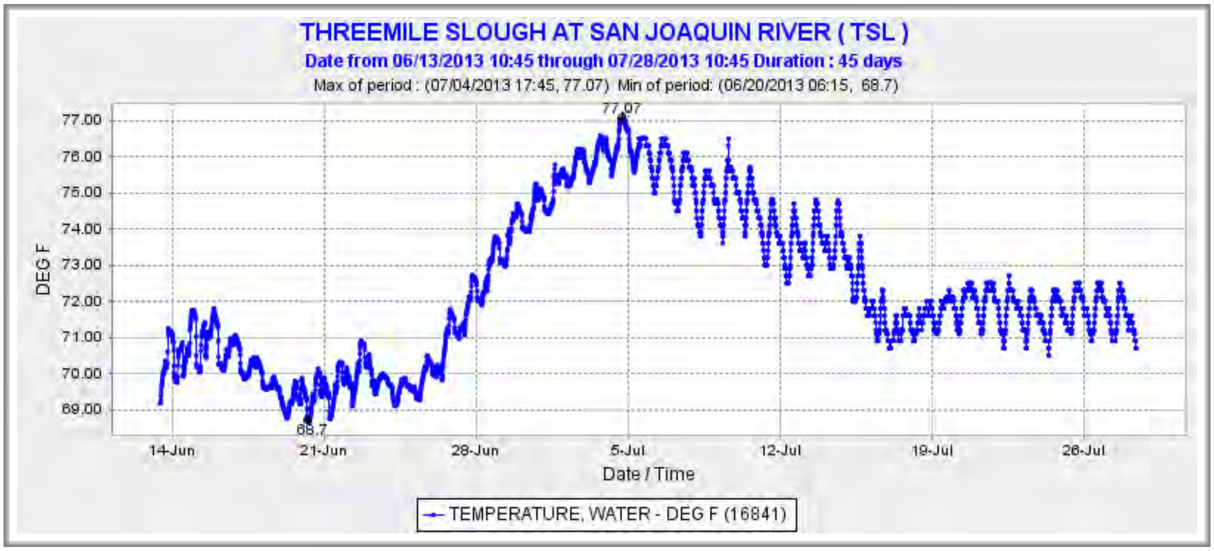

Figure 15. Water temperature at Threemile Slough mid June through July 2013. (Source: CDEC)

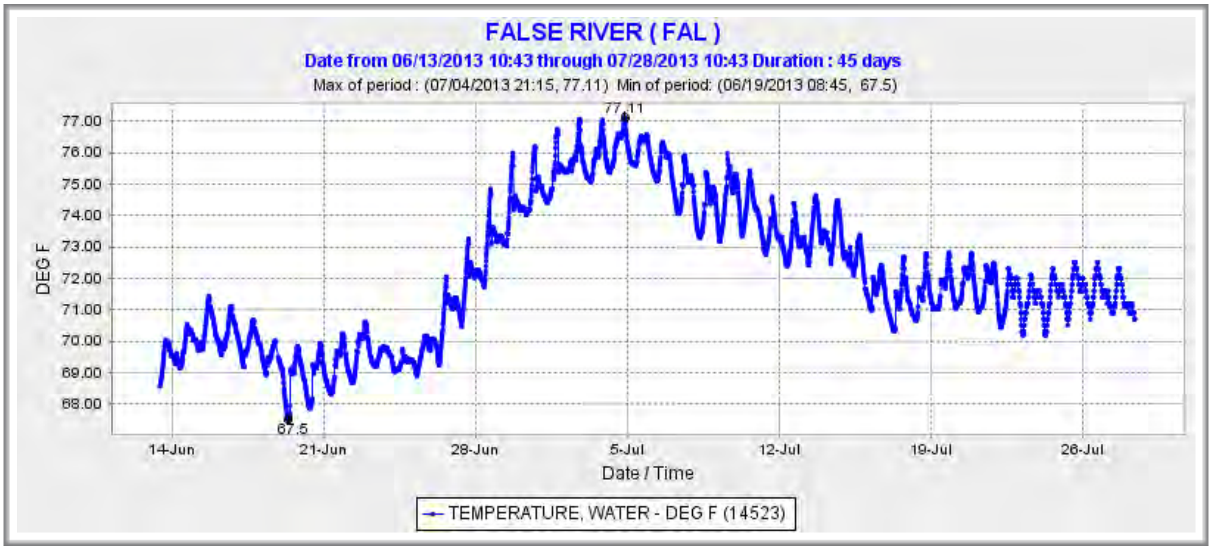

Figure 16. Water temperature at False River mid June through July 2013. (Source: CDEC)

South Delta

Water temperatures reached lethal levels for smelt (78-80F) in the South Delta by the beginning of July (Figures 17-18). Water temperatures rose sharply in late June due to the combination of warm air temperatures, sharply higher Delta inflows, and higher exports drawing warm water into the South Delta. Water temperatures declined thereafter through mid July with lower air temperatures, lower Delta inflows, and cooler waters moving into the South Delta from the western and central Delta with lower outflows.

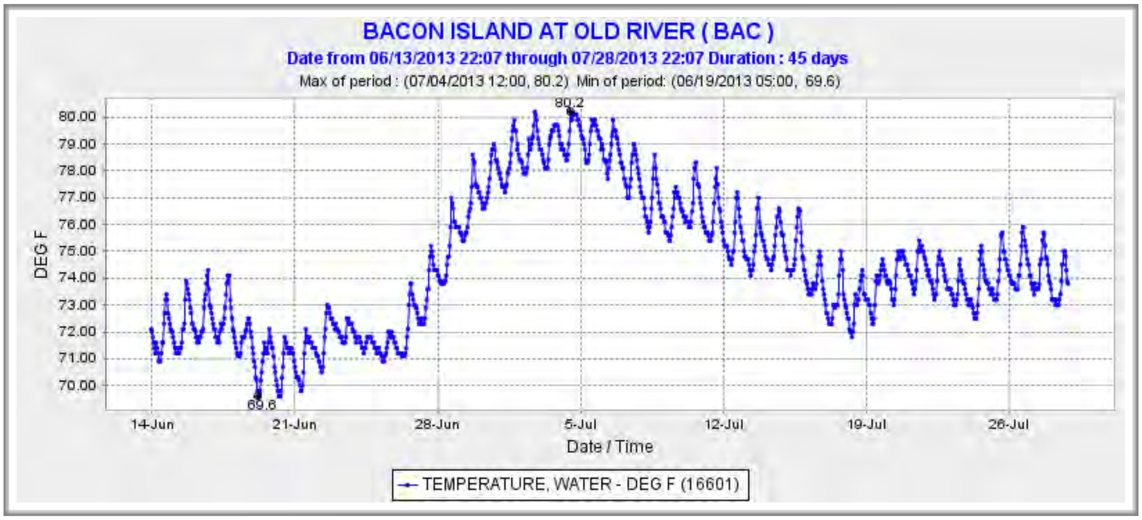

Figure 17. Water temperature in Old River near Bacon Is mid June through July 2013. (Source: CDEC)

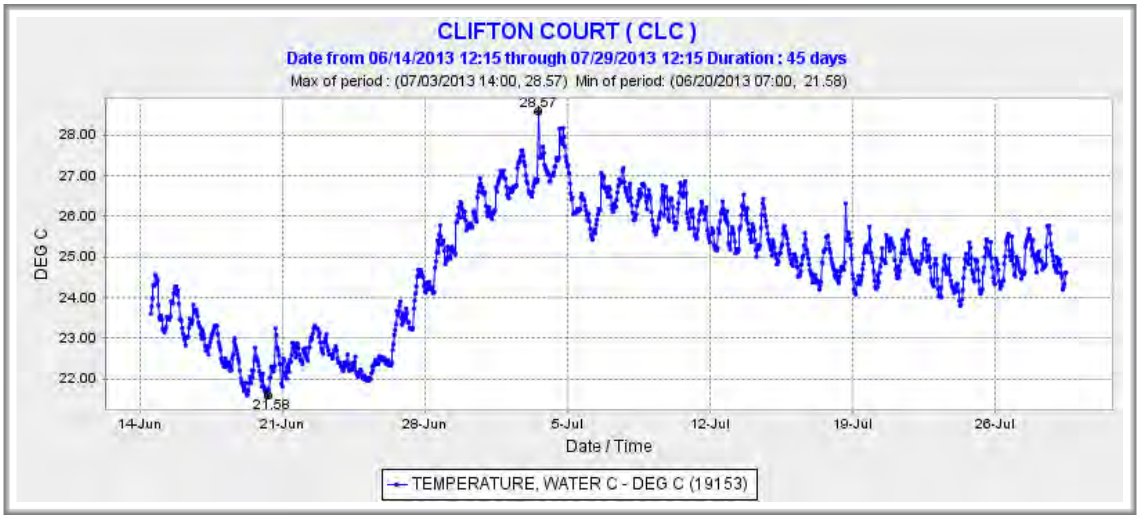

Figure 18. Water temperature in Clifton Court Forebay near Byron mid June through July 2013. (Source: CDEC)

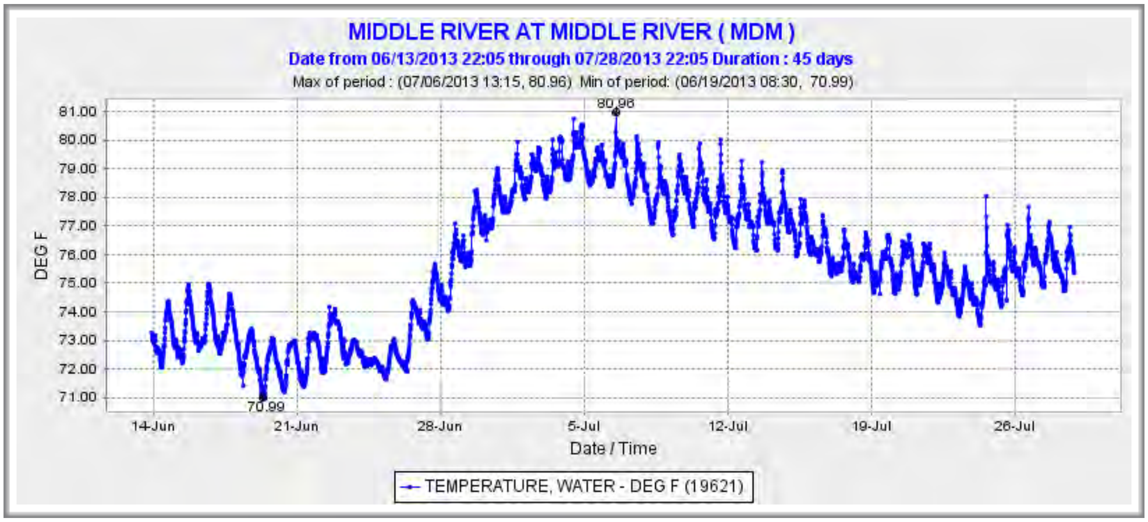
Eastern Delta

Water temperatures in the eastern Delta also reached lethal levels of 80-81F (Figures 19 and 20).

Figure 19. Water temperature in Middle River mid June through July 2013. (Source: CDEC)



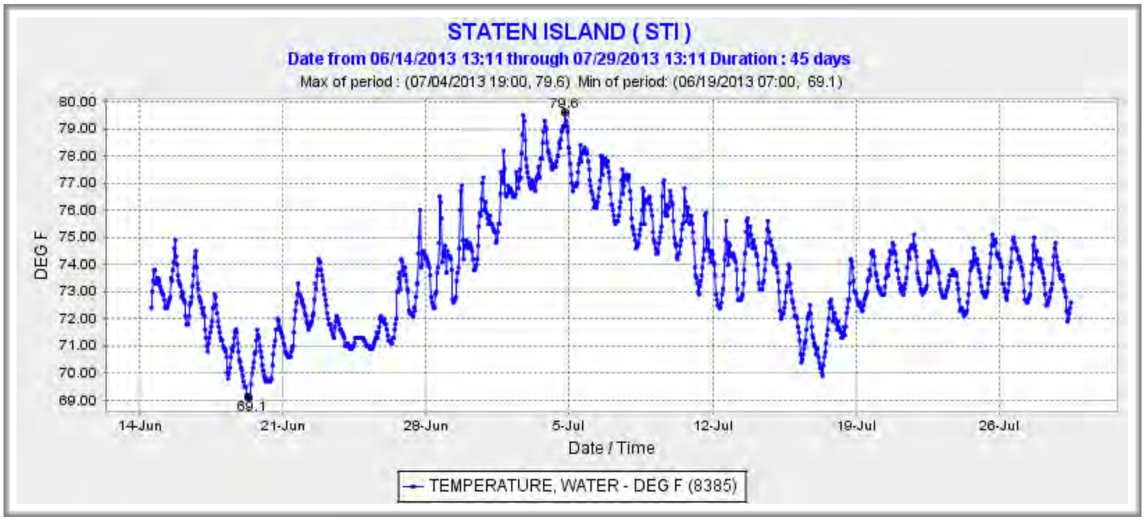


Figure 20. Water temperature near Staten Island mid June through July 2013. (Source: CDEC)

Delta Smelt Vulnerable

With the LSZ reaching into the Central and South Delta at high tides at a greater frequency through July than in wetter years it begs the question as to why were not more smelt salvaged. Clearly small salvage events occurred through mid June coincident with small pulses of exports (Figure 21). But, why not after mid June?

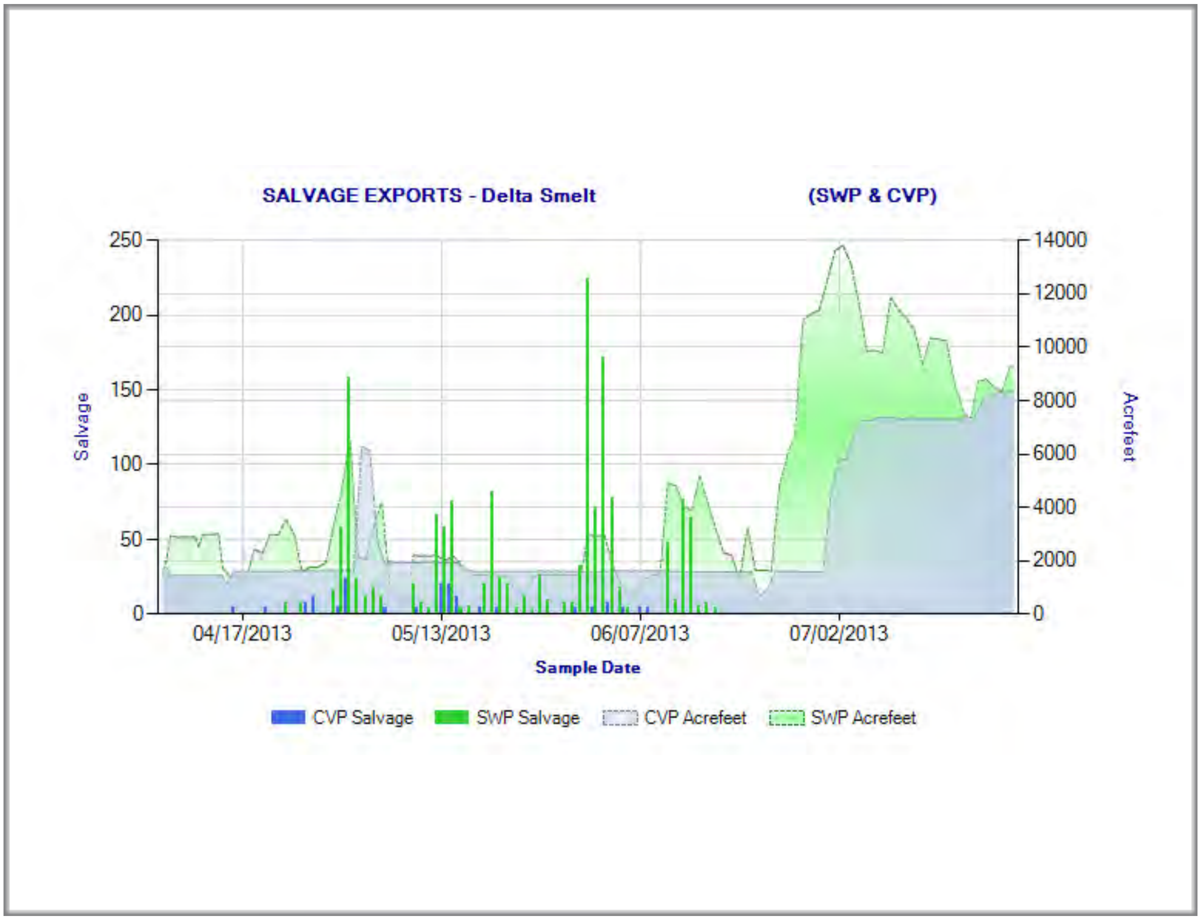

Figure 21. Delta exports and smelt salvage In spring and summer 2013. (Source: USBR MP)

First, the high inflows, low exports and high outflows kept the LSZ away from the influence of the pumps toward the end of June. Until about 8 July export demand was satiated by the pool of freshwater left over in the Delta from prior high inflows as observed in Clifton Court Forebay EC (Figure 11). But soon thereafter evidence of the LSZ being drawn to the pumps was apparent.

So why were no smelt salvaged after exports picked up and the LSZ entered the Central Delta? The answer is high water temperatures by early July. No smelt were able to survive passage to the

South Delta export salvage facilities because of lethal water temperatures in the Central and South Delta.

The high exports and high inflows at the end of June and beginning of July not only pulled the LSZ upstream into the Central Delta and under influence of the South Delta pumps at Clifton Court Forebay, but it also lead to a sharp increase in water temperature throughout much of the LSZ that was lethal to delta smelt (77-80F or 25-27C). Warm weather occurred at the beginning of July throughout the Delta (but reaching over 100F to the north and east), along with nearly a week of 20,000 cfs inflow (from the north and east) with high ambient water temperature, and near 10,000 cfs exports resulted in near lethal or lethal water temperatures in the North, Central, West, and South Delta. Smelt were able to survive only in the western portion of the LSZ of eastern Suisun Bay and extreme western Delta (Figure 22) where water temperatures remained sub-lethal at 22-24C.

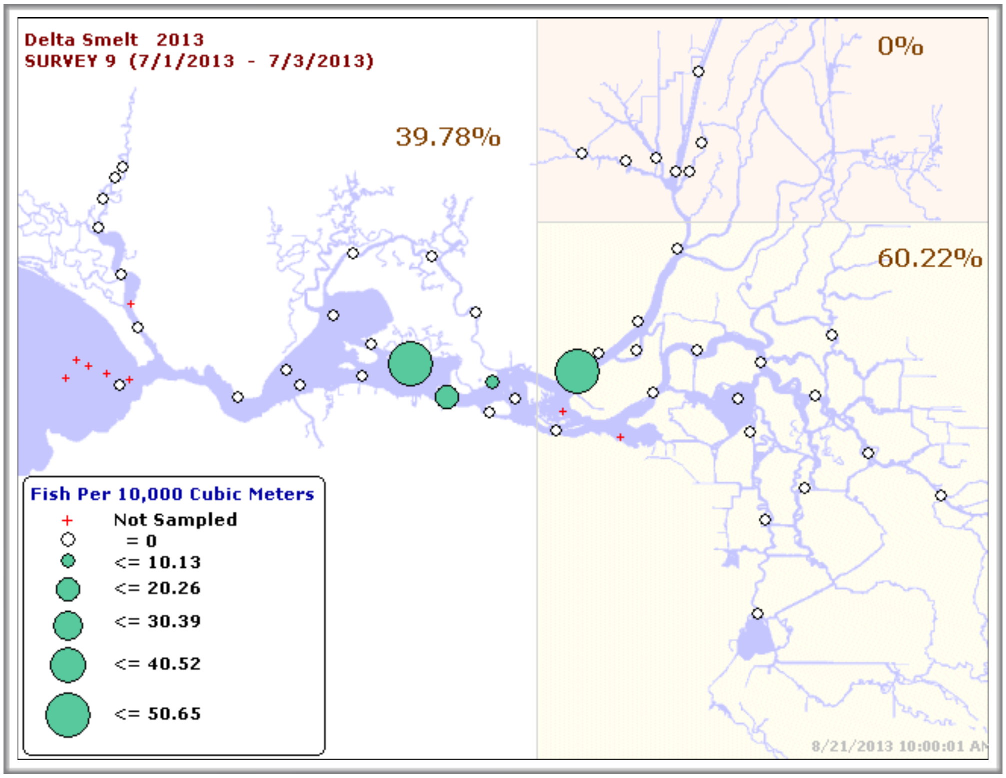

Figure 22. Early July 20-mm Smelt Survey results. (Source: http://www.dfg.ca.gov/delta/data/20mm/)

This ninth and last of the Department of Fish and Wildlife's 2013 20-mm Survey shows that the majority of smelt were in the Delta at the beginning of July. The Summer Townet Survey that began in mid June (unpublished CDFW data) has provided a Delta smelt abundance index based upon its first two surveys (weeks of June 10 and 24). The preliminary 2013 index is 0.7, down from last year's 0.9. The results from the remaining Summer Townet Survey and the Fall Mid-

Water Trawl Survey will help reveal the full extent to which Delta smelt were harmed by Project operations this summer. Based upon my decades of experience, I suspect that summer 2013 parallels the conditions during the Pelagic Organism Decline (POD) and record low smelt indices early in the last decade.

Solution

The problem remains that neither the D-1641 Water Quality Objectives for the Delta or the OCAP Biological Opinions have protections for Delta smelt after June. The demise of VAMP's limit on exports in the late spring has exacerbated the problem. The D-1641 dry and critical year standards for outflow are simply too low to protect delta smelt and their important habitats. Even with higher outflows, excessive exports remain a problem. The inflows necessary to sustain high exports reduce reservoir storage and cold-water pools, and bring warmer, low-productive reservoir water into the Delta and LSZ. Cooler, more productive, more turbid water, critical to delta smelt growth and survival is first exported from the Delta and then replaced with warm, low turbidity, low productivity reservoir water. Higher summer outflow and reduced exports (and a minimum of inflow necessary to sustain reduced exports) in drier years are fundamentally necessary for delta smelt recovery. A minimum of inflow and exports will increase residence time and productivity, allow higher productivity waters and smelt to remain in the Delta, and allow Delta waters to remain cooler to sustain smelt.

An Overview of Habitat Restoration Successes and Failures in the Sacramento-San Joaquin Delta

Thomas Cannon

Bill Jennings

California Sportfishing Protection Alliance

July 2014

Table of Contents

Executive Summary

The Bay Delta Conservation Plan (BDCP) proposes to create or restore approximately 150,000 acres of aquatic, riparian and terrestrial habitat in the Delta. Given the astonishing lack of specific details in BDCP's programmatic restoration plan, this report briefly reviews historical habitat restoration projects in the 222,902 acres of existing conservation lands within the Delta in an effort to evaluate the likely success of BDCP's conceptual restoration plan.

Despite numerous restoration projects, there have been few documented successes in the Delta. Many proposed projects failed to move beyond a conceptual stage because of a lack of funding. A number of projects succeeded in acquiring property but failed to secure the funding necessary for implementation. Other restoration projects were constructed but failed because they were poorly conceived or lacked sufficient funding to maintain or adaptively manage the habitat. Even relatively successful projects have too often experienced mixed results and unintended consequences. Cumulatively, the myriad restoration projects have failed to slow or reverse the precipitous decline in the estuary's native pelagic and anadromous fisheries.

The consistent flaw of previous restoration efforts in the Delta has been a failure to adequately meet the habit requirements of native fish. The estuary's native species evolved over many thousands of years in response to existing habitat conditions. And that habitat included adequate physical (flow, residence time, variability, etc.) and chemical parameters (salinity, temperature, turbidity, chemical constituents, etc.), as well as the nutrients necessary for primary production to support renewable fisheries. Upstream diversions and Delta exports have radically altered the Delta's hydrodynamics, which has resulted in a loss of critical flows, less variability, degraded water quality and reduced primary productivity. The yearly export of phytoplankton, the foundation of the aquatic food web, is equivalent to more than 30% of net primary production.

The Delta's altered hydrology has allowed numerous invasive non-native species to become entrenched to the detriment of native communities. A number of fishery scientists have observed that a variable freshwater Delta has been transformed into something resembling an Arkansas lake. Creating more Arkansas lake habitat will simply create more Arkansas lake fish.

Successful restoration of native species requires restoring the conditions under which they evolved and prospered. This entails increasing outflows, mimicking the natural hydrograph, improving water quality, protecting the critical low salinity zone (LSZ) and reducing export of primary productivity. However, these are the essential elements BDCP cannot provide.

Construction and operations of BDCP's north Delta diversion facilities will exacerbate existing poor conditions by decreasing outflow, moving critical LSZ pelagic habitat eastward, degrading water quality and exposing sensitive life stages of listed species to massive new water diversions. As mitigation, BDCP proposes a conceptual and highly speculative plan to restore habitat with uncertain public funding.

Our review of the habitat needs of native species and the history of habitat restoration projects in the Delta reveals that BDCP's optimistic projections of success are unrealistic and not likely to restore native Delta fisheries.

Introduction

The Bay Delta Conservation Plan (BDCP) proposes to increase water supply reliability by diverting the Sacramento River through twin 40-foot tunnels under the Delta for export to the San Joaquin Valley and Southern California. It also proposes creation of approximately 150,000 acres of new habitat in the Delta to restore the estuary and offset adverse impacts from diverting vast quantities of water around the Delta. The costs of tunnel infrastructure will be paid by the state and federal water contractors while the vast majority of habitat restoration costs will be borne by the general public.

The BDCP EIR/EIS analyzes the tunnels to a project specific level, while habitat restoration has only been analyzed at a programmatic level. There are few details on specific habitat restoration projects. Fishery agencies and scientists have bluntly questioned the likelihood that habitat creation will be as successful as claimed by BDCP proponents or whether habitat restoration can realistically offset the projected adverse consequences from increased exports and reduced outflow to San Francisco Bay.

For example, the Delta Independent Science Board, in its review of the Draft BDCP EIR/EIS and Draft BDCP Plan, observed, "Many of the impact assessments hinge on overly optimistic expectations about the feasibility, effectiveness, or timing of the proposed conservation actions, especially habitat restoration"[1] and "Positive and timely benefits of habitat restoration are highly uncertain. Failure to realize these benefits will invalidate the final conclusion of no net negative effect."[2] Likewise, the Panel Review of the Draft Bay Delta Conservation Plan, prepared for the Nature Conservancy and American Rivers said, "BDCP is too optimistic about benefits of tidal marsh and floodplain restoration for smelt, particularly the extent of food production."[3]

The National Marine Fisheries Service, in comments on the Draft EIR/EIS said, "There is too much benefit to steelhead smolts assumed from habitat restoration in the Delta."[4] The U.S. Fish and Wildlife Services wrote, "Scientific literature cited in the plan, new analyses provided by DWR, and conclusions of the independent scientific review panel have reinforced our concern

that the BDCP restoration plan has not been carefully thought out and has uncertain prospects for benefiting native aquatic estuarine species, particularly delta smelt and longfin smelt." [5]

Can habitat restoration offset the loss of flow due to diversion of massive quantities of fresh water around the estuary and restore severely degraded fisheries? The U.S. Environmental Protection Agency wrote in commenting on the Administrative Draft EIR/EIS, "There is broad scientific agreement that existing Delta outflow conditions are insufficient for protecting the aquatic ecosystem and multiple fish species, and that both increased freshwater flows and aquatic habitat restoration are needed to restore ecosystem processes in the Bay Delta and protect T & E fish populations. This includes statements from lead federal agencies."

Indeed, as the U.S. Fish & Wildlife Service testified during the State Water Resources Control Board's 2010 flow hearing, "flow in the Delta is one of the most important components of ecosystem function." Habitat is more than the spatial extent of acreage, and increases in habitat area doesn't ensure increases in habitat quality or functionality. Habitat requires adequate physical (flow, residence time, variability, etc.) and chemical parameters (salinity, temperature, turbidity, chemical constituents, etc.), as well as the nutrients necessary for primary production to support renewable fisheries. Yet, BDCP's principle strategy for fixing the Delta is based on the hypothesis is that increased habitat restoration acreage can substitute for flow.

The BDCP Conservancy Strategy identifies some 222,902 acres of existing conservation lands in the plan area. These include properties managed by conservancies and land trusts, agency restoration sites, designated biological mitigation sites, wetlands owned or managed by agencies or private parties, conservation easements, parks, and lands associated with implementation of HCPs and NCCPs.[6]

Since both the BDCP Plan and EIR/EIS contain few specific details of proposed habitat restoration, this report examines the history of habitat restoration in the Delta in order to provide some guidance on the likely success of future habitat restoration efforts. It summarizes our review of the habitat restoration that has taken place in the Delta over the past several decades with emphasis on habitat values for young Delta and longfin smelt as well as Chinook salmon.

Delta Habitat

Delta native fish species depend heavily on the Delta habitats, especially in drier years when flows are insufficient to move their young downstream to the Bay. Young smelt and salmon rear in brackish water in what is called the Low Salinity Zone or LSZ. This zone is typically defined as 0.5 to 6.0 ppt salinity (or roughly 500-10,000 EC conductivity). Another term referred to as X2 is defined as the center of the LSZ at 2 ppt salinity. After spawning upstream in freshwater, smelt tend to concentrate at X2 by summer. In drier years the LSZ and X2 are found mainly in the Delta in the main rearing period of young of both smelt species from late winter into early

---

[6] Public Draft, Bay Delta Conservation Plan: Chapter 3, Conservation Strategy, Table 3.2-2, page 3.2-20.

summer. The LSZ is important because it provides slightly brackish water, frequently suitable water temperatures, and abundant prey for the young fish. The smelt are pelagic species found predominantly in shoal and open water, and beaches near the open water. It is critically important that habitat be restored and developed within or near the LSZ if the expected benefits to smelt and other pelagic fishes are to be achieved.

Young salmon begin entering the Delta as fry soon after emerging from river spawning gravels from late winter to early spring. Fry and fingerlings (25-75 mm) concentrate in shoreline areas and adjacent margin habitats including tidal marshes, sloughs, and channels. Smolt salmon (80 mm +) are often collected in open channels migrating westward toward the ocean generally in winter and early spring, but are also found feeding in margin habitats. It is important that habitats be restored and developed along their Delta migration pathways to ensure successful passage from the river to the Bay. BDCP proposes to restore only about twenty miles of channel margin habitat over a span of thirty years.

Delta aquatic habitat has been greatly altered by 150 years of reclamation. The majority of the tidal marsh, slough, and open water habitats were reclaimed or altered by a vast system of levees and connecting sloughs by the second decade of the last century. More recently, two major ship channels were carved through the Delta. It should be noted, however, that the recent precipitous decline in pelagic and anadromous species and the listing of numerous species pursuant to state and federal endangered species acts only occurred after construction of the Central Valley Project (CVP) and State Water Project (SWP) and the diversion of massive quantities of water to the San Joaquin Valley and Southern California.

Between 1930 and 1943, an average of 82% of estimated unimpaired flow reached San Francisco Bay. That has declined to less than 50% in recent years,[7] well below the 75% level identified by the State Water Resources Control Board as necessary to protect public trust resources and estuarine health.[8] The State Board's conclusions on needed flows followed a comprehensive proceeding, mandated by the State Legislature, involving agency and independent scientists, academia, water agencies and pubic interest groups. The California Department of Fish and Wildlife, under a similar legislative mandate, reached similar conclusions.[9]

[9] CDFG, Quantifiable Biological Objectives and Flow Criteria for Aquatic and Terrestrial Species of Concern Dependent on the Delta, 2010.

A number of fishery scientists now refer to the Delta as being in a state of perpetual drought. The number of years of critically low inflow to the Bay has more than tripled to 62% of the time since the 1930s.[10]

The BDCP proposes upwards of 150,000 acres of habitat restoration, focusing primarily on tidal marsh restoration. Tidal marsh is proposed to provide direct and indirect benefits to Delta fish through the food web and as habitat for various fish species or specific life stages. One measure of the potential benefits of this large-scale restoration is to review the past history of restoration in the Delta. Have the various efforts to restore Delta aquatic habitats proved successful? This overview summarizes these restoration efforts and explains how that experience relates to habitat restoration efforts prescribed in the BDCP. But before examining historical habitat restoration efforts, we should consider a few of the inherent uncertainties of restoration efforts.

Uncertainties of Habitat Restoration

Much of the historical and BDCP habitat restoration has been focused on restoring tidal marsh. Recent scientific debate has focused on the relative merits of tidal marsh restoration on the shallow water and pelagic food web of the Delta. The key questions are whether smelt and salmon young use the tidal marsh habitats, whether tidal marshes contribute to food production in the preferred smelt and salmon open water (pelagic) and channel margins (shoreline) habitats of the Delta, whether restoration projects themselves create deleterious effects, and the uncertainties of funding and actual implementation.

One key BDCP hypothesis is that tidal marshes export nutrients and food web production to adjoining pelagic habitats. However, recent scientific reports question that hypothesis; “Tidal marshes can be sources or sinks for phytoplankton and zooplankton. Most appear to be sinks, particularly for zooplankton” and “ Even under the most highly favorable assumptions, restored marshes would have at best a minor contribution of plankton production in smelt rearing areas.” [11] Also, “Movement of plankton from a tidal marsh (beyond the immediate area of tidal exchange) is likely to be limited and to decrease strongly with distance. Even under ideal circumstances, plankton in water discharged from tidal marsh cannot greatly affect the standing crop of plankton in large, deep channels. Feeding by clams and other introduced species can further reduce contributions of marsh plankton to open-water food webs.” [12] As the Delta Independent Science Board recently wrote, “Whether or not any increases in primary production

[12] Herbold, B. et al., The Role of Tidal Marsh Restoration in Fish Management in the San Francisco Estuary, 2014, page A-11. http://www.escholarship.org/uc/item/1147j4nz

will be transferred to zooplankton and on to covered species that may reside in the restored area or outside of it is largely unknown."[13]

There is also the looming question of whether the proposed habitat can be created without exacerbating methylmercury problems. As the National Marine Fisheries Service (NMFS) put it, "There is no indication that the kinds of habitat restoration that can meaningfully contribute to estuarine fish viability can be created or restored without also methylating the ubiquitous mercury in the system because the management tools available conflict with these fishes' habitat needs. Minimization of water depth and reduction of turbidity to control mercury methylation conflict with the direct habitat needs of delta and longfin smelt and will in some locations favor invasive species such as sunfishes and water hyacinth. However, minimization of water depth and turbidity will maximize the potential for algal production and algal production will generate dissolved organic carbon (DOC). If, as the ADEIS implies, restoration sites will also be designed to minimize the export of DOC from restoration sites to minimize anoxic conditions (reducing methylation opportunities) these designs will also reduce their potential food web benefits."[14] BDCP found that the preferred alternative would increase mercury concentrations and exceed tissue toxicity thresholds in largemouth bass in the Delta.[15] Increases in mercury loading resulting from habitat restoration projects would exacerbate the problem.

This issue is not limited to mercury. Marshes are often sinks for organic contaminates like PCBs, PAHs, organochlorine compounds and organophosphate and pyrethroid insecticides. Selenium is a serious problem. NMFS commented on the BDCP EIR/EIS, "An expected increase in contribution of San Joaquin River water to the Delta will increase selenium loading in the Delta, especially in the southern Delta and Suisun Bay where bioaccumulation by bivalves is assured (Stewart et al. 2004). This in turn represents an increased risk of deleterious reproductive effects caused by selenium accumulation in fish and wildlife."[16] BDCP found that the preferred alternative would increase annual average selenium concentration in sturgeon over the existing conditions and no action alternatives.[17]

There is also a serious concern that diverting flow around the Delta and reducing outflow will expand the range of overbite clams, "Finally, only adverse effects are indicated resulting from conservation measures in the context of invasive mollusks. CM1 may increase *Corbula* habitat by moving X2 upriver, assuming greater freshwater diversion. Given that *Corbula* is the more effective trophic competitor with covered planktivorous fish, this suggests degradation of habitat characteristics due to CM1. Restoration involved in CM4 (tidal wetland), CM5 (seasonally

inundated floodplain), and CM6 (channel margin habitat) may increase potential benthic habitat for *Corbula* and *Corbicula*, overall exacerbating the impacts of these competitors. Tidal and shallow water habitat restoration, if invaded by *Corbula* or *Corbicula* may result in phytoplankton sinks actually worsening circumstances for fish.[18]

Another example of uncertainties in habitat restoration is the effect on tidal energy. As the Independent Science Board observed, "Tidal energy coming from outside the Golden Gate is another limited resource in the development of habitat in the Delta and its larger estuary. A major effect of many of the proposed habitat restoration activities (as well as potential island failures in the future) is likely to be the changes in tidal amplitude and mixing. This will affect the suitability of certain characteristics for restoration." [19] A number of agencies have expressed concerns that changes in tidal amplitude caused by creation of more open tidal habitat will increase salt intrusion in the Delta.

Given the programmatic level analysis of proposed habitat restoration, there is significant uncertainty that large-scale restoration projects will actually be implemented or implemented in a timely manner. The Independent Science Board acknowledged these concerns in saying, "Construction and flow operations may have impacts immediately, whereas the restoration impacts and benefits may lag a decade or more after construction" and "If proposed habitat restoration actions are not implemented in a timely fashion or are not as effective as assumed in the DEIR/DEIS, then the positive impacts of those actions would no longer be present, and the final assessment of a net positive or no net negative effect would not be valid." [20] They also noted, "The literature strongly suggests, however, that there are significant time lags between construction of a new habitat and its full functionality. This means that the benefits of habitat restoration may not occur for a long time and that the benefits may be too late for some species if negative impacts come first" and "Even if all acres are acquired and restoration actions are taken in a timely manner, whether those actions will deliver the anticipated benefits or not is also uncertain." [21]

The lack of funding commitments for BDCP's proposed restoration projects creates major uncertainties. Habitat restoration is extremely expensive. As we discuss below, many proposed restoration projects were unable to move beyond a conceptual stage because of a lack of funding. A number of projects were able to acquire property but couldn't secure the funding necessary for implementation. Other projects were constructed but failed because they lacked sufficient funding to maintain or adaptively manage the habitat.

What is clear is that populations of native species like salmon, steelhead, Delta and longfin smelt, splittail, threadfin shad, native phytoplankton and zooplankton, and several species introduced in the 1800s like striped bass and American shad are collapsing. In contrast to the rapid decline of native species: populations of recent invasive predatory species like inland silversides, bluegill, largemouth bass and overbite clams; troublesome invasive plants like water hyacinth, arundo, Brazilian waterweed, parrots feather and potamogeton; and less nourishing non-native copepods and mysids are flourishing.

Many scientists have observed that the state and federal project's massive water diversions and altered hydrograph have transformed the Delta into something resembling an Arkansas lake. In fact, the Delta is now home to a number of trophy bass fishing tournaments and Bass Master magazine recently ranked the Delta as the ninth best largemouth and smallmouth bass fishing spot in the entire nation. Creating additional Arkansas lake habitat will not restore the iconic native species of the Bay-Delta estuary.

The preceding examples are only a few of numerous critical comments by independent scientists and agencies regarding the highly speculative and questionable assertions by BDCP that habitat restoration is a magical bullet that will not only mitigate adverse impacts of diverting additional water around the estuary but will also restore seriously degraded fisheries. But these are not the subject and purpose of this review.

Instead, this report focuses on whether historical habitat restoration has met the physical goals and objectives of restoration. The following observations are focused primarily on the direct benefits to salmon and smelt based on four decades of sampling fish in Delta habitats. Are the altered habitats after levee breaching, channel digging, and vegetation planting functioning? Has water quality been sufficient to support fish? Have non-native invasive plants and fish taken over these new restored habitats? Are the habitats right for smelt and salmon?

History of Aquatic Habitat Restoration in the Delta

There are dozens of "restoration" sites around the Delta dating back several decades or more. There are even more in San Francisco Bay, which are not discussed in this report. As noted above, BDCP has identified almost 223,000 acres of existing conservation lands in the Delta. The majority of these lands were acquired in the last few decades.

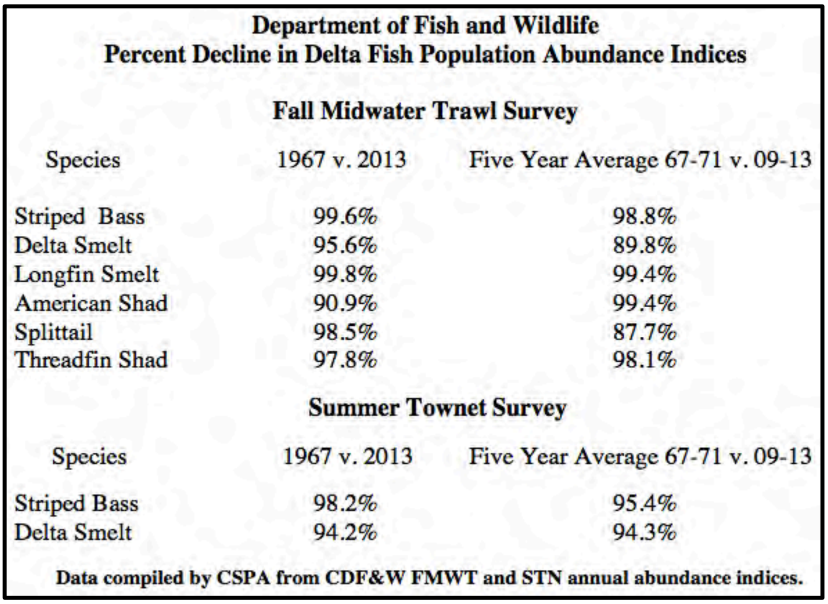
Delta restoration has occurred as mitigation for many large and small development projects throughout the Delta. Levee repair, dredging, dock construction, sand mining, new water intakes, bridges, flow barriers, and the large federal and state water projects have undertaken some form of habitat mitigation.

In the recent decade, restoration has been larger and more formal under directed water project mitigation, multi-agency programs such as the Central Valley Project Improvement Act, Corps Central Valley Flood Control Levee Program, Sacramento and Stockton Port Programs, Delta Wetlands Program (private), the state Delta Levees Program, and the CALFED program. Under the State Water Project, Delta Wetlands Project, Montezuma Wetlands Project, PG&E Delta Power Plant Mitigation Program (HCP), and CALFED programs monies were available for government and non-profits to purchase large-acreage projects such as Sherman Island, West Sherman Island, Twitchell Island, Yolo Bypass Wildlife Area, Big Break, Staten Island, Cosumnes River Preserve, Liberty Island, Stone Lakes NWR, Little Holland Tract, and many other significant areas.

In recent years, water districts have acquired large tracts of property in anticipation of future mitigation needs. The most notable is a 5000-acre portion (including 1,100 acres of wetlands) of the lower Yolo Bypass north of Liberty Island called the Lower Yolo Restoration Project.

However, habitat restoration projects have failed to achieve their stated purpose. They have neither slowed nor reversed the collapse of Delta fisheries. We see little on which to base any optimism that more of the same will lead to different results.

The California Department of Fish and Wildlife has conducted surveys of the Delta's pelagic species since 1959. The Fall Midwater Trawl (FMWT) survey was initiated in 1967, the year the State Water Project began exporting water from the Delta. It samples 122 stations each month from September to December, and the data is used to calculate an annual abundance index of pelagic species. These stations range from San Pablo Bay upstream to Stockton on the San Joaquin River, Hood on the Sacramento and the Sacramento Deep Water Ship Channel.[22]



Department of Fish and Wildlife
Percent Decline in Delta Fish Population Abundance Indices

Fall Midwater Trawl Survey

Species	1967 v. 2013	Five Year Average 67-71 v. 09-13
Striped Bass	99.6%	98.8%
Delta Smelt	95.6%	89.8%
Longfin Smelt	99.8%	99.4%
American Shad	90.9%	99.4%
Splittail	98.5%	87.7%
Threadfin Shad	97.8%	98.1%

Summer Townet Survey

Species	1967 v. 2013	Five Year Average 67-71 v. 09-13
Striped Bass	98.2%	95.4%
Delta Smelt	94.2%	94.3%

Data compiled by CSPA from CDF&W FMWT and STN annual abundance indices.

The Summer Townet Survey was begun in 1959 and samples striped bass and Delta smelt at 32 stations, ranging from eastern San Pablo Bay to Rio Vista on the Sacramento River and to Stockton on the San Joaquin River. Surveys begin in early June and continue on alternate weeks through August, and the data is used to calculate an abundance index.[23]

The annual abundance indices document the continued one to two orders of magnitude decline of the entire spectrum of native pelagic species in the estuary. The same magnitude declines hold true for the native lower trophic orders that comprise the base of the food web.

Central Valley anadromous fisheries have also not fared well and are far below the doubling levels mandated some 22 years ago by the Central Valley Project Improvement Act, California

[23] http://www.dfg.ca.gov/delta/projects.asp?ProjectID=TOWNET

Water Code and California Fish and Game Code.[24] For example, winter-run, spring-run, Sacramento fall-run and San Joaquin fall-run Chinook salmon are at 5.7, 20, 31 and 25.5 percent, respectively, of legally mandated levels.

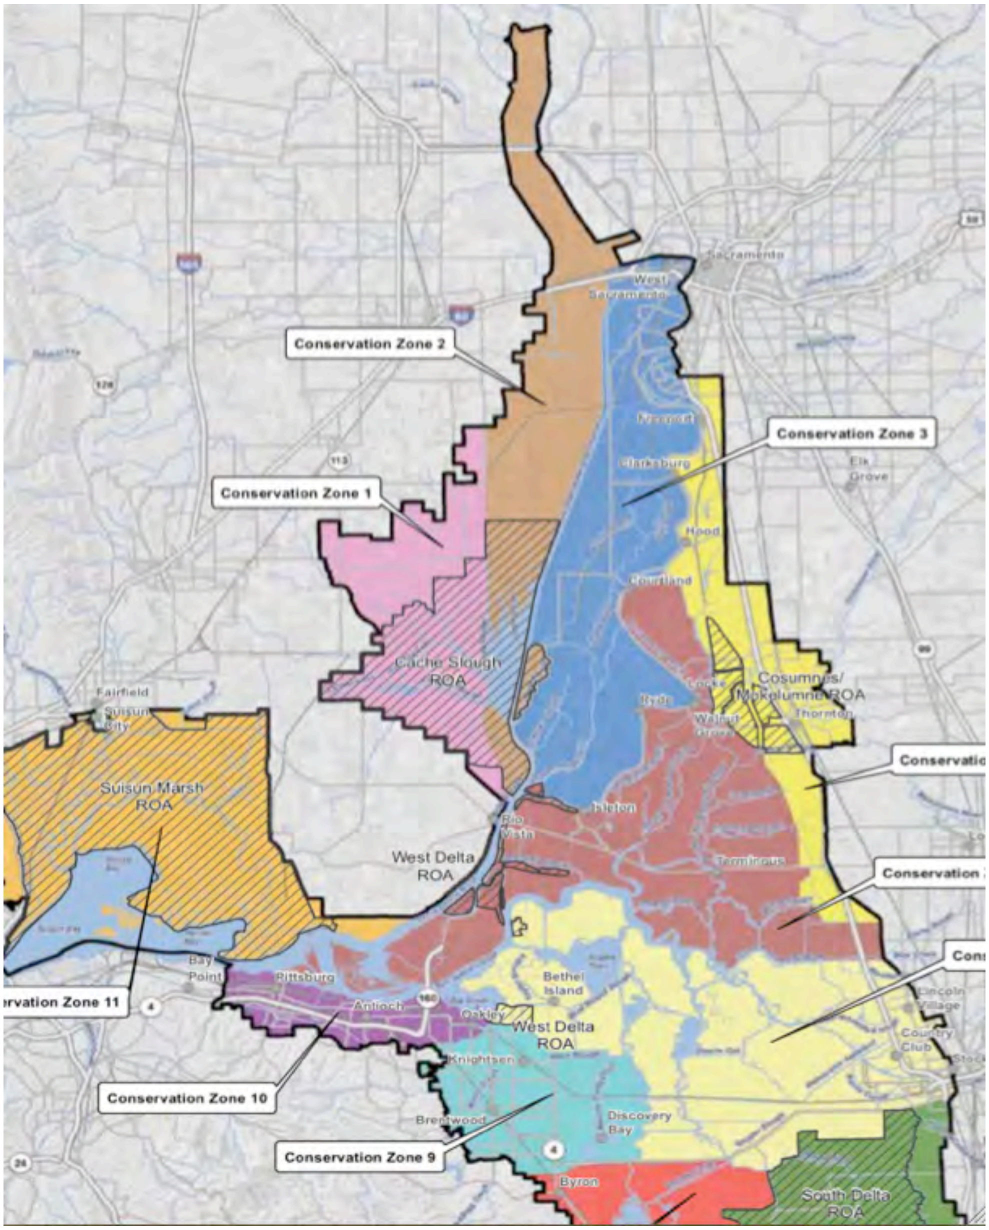

Figure 1. Delta habitat regions as defined in the Bay Delta Conservation Plan. Restoration sites included in the BDCP are shown by cross-hatching.

Geographic Coverage

The focus of this review is on restoration sites in the West, Central, East, and North Delta where habitats are potentially used by smelt and salmon. The South Delta is not addressed primarily

---

[24] http://www.fws.gov/stockton/afrp/Documents/Doubling_goal_graphs_020113.pdf

because there are few restoration sites and what there is may be of minimal benefit to smelt and salmon. There is discussion of lower San Joaquin River habitat in the discussion of the East Delta, as it is important habitat for salmon and splittail originating from the San Joaquin River system. For consistency, the BDCP Restoration Opportunity Areas (ROAs) are used for the various portions of the Delta. The areas are generally consistent with the BDCP designations (Figure 1), which include more area than the BDCP's Cache Slough ROA. The West Delta region includes the area from Collinsville to Rio Vista, Pittsburg to Antioch, including eastern Chipps Island.

Benefits, Successes, and Failures

This review discusses individual sites including benefits, successes, and failures. Failures include simply doing nothing with the specific properties and letting them deteriorate over time. Failures are common even for active restoration sites where what was built or constructed did not work or actually provided poor habitat. Given the large amount of overall effort and expense, there has been a disturbing lack of progress and overall success. There have been a few successes in protecting or restoring specific sites and considerable research on several of these sites has produced a wealth of restoration and ecological science.

However, what some characterize as new "paradigms" for Delta habitat restoration are, in reality, disasters in the making that jeopardizes both restoration success and the expenditure of billions of dollars. Fish cannot be coerced into thriving under conditions radically different than those in which they evolved over millennia. Restoration projects that fail to provide habitat that reflects conditions under which native species evolved cannot succeed in restoring native species.

West Delta

The West Delta has a rich history of failed habitat "restoration" and missed opportunities. Many of the habitats are managed as part of Suisun Bay/Marsh habitats and are described in the Suisun Marsh Habitat Management, Restoration and Preservation Plan.[25]

Figure 2. Chipps Island at the western boundary of the Delta on Suisun Bay is a failed mitigation site.

---

[25] http://www.fws.gov/sacramentøoutreach/2010/10-29/Documents/Tidal_CM_Chapter_1_Phys_Proc.pdf

Chipps Island

Chipps Island is a classic example of failed mitigation habitat. The roughly 700 acre "Delta island," at the west boundary of the Delta, has three main parcels: north, west, and east (Figure 2). Each has its own history and habitat characteristics. Today they are duck clubs. The north parcel was once purchased with mitigation funds by a non-profit but was eventually sold to a duck club for lack of restoration funds. The north and east parcels are muted tidal marshes that are flooded periodically during high tides. But, these are basically managed as freshwater marsh preferred by duck clubs in the Suisun Marsh area. The west parcel would be best described as brackish marsh, as the levees have long been breached and its channel network is fully tidal. The southern boundary of the island on the main ship channel is slowly eroding from ship wakes. Levees have been repaired in recent decades on the north parcel and have gates to allow water to enter the property when needed. Large numbers of native fishes including young salmon have been observed trapped within this parcel's ponds and channels. The island is in need of management and restoration, and the duck club owners have unsuccessfully attempted to sell the property. The island could potentially serve as important winter-spring rearing habitat for salmon and as Delta and Longfin smelt habitat in all but the driest years. However, Chipps Island is a restoration failure in that it should have been restored a decade after it was purchased with oil-spill mitigation funds.

Figure 3. The Collinsville site along the north shore of the lower Sacramento River channel. Collinsville is left center with Montezuma Island to its right.

Collinsville/Montezuma

Collinsville is at the west boundary of the Delta (Figure 3) and has a rich history. The two islands and most of the lowland shoreline (about 500 acres), at the base of the hills immediately east of Collinsville, were once PG&E property destined for a new Delta power plant.

After efforts to build a new plant failed, PG&E offered the property for restoration as part of the HCP permit mitigation to operate their two remaining power plants in the Delta. PG&E subsequently sold the two plants to Mirant/Southern. The plants are now included within the BDCP package of development actions to be permitted by the new BDCP-HCP process. The

Collinsville mitigation site remains in limbo having been once included in the original HCP permit.

However, it was never restored. Title to the property remains with the utility companies and was never transferred to the State, as intended under the original HCP permit. Once a navy base in World War II, the site's tidal channels have filled in with sediment and aquatic plants including invasive submergent aquatic vegetation (SAV) and water hyacinth.

The shoreline on the ship channel is eroding, along with its riparian vegetation. Invasive *Arundo* dominates the two islands. This area was once a designated mitigation site but was never restored as required under the utilities' permits. There is potential for restoration by creating tidal channels and shallow tidal marsh but only if intensive maintenance can control invasive weeds and insure adequate circulation. New permits are being sought under the BDCP without this site being included in the BDCP mitigation package. The BDCP, as an HCP/NCCP, would provide the power plants new ESA take permits, overriding the previous HCP that included the Collinsville site restoration. The new permits would not require the site to be restored. The hills adjacent to the site are now being developed by the utilities as wind farms.

West Sherman Area

The West Sherman area (Figure 4) includes Browns Island (far left), Winters Island (east of Browns), West Sherman (center) and West Island (southeast at right bottom corner).

Figure 4. West Sherman area with Browns and Winters Islands to west, West Sherman and Kimball in center, and Donlon and West Islands at lower right. All restoration opportunities of great potential value that were not included in BDCP. Cities of Pittsburg and Antioch are at lower left and right, respectively.

Browns Island

Browns Island is a 595-acre site generally referred to as "natural" and is part of the East Bay Regional Parks system. It was a reference site for the CALFED Breach study program. It has a dysfunctional tidal channel network with several large dead end channels and limited connection between its marshes and the nearby Bay waters. Its interior waterways are heavily impacted by water hyacinth and parrots feather. The occurrence and density of introduced fishes far exceeds native species. A 2007 report funded by CALFED found that Browns Island was a source of methylmercury production.[26]

Winter Island

Winter Island is a 453-acre private duck club managed as a freshwater marsh duck club with a functional levee system except for its northern tip, which is fully tidal brackish marsh. Its 4.7 miles of riprapped shoreline has unscreened manually operated tidal gates maintain water levels on the island's managed wetlands. Dredge materials from the Stockton Deep Water Ship Channel and various San Francisco Bay dredging projects have been placed on the island to strengthen the levees. As presently configured, the island provides little habitat to the estuary's pelagic or anadromous species and is somewhat of a missed opportunity to restore tidal marsh. Winter Island is 400 acres of "missed opportunity" to restore tidal marsh.

West Sherman Island

West Sherman Island comprises several thousand acres immediately to the west of Sherman Island proper (center of Figure 4). It has large partially disconnected ponds and a slough (dark areas) and is dominated by invasive SAV and invasive floating aquatic vegetation (green areas). It is considered "restored" and is now a state wildlife area. Ship channels are on the north, west, and south sides and its shorelines and remnant levees are slowly eroding from wakes.

The Lower Sherman Island Wildlife Area Land Management Plan states, *"In summer, extensive growth of blue-green algae and aquatic plants can contribute a considerable quantity of organic matter to shallow, dead-end sloughs; this may reduce the level of dissolved oxygen in these locations. Most channels at the wildlife area are clogged with such plant growth." And "Submerged aquatic vegetation within the open water area of Sherman Lake is dominated by the nonnative species egeria. Egeria also dominates submerged vegetation along the shallower margins of the Sacramento and San Joaquin rivers. Large expanses of open water at Sherman Lake are dominated by the invasive nonnative species water hyacinth. This plant readily forms dense, interconnected mats that drift along the water's surface."*[27] *"Mercury contamination is widespread in sediments and waters of the Delta, including at LSIWA.*[28]

The Goals for the wildlife area include, "*Pursue funding and develop plans for identified restoration projects. Cooperate with the development and implementation of local and regional restoration plans for upland and riparian ecosystems by the Ecosystem Restoration Program of*

---

[28] *Id*, page ES-4.

the California Bay-Delta Program and other programs that are consistent with the goals of this LMP."[29]

Lower Sherman Island was originally acquired to establish a public hunting and fishing area. The LSIWMP and CEQA document was finalized in 2007. The project was included as part of the CALFED Ecosystem Restoration Program Plan and Multi-Species Conservation Strategy. Given a lack of resources, restoration and maintenance have languished and the site is an example of failed restoration efforts. West Sherman Island is not included in the BDCP.

Kimball Island

Kimball Island is a 250-acre site on the south side of West Sherman. It is a "restored" tidal marsh, having been breached and channeled over a decade ago as a wetland mitigation bank. The original network of tidal channels has filled in with sediment and invasive aquatic plants and the SAV accelerate suspended sediment deposition and the reductions in turbidity. The lower turbidity water with abundant SAV is preferentially beneficial to non-native fishes including golden shiner, largemouth bass, sunfishes and silversides and detrimental to some native fishes. Constructed marshes like Kimball with limited tidal circulation are a recipe for backwater habitats dominated by invasive non-native aquatic vegetation and associated non-native fish community. While Kimball remains a somewhat functional tidal tule marsh, these subtidal backwater marshes also tend to have poor water quality in the form of low dissolved oxygen levels that also favor non-native fishes.

West Island to the southeast is a sandspit of dredge spoils with some channels and functional riparian shoreline. Its southern neighbor spoils island has nearly eroded away.

Donlon Island

Donlon Island a 200-acre site at the southeast corner of West Sherman is another "partially failed" restoration site. Its abandoned levee channels have long been clogged with invasive aquatic vegetation and associated non-native fish species. It was developed as a combination dredge spoils and mitigation site by the Corps of Engineers and the Port of Stockton in the 1980s.[30] Donlon Island is another example of a restored marsh with limited tidal circulation, which leads to backwater habitats dominated by non-native aquatic vegetation and fishes. It was in the CALFED Breach study and is not included in the BDCP.

West Island

West Island, to the southeast, is a sandspit of dredge spoils a few channels and some functional riparian shoreline. Its southern neighbor spoils island is nearly gone.

[29] *Id*, page ES-17.

[30] http://www.fs.fed.us/psw/publications/documents/psw_gtr110/psw_gtr110_i_england.pdf

Central Delta

The Central Delta area includes portions of the lower San Joaquin River, Big Break, False River, Dutch Slough, and Old River (including Franks Tract) (Figure 5). These areas are included in the West Delta ROA (see Figure 1).

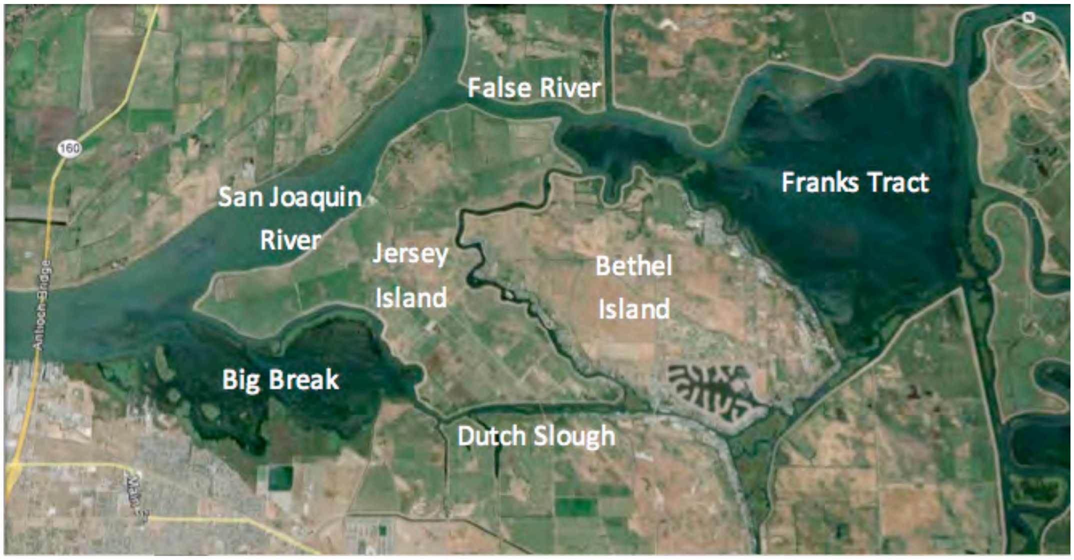

Figure 5. The Central Delta including Big Break at bottom left, Franks Tract at upper right, lower San Joaquin River at upper left, False River at upper center, and Dutch Slough at lower center. Old River runs along the eastern side of Franks Tract.

Big Break

East Bay Regional Park District’s Big Break Regional Shoreline Park is located along the south shoreline of Big Break. Once a leveed agricultural property, Big Break’s levees failed in 1928 and the 1500-acre shallow bay has remained open since. The bay was once reclaimed marsh along the south shore of Dutch Slough, which connected the central and south Delta with the lower San Joaquin River channel. Today the bay is clogged with non-native invasive aquatic plants with an ecological footprint more like an “Arkansas bass lake”. The oil company mitigation site at the west end of the Bay is also entirely dysfunctional, being clogged with invasive non-native submerged, emergent, and floating beds of aquatic vegetation (Figure 6). One of its two breaches is completely clogged with sediment and plants.

Big Break Regional Shoreline is on the northwest shoreline of the City of Oakley in Contra Costa County. In 1999 the U.S. Bureau of Reclamation purchased the 668-acre Lauritzen property that is situated along the west side of Big Break adjacent to the chemical company mitigation site as mitigation for the Rock Slough diversion project for the Contra Costa Canal in the Central Delta. This acquisition almost doubled the acreage of the Big Break Regional Shoreline. The site is described as “*a unique and valuable habitat area for several endangered fish and bird species”* in the East Bay Parks brochure.

The entire Big Break area is a prime example of establishing habitat that favors invasive non-native species over native species. It contains massive concentrations of non-native aquatic plants that dominate the shallow water habitat. Neither of the two mitigation sites at the west side of Big Break has been restored as promised. They remain typical of the "restored" habitats of the Delta that have failed in most respects. Not only are they failed habitats, but they enhance populations of non-native predatory fishes that compete with and prey upon Delta native fishes. The Big Break area is not included in the BDCP.

Figure 6. The west end of Big Break is a failed chemical company mitigation site. Some of the chemical waste facilities can be seen at the lower left. The site is virtually abandoned. Big Break Marina is located at the right.

Dutch Slough

The Dutch Slough Tidal Marsh Restoration Area (Figure 7) lies just to the east of Big Break. The 1,178-acre site is comprised of three parcels, partially separated by Emerson Slough and Little Dutch Slough. In the fall of 2003, the Department of Water Resources completed the purchase with funds from CALFED's now defunct Ecosystem Restoration Program. The project proposes to breech the levees to create large expanses on intertidal tule and/or cattail marshes plus areas of open tidal water, managed marsh and uplands. Construction was scheduled to begin in 2013.

However, when the levees are breeched, the site will likely end up similar to Big Break with poor aquatic habitats dominated by non-native invasive aquatic plants. Another fundamental problem with the site is its location on Dutch Slough. During most of the spring and summer, especially in drier years, Dutch Slough has a net flow to the east toward Old River and the state and federal export facilities in the south Delta. Fish in this area would tend to be drawn to the export pumps. Dutch Slough has been proposed for over a decade as mitigation for development projects in the Oakley area and now for the BDCP. It is not a good site and would provide poor habitat contiguous with Big Break and its non-native predatory fishes.

Figure 7. The Dutch Slough Project consists of breaching levees on the upper center tracts. Dutch Slough is located at top and upper right. Big Break is at upper left. The Contra Costa Canal at bottom center is the southern boundary of the project.

Franks Tract

Franks Tract is owned by the State and maintained as a State Recreation Area. It comprises nearly 4000 acres of tidal aquatic habitat with many of the features of an "Arkansas bass lake". It is infested with non-native invasive aquatic plants. The CALFED Record of Decision (August 2000) identified Franks Tract as a location for one of the programmatic Ecosystem Restoration Program (ERP) actions that was intended to provide improvements in ecosystem restoration, recreation, and Delta water quality.[31] "*The Franks Tract Project is one of several interim actions to address fish and water quality concerns in the near future*."[32]

One possible action was to block False River, its connection to the west with the Lower San Joaquin River. False River receives a strong tidal flood flow from the lower San Joaquin. The inflow of turbid San Joaquin water can be seen in Figure 8. Other options included isolating Franks Tract from the Delta channels, thus eliminating it as a refuge for non-native plants and fishes, and reducing the influx of native fish species from the lower San Joaquin River into Franks Tract and Old River (the eastern boundary of Franks Tract).

Native fishes do poorly in Franks Tract because of the low turbidity and high concentrations of non-native predatory fish that thrive in the clear aquatic plant infested habitat. Unfortunately, nothing has been done to date and Franks Tract restoration is not included in the BDCP mitigation.

[31] Action 1: Restore Frank's Tract to a mosaic of habitat types using clean dredge materials and natural sediment accretion. Control or eradicate introduced, nuisance aquatic plants." Ecosystem Restoration Program Plan – Strategic Plan for Ecosystem Restoration – Final Programmatic EIS/EIR Technical Appendix July 2000.

[32] http://www.water.ca.gov/deltainit/action.cfm

View of Mildred Island looking south along Middle River with McDonald Island to left and Lower Jones Tract in the distance.

Mildred Island

Mildred Island is a small agricultural island of approximately 1,000 acres that was breached in 1983 and not reclaimed. Like Franks Tract, it is open water habitat dominated by SAV. Nobriga et al. (2005)[33] pointed out that non-native fishes dominate such habitat. Local fishermen have long recognized it as a bass hot spot. No attempt has been made to restore this habitat and the site is not included in the BDCP.

Twitchell Island

Twitchell Island is a 3,516-acre island bounded on the north by Seven Mile Slough, on the east and south by the San Joaquin River and on the west by Three Mile Slough. Eighty-five percent of the island is owned by the State of California. Currently, the island is primarily agricultural land with the major crop being corn. It is the site of a 15-acre experiment by the U.S. Geological Survey to study wherther growing tules and catttails can reverse the soil loss caused by farming. It was also the site of a CALFED funded mercury study where two experimental wetland ponds were created. It was found that both ponds were sources of methylmercury production.[34]

However, Twitchell Island does contain a success story. In 2005, the Twitchell Island Reclamation District (RD 1601) constructed and planted approximately 2,100 linear feet of setback levee to increase levee stability and provide 3,000 linear feet of shaded riverine aquatic habitat and 1.4 acres of emergent freshwater marsh habitat along both sides of a back channel off the San Joaquin River.[35] The site (Figure 9) has remained stable and functional after more than a decade. Though small, it is one of the few successes for restoring natural shoreline habitats along Delta levees. The small setback levee provides a small tidal slough with connections to the San Joaquin River, as well as prolific riparian plant community. No specific projects of this type were proposed in the BDCP.

Figure 8. The Twitchell Island setback levee project is located along the lower San Joaquin River on the south side of Twitchell Island at the center of the photo. It consists of a small tidal channel and island connected at several locations with the river.

North Central Delta

The north-central Delta is also part of the BDCP's designated West Delta ROA. The north-central Delta is sometimes described as the north Delta, as it includes the north of the "interior" Delta in the lower Sacramento River on the north side of Sherman Island.

Decker Island

Decker Island is a 648-acre island that was created between 1917 and 1937 when the Sacramento Ship Channel was dredged out and more than 30 million tons of dredge spoils were placed on top of existing wetlands. The island retains much of the original dredged sediment and has a spoils easement for U.S. Army Corps of Engineering dredging material. D.I Aggregate management LLC owns approximately 473 acres and, as seen in Figure 10, operates a large sand-sediment mining operation on the island. The Port of Sacramento owns approximately 140 acres.

The California Department of Fish and Wildlife purchased 34 acres in 1999 and, in conjunction with the Department of Water Resources, created a 26-acre wetland.[36] The restoration site was constructed similarly to the Kimball Island site by digging out interior channels and connecting them to the Sacramento River via a single breach. This design fails as it creates a dead-end slough system that clogs with aquatic plants (Figure 11) and provides habitat for non-native fish species. By 2003, over 90% of the tidal channels were clogged with water hyacinth (Rockriver, 2003, p. 91).

---

[36] http://www.water.ca.gov/floodsafe/fessrøenvironmentałdee/decker.cfm

Figure 9. Decker Island in the lower Sacramento River. The entrance to Three Mile Slough is at upper right.

Figure 10. Mosaic of Decker Island State Wildlife Area development at north end of island. Channels dug have eventually filled with sediment and non-native aquatic plants (light green areas are predominantly water hyacinth). (DWR figure)

Figure 11. The southeast portion of Decker Island. Dark areas are invasive Egeria, while the light green are non-native aquatic plants including water hyacinth. Light brown is interior muted tidal marsh. The light tan between marsh and shoreline is remnant sand levee. The channel at right is the original Sacramento River channel.

Dead end tidal channels like the Decker and Kimball (see Figure 4, above) projects fill with submerged aquatic plants that strain the fine sediments for the water resulting in clear water favored by non-native fishes and avoided by many native fishes including Delta smelt. The dark channels in Figure 11 indicate clearer water than the turbid river. The site also has riparian plantings along its river shoreline, which are generally functional sandy beaches.

The southeastern portion of the island consists about 200 acres of “natural” shoreline used for pasture grazing (Figure 12). This site was once slated for CALFED restoration as it has a low elevation and much potential for tidal marsh-slough habitat. The black areas seen in Figure 12 are nonnative submerged aquatic plants, probably egeria, with the lighter green being other invasive aquatic plants including water hyacinth inshore. Decker Island restoration is included in the BDCP (see Figure 1), although no specific design is provided.

Sherman Island Levee Setback Project

The Sherman Island Levee Setback Project was constructed a decade ago by the Sherman Island Reclamation District (RD 341). The project consists of approximately 6,000 linear feet of setback levee to increase levee stability and provide 6.87 acres of intertidal channel margin habitat and 1.68 acres of riparian scrub shrub along Mayberry Slough (adjacent to Donlon Island site). The project is another example of mitigation provided by the State for the Delta Levees Program. Like the Twitchell Island setback project, this project was successful in restoring a narrow band of riparian and intertidal shoreline habitat along a Delta channel that has been sustained for over a decade on what was otherwise 100% unvegetated rock riprap.

Figure 12. The Sherman Island Levee Setback Project is shown on the southwest shoreline of Sherman Island on Mayberry Slough across from Donlon Island as a narrow strip of green on a new near-white rock levee.

North Delta

The North Delta is the northern component of the North Delta Arc of fish habitat connecting Suisun Bay/Marsh ROA with the Cache Slough ROA via the lower Sacramento River (see Figure 1).[37] The Cache Slough ROA is the BDCP component of the North Delta. It includes Liberty Island, Little Holland Tract, Cache Slough, Lindsey Slough, Barker Slough, Prospect Island, and the Sacramento Deep Water Shipping Channel (Figure 14). This area is considered the new "paradigm" for Delta restoration and thus is a key focus of the BDCP mitigation package.

The area has several features that potentially make it "good habitat." Bypass floods wash it clean several times a decade; it is a back water with long residence time except in floods, and it is a perfect elevation for shallow turbid water and intertidal habitats preferred by many Delta native fishes.[38] The area also has several negative features: low freshwater inflow, high nutrient loadings, and warm summers. Much of the area generally reaches lethal water temperatures for Delta smelt (25C/77F) in summer, particularly in heat waves.

Liberty Island, Little Holland Tract, Little Hastings Tract, and Prospect Island were once leveed reclaimed agricultural lands in the lower Yolo Bypass/Cache Slough region of the Delta. Over the decades all the island levees failed and breached and were subsequently purchased by the government and left for Mother Nature's tides and Bypass floods. Liberty Island is the largest of the reclamations at about 5000 acres. The tides flood all but about 1000 acres of the northern portion of the island. The middle and lower portions of the island are subtidal. The lower

---

[37] http://californiawaterblog.com/2013/10/26/north-delta-arc-lifts-hope-for-recovery-of-native-fish/

[38] http://www.water.ca.gov/aes/docs/Sommer_Mejia_SFEWS_Smelt_Habitat_2013.pdf

several thousand acres remain open water connected to Cache Slough. Tules invaded the intertidal habitats of the flooded islands early, but tule expansion has since been limited.

Figure 13. Cache Slough – Lower Yolo Bypass region of North Delta. Lindsey/Barker sloughs are at lower left. Upper Cache Slough is at upper left. Sacramento Deep Water Ship Channel is at right edge. The flooded islands including Liberty (center) and Little Holland Tract (upper center right) of the lower Yolo Bypass are at center right. Prospect Island is east of Ship Channel at lower right.

The shallow waters with long residence time with abundant nutrients and sunshine make the open waters around Liberty Island very productive. The areas relatively high turbidity, mainly from wind-wave erosion along with periodic flood scouring, limit invasive rooted aquatic plants. The aquatic habitat of the area including the Ship Channel appears ideal for Delta smelt and other native Delta fishes.[39]

---

[39] http://www.water.ca.gov/aes/docs/Sommer_Mejia_SFEWS_Smelt_Habitat_2013.pdf

The 200 acres of northern Liberty Island have been "restored" as a Delta smelt conservation bank with credits being sold for Delta smelt mitigation (Figure 15). Channels have been dug in uplands area to create slough and marsh habitats. The channels are connected to Liberty Slough and the main open waters of Liberty Island.

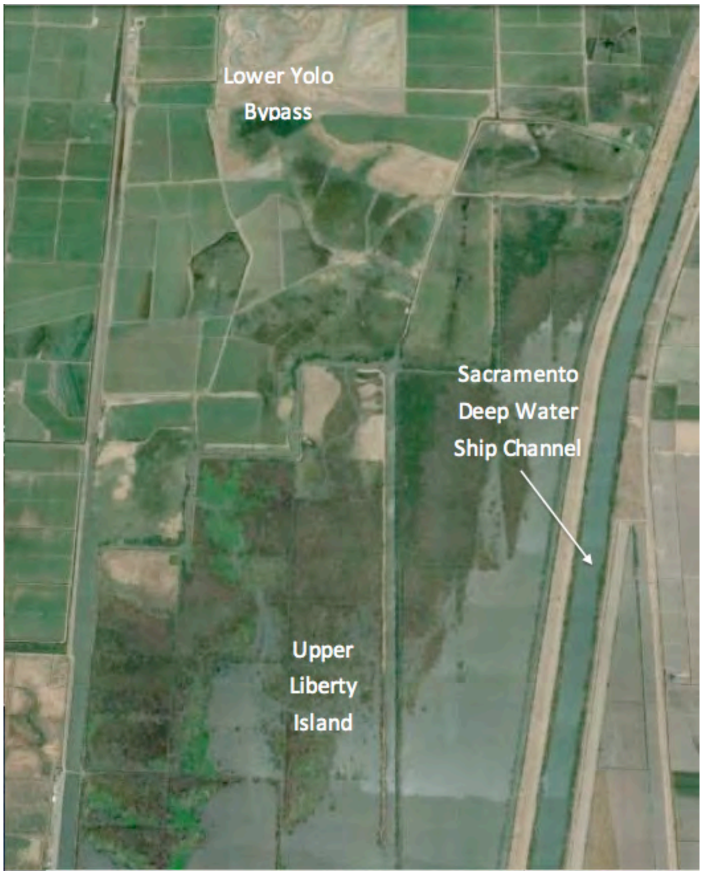

Figure 14. Upper Liberty Island (left center) and Little Holland Tract (right center). Ship Channel is at right. Stair-step levee remnants and Liberty Slough are north boundary of Liberty Island. Dark aquatic vegetation is tules. Light green is invasive non-native yellow primrose (able to take hold in the lee of high remnant levees). North staircase sections have brown upland habitats. Liberty Island Conservation Bank is upper right staircase with manmade channels and lowlands excavated from uplands. To the north of Liberty north or Liberty Slough is Yolo Ranch, which is also slated for BDCP mitigation.

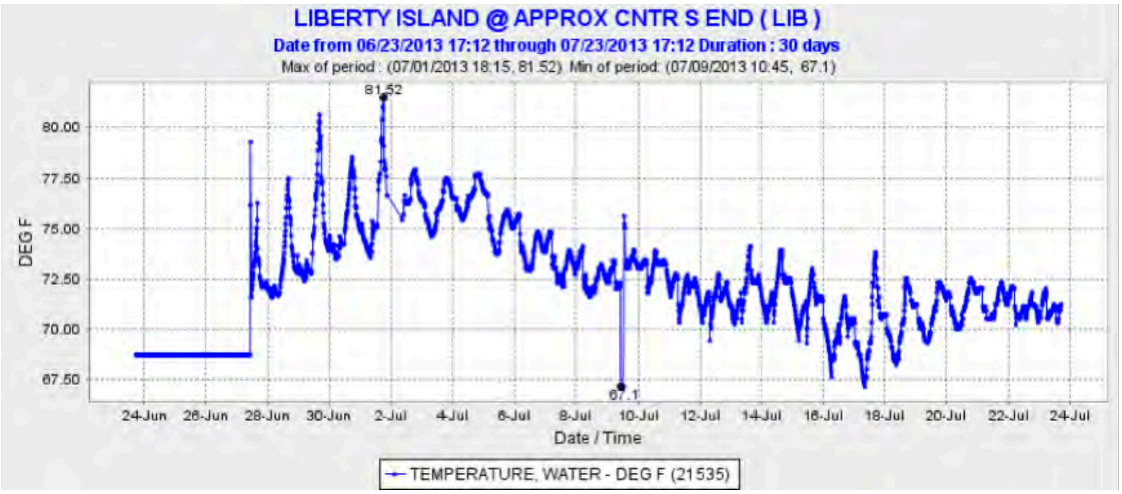

Figure 15. Water temperature during early summer 2013 at Liberty Island. (Source: DWR CDEC)

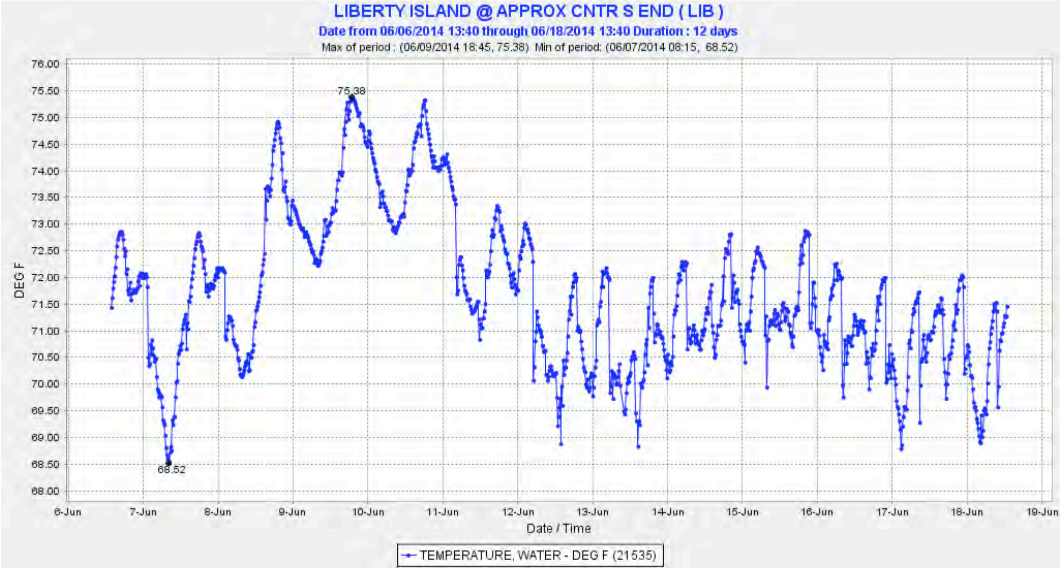

Figure 16. Water temperature during late spring 2014 at Liberty Island. (Source: DWR CDEC)

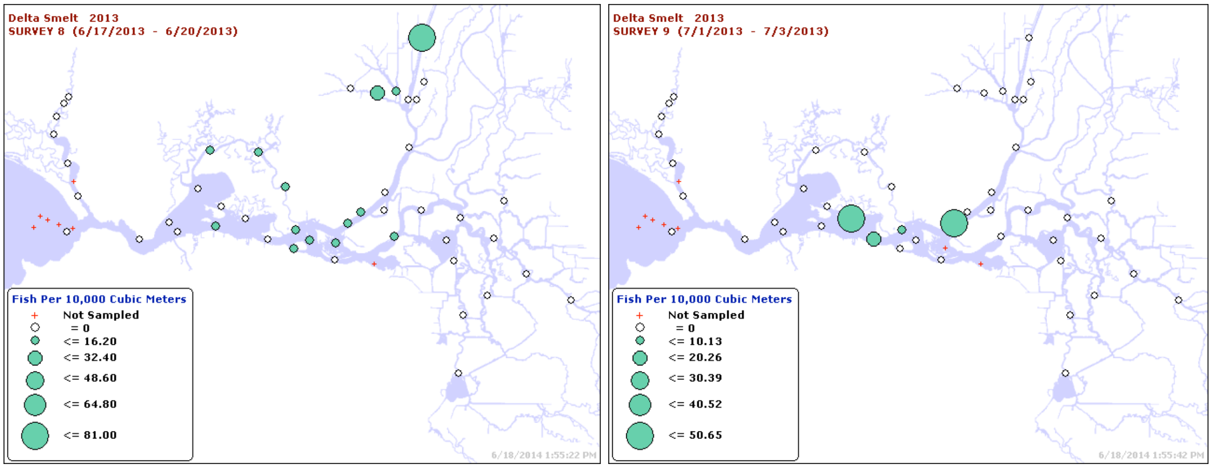

Figure 17. Comparison of Delta smelt distributions in early summer 2013 20-mm surveys before and after heat wave at beginning of July. Note the concentration of smelt in Cache Slough area before the heat wave and the lack of smelt in that area after the heat wave.

The main problem with the Cache Slough area is its periodic warm water temperatures as seen in Figures 16 and 17. With water temperatures generally considered lethal for Delta smelt above 75F, the area is basically inhospitable in summer for smelt. If not for the regular occurrence of the “Delta Breeze”, the entire area would only be suited for non-native catfish and carp. Though there may be periodic refuge for smelt in deeper channels of Cache Slough and the Sacramento Deepwater Ship Channel (SDWC), there has been little study of the ability of smelt to use these deep-water refuges and successfully survive the summer of warm dry years like 2013 (Figure

18). While Summer Townet Survey collected some Delta smelt in the Ship Channel in July surveys, none were collected in August surveys.[40]

Recent surveys of the Ship Channel by CDFW question the ability of Delta smelt to survive the summer: "*While the extent of SDWC usage by delta smelt is still unclear, these surveys have shown that delta smelt are limited in their ability to utilize the SDWC year round*." [41]

The Cache Slough complex experiences frequent toxicity from agricultural and urban discharges of chlorpyrifos and pyrethroid insecticides to copepods on which Delta smelt feed and to invertebrates in general. High temperatures tend to increase the toxicity of pyrethroids.[42]

Figure 18. Prospect Island is located between the Ship Channel and Miners Slough. The lower 300 acres are a Port mitigation area. The northern 1600 acres are owned by DWR and intended as a BDCP mitigation site.

Lower Yolo Restoration Project

The Lower Yolo Restoration Project is a proposed tidal restoration project by the State and Federal Water Contractors Water Agency to partially fulfill the habitat restoration requirements of the biological opinions for the Operations Criteria and Plan (OCAP) of the state and federal water projects. It would also help meet restoration objectives of BDCP. The project is located on a 3,795-acre site to the west of the Sacramento Ship Channel and to the north of Liberty Island and would result in the creation of approximately 1,226-acres of perennial emergent marsh (tidal) wetlands and 34-acres of non-tidal marsh.

The proposed enhancement of tidal wetlands at Yolo Ranch to the north of Liberty Island as well as breaching of leveed lands along Cache Slough (see Figure 15) would increase the area of shallow open waters that would warm in the summer sun to levels lethal to Delta smelt. This is a concern as the Sacramento Ship Channel and the general Cache Slough provides habitat for the northern spawning population of Delta smelt. The creation of

[42] Weston, DP. et al., Urban and agricultural pesticide inputs to a critical habitat for the threatened delta smelt (Hypomesus transpacificus), Environ Toxicol Chem, 2014.

additional open water will likely increase the amount of seawater that enters the Delta, leading to increased violations of salinity standards and expansion of the overbite clam and a resulting reduction in estuarine food availability. The site will also likely become a net sink for phytoplankton and zooplankton.

The project will likely become a net producer of methylmercury, and even if MeHg is not exported it will tend to bioaccumulate in resident and migratory species. Further, the area will be highly vulnerable to colonization by invasive weeds that will require extraordinary and expensive long-term management to control, something that has not been evidenced by the vast majority of habitat restoration efforts in the past.

Project implementation will likely go forward but, like numerous previous restoration projects, is likely to create unintended and detrimental impacts.

Prospect Island

Prospect Island is located between the Ship Channel and Miners Slough east of Liberty Island (Figure 19). Prospect Island was once a leveed farmland likes its neighboring tracts. Its lower end became a mitigation site for the Port of Sacramento. The upper portion failed in the recent decade and flooded, stranding thousands of fish. The island has since been purchased and levees repaired by the state with intention of the site being part of the BDCP mitigation package. DWR acquired the northern 1,300 acres from the U.S. Bureau of Reclamation in 2010, which had purchased the property in 1994 for restoration purposes that never occurred. The Port of West Sacramento owns the southern 300 acres and has used it for dredge spoil placement.

The Prospect Island Tidal Habitat Restoration Project is a component of the Fish Restoration Program Agreement (FRPA) comprised of a joint effort by the California Department of Water Resources (DWR) and the California Department of Fish & Wildlife (CDFW) to restore the property to freshwater tidal wetland and open water (subtidal) habitats to benefit native fish and improve aquatic ecosystem functions. "*Restoration will entail interior grading, vegetation management, possible clean fill import for subsidence reversal, possible weir installation, breaching of exterior levees, and addressing various property considerations. Monitoring will take place as part of a science- based adaptive management plan. The design of future restoration projects will incorporate knowledge gained through the implementation and monitoring of this project.*" [43] Planning and design is expected to be completed by late 2015, with construction commencing by early 2016.

Restoration of the site is complicated by local seepage problems for agricultural lands to the east of Prospect. Full tidal access to the northern portion of the island would result in extensive open water, not unlike Liberty and Little Holland Tract (Figure 20). However, without the scour provided by periodic Bypass floods, upper Prospect like lower Prospect would likely become infested with non-native invasive aquatic plants. Additionally, hydrodynamic modeling shows that open water restoration projects have the potential to increase seawater intrusion into the Delta. Flooding the island also has the potential to increase soil saturation and impact

---

[43] http://www.water.ca.gov/environmentalservices/frpa_prospect_restoration.cfm

neighboring islands because of the horizontal sand lens that runs under the islands. Restoration might result in the island becoming a net exporter of methylmercury.

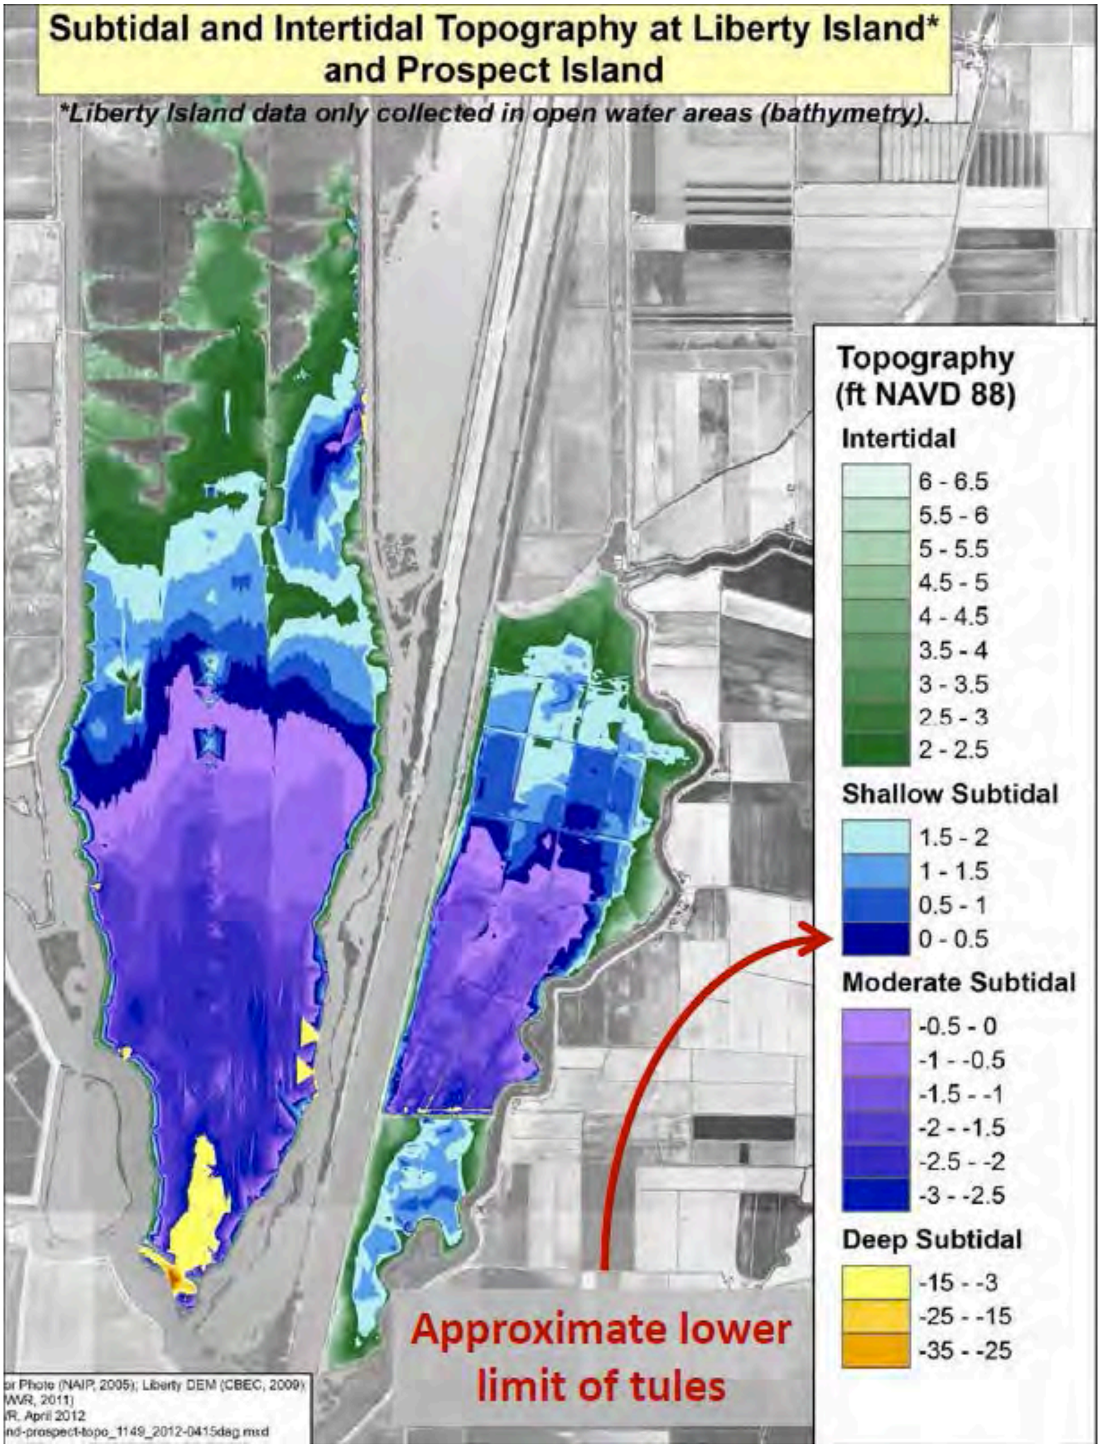

Figure 19. Liberty-Prospect area project water elevations.[44]

---

[44] http://www.delta.ca.gov/res/docs/meetings/2013/2013%20DC%20Board%20Mtg_Prospect_FINAL.pdf

The lower island mitigation site is entirely dysfunctional as native Delta fish habitat because of the lack of circulation and dominance of invasive non-native aquatic plants. As seen in Figure 19, the open waters lack turbidity (dark color) and provide habitat more suited for non-native warm water fish species. Miners Slough reached 77F during the early July 2013 heat wave and early June 2014 heat wave. More shallow open water habitats would increase warming of the area.

Upper Yolo Bypass

An example of a restoration project that has been largely beneficial with significant unresolved and potential adverse impacts is the Yolo Basin Wetlands Project. And it should be kept in mind that this project, coupled with all of the other restoration projects implemented over the last 30 or 30 years in the estuary, has not reversed the precipitous decline of the Delta's pelagic and anadromous fisheries.

The Yolo Bypass is seasonal floodplain to the west of Sacramento that typically floods in about 60% of years, when winter and spring floodwaters enter from the Sacramento River and several small streams. The floodplain appears to be particularly good spawning and rearing habitat for splittail and young Chinook salmon. The Bypass supports 15 native and 27 non-native fish species. The Yolo Basin Wetlands Project comprises 2,223-acres of seasonal wetlands and 185-acres of perennial wetlands and was dedicated in 1997.[45] Potential enhancements that have been discussed include additional wetlands, fixing fish passage and stranding problems and increasing the frequency of floodplain inundation in drier years.

Measures to address fish stranding in the Bypass were proposed by the Anadromous Fisheries Restoration Program in 1995, by the CALFED Record of Decision in 2000 and the National Marine Fisheries Service OCAP Biological Opinion in 2009, but never occurred. In 2011, biologists documented the stranding of hundreds of listed green sturgeon, spring-run Chinook salmon and steelhead trout in the Bypass. In July 2013, National Marine Fisheries Service biologists estimated that the numbers of stranded endangered winter-run Chinook salmon could be as high as half of the year's returning population.[46] BDCP proposes to facilitate additional periods of inundation and address the stranding issue.

The area is a net producer and exporter of methylmercury. For example, The State Water Board has found that when the Yolo Bypass is flooded, it becomes the dominant source of methylmercury to the Delta.[47] Restoration actions that lead to an increase in wetting and drying

---

[45] http://www.water.ca.gov/aes/docs/Yolo_Fisheries_Paper_2001.pdf

[46] http://calsport.org/news/?s=winter+run+stranding

[47] State Water Resources Control Board, 2009 Periodic Review of the 2006 Water Quality Control Plan for the San Francisco Bay/Sacramento-San Joaquin River Delta Estuary, adopted resolution 2009-0065, page 29. http://www.swrcb.ca.gov/waterrights/water_issues/programs/bay_delta/periodic_review/docs/periodicreview2009.pdf

periods could exacerbate existing mercury problems.[48] A 2010 report of a study funded by the Central Valley Regional Water Quality Control Board to evaluate methylmercury cycling and export from agricultural and natural wetlands in the Yolo Bypass found that periodic flooding of rice fields promotes the production of methylmercury beyond rates seen in naturally vegetated wetlands, whether seasonally or permanently flooded.[49]

A potential and unresolved issue of concern is the loading of urban and agricultural wastes into the Bypass, especially toxic concentrations of insecticides. Another potential issue is expansion of invasive aquatic plants in the perennial wetlands, without continual and costly oversight.

North East Delta

Planning for the Cosumnes/Mokelumne ROA habitat restoration has been going on for decades. Yet other than the lower Cosumnes Preserve, little has been done to restore tidal aquatic habitat in the East Delta. With federal and state grants, the Nature Conservancy has purchased much of the corridor from Walnut Grove east to the Cosumnes Preserve including most of the properties in Figure 1. Staten Island and McCormick Williamson Tract were purchased by the nature Conservancy more than a decade ago in the 1990s with CALFED funding. Invertebrates in the Cosumnes area have been found to have the highest concentrations of methylmercury in the Delta.

Aquatic habitat restoration in the area would be problematic considering the close association of the tidal channels with the Delta Cross Channel at Walnut Grove. Waters in the area are also warmer than other parts of the Delta and subject to warm summer inflows of the lower Sacramento River at the Delta Cross Channel. Restoration planning on projects such as the McCormick Williamson Tract is proceeding.[50]

Delta Meadows State Park was designed to preserve some of the original Delta habitats. The Park is now closed. The following is an excerpt from page 1 of the McCormack-Williamson Tract Restoration Planning, Design and Monitoring Program: *"The ultimate significance of these findings for the restoration is that regardless of careful design of a tidal gradient as has been done in other Delta projects, a restored upper Delta will be subjected to an unpredictable flood regime that will result in a spatially complex assemblage of geomorphic units that will defy conventional criteria for "success" in restoration. That is not inherently bad in that it is the natural condition of the system. However, the assumption of a well-ordered tidal geomorphic process as exists in other modern tidal freshwater wetlands is not appropriate for MWT (McCormick Williamson Tract). In addition, the presence of extremely high mercury*

[50] https://watershed.ucdavis.edu/project/mccormack-williamson-tractnorth-delta-project-restoration-planning-design-and-monitoring

concentrations in both the Delta Meadows and MWT create significant uncertainty in the biogeochemical fate of wetland restoration of MWT, though the opportunity exists for experts to study the biogeochemistry of Delta Meadows and establish how such a wetland functions in the face of existing pollution."[51]

East Delta

The lower San Joaquin channel in the Delta from Mossdale downstream to Prisoners Point (Figure 20) is also part of the East Delta that has been largely ignored by Delta restoration programs. The corridor is important for many fishes including salmon and steelhead from San Joaquin tributaries, as well as Delta species such as splittail. It suffers in summer from low flows, high water temperatures, low dissolved oxygen, algal blooms and heavy pollution loads, but it is an important corridor for many species in winter and spring.

The Stockton or San Joaquin Deep Water Ship Channel dominates the area. The channel converted the once sinuous channel to a straight channel for shipping by cutting through many points creating a series of dredge-spoil islands. The Port of Stockton owns most of these created "islands." The lower San Joaquin channel from Mossdale downstream to Prisoners Point (Figure 21) has been largely ignored by Delta restoration programs.

Figure 20. South East Delta – San Joaquin River between Stockton and Prisoners Point. The ship channel can be seen cutting through a series of Delta islands at the center of the photo. Mildred Island is at the lower center and eastern edge of Franks Tract and Old River are at the upper left.

[51] https://watershed.ucdavis.edu/pdf/crg/MCWTFinal.pdf

Conclusion

Research over the past several decades indicates that Delta native fishes, especially Delta smelt, have very refined habitat preferences that should be the focus of any habitat restoration projects. The main habitat features of importance include salinity, turbidity, tidal flows, productivity, and water temperature. Creating habitat that meets most or all of these criteria is extremely difficult but necessary. Very few of the restoration projects undertaken to date meet these criteria.

Many implemented and proposed projects have fatal flaws (e.g., Liberty Island - lethal water temperatures) and did not consider these basic needs when designed and built (e.g., Decker Island, Kimball Island). Many project areas have actually deteriorated after purchase and little actual restoration was implemented (e.g., PG&E's Collinsville property). Other projects failed because necessary funds to restore, maintain and adaptively manage the areas were never provided (e.g., Chipps Island, Franks Tract). Consequently, many of these restoration sites evolved into havens for an astonishing assemblage of invasive plants and fishes and adversely impacted native species (e.g., Big Break, West Sherman Island, Donlon Island). A number of projects that could be considered a success have had mixed results with unintended consequences (Yolo Bypass).

The blunt fact is that the cumulative effects of all of the myriad restoration project that have been constructed in the Delta have not reversed the continued decline of native fisheries. This is because few restoration projects have been designed with the needs of fish in mind. And there is nothing in BDCP's proposed habitat restoration scheme that indicates it can or will produce habitat that meets the needs of fish. Indeed, BDCP proposes to exacerbate existing habitat problems.

As we've observed, native species evolved over many thousands of years in response to habitat. And that habitat included adequate physical (flow, residence time, variability, etc.) and chemical parameters (salinity, temperature, turbidity, chemical constituents, etc.), as well as the nutrients necessary for primary production to support renewable fisheries. The export projects have radically altered the Delta's hydrodynamics, which has resulted is a loss of critical flows, less variability, degraded water quality and reduced primary productivity. The yearly export of phytoplankton biomass is equivalent to more than 30% of net primary production. And BDCP proposes to expand the export of primary production to the north Delta. It proposes to move the critical LSZ habitat further east where smelt will more frequently encounter lethal water temperatures and entrainment in project pumps. It proposes make Sacramento salmonids run a gauntlet past massive new diversion facilities.

The Delta's altered hydrology has allowed numerous invasive non-native species to become entrenched to the detriment of native communities. We have transformed a variable freshwater estuary into something resembling an Arkansas lake. Creating more Arkansas lake habitat will simply create more Arkansas lake fish.

The best options for meeting the necessary fish habitat criteria is to increase flow and variability, mimic the natural hydrograph, protect the LSZ, improve water quality and reduce the export of primary productivity. But, those are the things BDCP cannot offer. Instead, the EIR/EIS predicts less flow and variability, a less protective LSZ, reduced water quality and increased export of primary production. That is not a recipe for improved habitat.

BDCP even ignores or marginalizes the obvious habitat improvements that could be undertaken. Migrating young salmon fry and fingerlings tend to concentrate in shoreline areas and adjacent and adjacent margin habitats along channels. Salmon smolts are frequently collected in the open channels migrating westward but are also found feeding in margin habitats. The shoreline restoration efforts on Twitchell, Decker and other west Delta sites have been successful. Yet, BDCP proposes to restore only about twenty miles of channel margin habitat over a span of thirty years.

Franks Tract is a death trap for smelt. Once drawn into Franks Tract, Delta and longfin smelt are unlikely to survive lethal temperatures, predation or entrainment at the south Delta pumps. There have been numerous proposals to place a barrier across False River or to wall off Franks Tract from surrounding channels. BDCP is silent on the issue.

In closing, we offer a bottom line. Habitat restoration cannot be successful if it doesn't meet the flow and water quality needs of native species that evolved over millennia. The history of habitat restoration in the Delta is that it hasn't met those needs, and BDCP will not meet those needs.

Attachment A: Comparison of this Review with the Habitat Assessment in BDCP HCP Appendix 5E

Appendix 5E of the BDCP HCP discusses some of the above areas and specific sites in the context of the proposed Conservation Measures. Unfortunately, the BDCP assessments, which are predicated on a conceptual programmatic level with few specific details, are seriously over optimistic of both the results of past efforts and the potential benefits of future restoration projects.

For example: page 5E-iv; "*In this appendix we evaluate the potential of restored habitat to enhance productivity of the Delta based on a simple depth relationship (Lopez et al. 2006) while cautioning that the realities highlighted by Lucas and Thompson (2012) may limit the value of restoration in regard to phytoplankton production."*

The BDCP fails to consider the both the benefits and detriments of shallow water habitat, while focusing on water depth and phytoplankton. Shallow water provides key spawning and rearing habitat for most Delta native fish with its cover, turbidity, and food via aquatic and terrestrial insect and benthic invertebrate communities. However, shallow water can also contain lethal water temperature, harbor invasive plants and be detrimental to native fish.

CM5 Seasonally Inundated Floodplain Restoration

"*The proposed restoration of 10,000 acres of seasonally inundated floodplain habitat and the increase in flooding in the Yolo Bypass are expected to increase the amount and value of accessible rearing habitat for juvenile salmon and splittail. For salmon, the intent is to route salmon away from the interior Delta and through habitat that is favorable for growth.*" (p. 5.E-v)

The Bypass may be favorable to juvenile fish growth in winter compared to rivers, but its flows attract and strand many adult anadromous fish. Springtime warming of the water also increases water temperatures to lethal levels for smelt and salmon. Pollution from adjacent agricultural and industrial dischargers is a serious problem, as is methylation of mercury. Numerous unscreened diversions (some simple tide gates) pose a threat to fish. These problems are ignored in the assessment.

"*Floodplain restoration also is expected to increase the export of production downstream, providing increased food supplies (phytoplankton, zooplankton, insects, and small fish) for pelagic fish species such as delta smelt and longfin smelt (Kneib et al. 2008)."* (p. 5.E-v*)*

While Bypass floods are one of the benefits of wet years, BDCP provides no added Bypass flooding in drier years, when such benefits are in short supply and critically needed.

CM4 Tidal Natural Communities Restoration

"*Under the hypothetical restoration footprint, BDCP restoration is expected to add about 55,800 acres of subtidal and intertidal habitat for covered fish in the Delta by the end of the permit term, representing a 54% increase in these communities relative to current levels. The greatest* *increase in tidal acreage would be in the South Delta, followed by Cache Slough, Suisun Marsh, West Delta, and East Delta subregions; there is no restoration under CM4 in the North Delta or Suisun Bay subregions.*" (P. 5.E-xi)

As we pointed out above, there is little value in developing subtidal and tidal habitats in the South Delta. There are huge problems associated with increasing such habitat in the Cache Slough area (e.g., warm isolated habitats, mercury methylation), especially in the areas proposed (e.g., Prospect Island and leveed lands south of Cache Slough). Suisun Marsh simply is not in play in drier years. Emphasis should be on West and Central Delta.

"Splittail are expected to benefit from the restoration of tidal marsh and floodplain habitats. Splittail exhibit a wide tolerance for conditions in the Delta. Their abundance is believed to relate more to the amount and duration of flooding of Yolo Bypass and other floodplain areas used for spawning. Splittail are expected to benefit from the expansion of food production in tidal wetlands due to the expanded flooding of Yolo Bypass (CM2) and, to a much lesser extent, other floodplain areas (CM5)." (P. 5.E-xii)

Splittail do relatively well in wet years with existing floodplains; it is in drier years when they would benefit from such actions, which are not provided in the BDCP floodplain prescriptions. Splittail may benefit from South Delta floodplain restoration, but in drier years most splittail production is lost to South Delta exports.

"The expectation is that restored shallow areas would promote production of tules and other native macrophytes that will increase the availability of aquatic insects, other invertebrates, and detritus to augment food for covered fish species. The change in the prod-acres index over the implementation period relative to the current level suggests that, by the end of the permit term (LLT), restoration benefits to food production would be greatest in Cache Slough followed by the South Delta… Transfer of this production to food for listed fish species could be complicated by potential consumption by clams, nutrient levels in the Delta and hydrodynamic factors. However, benefits can be maximized by restoration design and adaptive learning of restoration methods in the Delta." (P. 5.E-xii)

This is another example of the gross over-estimation of benefits from the proposed BDCP restorations. First, the Cache Slough area is already highly productive and shows no sign of food limitations. Second, there is little evidence that any of the productivity from the area is transferred to the Delta in drier years when benefits would be greatest. There is little chance that benefits can be "maximized" by design or adaptive learning. The three major areas proposed, leveed lands south of Cache Slough, Prospect Island, and Yolo Ranch, if converted to tidal habitats as discussed earlier, would have devastating negative effects on Cache Slough area habitats as well as habitats downstream in the Central and West Delta.

"BDCP restoration will modify flood conveyance levees and infrastructure to restore 10,000 acres of seasonally inundated floodplain along river channels in the South Delta." (P. 5.E-xii)

Again, the need for and potential benefit of South Delta floodplain restoration are greatly overestimated. Much of the benefit is estimated to accrue from the South Delta to salmon and splittail in wet years. Production of both species is already relatively good in wet years in the San Joaquin, but minimal in drier years when the proposed habitat benefits would not accrue.

CM6 Channel Margin Enhancement

"*There is some indication that channel margin could be extremely important rearing habitat in years with low precipitation when floodplains are not functioning. A study by McLain and Castillo (2009) found that densities of Chinook salmon fry in the Sacramento River and Steamboat Slough were higher compared with Miner Slough and Liberty Island Marsh during a low outflow year. Fry apparently bypassed marshy habitats at the downstream end of the Yolo Bypass because outflow during the winter was relatively low and flows into the Yolo Bypass were negligible (McLain and Castillo 2009*)." (P. 5.E-vi)

The majority of BDCP channel margin habitat restoration is located above Rio Vista on the Sacramento. The crucial channel margin habitats of the Delta migration corridors of the lower Sacramento and San Joaquin rivers are ignored. In drier years, these habitats are critically important to many Delta fishes including young salmon, steelhead, splittail, and Delta smelt. The BDCP proposal for channel margin restoration is totally inadequate given the importance of such habitat. As mentioned above, channel margin restoration has been some of the most successful restoration efforts to date in the Delta.

"By targeting areas that have been shown to have poor habitat value and biological performance coupled with extensive occurrence of covered fish species, it is possible that channel margin enhancement, together with associated restoration activities such as CM7 Riparian Natural Community Restoration, can provide more than a proportional 4% increase in overall habitat value. Such locations include the greatly altered reach of the Sacramento River between Freeport and Georgiana Slough, for example." (P. 5.E-xiv)

The 20-mile prescription for channel margin restoration in the BDCP is inadequate. The spot treatments prescribed are totally inadequate for a restoration category that has been proven successful and needed. The greatly altered large leveed channel upstream of Rio Vista would be difficult to restore and is not the area of greatest need. The many miles of channel margins between Rio Vista and Collinsville, Antioch and Pittsburg, and around Sherman Lake are more important and largely un-leveed. These areas are also adjacent to important shoal and pelagic habitats, unlike the prescribed Freeport to Georgiana Slough reach upstream of Rio Vista that will be subject to the direct effects of the BDCP tunnel intakes.

Expected Benefits to Fish from BDCP Restoration

Appendix 5E is wildly optimistic as to the potential benefits to key fish species from BDCP-prescribed restoration.

Cache Slough ROA

Delta Smelt: *"The decrease in HSI for the egg-larvae stage is the result of increased water temperatures in the subregion by the LLT primarily due to climate change impacts. There was* *almost no change in the HSI value for temperature over the period due to covered activities alone reflecting the lack of impact of the BDCP on temperature in Cache Slough.*" (P. 5.E-95)

Our earlier discussion of the Cache Slough locations especially Liberty Island and Prospect Island clearly point out that these areas are too warm for Delta smelt from spring through summer, especially in dry years. The BDCP analysis of the effect on water temperature of adding 10,000 acres of open water on water temperatures is seriously flawed. The added tidal exchange alone will draw the LSZ further into Delta and expose fish to potentially lethal water temperatures. Water diversions from the area including the NBA will also have an impact. There may be little change in HSI values because the area is already too warm in spring and summer, especially in dry years.

Salmon: **"***Salmonids, those that enter the Yolo Bypass, make extensive use of the Cache Slough area. Fish can move down through the bypass and into Cache Slough where their survival is affected by local conditions. Tidal marsh restoration in Cache Slough is likely to benefit primarily juvenile foraging salmon by providing access to high-value areas for rearing. Increases in size at ocean entry have been shown to correlate with increased ocean survival (Claiborne et al. 2011). The aggregate effects of these improvements in habitat availability and environmental condition are likely to result in better outmigration success for juvenile Chinook salmon.*" (P. 5.E-100)

The prescribed actions for the Yolo Bypass only affect habitat in winters of wet years and do little for salmon in dry years when such benefits are critically needed. Adding slightly to the frequency of inundation in wet years will not provide the needed benefits for salmon.

Longfin Smelt: **"***The overall impact was toward appreciably greater habitat for longfin smelt in Cache Slough although it is not clear from this analysis whether the increase in habitat quantity compensates for the decrease in habitat value (HSI) related primarily to increasing temperatures*" (from climate change).

West Delta ROA

Delta Smelt: "*The West Delta subregion currently provides HUs largely for larval and juvenile delta smelt with relatively small amount of habitat for delta smelt spawning (Table 5.E.4-24). This is because most of the subregion is subtidal with a small amount of tidal freshwater (Figure 5.E.4-67).*" (P. 5.E-105)

This statement is simply not true. The entire West Delta ROA from Collinsville to Rio Vista is generally freshwater in winter and spring of most years and has ideal shoreline habitat for spawning smelt. Such statements reflect the lack of understanding in the BDCP of the actual habitat requirements of many of the species of interest.

"*Suitability was lowest in all time periods for juvenile delta smelt because of low turbidity in summer and fall months*." (P. 5.E-106)

One reason for the lower turbidity is that the South Delta water export facilities pump water from the LSZ, which is replaced by high inflows from Sacramento River reservoir releases. Despite such effects, Longfin and Delta smelt still concentrate in the LSZ in the West Delta in all but the wetter years. The increases in habitat values predicted are small because so little habitat restoration is proposed in the West Delta. What habitat is proposed, at Dutch Slough, North Sherman, and Decker Island, as outlined in my report above have overly optimistic benefits predicted for these sites given their location, restoration design, and potential function. It should be noted that the proposed North Delta water exports would further reduce turbidity by 7 to 8 percent.

Comments on Appendix 5EB – Review of Restoration in the Delta

"*This report summarizes the lessons learned from previous restoration activities in the Delta, to provide a starting point for planning and study of restoration concepts: what should we try to replicate or avoid?"* (P. 5.E.B-1)

These conclusions, as to benefits of past restoration efforts, are overly generous and lack scrutiny on many levels.

Liberty Island

Liberty Island is a case in point: *"In some cases, accidental changes have resulted in improved conditions for native fish species (e.g., Liberty Island)"* (P. 5E.B-1).

The many problems with Liberty Island (e.g., warm water, high inorganic turbidity, high methylation of mercury, etc.) make it a poor model for future restoration.

"*For example, the apparent success of the Liberty Island transformation appears to be due in part to the juxtaposition of flow from the Sacramento River (Yolo Bypass) and Cache Slough, tidal flux and wind that result in high turbidity, movement of sediment, and local prey production. Sediment comes primarily from Yolo Bypass and the inward movement of sediment from Suisun Bay during the summer, which, along with strong summer winds, keeps the area turbid during the portions of the year that Yolo Bypass is not flooded. The result appears to be that the island provides on-site habitat and food for delta smelt and other species (Whitley and Bollens 2013) while also exporting some of its production.* " (p5E.B-5) *"This site is perhaps the best example of the potential for restoration to provide habitat and food for native fish species. Liberty Island is part of a large complex of planned restoration areas and naturally restoring areas, including Cache Slough, Little Holland, and Prospect Island, and it is also hydrologically connected to the Sacramento River and is downstream of Yolo Bypass*." (P. 5E.B-13)

The wide, open, shallow embayments of Liberty Island and Little Holland Tract are very turbid from wind fetch across the islands. However, the shallow, muddy waters are not natural and certainly not tidal marsh as they were historically before reclamation. Waves and floods are continually eroding the inorganic soils of the two areas, which were previously under intensive agriculture and are now part of the Bypass. The shallow waters warm excessively in the intense sun and warm air of late spring through early fall. Water entering the area from the Bypass Tule

Canal can be best described as agricultural “return” water with high levels of organics, nutrients, agricultural chemicals, and other pollutants. Smelt are able to survive the summer only by seeking refuge in deeper nearby channels and holes scoured by historic floods. Their ability to survive the summer is highly questionable. The habitat may in fact have been better before the island breaching when narrow deep sloughs surrounded the original marshes or more recently the reclaimed agricultural islands (this would apply to both Liberty Island, Prospect Island and Little Holland Tract). Adding thousands of acres more of such habitat by breaching levees south of Cache Slough, north of Liberty Island, and on Prospect Island following the Liberty paradigm could be disastrous.

“*An important feature of the Liberty Island site it that it is hydrologically complex; these hydrodynamics shape environmental conditions and the resulting biological response. The site is at the downstream end of the Yolo Bypass and is heavily influenced by freshwater flow from the Sacramento River. It is also subject to significant tidal fluctuations that push water upstream and then pull water back downstream. The result is high turbidity and flow conditions that appear to have limited the growth of SAV.”…”Tidal flow rather than river discharge was 43 responsible for 90% or more of the material flux into and out of Liberty Island* (P. 5E.B-14).

The site is not heavily influenced by freshwater flow from the Sacramento River except during floods. Normally its minor inflows are from the Bypass Tule Canal. Tidal flows do enter the lower end of Cache Slough near Rio Vista, but only have a minor influence on lower Bypass water quality and habitat conditions.

“*The landward transport of sediment, surrounding backwater sloughs with high residence time, and complex morphology—along with large open areas where sediment is resuspended by wind and tidal currents—are all physical drivers that allow Liberty Island to have habitat suitability that favors native species like delta smelt.*” (P. 5E.B-15).

The Liberty Island habitat does not favor Delta smelt. By midsummer most smelt in the area are found in the Sacramento Deepwater Ship Channel to the east of the Bypass. Liberty Island is generally too warm for smelt by early summer.

Decker Island

“*Restoration at Decker Island, which involved restoration of a U.S. Army Corps of Engineers dredge spoils site, has been plagued by development of dense Egeria beds, especially in shallow channels that were created at the site (Rockriver 2008). Nonnative fish species were more abundant than native species in restored channels with dense vegetation. Rockriver (2008) recommended substrate changes to discourage centrarchid fish species (e.g., bass), and chemical applications to control SAV.*” (P. 5E.B-6).

The site is also plagued with water hyacinth (FAV), which requires chemical treatment by the Department of Boating and Waterways. Shallow channels primarily a problem when they “dead end.” Flow-through channels tend to stay open, although Egeria and other invasive SAV plants invade most Delta shallow water habitat.

Franks Tract

"*In contrast to the more complex hydrodynamics of Liberty Island, the lake is primarily influenced by tidal flow*." (p5E.B-15).

Franks Tract has very complex hydrodynamics beginning with tidal inflows from False River and Old River, along with negative flows down Old River from the Tract to the South Delta export pumps.

Mildred Island

"*Currently, the deep water at Mildred Island appears to prevent Egeria and clams while allowing phytoplankton production (Lucas et al. 2002)… Breaching of Mildred Island, on the other hand, resulted in relatively little Egeria and net production of phytoplankton to the Delta, though it also harbors large populations of nonnative predatory fish (Nobriga et al. 2005*)." (P. 5E.B-16)

Any plankton production would likely be exported at the South Delta export pumps, as net flows are almost always in that direction, which is why there are few native fish. Neither Franks nor Mildred should be left in their present state, as they offer refuge and breeding areas for nonnative fishes, as well as sinks for native fishes.

Big Break

"Big Break is presently a flooded island similar to Franks Tract. Pilot-scale restoration projects within it will: (1) restore tidal marsh, floodplain, and Antioch dune habitat on the Delta of Marsh Creek to restore target fish and dune species, (2) restore bio-filtration floodplains along urbanizing reaches of Marsh Creek to protect and improve water quality entering the Delta, (3) monitor aquatic species in Big Break and water quality along Marsh Creek, (4) develop a volunteer-driven native plant nursery to generate plants for restoration, and (5) continue a public outreach, education, and citizen planning program in the watershed to monitor the project over time." (P. 5E.B-17)

As discussed previously, the Big Break pilot projects offer little value for Delta native fishes, leaving another extremely poor habitat complex within the West Delta low salinity zone area that should be restored.

Donlan Island (P.5E.Bp-17)

The EIR/EIS fails to mention the dysfunctional nature of this restoration site. (See previous discussion of this site.)

Sherman Lake (P. 5E.Bp-18)

The EIR/EIS fails to mention the dysfunctional nature of much of this site (e.g., large areas of invasive FAV). (See previous discussion of this site.)

Prospect Island

"*Prospect Island has flooded seven times since 1981, and likely has little value for agriculture (Sanderstom et al. 2010). Therefore, the intentional breaching and re-flooding of Prospect Island could create beneficial habitat for Delta and migratory fish species (Sanderstom et al. 2010).*" (P. 5E.Bp-18)

Or it could just as easily create very poor habitat conditions as discussed previously.

Dutch Slough

"*The 1,200-acre pasture site has the potential for restoring over 6 miles of shoreline and a mosaic of tidal, riparian, and upland habitats, to provide enhanced fish and wildlife habitat in the western Delta. The unique, relatively unsubsided site topography would allow restoration of intertidal dendritic channels.*" (P. 5E.B-19)

As stated earlier, the Dutch Slough project would create poor habitat similar to Big Break and Franks Tract and its waters and aquatic production would drawn eastward toward the South Delta export pumps.

McCormack-Williamson Tract

"*The McCormack-Williamson Tract is a 1,654-acre island located immediately downstream of the confluence of the Cosumnes and Mokelumne Rivers, owned by The Nature Conservancy. The island offers opportunities for restoration of critical tidal freshwater marsh and floodplain habitat (Grosholz and Gallo 2006; Moyle et al. 2007) and may also moderate flood flows in the northern Delta, and is particularly suitable for expanding shallow water and tidal marsh habitat in the Delta.*" (P. 5E.B-20)

As discussed earlier, the island is "downstream" of the Delta Cross Channel, thus its flows are destined for the South Delta exports. The area is too warm in summer for Delta smelt. It does not lie in the spawning and rearing zone of Delta smelt.

Decker Island

"*Collectively, these efforts should lead to the long-term sustainability of a complex wetland ecosystem with considerable wildlife, water quality, and aesthetic benefits (California Department of Water Resources 2013).*" (P. 5E.B-21)

As discussed previously, the Decker Island DWR mitigation site is largely dysfunctional. There are no plans to adaptively rebuild the site to make it functional nor are there any specific plans to restore the remainder of the island that has a Corps dredge spoil easement.

What are the Major Flaws in BDCP's Proposed Native Delta Fish Habitat Restoration Program?

Given the described weaknesses in the BDCP habitat restoration prescriptions described above, what are the fundamental flaws in BDCP's approach to habitat restoration?

1. Above all, BDCP assumes that the quantity of habitat is more important than the quality of habitat. It ignores the fact that habitat restoration must replicate the quality of habitat under which species evolve over eons.
2. There is too much focus on tidal marshes that the fish will not use, which provide little indirect benefit to fishes through foodweb enhancement, and are located in areas of the Delta that are not beneficial.
3. There is a lack of focus on pelagic habitats particularly in the key Low Salinity Zone which typically occurs from lower Suisun Bay into the West Delta (most important is the Collinsville to Rio Vista reach of the lower Sacramento River and the Pittsburg to Prisoners Point reach of the lower San Joaquin River, as well as the confluence waters of the two rivers of Eastern Suisun Bay).
4. There is little emphasis on channel margin habitat particularly in the regions mentioned above in #2.
5. There is disregard for the many neglected areas that need restoration funding to fix poor habitat conditions despite decades of pleas from their government and NGO owners and managers (e.g., Sherman Lake, Big Break, Franks Tract, McCormick-Williamson Tract).
6. There is too much emphasis on areas that are too salty (Suisun Marsh), too warm (Cache Slough/Bypass and South Delta), and where waters are destined for South Delta exports (South and East Delta).
7. There is a lack of emphasis on salinity control and water temperature, and tidal flows and mixing, freshwater inputs, and Delta exports that control these key habitat features.
8. More emphasis is needed on the physical controls that are available or could be installed to enhance salinity and water temperatures of the important habitats (e.g., Montezuma Salinity Control Weir, Delta Cross Channel Gates, temporary installed weirs, Head of Old River Gates, and South Delta export facilities).
9. There is no mention of managing the open water (pelagic) habitats along the hundreds of miles of deepwater dredged shipping channels that have greatly affected the Delta, or mitigating for the ongoing effects of dredging on these habitats.
10. There is a disturbing disregard for water quality in the Delta, not just water temperature and salinity. Methylmercury is a serious problem in tidal marshes and seasonally flooded habitats emphasized by BDCP. Many of the solutions recommended (e.g., source control, etc.) for these problems are infeasible or unlikely to be successfully implemented.
11. Many important areas have simply been left out of the plan (e.g., Grizzly Bay, Montezuma Slough, Chipps Island, Collinsville, West Sherman, Big Break, Franks Tract, northern shoreline between Collinsville and Rio Vista, lower San Joaquin from Jersey Point to Prisoners Point, lower Old and Middle Rivers, lower San Joaquin downstream of Stockton to Prisoners Point, eastern Suisun Bay from Pittsburg to Antioch including New York slough and the southern shoreline).
12. There is a lack of emphasis on fixing hydrological connections such as Montezuma Slough, False River, Dutch Slough, Three Mile Slough, Delta Cross Channel, Sacramento

Deepwater Ship Channel, Georgianna Slough, Miners Slough, Sutter Slough, and Steamboat Slough to enhance the Low Salinity Zone of the Bay/Delta.

13. There is nothing in the Plan that will effectively address non-native invasive aquatic species that have undermined the native habitats and fish communities.
14. There is little in the Plan that addresses basic nutrients and the base of the food chain – phytoplankton production.

About the Authors

Tom Cannon has studied and surveyed many of these habitats over the past four decades in various roles as a fishery biologist involved in the Delta. His professional career has focused on estuarine fisheries ecology with experience on East Coast and West Coast estuaries and degrees in fisheries ecology, biology and biostatistics.

From 1977-1980, Tom was project director of Bay-Delta ecological studies for PG&E's Bay-Delta power plants effects studies that included habitat assessments of each of their Delta sites. From 1980-1982, he was a consultant to the State Water Contractors, the National Marine Fisheries Service and the State Water Resources Control Board (State Board) determining the effectiveness of the 1978 Bay-Delta water quality standards in protecting the Bay-Delta ecosystem and striped bass population. In 1986-1987, he consulted to the State Water Contractors and Bureau of Reclamation during State Board hearings on water quality standards.

From 1994-1995, he consulted to the State Water Contractors and the California Urban Water Agencies working on the 1995 Bay-Delta water quality standards and how the new standards would affect the Bay-Delta ecosystem and its fish populations. Between 1995-2003, he was a consultant to the CALFED Bay-Delta Program where he worked on various teams assessing the effects of alternative Delta operations, habitat improvements and water supply infrastructure. From 2002-2010, he was involved in activities related to the Striped Bass Stamp Program, Salmon Hatchery Program and Delta fish surveys funded by the U.S. Fish and Wildlife Service to assess the effects on Delta fish and habitats.

In the past decade, Tom worked closely with the Fishery Foundation of California, California Striped Bass Association and the California Sportfishing Protection Alliance on Delta science related to fisheries, water quality standards and the Bay Delta Conservation Plan. For Wildlands Inc. he supported efforts to develop wetland and fisheries habitat throughout the Delta region and co-authored a 2007 report on fish use of shallow water habitats of the Western Delta for Wildlands Inc. and Fishery Foundation. There he compared fish populations and habitat from surveys conducted between 2002-2007 in the Western Delta with earlier surveys conducted in 1978-1979.[52] He has personally surveyed many of the restoration sites in this report.

Bill Jennings is a life-long fisherman who has been with the California Sportfishing Protection Alliance for more than thirty years, serving as both its Chairman and Executive Director. Between 1995 and 2005, he also served as Deltakeeper, where he oversaw an extensive water quality monitoring program that was approved by the State of California and which worked closely with the Aquatic Toxicology Laboratory at U.C. Davis and state and federal agencies in collecting water samples throughout the Delta. Bill has spent thousands of days on Delta waters patrolling, monitoring and fishing and thousands of additional days participating in administrative and legal proceedings before state and federal agencies protecting water quality and fisheries. He is personally familiar with many of the restoration sites discussed in this report.

AQUALLIANCE
DEFENDING NORTHERN CALIFORNIA WATERS

July 30, 2015

Glenn-Colusa Irrigation District
Thaddeus Bettner, General Manager
344 East Laurel Street
Willows, CA 95988

Re: Comments on the Draft Environmental Impact Report for the Glenn Colusa Irrigation District 10-Wells Project (Groundwater Supplemental Supply Project SCH# 2014092076)

Dear Mr. Bettner:

AquAlliance submits the following comments and questions on the Draft Environmental Impact Report ("DEIR") for the Glenn Colusa Irrigation District ("GCID") 10-Wells Project (Groundwater Supplemental Supply Project) ("Project"). These comments represent the comments of AquAlliance and its members. The Project proposes to install five new production wells and continue operating five additional production wells during dry and critically dry years for 8.5 months from approximately February 15-Marh 15 and April 1-November 15. The annual, maximum, cumulative total pumping is 28,500 acre-feet ("af") and is more water than the annual use of the Chico district of California Water Service Company that serves over 100,000 people.[1]

Unfortunately, the Project description fails to disclose details that are necessary for the public to review and comment. Moreover, there are no alternatives presented to the public beyond the No Project Alternative. The repeated use of conclusory statements leads to an absence of impacts in the EIR that are not supported by evidence. The DEIR as written fails to make a technically persuasive case for the 10 wells, and therefore the proposed Project should be rejected until the lead agency/Project proponent, GCID, can more effectively present scientific principles and analysis instead of mere assertions of negligible impact to third-parties and the environment. The recirculation of a new Draft EIR will be required because of the extreme deficiencies in the DEIR currently out for public review. The deficiencies in the DEIR cannot and will not be evaded by responses to comments in a Final EIR.

We include by reference all other letters submitted in response to this DEIR and submit comments and attachments created for AquAlliance by Kit Custis, AquAlliance's comments and attachments to the 10-Year Water Transfer Program, and an electronic copy of the report *Hydrostratigraphy and Pump-test Analysis of the Lower Tuscan/Tehama Aquifer, Northern Sacramento Valley, CA* that was hand delivered to the GCID office on July 28, 2015.

I. Legal Requirements Under CEQA

Under CEQA, the project must include “the whole of an action, which has a potential for resulting in either a direct physical change in the environment, or a reasonably foreseeable indirect physical change in the environment…”[2] To comply with CEQA’s standards for completeness, the project description must address “not only the immediate environmental consequences of going forward with the project, but also all ‘reasonably foreseeable consequence[s] of the initial project’.”[3] As courts have recognized for decades, “an accurate, stable and finite project description” is “the sine qua non of an informative and legally sufficient EIR.”[4] Reliance on a “curtailed, enigmatic or unstable definition of the project” stands as the paradigm of legal error under CEQA, because it “draws a red herring across the path of public input.”[5] An “EIR may not define a purpose for a project and then remove from consideration those matters necessary to the assessment whether the purpose can be achieved.”[6] CEQA requires “interactive process of assessment of environmental impacts and responsive project modification which must be genuine.”[7]

A lawful project description under CEQA helps the lead agency “develop a reasonable range of alternatives to evaluate in the EIR [that] will aid the decision-makers…”[8] However, “a lead agency may not give a project’s purpose an artificially narrow definition….” [9] A “curtailed or distorted project description may stultify the objectives of the reporting process.”[10] In Inyo III, the court rejected the Los Angeles Department of Water and Power’s attempt in its EIR to “narrow the city’s obligation—and the scope of this lawsuit—down to the relatively small flow of underground water destined for in-valley use.”[11] That narrow definition evaded the county’s warning that EIR simply assumed the “filling of the second aqueduct,” and the State Board’s warning that the narrow definition diverted attention “from the impacts of the major project which is the importation of additional water to Los Angeles.”[12] The “selection of a narrow project as the launching pad for a vastly wider proposal frustrated CEQA’s public information aims The department’s calculated selection of its truncated project concept was not an abstract violation of CEQA,” but rather, a failure to proceed “in a manner required by law.”[13] The “impermissibly truncated” and inconsistent project definition in the EIR also unlawfully skewed the lead agency’s assessment of the “no project” alternative and project alternatives.[14]

In Communities for a Better Environment, the court held that the City of Richmond's EIR for a refinery project "fails as an informational document," in part because the EIR's project description "is inconsistent and obscure as to whether the Project enables the Refinery to process heavier crude."[15] The court noted that conflicting information in the EIR, and in 10-K statements filed with the Securities and Exchange Commission, contradicted the benign account provided in the EIR. The substantial evidence test was "not relevant" to assessment of violations of CEQA's information disclosure provisions. If the EIR does not "adequately apprise all interested parties of the true scope of the project for intelligent weighing of the environmental consequences, informed decision-making cannot occur under CEQA and the final EIR is inadequate as a matter of law.[16]

Project Definition in DEIR

Fundamental Purpose

The DEIR simply states that the Project "is proposing to install and operate five new groundwater production wells and operate five existing groundwater wells to augment District surface water supplies during dry and critically dry water years." (p. 2-1) The wells are proposed to operate "as needed during dry and critically dry years" until they reach a "maximum cumulative total annual pumping volume of 28,500 ac-ft." (Id.)

A complete and accurate description of the existing and affected environmental setting is critical for an adequate evaluation of impacts to it. *See e.g. San Joaquin Raptor/Wildlife Rescue Ctr. v. County of Stanislaus* (1994) 27 Cal.App.4th 713; *Galante Vineyards v. Monterey Peninsula Water Mgmt. Dist.* (1997) 60 Cal.App.4th 1109, 1122; *County of Amador v. El Dorado County Water Agency* (1999) 76 Cal.App.4th 931, 955; *Cadiz Land Co. v. Rail Cycle* (2000) 83 Cal.App.4th 74, 94.

As discussed, below, and in the expert reports created by Kit Custis on behalf of AquAlliance, the DEIR fails to comport with these standards.

Relationship to Past Projects and Plans

The Project is part of larger GCID projects, plans, grants, and agreements to transfer water (aka conjunctive use) and is also integrally related to other inter-connected actions by GCID, the California Department of Water Resources ("DWR"), the U.S. Bureau of Reclamation ("Bureau"), and others in the Sacramento Valley, and has the potential to have significant and far-reaching environmental impacts. However, the DEIR fails to make these connections that illustrate GCID's pursuit of conjunctive use projects.

For example, the broader history of the existing wells and GCID's delay in analyzing their planned long-term use for transfers and non-overlying water projects is not revealed. First, GCID was sued in 2007 over the claim that installing the wells (7 at the time) was exempt from CEQA because they were planned just for "research," despite the fact that GCID and local partners engaged in the Stony Creek Fan Project ("SCFP"). The SCFP's aquifer performance testing was hardly research, but preparation to enter the emerging water market as described in the 2005 Lower Tuscan grant proposal: "…this [conjunctive water use] program would provide

---

[15] 184 Cal.App.4th at 89.

[16] Id. at 83 (citations omitted).

opportunities to benefit from water transfers through the state and federal water projects. Overall program recovery would occur through groundwater substitution from wells tapping the lower Tuscan Formation aquifer system. These wells could be operated in the Butte Basin in conjunction with the SWP [State Water Project – Oroville] or in eastern Glenn and Colusa County in conjunction with the CVP [Central Valley Project– Shasta]."[17] The district's attempt to now evaluate impacts from these wells in this DEIR cannot be limited to this project's artificially limited project description, but rather, must evaluate the whole of the impacts of operating these wells. Similarly, and as discussed further below, the DEIR should not simply assume that the construction of new wells will not foreseeably result in environmental impacts greater than those contemplated by this project's artificially narrow project description.

Also omitted from the DEIR is the assurance in the Bureau's 2009 Environmental Assessment for the *Glenn-Colusa Irrigation District Stony Creek Fan Aquifer Performance Testing Plan* that use of the wells in any way beyond "research" required additional analysis. The Findings of No Significant Impact document for that project states, that: "The data and information compiled during implementation of this aquifer testing plan would be used as input prior to longer term use of the wells and would require future environmental review." (U.S. Bureau of Reclamation, p. 10) In addition, the Glenn-Colusa Irrigation District Stony Creek Fan Aquifer Performance Testing Plan ("APT") response to comments claimed: "The APT is a two-year program and the test production wells would not be used after conclusion of the program unless there is a subsequent decision to do so that is supported by the appropriate level of environmental review. This commitment is confirmed in the SCF APT itself, the notice of exemption issued by GCID in the related CEQA review process (See Appendix A), the EA (page 15), as well as briefs filed in the Superior Court litigation and the Court's ruling in that case." (p.7)

Despite the promises and legal commitments, GCID waited until 2015 to produce this DEIR while using the wells for multiple purposes: "GCID first pumped these wells in 2007, at 547 ac-ft for that year. In 2008 and 2012, the wells were pumped at less than 500 ac-ft; and in 2009, a dry year, GCID pumped 1,405 ac-ft. In 2010, no groundwater was pumped. GCID entered into two water transfer agreements, in 2011 and 2013, and pumped 6,300 and 5,000 ac-ft, respectively, in those years to supply the water transfer programs (GCID, 2013)." (DEIR p. 3-15). What is not disclosed in the DEIR is that GCID planned to sell 85,000 af to San Luis Delta Mendota Water Authority ("SLDMWA") in 2008 by fallowing no more than 20 percent of the district's irrigated acreage, crop shifting, and "[2],500 acre-feet that could be transferred would be made available by groundwater substitution attributable to pumping from two GCID-owned electric wells."[18] The contribution the existing five and newly-proposed five wells would provide to these and similar projects cannot be circumscribed by an artificial label on the project description, but instead, must be considered in conjunction.

It is clearly a significant omission that the DEIR doesn't disclose what transpired in 2014 or what is planned for 2015. What is known by AquAlliance to date is:

---

[17] Glenn Colusa Irrigation District and the Natural Heritage Institute, June, 2005. Proposition 50 planning grant proposal to create the Lower Tuscan IRWMP entitled: *Regional Integration of the Lower Tuscan Groundwater Formation into the Sacramento Valley Surface Water System Through Conjunctive Water Management.*

[18] GCID 2008. *Initial Study and Proposed Negative Declaration for Option Agreement Between Glenn-Colusa Irrigation District, San Luis & Delta-Mendota Water Authority and the United States Bureau of Reclamation for 2008 Operations, and Related Forbearance Program*, pp. 2-3.

- After GCID"s General Manager, Thad Better, assured the public at a 2014 Chico water forum that the GCID wells weren't being used, it turned out that GCID had the 5 wells running to help landowners flood their fields and pumped 459 af. [19]
- The 5 wells were also used to transfer 4,512 af to the Tehama Colusa Canal Authority in 2014.[20]
- In 2015 GCID is selling water again to Tehama Colusa Canal Authority by allowing their members to use personal wells - 15,269 acre-feet (af) of which 11,494 af will be made available by pumping groundwater.
- GCID also committed to sell 55,283 af of Sacramento River water to San Luis Delta Mendota Water Agency south of the Delta in 2015.
- On June 16, 2015 GCID turned on its existing five production wells while issuing a Notice of Exemption (NOE) based on an "emergency." To provide some history about these wells, they were installed eight years ago under a previous exemption that asserted that they were necessary for "research." The 2015 NOE claims that because of the 25% cut-back to their river water that was made clear in April, and new requirements to withhold additional water to attempt to save the 2015 winter-run salmon, they are facing emergency conditions. However, the most recent conditions could be foreseen by GCID, a water district that is in constant contact with the regulatory agencies and was fully aware of the serious hydrologic conditions and obliteration of the winter, fall, and spring salmon runs in 2014. There is no limit in time or volume in the NOE for the 5 wells.

GCID's failure to disclose its commitment to implement the SVWMA and its participation in repeated transfers, even when it claims in-district emergencies, proves that a shell game is operating. More of this will be discussed below.

Project Goals and Objectives

The fundamental purpose of the 10-Wells Project gives rise to more specific project objectives on page 1-5:

- Increase system reliability and flexibility
- Offset reductions in GCID Settlement Contract allotments during the irrigation season in drought years
- Periodically reduce Sacramento River diversions to benefit migrating fish
- Protect and maintain agricultural production in times of water shortage to minimize economic disruption

Below are specific comments and questions about the objectives presented.

1) "Increase system reliability and flexibility"
What "system" will receive "reliability and flexibility" from the 10-Wells Project? The vagueness of the objective leaves the reader unsure of the need for the Project. The Project is depicted as a "Supplemental Supply Project," however GCID is simultaneously selling river water to buyers north and south of the Delta in 2015.[21] The 10-Wells Project claims shortages yet in practice

[19] Bettner, Thad e-mail to Barbara Vlamis June 2, 2014.
[20] Bettner, Thad letter to Jim Brobeck June 30, 2014.
[21] Bureau of Reclamation, 2015. *2015 Transfer Proposals as of May 19, 2015* obtained by AquAlliance through the Freedom of Information Act.

GCID has enough to sell water. It is in this way that groundwater is actually connected to water transfers, even if the Project's stated use is for district needs.

2) "Offset reductions in GCID Settlement Contract allotments during the irrigation season in drought years" The DEIR fails to address how GCID has specifically managed reductions in the past and that recent dam operations, or dam mismanagement is more likely, are part of the shell game to push CVP districts toward groundwater.[22] This objective directs the reader to the Alternatives that were considered and rejected, two of which make for shared sacrifice during extremely rare CVP reductions. The DEIR can't have it both ways – either reductions are rare or they are regularly expected and, therefore, the additional stress of the 10-Wells Project to the hydrologic system is against the best interests of even GCID and certainly its neighbors. If CVP reductions are planned to be much more regular, this must be disclosed and analyzed in the DEIR.

3) "Periodically reduce Sacramento River diversions to benefit migrating fish"
How will fish benefit from the extraction of 28,500 af of groundwater that has not been historically needed when it is well documented that groundwater loss comes at the expense of stream flow? "Groundwater pumping can alter how water moves between an aquifer and a stream, lake, or wetland by either intercepting groundwater flow that discharges into the surface-water body under natural conditions, or by increasing the rate of water movement from the surface-water body into an aquifer."[23]

4) "Protect and maintain agricultural production in times of water shortage to minimize economic disruption"
This is another laudatory goal that fails the sniff test. GCID's 2008 Negative Declaration for a project to transfer 85,000 af to San Luis Delta Mendota Water Authority by fallowing no more than 20 percent of the district's irrigated acreage determined that it would have "no impact" on "human beings, either directly or indirectly." The ability to absorb an 85,000 af loss of water during a Critical water year was GCID's legal position in the 2008 CEQA document, so why would the district possibly need 28,500 af from the existing and proposed wells to minimize economic disruption now and into the future? [24] In addition, the district regularly supports crop

[22] Restore the Delta Protest Petition to the State Water Resources Control Board, July 22, 2015. "While we concede that DWR and the Bureau have in the near term diligently petitioned for temporary urgency changes reasonably promptly given natural conditions of drought in California and the Central Valley watershed of the Delta, the Board's authority to evaluate the temporary urgency change petition, and the petitioners' exercise of due diligence with respect to the substance of the petition, does not end with natural conditions. Instead, the California Constitution, Article X, Section 2, and the Public Trust Doctrine, as well as California Water Code sections 850546, 850217, and 850238 require the Board to consider whether the petitioners have also exercised due diligence in reasonably using and diverting water, as well as protecting public trust resources." (p. 5.)

[23] U.S. Geological Survey web site regarding groundwater depletion: http://ga.water.usgs.gov/edu/gwdepletion.html

[24] GCID 2008. *Initial Study and Proposed Negative Declaration for Option Agreement Between Glenn-Colusa Irrigation District, San Luis & Delta-Mendota Water Authority and the United States Bureau of Reclamation for 2008 Operations, and Related Forbearance Program*. "No Impact. The negative declaration assesses the potential impacts of the proposed Project. There would be no construction activities associated with the proposed Project. Typical farming practices with the idling of land in GCID would comply with applicable health and safety ·requirements. The potential increase in farmed acreage within the SLDMW A service area is within annual variability and could provide a minor beneficial effect on human economic activity. Therefore, the proposed Project would not cause substantial adverse effects on human beings, either directly or indirectly."

idling water transfers during dry and critical years, which the DEIR admits thwarts agricultural production. The district's on-again off-again support of this goal is arbitrary. Moreover, the project itself supports crop idling transfers by providing alternative water sources for the district in dry and critical years.

In 2010, a Below Normal water year, the *Glenn-Colusa Irrigation District 2010 Water Transfer to San Luis & Delta-Mendota Water Authority Draft Initial Study and Negative Declaration* had GCID planning to sell 20,000 af using groundwater substitution and didn't even *mention* impacts to the economy or humans. This pattern was repeated again in 2013, a Dry water year, when the water transfer CEQA document failed to mention, let alone consider, impacts to the economy or humans.[25] Clearly, GCID has through time demonstrated a lack of concern for impacts to the economy and humans, yet minimizing "economic disruption" has been elevated to an objective in the DEIR. The use of this goal obscures the district's historic behavior in feathering its own cap at the expense of the region's water and economy, which misleads the public.

In short, science and law should now converge to prevent GCID from framing the 10-Wells Project in a manner that forecloses meaningful alternatives and consigns the Sacramento Valley's future to fairy tales. As presented in the DEIR, the approach to project definition includes significant errors and omissions.

Key Problems with the GCID Project

GCID May Not Avoid Consideration of the Significant Environmental Impacts By Improperly Segmenting the Proposed Activities

The Project is part of GCID's multi-decade involvement in planning and implementing a much larger project, the Sacramento Valley Water Management Agreement ("SVWMA"), which still requires programmatic CEQA review. The SVWMA is not disclosed in the DEIR and has been gradually implemented by GCID and other parties absent the programmatic CEQA document (see Cumulative Impacts). The DEIR further fails to describe the numerous other programs of which this Project is a small component part. The review in the DEIR violates CEQA's prohibition against segmenting a project to evade proper environmental review (*Laurel Heights Improvement Association v. Regents of the University of California*, 1988, 47 Cal.3d 376).

The Project is a direct link to implementing the SVWMA and other subsequent plans and programs. Please consider the following:

- The SVWMA was signed in 2002 and the need for a programmatic EIS/EIR was clear and initiated, but never completed.[26] GCID is a signatory.

---

[25] *Notice Of Preparation Initial Study And Proposed Negative Declaration Glenn-Colusa Irrigation District 2013 Water Transfer To San Luis & Delta-Mendota Water Authority.*

[26] Perhaps even more telling, the Bureau actually began its own Programmatic EIS to facilitate water transfers from the Sacramento Valley, and the interconnected actions that are integrally related to it, but never completed that EIS and now has impermissibly broken out this current segment of the overall Program for piecemeal review in the present draft EA. See 68 Federal Register 46218 (Aug 5, 2003) (promising a Programmatic EIS on these related activities, "includ[ing] groundwater substitution in lieu of surface water supplies, conjunctive use of groundwater and surface water, refurbish existing groundwater extraction wells, install groundwater monitoring stations, install new groundwater extraction wells…" Id. At 46219. See also

- Sacramento Valley Integrated Regional Water Management Plan (2006). GCID serves on the Joint Powers Authority and has been implementing the SVWMA through state grants and federal appropriations and agreements. (see more in Cumulative Impact section below).
- The Sacramento Valley Water Management Plan prepared by the Sacramento River Settlement Contractors in cooperation with the Bureau. (2006). GCID is a Settlement Contractor. "[t]o examine the potential for groundwater production and recharge within a gravely strata located in Glenn County, the Stony Creek Fan. GCID's Conjunctive Use Program is being developed in conjunction with the Stony Creek Fan Program and build upon data contain [sic] though this investigation and the Sacramento Valley Water Management Program." (p. 2-56).
- The Stony Creek Fan Partnership Orland Project Regulating Reservoir Feasibility Investigation. GCID is one of the partners. (Id.)
- GCID's Stony Creek Fan Aquifer Performance Testing Plan to install seven production wells in 2009 that will extract 26,530 AF of groundwater as an experiment.
- GCID's Lower Tuscan Conjunctive Water Management Program (Bureau provided funding). "GCID shall define three hypothetical water delivery systems from the State Water Project (Oroville), the Central Valley Project (Shasta) and the Orland Project reservoirs sufficient to provide full and reliable surface water delivery to parties now pumping from the Lower Tuscan Formation. The purpose of this activity is to describe and compare the performance of three alternative ways of furnishing a substitute surface water supply to the current Lower Tuscan Formation groundwater users to eliminate the risks to them of more aggressive pumping from the Formation and to optimize conjunctive management of the Sacramento Valley water resources."[27]
- GCID's water transfers in 2008 and in 2010.
- GCID's participation in the California Drought Water Bank for 2009. "In 2009, GCID transferred 6,585acre-feet to the California Department of Water Resources (DWR), as part of the 2009 Drought Water Bank. GCID made the transfer water available through crop idling."[28]
- The Bureaus of Reclamation's 2010/2011 Water Transfer Program of 395,910 af of CVP and non-CVP water with 154,237 AF of groundwater substitution (EA/FONSI p. 2-4 and 3-107). GCID was prepared to participate by selling 40,000 af of which 20,000 would have been available from groundwater substitution. (Final EA at p. 2-4)
- "One-year GCID transfer of surplus Base Water Supply and US Bureau of reclamation Project Water during calendar year 2011 to 8,200 acres of Colusa Drain Mutual Water Company, comprised of previously cultivated, agricultural land outside, but contiguous to

---

[27] U.S. Bureau of Reclamation Assistance Agreement, 2006.

[28] Glenn-Colusa Irrigation District 2010 Water Transfer to San Luis & Delta-Mendota Water Authority Initial Study and Negative Declaration p. 1-2.

existing GCID boundaries, or otherwise, conveniently served with water from the Colusa Basin Drain when water is available within the Basin."[29] 6,300 af was transferred using groundwater substitution from GCID's wells for the first time.[30]

- In 2012 GCID's Critical Year Groundwater Well Program would pump 12,000 af. The Bureau planned water transfers of 76,000 af of CVP water all through ground water substitution.[31]
- In 2014 GCID planned to sell water north and south of the Delta.
  - Buyer Tehama Colusa Canal Authority sought 7,852 af with 4,154 af from groundwater substitution.
  - SLDMWA sought15,951 af.
- The 10-Year Water Transfers Program allows GCID to sell up to 91,000 af per year, including through groundwater substitution, from 2015-2024, to the San Luis Delta Mendota Water Agency.

The proposed project would facilitate additional water transfers that must be analyzed as part of the whole of the project. (See, *Citizens Association for Sensible Development of Bishop Area v. Com& of Invo* (1985) 171 Cal.App.3d 151, 165-166; *McQueen v. Board of Directors of the Midpeninsula Regional Open Space District* (1988) 202 Cal.App.3d 1136, 1144; *Laurel Heights Improvement Ass'n v. Regents of the University of California*, supra, 47 Cal.3d at pp.395-396.) The DEIR explains that GCID is a participant in the Long Term Water Transfer program ("LTWT") coordinated by and between the Bureau of Reclamation and the SLDMWA. (DEIR 3-76.) The DEIR notes that while the LTWT EIR originally evaluated GCID groundwater substitution transfers as part of the LTWT program, GCID now voluntarily seeks to convert all of its transfers under that program to cropland idling, while eliminating groundwater substitution, "originally shown at 25,000 ac-ft." (DEIR 3-76.) The DEIR explains that, "GCID elected to reduce the quantities from what was originally presented in the LTWT EIS/EIR in order to reduce potential conflicts between the proposed project and the LTWT." (DEIR 3-76.) In other words, to support and further the LTWT, GCID now proposes to pump a roughly equivalent amount of groundwater on its own, while still utilizing crop idling transfers as proposed under the LTWT. Moreover, nothing will prevent GCID from utilizing the existing or new wells to support groundwater substitutions under the LTWT. For each of these reasons, the direct, indirect, and cumulative impacts of GCID's participation in the LTWT should be considered here. See, AquAlliance, comments on the Long Term Water Transfer EIS/EIR, December 1, 2014.

Thus, while the DEIR provides no express explanation of why the proposed maximum groundwater pumping capacity of the project would be 28,500 ac-ft per year, the DEIR clearly explains that this project will be used to provide groundwater to the district in amounts almost identical to that which the district has voluntarily foregone in groundwater substitution under the LTWT. Nothing, however, under the LTWT nor under the proposed project affirmatively binds

---

[29] http://www.ceqanet.ca.gov/DocDescription.asp?DocPK=651108

[30] Glenn Colusa Irrigation District Draft EIR Groundwater Supplemental Supply Project2015, p. 3-15.

[31] U.S. Bureau of Reclamation Memorandum to U.S. Fish and Wildlife Service January 24, 2012. *Section 7 Endangered Species Act Consultation with U.S. Fish and Wildlife Service (USFWS) for 2012 "North-to-South" Water Transfers.*

the district to these proposed amounts. Accordingly, and in order to avoid this shell game of simply taking the same groundwater under the pretense of a separate project under another name, these two projects must be evaluated together.

Indeed, GCID's participation in the LTWT itself belies the fundamental purposes of this proposed project, to provide additional water to the district in times of supposed shortages. In fact, the district proposes to sell off water rights under the LTWT during dry and critically dry years, and now proposes to pump an equivalent amount to offset the "shortage" it creates voluntarily by selling its water to south of delta users. As the DEIR states, these two projects are inextricably linked, and subject to the broad discretion of the GCID board to allocate water between the two on an annual basis.

<u>The DEIR must evaluate higher rates of groundwater extraction than proposed by the DEIR.</u>

The DEIR incompletely describes the project in the following, limited, terms:

> GCID is proposing to install and operate five new groundwater production wells and operate five existing groundwater wells to augment District surface water supplies during dry and critically dry water years (see Figure 2-1). The proposed project wells would be operated as needed during dry and critically dry water years to achieve a maximum cumulative total annual pumping volume of 28,500 ac-ft. Total capacity per well would be approximately 2,500 gallons per minute.

(DEIR 2-1.) The DEIR, however, provides no justification for limiting its analysis of the whole of the project to additional pumping of 28,500 ac-ft per year during dry and critically dry years. Nothing in the DEIR explains how or why groundwater extraction from these wells will be so limited.

What is the basis for the 28,500 ac-ft target? How, specifically, does this target amount of water satisfy each of the project objectives? What legal constraints, if any, are in place to ensure that no greater amounts could be withdrawn from these pumps? As the DEIR discloses in Table 3-4, the pumping capacities of the existing wells are far greater than the projected 2,500 gpm rate planned in the Project. (p. 3-15.)

Once constructed, additional operations of these pumps is entirely foreseeable. According to the DEIR at least, no further regulatory approvals would be needed to utilize the new and existing pumps in non-dry and critically dry years, and in amounts greater than 28,500 ac-ft per year (only construction approvals are referenced in the DEIR). The DEIR states that the pumps will be operated 24 hours a day and 7 days a week, but for only 8.5 months a year. Should the pumps be operated for the entire year, production increases to 40,300 ac-ft per year. Should the pumps be operated during any normal or wet year, the groundwater recovery anticipated by the DEIR would not be realized.

The DEIR states that "[a]ny future uses of groundwater facilities other than for supplementing GCID's water supply sources (for example, a water transfer) would require a separate evaluation and approval, at the time any such specific action is proposed, in compliance with NEPA and/or CEQA, as appropriate." (DEIR 2-3.) But this is simply not the case. As discussed above, five of the wells included in the present project were constructed, and have been operated on numerous occasions for numerous reasons, without CEQA review. Similarly, the DEIR itself notes that “GCID can augment its surface water supply with a maximum of 5,000 ac-ft of groundwater available annually from existing District-owned wells.” (DEIR 1-2.) Though the basis for the 28,500 af cap is not provided, it is evident that GCID intends to use its own wells to pump groundwater as needed and at any capacity.

The Supreme Court in *Laurel Heights I* held that an EIR must analyze future effects of a project where such effects are (1) reasonably foreseeable, and (2) significantly greater in scope or degree. 47 Cal.3d 376, 393-399. For example, in *Communities for a Better Environment v. City of Richmond*, 184 Cal.App.4th 70 (2010), the Court set aside an EIR for its failure to analyze Chevron’s ability to process lower grade crude oil as a result of equipment upgrades, even where the proposed air district permit for the project could have prevented the throughput of lower grade and more polluting crude oil. As here, the project purpose stated in the *CBE* EIR was “to allow more flexibility in refining future crude supplies.” But, as here, the “flexibility” Chevron achieved through its equipment upgrades allowed for more and different impacts than those put forth in the artificially limited project description. With no actual restrictions on the new infrastructure, the Court held the EIR to be inadequate, stating, “[f]ar from being an informative document, the EIR’s conclusions call for blind faith in vague subjective characterizations.” Such is the case with the project description at hand, which claims a maximum groundwater extraction of 28,500 ac-ft per year in dry and critically dry years only, while providing no binding requirements or even practical limitations that would so limit future groundwater extraction from these new wells, once constructed, to the proposed project amounts.

Nor may GCID simply rely on the DEIR’s proposed mitigation measures to truncate review of the project’s impacts. The Court in *Stanislaus Natural Heritage Project v. County of Stanislaus*, 48 Cal.App.4th 182 (1996), overturned an EIR where the lead agency failed to fully analyze future water supply impacts based on a mitigation measure designed to avoid such future impacts. The court rejected this as insufficient under CEQA, holding that the whole of the project must be evaluated, and only then may the efficacy of mitigation measures be considered. (205-206.)

In contrast, in *Kings County Farm Bureau v. City of Hanford*, 221 Cal. App. 3d 692, the Court of Appeal upheld an EIR that considered only a 20 year lifespan for a project, where the facility at issue obtained only a 20 year contract and permit to operate. Any future decision to extend the plant operation would require a new permit approval, and therefore, subsequent CEQA review. (739.) Here, in contrast, no future, binding, limitations, such as an expiring contract or regulatory permit, might limit GCID’s future uses of the newly constructed pumps to the stated project timing and amount.

In sum, the DEIR is premised on an improperly "curtailed" and "distorted" project description. (*County of Inyo* v. *City of Los Angeles* (1977) 71 Cal. App.3d 185, 192.) Since "[a]n accurate, stable and finite project description is the *sine qua non* of an informative and legally sufficient EIR" (*id.* at p. 193), even were the FEIR deemed to be adequate in all other respects, the selection and use of a "truncated project concept" violated CEQA and mandates the conclusion that the County did not proceed "in a manner required by law.'" (*Id.* at p. 200)

Any need for additional groundwater pumping can only be the result of either increased demand, decreased supplies, or a combination of the two. However, the DEIR fails to provide any quantitative information on these project drivers. Based on historic climatic variation, the DEIR simply projects forward that "it is anticipated that GCID could operate the proposed project approximately 16 times in a 40-year period." (DEIR 2-3.) But the DEIR fails to provide any substantial evidence to support this future baseline projection. Over the prior 40 year period used to project the scope of the project going forward, haven't demands increased while supplies have simultaneously diminished? Indeed, the DEIR itself cites to decreasing supplies as a project driver, effectively rendering the past 40 years of pumping rates totally inapplicable to the 40 future years of project operations that the DEIR analyzes. The DEIR fails to make any adjustments to its projections, which rely on historic data, to account for present and future changes in demand and supply. As just one example, demands within Glenn County alone have increased significantly from 2000-2013 as agriculture is expanded or converted to tree crops.[32] Meanwhile, supplies are decreasing statewide, regionally, and locally, as a result of increasing average temperatures, and decreasing precipitation. See, AquAlliance, Comments on Long Term Water Transfer EIS/EIR, December 1, 2014, pp. 41-44. The EIR must make some good faith attempt to evaluate these and similar factors when projecting the scope of operation of the proposed project.

II. The DEIR Does Not Establish that GCID has Any Legal Right to Pump this Additional Groundwater.

The DEIR fails to meaningfully address whether GCID has a legal right to increase groundwater pumping, whether in its existing wells, or within the newly proposed wells, for distribution of this pumped groundwater throughout the district. In contrast to GCID's appropriative surface water rights, which it may allocate to a non-overlying use, any overlying right to pump groundwater is limited to the beneficial use of said groundwater upon the property of the overlying landowner within the same basin or watershed. (*California Water Service Co. v. Edward Sidebotham & Son* (1964) 224 Cal. App.2d 715, 725; see also, *City of Barstow v. Mojave Water Agency* (2000) 23 Cal.4th 1224.) The DEIR does not demonstrate that GCID would, in fact, solely limit its use of extracted groundwater to lands it owns throughout the same basin or watershed. GCID was put on notice that construction of its five existing wells did not provide this right, and is reminded of that again here.

III. Hydrology

Groundwater Conditions

A complete and accurate description of the existing and affected environmental setting is critical for an adequate evaluation of impacts to it. *See e.g. San Joaquin Raptor/Wildlife Rescue Ctr. v. County of Stanislaus* (1994) 27 Cal.App.4th 713; *Galante Vineyards v. Monterey Peninsula Water Mgmt. Dist.* (1997) 60 Cal.App.4th 1109, 1122; *County of Amador v. El Dorado County Water Agency* (1999) 76 Cal.App.4th 931, 955; *Cadiz Land Co. v. Rail Cycle* (2000) 83 Cal.App.4th 74, 94.

---

[32] AquAlliance 2015. Summary of Agriculture Reports 2000-2013. Based on actual reports found at: http://www.countyofglenn.net/govt/departments/ag/crop_reports.aspx

The 3.1.1 Environmental Setting section is deficient with its general description of the region's climate based on the work of Bertoldi in 1991. Even if the region experiences "typical years" in the future, it certainly has experienced shifting patterns since 2000. More current annual data and trends must be presented that reflects these changing conditions and specifically for Glenn County, where the wells are proposed for use and its surrounding counties.

The DEIR similarly provides limited groundwater elevation data of the Sacramento Valley groundwater basin in the subsection Groundwater Conditions. (pp. 3-7 to 3-10.) Table 3-2 provides groundwater level changes from the summer of 2004-2014. (DEIR p. 3-8.) DWR provides a number of additional groundwater level and depth to groundwater maps that the DEIR should use to help complete its description of the affected environment.[33]

AquAlliance's tables below illustrate maximum and average groundwater elevation decreases for Butte, Colusa, Glenn, and Tehama counties, all the counties believed to overly the Tuscan Aquifer, at three aquifer levels in the Sacramento Valley between the fall of 2004 and 2014.[34]

County Fall '04 - '14	**Deep Wells (Max decrease gwe)**	**Deep Wells (Avg. decrease gwe)**
Butte	-12.7 (-11.4)	-10.5 (-8.8)
Colusa	-59.5 (-31.2)	-59.5 (-20.4)
Glenn	-79.7 (-60.7)	-44.3 (-37.7)
Tehama	-34.6 (-19.5)	-10.9 (-6.6)

County Fall '04 - '14	**Intermediate Wells (Max decrease gwe)**	**Intermediate Wells (Avg. decrease gwe)**
Butte	-21.8	-6.5
Colusa	-39.1	-16.0
Glenn	-40.2	-14.5
Tehama	-20.1	-7.9

County Fall '04 - '14	**Shallow Wells (Max decrease gwe)**	**Shallow Wells (Avg. decrease gwe)**
Butte	-13.3	-3.2
Colusa	-20.9	-3.8
Glenn	-44.4	-8.1
Tehama	-15.7	-6.6

---

[34] Id.

Below are the results from DWR's spring monitoring for Sacramento Valley groundwater basin from 2004 to 2014.

County Spring '04 - '14	Deep Wells (Max decrease gwe)	Deep Wells (Avg. decrease gwe)
Butte	-20.8	-14.6
Colusa	-26.9	-12.6
Glenn	-49.4	-29.2
Tehama	-6.1	-5.3

County Spring '04 - '14	Intermediate Wells (Max decrease gwe)	Intermediate Wells (Avg. decrease gwe)
Butte	-25.6	-12.8
Colusa	-49.9	-15.4
Glenn	-54.5	-21.7
Tehama	-16.2	-7.9

County Spring '04 - '14	Shallow Wells (Max decrease gwe)	Shallow Wells (Avg. decrease gwe)
Butte	-23.8	-7.6
Colusa	-25.3	-12.9
Glenn	-46.5	-12.6
Tehama	-38.6	-10.8

The additional DWR data in multiple counties that depend on the Tuscan Aquifer clearly present a more comprehensive picture of the conditions of the Sacramento Valley groundwater basin over time than what is provided in the DEIR. It also highlights significant data that is intentionally omitted from the DEIR. For Glenn County alone (all that is provided in the DEIR), the fall measurements indicate much more dramatic declines from summer measurements in the deep wells and all the spring levels punctuate the serious lack of groundwater recovery. Obfuscating basic and foundational material regarding existing conditions leaves the public and policy makers with a lack of confidence in the 10-Wells Project, the DEIR, and the lead agency, GCID. Therefore, the DEIR will need to be revised, once these data are obtained, and recirculated as a Draft EIR in order to ensure the public and relevant decision makers receive full disclosure of the existing conditions and trends that are used for analysis and the development of conclusions for the 10-Wells Project.

Groundwater Properties

The DEIR fails to discuss the pressurized condition of the down-gradient portion of the Tuscan formation, which underlies the Project area. Dudley finds significant importance in the pressurized state of the lower Tuscan aquifer located in the Butte Basin. "It is interesting to note that groundwater elevations up gradient of the Butte Basin, in the lower Tuscan aquifer system, are higher than the ground surface elevations in the south-central portion of Butte Basin. This creates an artesian flow condition when wells in the central Butte Basin are drilled into the lower Tuscan aquifer."[35] The artesian pressure indicates recharge is occurring in the up-gradient portions of the aquifer located along the eastern margin of the Sacramento Valley several miles east of the project.

The DEIR fails to provide recharge data for the aquifers although GCID was provided this information seven years ago. Professor Karin Hoover, Assistant Professor of hydrology, hydrogeology, and surficial processes from CSU Chico, found in 2008 that, "Although regional measured groundwater levels are purported to 'recover' during the winter months (Technical Memorandum 3), data from Spangler (2002) indicate that recovery levels are somewhat less than levels of drawdown, suggesting that, in general, water levels are declining."[36] According to Dudley, "Test results indicate that the 'age' of the groundwater samples ranges from less than 100 years to tens of thousands of years. In general, the more shallow wells in the Lower Tuscan Formation along the eastern margin of the valley have the 'youngest' water and the deeper wells in the western and southern portions of the valley have the 'oldest' water," adding that "the youngest groundwater in the Lower Tuscan Formation is probably nearest to recharge areas."[37] "This implies that there is currently no active recharge to the Lower Tuscan aquifer system (M.D. Sullivan, personal communication, 2004)," explains Dr. Hoover. "If this is the case, then water in the Lower Tuscan system may constitute fossil water with no known modern recharge mechanism, and, once it is extracted, it is gone as a resource."[38] The DEIR must account for this feature in its description of existing conditions, and its projections of recharge rates.

Groundwater Depletion

The DEIR illegally defers formulation and evaluation of mitigation measure WR-1. (*See, e.g.*, *POET, LLC v. State Air Resources Board* (2013) 218 Cal.App.4th 681; *Preserve Wild Santee v. City of Santee* (2012) 210 Cal.App.4th 260; *Sacramento Old City Association v. City Council* (1991) 229 Cal.App.3d 1011; CEQA Guidelines § 15126.4(a)(1)(B); *Defend the Bay v. City of Irvine* (2004) 119 Cal.App.4th 1261, 1275.) In relying on WR-1, the DEIR goes so far as to defer the environmental impact analysis that should be provided now, as part of the DEIR itself. Moreover, WR-1 fails to include clear performance standards, criteria, thresholds of significance, evaluation of feasibility, analysis of likelihood of success, and even facially permits significant impacts to occur. And importantly, WR-1 does not, in fact, reduce potentially significant impacts to less-than-significant levels, but rather, attempts to monitor for when significant effects occur.

WR-1 requires GCID "implement a groundwater monitoring program," but a monitoring program itself cannot prevent significant impacts from occurring. "The monitoring program will rely on DWR's CASGEM program and the District's monitoring network. The monitoring program will include semiannual measurements of groundwater levels at a network of wells throughout the Sacramento Valley. Many of the established observation wells (including multi-completion well clusters) are instrumented with data-logging pressure transducers to provide continuous

[38] Hoover, Karin A. 2008. Id.

groundwater level data." (EIR 3-40.) Although monitoring does not disclose or analyze impacts for CEQA purposes, the DEIR still fails to provide any of the most foundational information about its proposed "groundwater monitoring program," such as how many wells will be monitored, what is a sufficient number of wells, how many will be monitored semiannually, how many will be monitored continuously, where are the monitoring wells located, what strata are the wells monitoring, who will manage and report on the data, and how will the public have access to the data and reports?

To elaborate on the timing of monitoring, it is absolutely crucial. Common sense suggests that significant groundwater pumping could occur in less than six months – one of the periods planned for monitoring. And monitoring after transfer-related pumping can only show whether significant impacts have occurred; it cannot prevent them. Yet this is exactly what the EIR proposes: "A subset of the well network will be selected for groundwater level monitoring prior to (monthly), during (weekly), and after (weekly for 1 month and monthly thereafter) groundwater pumping for the proposed project. The monitoring network will incorporate a sufficient number of monitoring wells and adequate spatial distribution to evaluate groundwater levels prior to, during, and after project operations." (EIR 3-40.) Hence, WR-1 only requires elements of the mitigation plan to kick in after monitoring shows significant impacts are occurring, which are extremely likely to occur given the fact that monitoring alone amounts to no mitigation or avoidance measures. Additionally, the DEIR fails to provide any guidance on what constitutes "a sufficient number of monitoring wells." (Id.)

Compounding WR-1's inadequacy as a mitigation measure, the DEIR asserts that, "As part of the monitoring program, GCID will use data from DWR's existing monitoring programs to establish longer-term antecedent trends in groundwater levels within the basin." (p. 3-40). But this is exactly the kind of information that must be provided to the public in the DEIR. When would GCID finally establish these trends, how would they be disclosed to the public, and what would they possibly alter with the Project?

Even still, the proposed mitigation measure WR-1 doesn't mitigate significant impacts. The mitigation proposal includes the following requirements: 1) "Reduce or relocate pumping until natural recharge corrects the issue." This, of course, could take years[39] and really amounts to no mitigation of the significant impact at all. (See also, AquAlliance, comments on the Long Term Water Transfer EIS/EIR, pp. 19-22, 36, 47, 59-61, 66.) 2) How GCID would feasibly and legally "relocate" pumping is not explained. 3) "Reimburse third parties for significant increases in pumping costs due to an increase in lift." In what amount, at what time, as decided by whom? Monetary compensation is not always sufficient to cover damages to business operations. (*See* CEQA Guidelines § 15370; *Gray v. County of Madera* (2008) 167 Cal.App.4th 1099, 1122.) 4) "Lower the pump in third-party wells affected by the proposed project," may help an injured third-

---

[39] Custis, Kit 2015. "Although the DEIR doesn't provide an estimate of the stream depletion rate as a percentage of the stream flow, it appears from the maximum values listed in Table 3-6 that the depletion rates for the listed streams and rivers are less than 48% of the average stream flow. This would suggest that the time it takes until the aquifers pumped by the GCID well are 95% recharged by stream depletion may take decades. In fact, a report on the impacts from the 2009 groundwater substitution transfers simulating from 1976 to 2003 using the SACFEM groundwater model showed aquifer recovery following a single 1976 pumping event was only 60% after 30 years (Figure 4d in CH2MHill, 2010). This suggests that the impacts from a single year of GCID's groundwater extraction project and the impacts from reoccurring pumping events will continue for many years."

party, but like monetary damages may not sufficiently cover damages or be done in a timely manner with well companies months behind due to the existing dry conditions. Finally, "[o]ther actions as appropriate" is so vague as to be meaningless. (EIR 3-40.)

Mitigation measure WR-2 is similarly flawed with its reliance on monitoring and deferred analysis of impacts of the present project. WR-2 also assumes that subsidence impacts will take place quickly allowing GCID to determine exclusive culpability or deflect it to "regional conditions." (DEIR p. 3-41/42.) This simplistic view is not founded in science – more likely wishful thinking. The DEIR instead should disclose how long-term physical responses result from repeated lowering of groundwater. The following evidence demonstrates that the Project's subsidence impacts may be significant and it was first provided to GCID in 2008.[40]

Dr. Kyran Mish, former Presidential Professor, School of Civil Engineering and Environmental Science at the University of Oklahoma related: "It is important to understand that *all* pumping operations have the potential to produce such settlement, and when it occurs with a settlement magnitude sufficient enough for us to notice at the surface, we call it *subsidence*, and we recognize that it is a serious problem (since such settlements can wreak havoc on roads, rivers, canals, pipelines, and other critical infrastructure)."[41] Dr. Mish further explains that "[b]ecause the clay soils that tend to contribute the most to ground settlement are highly impermeable, their subsidence behavior can continue well into the future, as the rate at which they settle is governed by their low permeability." (Id.) "Thus simple real-time monitoring of ground settlement can be viewed as an *unconservative* measure of the potential for subsidence, as it will generally tend to underestimate the long-term settlement of the ground surface." (Id.) (emphasis added).

However, the DEIR asserts that, "If groundwater levels do not recover above historical lows within 6 months following cessation of project operation and project operations will not resume the next year, GCID will assume groundwater level drawdown is due to regional conditions and land subsidence monitoring may be stopped." (pp. 3-41 and 3-42.) This conclusory assertion falsely assumes that 1) Any water level above the *historic lows* avoids or offsets damage from non-reversible subsidence. 2) If groundwater recovers above historic lows, subsidence isn't occurring and therefore can't be attributed to the 10-Wells Project and 3) If groundwater levels don't recover above historical lows, when there is a planned one-year lapse in GCID's pumping, there are no impacts from GCID's pumping. However, the DEIR contains conclusions reached by the U.S. Geological Survey ("USGS") that affirm the long-term and gradual nature of subsidence that accrues from continuous groundwater depletion,: "These small changes accumulate over time and can lead to impacts such as changes in stream, canal, or levee elevations and slopes; damage to infrastructure such as roads, bridges, and utilities; damage to building foundations; and collapse of well casings (USGS, 2015b)." (p. 3-13.)

USGS also confirms that, "In many aquifers, ground water is pumped from pore spaces between grains of sand and gravel. If an aquifer has beds of clay or silt within or next to it (figure 2), the lowered water pressure in the sand and gravel causes slow drainage of water from the clay and silt beds. The reduced water pressure is a loss of support for the clay and silt beds. Because these beds

[40] Mish, Kyran 2008. *Commentary on Ken Loy GCID Memorandum*. White Paper. University of Oklahoma.
[41] Id.

are compressible, they compact (become thinner), and the effects are seen as a lowering of the land surface. The lowering of land surface elevation from this process is permanent. For example, *if lowered ground-water levels caused land subsidence, recharging the aquifer until ground water returned to the original levels would not result in an appreciable recovery of the land-surface elevation*."[42] (emphasis added) It is quite clear that WR-2 is a completely inadequate mitigation measure for subsidence impacts.

The DEIR's evaluation of subsidence suffers from the same flaws as that of the Long Term Water Transfer Final EIS/EIR, and AquAlliance's April 8, 2015 comments on these deficiencies (pp. 2-5) are incorporated here.

Groundwater Quality

The DEIR fails to disclose the existence or extent of all the hazardous waste plumes in the Tuscan groundwater basin where GCID's wells are and will be located or in the Tehama formation that intermingles with the Tuscan in Glenn County. (*See e.g. San Joaquin Raptor/Wildlife Rescue Ctr. v. County of Stanislaus* (1994) 27 Cal.App.4th 713.) For example, the Orland dry cleaners plume is certainly within the incremental drawdown forecast in Figure 3-6. There is also no discussion of whether the increased groundwater extraction proposed by the Project may mobilize some of the PCE and TCE plumes under Chico since the pressurized condition of the down-gradient portion of the Tuscan formation, which underlies the 10-Wells Project area, benefits from recharge waters in the foothills and mountains to the east and north of Chico.[43] Toccoy Dudley et al support this finding of a pressurized lower Tuscan aquifer across the Sacramento River from GCID. "It is interesting to note that groundwater elevations up gradient of the Butte Basin, in the lower Tuscan aquifer system, are higher than the ground surface elevations in the south-central portion of Butte Basin. This creates an artesian flow condition when wells in the central Butte Basin are drilled into the lower Tuscan aquifer." [44] The artesian pressure indicates recharge is occurring in the up-gradient portions of the aquifer located along the eastern margin of the Sacramento Valley many miles into Butte County. This indicates that flow moves through the Chico plume areas toward the down-gradient portion of the Tuscan Aquifer where the existing GCID wells are located and new wells are proposed.

In addition, the DEIR fails to describe a significant saline portion of the aquifer stratigraphy of the project area. According to Toccoy Dudley, former Groundwater Geologist with the Department of Water Resources and former director of the Butte County Water and Resources Department, saline groundwater aquifer systems of marine origin underlie the various freshwater strata. The approximate contact between fresh and saline groundwater occurs at a depth ranging from 1,500 to 3,000 feet.[45]

[45] Id.

More recent research has documented threats of contamination. "The BFW [base of fresh water] boundary occurs primarily in late Tertiary to Quaternary unconsolidated sediments at depths near land surface to more than 3,500 feet below ground surface. The BFW is an uneven boundary that in some places reflects the major geologic structures underlying the Sacramento Valley, and in other areas, transgresses underlying geologic structures. In some areas, the BFW boundary is well above the base of post-Eocene marine strata. This is most likely caused by high artesian pressures and upward vertical gradients in deep aquifers in the Sacramento Valley, which have been documented in DWR monitoring wells. This suggests that migration of poor quality water into continental sediments that previously contained freshwater has occurred over geologic time. This finding has implications for brackish and saline water upconing beneath areas of prolonged groundwater pumping in the Sacramento Valley."[46]

Certainly the public has no idea of or ability to comment on the important water quality conditions not presented in the DEIR, which fails the full-disclosure mandate in CEQA. The 10-Wells Project must either be withdrawn or full disclosure must be presented in a recirculated DEIR. (See, e.g., *Laurel Heights Improvement Ass'n v Regents of Univ. of Cal.* (1993) 6 Cal.4th 1112; 14 Cal Code Regs., § 15088.5(a); 40 C.F.R. § 1502.9(c); *California v. Block* (9th Cir. 1982) 690 F.2d 753, 770.)

IV. Species Impacts

Aquatic Species

It is useful that the DEIR acknowledges the demise of four anadromous fish runs in Stony Creek (spring, fall, late-fall, and winter salmon). (pp. 3-43 - 3-44). The acknowledgement serves to illustrate the existing strains on the hydrologic system, both surface and ground, once supported these runs of salmon. We select one tributary mentioned as an example to elucidate many points. Stony Creek is simulated with the 10-Wells Project to have an average depletion of 1.8 cfs and a maximum of 11.6 cfs. The text that follows these figures in the 3.1 Water Resources section, states, "As shown in Table 3-6, the majority of the maximum streamflow depletions occur during or shortly following the drought of water years 1987–1992. During critically dry year types, it is expected that many of the surface streams within the drawdown area would naturally have minimal or no flow (for example, Stony Creek, Little Chico Creek, and Walker Creek). Furthermore, these streams do not substantially contribute supply to the CVP, SWP, or non-project water users." (p. 3-39).

The text is troubling for many reasons.

1) The conclusion that "many of the surface streams within the drawdown area would naturally have minimal or no flow," during critically dry years and therefore the impacts would be "less than significant" avoids serious consideration of the importance of underflow. "The DEIR's evaluation of impacts from stream depletion is also inadequate because it assumes that once a streambed becomes dry continued pumping of groundwater has no effect on surface flow. This

---

[46] Springhorn, Steven T., el al, May 2013. *Base of Fresh Groundwater in the Sacramento Valley, California*, Geological Society of America Abstracts with Programs. Vol. 45, No. 6, p.51. https://gsa.confex.com/gsa/2013CD/webprogram/Paper219191.html

assumption ignores the role that stream underflow plays on maintaining pools and riparian habitats. The assumption also ignores the fact that the depth to saturated ground water beneath a streambed will impact the volume and duration of flow needed to re-wet the channel at the beginning of the next rainy season. The deeper the depth of ground water, the more aquifer voids there are that need to be re-filled in order for the stream to sustain constant flow. In other words, a greater volume of water for a longer period of time is needed at the beginning of the rainy season to sustain surface flows."[47] (p. 11.)

2) "Furthermore, these streams do not substantially contribute supply to the CVP, SWP, or non-project water users." On what basis is this conclusion made? The DEIR does not say. How much water in the streams is backfilling over used groundwater? How does contributing, substantially or otherwise, "to the CVP, SWP, or non-project water users" constitute the only value from a stream?

3) If the simulations are correct and the "majority of the maximum streamflow depletions occur during or shortly following the drought of water years 1987–1992," how is that not a significant impact when streams may already have minimal or no flows even according to the DEIR? Dewatering streams, be they ephemeral or annual, no matter how low the flow can be essential for fish species. For example, according to research conducted by Dr. Paul Maslin, Mud Creek provides advantageous rearing habitat for out-migrating Chinook salmon (1996). Salmon fry feeding in Mud Creek grew at over twice the rate by length as did fry feeding in the main stem of the Sacramento River. *Id. The Recovery Plan For The Evolutionarily Significant Units Of Sacramento River Winter-Run Chinook Salmon And Central Valley Spring-Run Chinook Salmon And The Distinct Population Segment Of California Central Valley Steelhead* confirms this importance of small areas of refugia for out-migrating salmon in tributaries to the Sacramento River: "Non-natal rearing tributaries to the Sacramento River include freshwater rearing habitat. Some non-natal rearing areas potentially have a high value because they provide critical and improved growing conditions, particularly during high winter flow events on the Sacramento River."[48]

4) The 10-Wells Project will further deplete the hydrology in Glenn County and may also affect the hydrology in surrounding counties, streams, and the Sacramento River. Dewatering of salmon bearing streams that interface with the targeted Lower Tuscan Formation Aquifer would result in physical changes to these streams that may result in significant adverse impacts to biological resources. This effect has been observed in the Cosumnes River, where "[d]eclining fall flows are limiting the ability of the Cosumnes River to support large fall runs of Chinook salmon." This is a river that historically supported a large fall run of Chinook Salmon.[49] Indeed, "[a]n early study by the California Department of Fish and Game . . . estimated that the river could support up to 17,000 returning salmon under suitable flow conditions." (Id.), citing CDFG 1957 & USFWS 1995. But "[o]ver the past 40 years fall runs ranged from 0 to 5,000 fish according to fish counts by the CDFG (USFWS 1995)," and "[i]n recent years, estimated fall runs have consistently been below 600 fish, according to Keith Whitener." (Fleckenstein, et al. 2004). Indeed, "[f]all flows in

[47] Custis, Kit, 2015. *Comments and Recommendations on Draft Environmental Impact Report for Glenn Colusa Irrigation District's Groundwater Supplemental Supply Project, June 2015* for AquAlliance.
[48] National Marine Fishery Service, 2014.
[49] Fleckenstein, Jan; Anderson, Michael; Fogg, Graham; and Mount, Jeffrey 2004. *Managing Surface Water-Groundwater to Restore Fall Flows in the Cosumnes River*, Journal of Water Resources Planning and management.

the Cosumnes have been so low in recent years that the entire lower river has frequently been completely dry throughout most of the salmon migration period (October to December).” (Id.)

Research indicates that “groundwater overdraft in the basin has converted the [Cosumnes River] to a predominantly losing stream, practically eliminating base flows….” (Id.) And “investigations of stream-aquifer interactions along the lower Cosumnes River suggest that loss of base flow support as a result of groundwater overdraft is at least partly responsible for the decline in fall flows.” (Id.) Increased groundwater withdrawals in the Sacramento basin since the 1950s have substantially lowered groundwater levels throughout the county.” (Id.) The DEIR fails to consider such broader ecological and hydrological impacts stemming from increased groundwater extraction during already dry and critical years.

5) Lower Stony Creek is designated as critical habitat for spring-run salmon and Central Valley steelhead (p. 3-44), yet the DEIR concludes that because Stony Creek is already impaired, “[p]otential drawdown effects on surface waters of lower Stony Creek are anticipated to have less-than-significant impacts on anadromous salmonids.” (p. 3-53) The DEIR’s empty conclusion, without any supporting data or analysis, is taken by GCID as a release from even offering a mitigation measure for struggling Stony Creek that is suffering death by a thousand cuts. However, the federal register for critical habitat provides a different view of the needs and potential of Stony Creek.

> “The CHART [Critical Habitat Analytical Review Teams] has evaluated the available information, particularly with regard to Stony Creek (HSA 550410), and concluded that this stream is occupied by both spring run Chinook and steelhead. Juvenile spring run Chinook have been consistently documented using Stony Creek as rearing habitat since 2001 (Corwin and Grant, 2004), as well as in previous years (Maslin and McKinney, 1994). Similarly, juvenile steelhead have been periodically documented rearing in Stony Creek (Corwin and Grant, 2004; Maslin and McKinney, 1994). The CHART also concluded that Stony Creek has PCEs that support both species. Water temperature monitoring from 2001 through 2004 has shown that temperatures in Stony Creek under current operations are generally suitable for adult and juvenile salmonids (below 65 °F) from mid-October through late May. Water temperatures have been found to be suitable for salmonid spawning and incubation (below 56 °F) from mid-November through early May (Corwin and Grant, 2004). Though successful steelhead spawning has not been documented recently in Stony Creek, habitat conditions under current operations are considered marginally suitable to support steelhead reproduction. Because of ongoing restoration actions and ESA section 7 consultations, progress is being made toward improving these habitat conditions, and we expect conditions to continue to improve into the future.”[50]

We must be clear: any additional impairment by the 10-Wells Project is adverse modification of critical habitat, yet that is not addressed in the DEIR. Added to this significant lapse is the failure

---

[50] National Marine Fisheries Service, 2005. *Federal Register /Vol. 70, No. 170 / Friday, September 2, 2005 /Rules and Regulations, Endangered and Threatened Species; Designation of Critical Habitat for Seven Evolutionarily Significant Units of Pacific Salmon and Steelhead in California*.

of the DEIR to disclose many relevant recovery recommendations[51] for Stony Creek that the 10-Wells Project clearly undermines. Examples include, but are not limited to:

- Improve water temperature conditions in Stony Creek by identifying and implementing projects that would increase stream flows and increase shaded riverine habitat.
- Implement projects to increase floodplain habitat availability in Stony Creek to improve juvenile rearing habitat.
- Monitor and evaluate sportfishing impacts in Stony Creek to ensure that the fishery allows for the recovery of steelhead; modify regulations as necessary. (Id.)

The DEIR assumes an average depletion of 0.5 cfs in Little Chico Creek and a maximum of 3 cfs. (p. 3-53) The DEIR assumes an average depletion of 0.3 cfs in Big Chico Creek and a maximum of 11.6 cfs. (Id.)

Big Chico and Little Chico Creeks are also listed as critical habitat for Central Valley steelhead (Oncorhynchus mykiss) and Central Valley Spring Run Chinook Salmon (Oncorhynchus tshawytscha), although the DEIR fails to point out the salmon critical habitat designation for Little Chico Creek. (pp. 3-48 to 3-49). Again, any additional impairment by the 10-Wells Project is adverse modification of critical habitat, yet that is not addressed in the DEIR. Recovery actions for Big Chico Creek that are undermined by additional strains on streamflow include, but are not limited to:

- Implement projects to increase Big Chico Creek floodplain habitat availability to improve habitat conditions for juvenile rearing
- Increase monitoring and enforcement in Big Chico Creek to ensure that the water quality criteria established in the Central Valley Water Quality Control Plan (Basin Plan) are met for all potential pollutants (SWRCB 2007).

Giant Garter Snake

Section 2-4 presents permits and approvals that are required for the 10-Wells Project. Noticeably absent are requirements for a permit from the California Department of Fish and Wildlife and from the U.S. Fish and Wildlife Service for impacts to the giant garter snake ("GGS"). However, the DEIR acknowledges the potential for construction impacts: "Additionally, the proposed well sites are located within 200 feet of rice fields and canals, both of which provide suitable habitat for giant garter snake (GGS). Though the construction sites do not directly provide suitable habitat for GGS, nor do the sites contain suitable winter hibernacula for the species, it is possible that, due to their close proximity to suitable habitat at all well locations, GGS could be present within the project construction areas during construction. Though the likelihood of impacts on GGS are low, any impact on GGS would be significant. Implementation of avoidance measures listed in MM BIO-4 would eliminate impacts to GGS." (DEIR p. 3-52)

---

[51] National Marine Fisheries Service, 2014. *Recovery Plan For The Evolutionarily Significant Units Of Sacramento River Winter-Run Chinook Salmon And Central Valley Spring-Run Chinook Salmon And The Distinct Population Segment Of California Central Valley Steelhead.*

It may be a good first step to prepare for "avoidance measures," but that does not eliminate the requirements under the California and federal Endangered Species Acts. The presence of wetlands in the Project area will require a permit from the U.S. Army Corps of Engineers (DEIR p. 3-50) that will lead to consultation with the U.S. Fish and Wildlife Service. GCID must also apply to the California Department of Fish and Wildlife for an incidental take permit.

Substantively regarding GGS, there is developing research that GGS may spend a great deal of time underground during the active season. "As for the probability of being in a terrestrial environment, much individual variation existed in the probability of being underground (logit-normal SD for individual-specific random intercept = 1.85 [1.63–2.12]). Predicting whether a given individual will be on the surface or underground is therefore fraught with uncertainty, despite high posterior precision of estimates of the behavior of an average Giant Gartersnake (Figs. 4 and 5)."[52]

This significant research must be considered if the 10-Wells Project moves forward. The DEIR also fails to acknowledge that there may be operational impacts to GGS. This must be developed and, if the Project goes forward, recirculated in a revised DEIR.

Additional Comments

The reader is referred to Figures 3.3 and 3.6 to view the potential drawdown effects on Stony Creek (DEIR p. 3-53) with Tehama-Colusa Canal mentioned as a reference point, however, it is not on either Figure.

As mentioned previously, the two-year and six-year scenarios leave out serious periods of drought or dry conditions, such as 2007-2010 and 2012-2015, a four-year drought that has been declared an emergency by Governor Brown multiple times. This is a serious omission undermining the description of baseline environmental conditions, analysis of supplies and demands associated with foreseeable project production, and exacerbated impacts of the project itself, that must be corrected in a recirculated DEIR.

Tables 3.1 and 3.6 are incapable of presenting data with which to simulate streamflow depletion because, as stated in the DEIR, there are "limitations of the available gaging data." (pp. 3-6 and 3-39). In an effort to locate existing data, AquAlliance checked the Big Chico Creek Near Chico (BIC) gage on July 24, 2015 and there is insufficient flow to even register a reading at this time.[53] In addition, the USGS no longer maintains a gage on Big Chico Creek.[54] Regarding Little Chico Creek estimated flows, Table 3-1 indicates that the period of record for DWR gage A04270 Taffee Road near Chico, CA was 1991-2002 and that gage A04280 Near Chico, CA was from 1975-1996 and that, "Data for this gage were downloaded in 2011; the data are no longer available from

[54] https://water.usgs.gov/nsip/

original data source: DWR, 2015a," (footnote "e" p. 3-6). Stony Creek's flows are also based on distant years and 1955 -1990 and 1941-1973 (p. 3-6). It is impossible for the public to have any confidence in modeling results that are using such antiquated input data. The DEIR relies on only modeling to consider impacts from the Project when it must compile and present results from actual monitoring and reporting prior to recirculating a revised DEIR.

Shallow Groundwater Monitoring Framework

A comprehensive monitoring program was proposed in the mid-2000s and is still absolutely necessary. The Sacramento Valley Integrated Water Management Plan lead to a draft Framework for Sacramento Valley regional water resource monitoring that would also benefit shallow domestic-well owners. Starting on page five, it reads: "Habitat Monitoring; The long-term health of riparian vegetation, wetland species, and a number of other native habitat are commonly associated with maintaining a minimum range of groundwater levels and an appropriate level of interaction between surface water and groundwater resources. The lowering of groundwater levels due to the interception of groundwater underflow to surface water systems due to the increased groundwater extraction associated with conjunctive water management programs, have the potential to impact the native habitat areas," and that, "In order to identify potential habitat impacts associated with implementation of conjunctive water management alternatives, a program-specific network of shallow monitor monitoring wells should be developed to detect changes in water levels over the shallowest portion of the aquifer. The groundwater monitoring network should contain shallow monitoring wells that will record changes to the water table elevation in the vicinity of these sensitive habitat areas."[55] The Framework has many other valuable suggestions that were protective of the region's residents and environment. Unfortunately, the Framework was shelved, and the shallow monitoring network never got off the ground.

This Framework could have been operation for over seven years and it should definitely be in place prior to the 10-Wells Project and continue in perpetuity. It should also be presented in a recirculated Draft EIR as a viable mitigation measure, or project alternative

V. Climate Change

Once SB 97 was approved in California in 2007, analysis of greenhouse gas emissions became a part of the CEQA process[56] and that is reflected in the DEIR from an air quality and air pollution perspective. Unfortunately, the DEIR fails to discuss Climate Change, the result of greenhouse gas emissions and its impacts on the hydrology of the region or the Sacramento River watershed upon which GCID's river and stream water claims depend. This obvious omission is at the heart of the 10-Wells Project that claims the need for more water in a district with an exorbitant claim to water - 825,000 af per year.

The gross omission of any climate change analysis in the DEIR fails to accurately describe the existing climatological conditions into which the project may be approved, fails to accurately describe the diminution of water and natural resources over recent and future years as a result of

---

[55] McManus, Dan et al, 2007. *Sacramento Valley Water Resource Monitoring, Data Collection and Evaluation Framework*

[56] http://opr.ca.gov/docs/SB_97_bill_20070824_chaptered.pdf

climate change, fails to integrate these changing circumstances into any future baseline or cumulative conditions, and fails to completely analyze or support the DEIR conclusions regarding the project's potentially significant impacts. See, AquAlliance, comments on LTWT EIS/EIR, pp. 30, 40-45.

Both climate change and the 10-Wells Project have the potential to degrade the hydrology of the counties within GCID's district, surrounding counties, and flows in the Sacramento River.
This must be remedied in a recirculated DEIR

VI. The EIR fails to analyze a reasonable range of alternatives.

As discussed in Sections I and II above, the DEIR fails to explain what is driving the suggested demand for more water, which leads to a failure to produce viable alternatives. The 10-Wells Project is being sold as an essential need for GCID without providing the context of the Sacramento Valley Water Management Agreement, climate change, demand from outside the Sacramento Valley, and GCID's regular participation in the water market. Additionally, there is no discussion of the Water Fix's premise (formerly the Bay Delta Conservation Plan) that Delta exports through the Twin Tunnels will not only increase in the wetter years, but they will also rise in drier years from water transfers.

The "no project alternative" itself does not constitutes a reasonable range of alternatives.

CEQA requires public agencies to identify in an EIR feasible alternatives that could avoid or substantially lessen a project's significant environmental effects. (Pub. Res. Code §§ 21002, 21002.1(a), 21100(b)(4), 21150.) CEQA's procedures require that an EIR must present a "reasonable range" of alternatives to the project that "foster meaningful public participation and informed decisionmaking." (Guidelines, § 15126.6(f), Guidelines, § 15126.6(a) citing *Citizens of Goleta Valley v. Board of Supervisors* (1990) 52 Cal.3d 553 (*Goleta Valley II*), and *Laurel Heights I, supra,* 47 Cal.3d 376.)

However, this does not mean that the "rule of reason" allows the lead agency to concoct an arbitrary assemblage of "alternatives" selected to make the agency's preferred project a foregone conclusion. The "rule of reason" requires that the action alternatives selected for substantive discussion in an EIR must satisfy specific, objective criteria that would allow the decision makers a reasoned choice. For example, each alternative must be capable of "feasibly attain[ing] most of the basic objectives of the Project." (Guidelines, § 15126.6(a), (f).) The Guidelines provide that,

> The range of potential alternatives to the proposed project shall include those that could feasibly accomplish most of the basic objectives of the project and could avoid or substantially lessen one or more of the significant effects. The EIR should briefly describe the rationale for selecting the alternatives to be discussed. The EIR should also identify any alternatives that were considered by the lead agency but were rejected as infeasible during the scoping process and briefly explain the reasons underlying the lead agency's determination.

(Guidelines, § 15126.6(c) [emphasis added.) Hence, alternatives rejected as infeasible are not considered to be among the reasonable range of alternatives required to be considered. Nor can it be said that the no project alternative can be among the reasonable range of alternatives considered, as it is required to be evaluated regardless of whether it feasibly meets most of the project objectives, which it normally won't. Accordingly, an EIR that limits its substantive discussion to alternatives that the agency has already has determined are not feasible or will not attain the basic objectives of the project, fails to present a "reasonable range" of alternatives that fosters meaningful public participation or informed decisionmaking. (*Id.*)

Here, the DEIR has failed to satisfy CEQA's legal requirement to analyze a reasonable range of alternatives that would reduce or avoid the Project's significant impacts. Rather than evaluate the environmental benefits of any alternatives at all, the DEIR instead rejects out of hand a proper evaluation of any alternative mentioned in the EIR, discussing the environmental impacts of only the no project alternative and the proposed project alternative.

In addition, the DEIR eliminates from discussion alternatives that would not yield 28,500 ac-ft of water per year, but nothing in the project objectives indicates whether or why 28,500 ac-ft per year is a necessary project component. (DEIR 5-3.) Alternatives should only be eliminated if infeasible or do not meet most project objectives.

The DEIR fails to meaningfully evaluate the no project alternative.

The DEIR's discussion of the no project alternative is internally contradictory. On one hand, the DEIR states that, under the no project alternative, "[t]he five existing wells would be used as needed under GCID's discretion," such that "[a]s water shortages occur, GCID anticipates that groundwater pumping would increase both within the District's service area and in adjacent areas to meet future water demands." (DEIR 5-1.) On the other, the DEIR states that "[u]nder the No Project Alternative, GCID would not use its existing wells as part of a coordinated pumping program . . . to supplement water supplies to offset critical water year reductions." (DEIR 5-2.) In conjunction, this description renders the no project evaluation impossible to discern.

More troubling, the DEIR states that, under the no project alternative, the same project would still be built: "Under the No Project Alternative it is assumed that GCID would construct new wells on an as-needed basis for specific District use and that the existing wells included as part of the proposed project would be fully used as needed during years of shortages, once appropriate environmental analysis has been conducted." (DEIR 5-1.) Again, the DEIR's assessment that, under the no project alternative, the district's existing and proposed wells both would, and would not, be used, fails to support CEQA's fundamental purpose of informed environmental decision-making. The DEIR must evaluate the environmental consequences "as what would be reasonably expected to occur in the foreseeable future if the project were not approved." (Guidelines, § 15126.6(e)(2).) While the Guidelines do provide that, "If disapproval of the project under consideration would result in predictable actions by others, such as the proposal of some other project, this "no project" consequence should be discussed," here, the DEIR does not suggest that substantially the same project would be proposed "by others," as the Guidelines allow for, but rather, the DEIR simply suggests that GCID itself would go forward with the same project. This does not comply with CEQA.

In fact, through the no project alternative, the district could defend existing water rights in a way that would satisfy all of the project objectives. Recently past and current water management and allocation decisions by state and federal water project operators and managers have reverberated through the past four year's dire supply conditions.[57] These decisions are not just artifacts of current natural conditions. Not only could the CVP and SWP been managed better in the recent past, but the sellers, like GCID, who are also the holders of very senior water claims, could have fought for themselves, their regions, and the environment in which they live, do business, and recreate. How could they do this, one might ask, and how would it apply to the 10-Wells Project?

This could meet three of the Project's objectives. If the objective is to increase reliability and flexibility for GCID and not, as we wonder in Section I above, the system that facilitates the expansion of the water market, protecting the senior claims to water would meet this objective. It would also provide more flexibility to, "Periodically reduce Sacramento River diversions to benefit migrating fish," and "Protect and maintain agricultural production in times of water shortage to minimize economic disruption." By virtue of its senior water claims, in 2015 alone GCID has proposed to sell 55,283 af to SLDMWA south of the Delta and 15,269 af to TCCA north of the Delta.

While it wouldn't "Offset reductions in GCID Settlement Contract allotments during the irrigation season in drought years," the DEIR acknowledges that this has been extremely rare.

In addition, the DEIR's discussion of biological impacts under the no project alternative contains no explanation of how impacts would be reduced at all, simply stating, in its entirety: "Under the No Project Alternative, GCID would continue to implement its current water management program. Resulting effects on biological resources would be similar to what is presently occurring within GCID's service area." (DEIR 5-2.) This fails to provide any "compar[ison of] the environmental effects of the property remaining in its existing state against environmental effects which would occur if the project is approved," as CEQA requires. (Guidelines, § 15126.6(e)(3)(B).)

<u>The EIR should evaluate an alternative that reduces or eliminates water transfers.</u>

As discussed above, GCID admits it desires to forego groundwater substitution water transfers as part of the LTWT Program, instead selling water through crop idling under the LTWT, and pumping a roughly equivalent amount of groundwater through this project as it originally proposed to use for groundwater substitution under the LTWT. Further, this DEIR proposes that groundwater pumping for this project will only occur during dry and critical years to help offset diminished supplies during those times. And, the LTWT similarly asserts that transfers will only occur during dry and critical years, to help offset diminished supplies during those times; where GCID plans to act as a willing seller of water claims, via crop idling, under the LTWT.

Considering these inextricably interconnected programs in tandem, then, a reasonable alternative to the proposed project would be to not participate in cropland idling and water transfers during

---

[57] California Sportfishing Protection Alliance, February 2014. Presentation to the State Water Resources Control Board. "In water year 2011, the Department of Interior used only 348.8 TAF of the 800 TAF of CVPI § 3406(b)(2) water. 'Interior decided to not bank the unused (b)(2) water from water year 2011.' In water year 2013, DWR exported more than 826,000 acre-feet of water beyond what it had informed its contractors it could deliver."

dry and critical years. Indeed, the DEIR itself provides strong reasoning for why this should be considered to be a potentially feasible alternative that would reduce or avoid significant environmental impacts. The DEIR, for example, rejects a potential alternative to *increase* crop idling as infeasible, stating that,

> Idling would counter the goals and objectives of the proposed project. Cropland idling would neither increase system reliability nor protect agriculture, and it has the potential to result in significant adverse impacts on land use, water quality, air quality, and wildlife.

(DEIR 5-4.) Because cropland idling is assuredly contrary to the proposed project's goals and objectives, and results in greater environmental impacts, an alternative to not voluntarily participate in the LTWT cropland idling program is, logically, wholly consistent with the proposed project's goals and objectives, and would lessen significant environmental impacts.

Accepting Shortages

When GCID experienced water cutbacks in the past, the entire State of California was also impacted by the multiple year dry conditions. This couldn't be more true in the current drought of 2012-2015. In the past, GCID and other districts in the Sacramento Valley lived within the means of less than 100% supply when times were hard. After all, fallowed fields can be replanted and shared sacrifice by hydrologic region benefits the whole.

VII. Growth Inducing Impacts

This Project has the potential to cause numerous growth-inducing impacts. Section 21100(b)(5) of CEQA requires that an EIR discuss the growth-inducing impacts of a proposed project. A project could have a growth inducing impact if it could:

- Foster economic or population growth, or construction of additional housing;
- Remove obstacles to population growth, for example, developing service areas in previously unserved areas, extending transportation routes into previously undeveloped areas, and establishing major new employment opportunities;
- Encourage and facilitate other activities that could significantly affect the environment, either individually or cumulatively.

The CEQA Guidelines, for example, provide an illustration of how a major expansion of a wastewater treatment plant that might remove wastewater treatment capacity as a constraint on growth in its service area. (CEQA Guidelines, § 15126.2(d).) The DEIR argues, contrary to the CEQA Guidelines, that "Except where supply limitations have been specifically identified as an impediment to development approvals, water supply reliability alone is not the determinative factor inducing growth in any region of California." (DEIR 4-1.) Nothing, however, in the Guidelines or statute suggest that a growth inducing impact is limited to "the determinative factor inducing growth," as if such a factor could ever even be objectively isolated. On the contrary, the removal of any growth limiting factor should be seen as inducing growth.

The DEIR concludes its analysis of growth inducing impacts by stating, "it is not expected that new agricultural opportunities would be of a significant magnitude to drive economic growth resulting in the demand for new housing above that anticipated by Glenn County's or Colusa County's general plans. Therefore, growth inducement is not expected as a result implementing the proposed project." (DEIR 4-1.) Not only does the DEIR not explain what "new agricultural opportunities" would occur, or what would actually constitute a "significant magnitude," but the DEIR also again relies on a false standard of significance by claiming that any such growth would not be meaningful if it was less than that contemplated by the Counties' general plans. (See, *Federation of Hillside & Canyon Ass'ns v. City of Los Angeles* (2000) 83 Cal.App.4th 1252, 1265 (growth inducement must be discussed even where consistent with general plan.) CEQA nonetheless requires this EIR to incorporate the discussion from any general plan and/or general plan EIR that describes the growth this project would induce. (*Friends of the Eel River v. Sonoma County Water Agency* (2003) 108 Cal.App4th 859, 877; *Sierra Club v. West Side Irrig. Dist.* (2005) 128 Cal.App4th 690. It is unlikely these wells or their water supply capacity were evaluated by the respective general plan EIRs. Moreover, and perhaps most importantly, the DEIR only seems to contemplate here the arbitrary pumping levels proposed in the project description, not the actual capacity of these pumps on an annual basis. It is precisely this development of additional capacity, not analyzed by this DEIR, that serves to induce growth.

The Bureau, DWR, the SWRCB, and the Settlement Contractors have all participated in the creation and implementation of the SVWMA that extracts water from areas of origin north of the Delta for export. This opening up of supply on a finite water supply, has only fueled additional demand, which again fuels pursuit of more supply. This is the essence of the dog chasing its tail. As demonstrated above and below, installing wells has been a pivotal piece of the SVWMA and the SVIRWM. This is the essence of growth inducement: creating more capacity. The 10-Wells Project is producing the amount of water needed by a city of over 100,000 people.

Added to this is what we discussed previously: Table 3-4 illustrates that the pumping capacities of the existing wells are far greater than the projected 2,500 gpm rate planned in the Project. (DEIR p. 3-15.) Additionally, the DEIR uses loose language to define the capacities of the new wells: "Each well would have a target pumping capacity of 2,500 gallons per minute and would require a 100- to 250-horsepower pump motor." (p. 2-3.) Having existing infrastructure with greater capacity than proposed in the Project, installing new infrastructure with higher capacity than the proposed Project, and retaining the ability to use that infrastructure for longer periods of time, from the proposed 8.5 months to 12 months, provides GCID with pre-approved and pre-installed infrastructure for future demand.

VIII. Cumulative Impacts

CEQA requires evaluation of a project's incremental effects "viewed in connection with the effects of past projects, the effects of other current projects, and the effects of probable future projects." (CEQA Guidelines § 15065(a)(3).) "[A] cumulative impact consists of an impact which is created as a result of the combination of the project evaluated in the EIR together with other projects causing related impacts." (CEQA Guidelines § 15065(a)(3).)

An EIR must also discuss significant cumulative impacts. CEQA Guidelines §15130(a). Cumulative impacts are defined as two or more individual effects which, when considered together, are considerable or which compound or increase other environmental impacts. CEQA Guidelines § 15355(a). "[I]ndividual effects may be changes resulting from a single project or a number of separate projects. CEQA Guidelines § 15355(a). A legally adequate cumulative impacts analysis views a particular project over time and in conjunction with other related past, present, and reasonably foreseeable future projects whose impacts might compound or interrelate with those of the project at hand. Cumulative impacts can result from individually minor but collectively significant projects taking place over a period of time. CEQA Guidelines § 15355(b). The cumulative impacts concept recognizes that "[t]he full environmental impact of a proposed . . . action cannot be gauged in a vacuum." *Whitman v. Board of Supervisors* (1979) 88 Cal. App. 3d 397, 408 (internal quotation omitted).

Following these standards, the DEIR must evaluate the cumulative impacts to water resources caused by the project in conjunction with the closely-related projects, below.

The Sacramento Valley Water Management Agreement

The DEIR omits discussion of the SVWMA. The close connection of the 10-Wells Project to the SVWMA is laid bare through documents associated with the [Sacramento Valley] Integrated Regional Water Management Program ("SVIRWMP"), which is discussed briefly. (DEIR p. 3-76.) The DEIR's Section 3.8.2.3 highlights the following districts that benefitted from funds garnered through the SVIRWMP: Browns Valley Irrigation District, Anderson-Cottonwood Irrigation District, Feather Water District, GCID, Natomas Central Mutual Water Company, Sutter Mutual Water Company, Meridian Farms Mutual Water Company, Pelger Mutual Water Company, Reclamation District 108, River Garden Farms Company, and Butte Water District. Moreover, the DEIR discloses that public money through Proposition 50 has been used for 11 implementation projects in the Sacramento Valley. However, the details of the projects are not disclosed. Instead, the DEIR asserts that, "Although several of the projects funded by this grant are generally similar in nature, each project has independent utility, and is implemented by each grantee as needed to supplement their current surface water supplies in various water-year types." Nevertheless, the SVWMA and the Sacramento Valley Regional Water Management Plan's documents unveil a very different picture.

In 2003, the Bureau published an NOI/NOP for a "Short-term Sacramento Valley Water Management Program EIS/EIR." (68 Federal Register 46218 (Aug 5, 2003).) As summarized on the Bureau's current website:

> The Short-term phase of the SVWM Program resolves water quality and water rights issues arising from the need to meet the flow-related water quality objectives of the 1995 Bay-Delta Water Quality Control Plan and the State Water Resources Control Board's Phase 8 Water Rights Hearing process, and would promote better water management in the Sacramento Valley and develop additional water supplies through a cooperative water management partnership. Program participants include Reclamation, DWR, Northern California Water Association, San Luis & Delta-Mendota Water Authority, some Sacramento Valley water users, and Central Valley Project and State Water Project contractors. SVWM Program actions would be locally-proposed projects and actions that include the development of groundwater to substitute for surface water supplies, conjunctive use of groundwater and surface water, refurbish existing groundwater

> extraction wells, install groundwater monitoring stations, install new groundwater extraction wells, reservoir re-operation, system improvements such as canal lining, tailwater recovery, and improved operations, or surface and groundwater planning studies. These short-term projects and actions would be implemented for a period of 10 years in areas of Shasta, Butte, Sutter, Glenn, Tehama, Colusa, Sacramento, Placer, and Yolo counties.[58]

The resounding parallels between the SVWMA NOI/NOP and the presently proposed project are not merely coincidence: they are a piece of the same program, and are closely-related activities that will result in similar effects upon the same environmental resources.

Page 2 of the SVIRWMP's *Proposal for Implementation Grant, Step 2 Attachment 5, Work Plan*[59] presents the centerpiece project, the Conjunctive Water Management Project. "A successful Conjunctive Water Management Project within the Sacramento Valley requires three critical activities that must proceed in unison. These include (1) groundwater production, (2) groundwater recharge, and (3) monitoring and assessment." What follows are the participating districts with the number of productions wells they sought:

- Anderson Cottonwood Irrigation District Groundwater Production Element 4 wells
- Browns Valley Irrigation District Water Groundwater Production Element 1 well
- Feather Water District Water Management Groundwater Production Element 1 well
- Glenn-Colusa Irrigation District Groundwater Production Element 8 wells
- Lewis Ranch Groundwater Production Element 1 well
- River Garden Farms Groundwater Production Element 2 wells
- Meridian Farms Groundwater Production Element 1 well
- Pelger Mutual Water Company Groundwater Production Element 1 well
- RD 108 Groundwater Production Element 5 wells

How are these districts' projects, including the Lead Agency GCID's, viewed as "generally similar in nature," but with "independent utility" when they are pursuing the specific goals of the SVWMA and the SVIRWMP? And let us be clear, those goals are *not* just for "supplemental supply" within their districts as suggested. The SVIRWMP elucidates that, "These elements were strategically formulated under the adopted Sacramento Valley Water Management Agreement (SVWMA, Phase 8, included in Attachment 4), which was executed in December 2002 by more than 40 Sacramento Valley water users, the Department of Water Resources, the Department of Fish and Game, the Bureau of Reclamation, the Fish and Wildlife Service, and various water users throughout the state. **Fifty percent of the Conjunctive Water Management Project capacity will be dedicated to meeting water quality standards in the Bay-Delta while the remaining 50 percent will be used to improve local and regional water supply reliability or to help meet other water needs in the state**." [emphasis added] [60]

The DEIR also fails to disclose how many of the SVWMA districts and/or the SVIRWMP Participating Entities have installed wells that have been used in water transfers and how many are

---

[58] http://www.usbr.gov/mp/nepa/nepa_projdetails.cfm?Project_ID=788
[59] Northern California Joint Exercises of Powers, June 2006.
[60] Id. p.2.

committed to participate in the 10-Year Water Transfer Program (aka Long-term Water Transfers)[61] or continuing transfers outside it.[62] In addition, where is the disclosure that the production wells above, added to others installed by SVWMA districts and SVIRWMP Participating Entities, have been used to facilitate the goals from the SVIRWMP quote immediately above?

The 10-Wells Project that is presented as a seemingly innocuous attempt to "augment District surface water supplies during dry and critically dry water years" (DEIR p. 2-1) is part of a much larger agreement and multiple planning efforts. GCID's past and current actions make it abundantly clear that the stated 10-Wells Project is just another attempt to obfuscate its involvement in implementing the SVWMA through massive public funds from SVIRWM grants and federal appropriations (see Section I).

The 10-Year Water Transfer Program (aka Long-Term Water Transfers)

The DEIR mentions the 10-Year Water Transfer Program ("10-Year Program") in section 3.8.2.1. It does *not* reveal that the 10-Year Program contains significant numeric figures that should be incorporated into the cumulative impact analysis, such as:

1. The EIS/EIR analyzed transferring up to 600,000 af per year from the selling districts. No matter what figure the Bureau transfers year-to-year, this program has the ability to transfer up to 600,000 af each year.
2. GCID may have provided internal direction to itself, subject to change, that counter numbers in the 10-Year Program's EIS/EIR (DEIR p. 3-76), but the 10-Year Program's Final EIS/EIR retained the original number and will allow the sale of up to 91,000 af per year from GCID in any given year. (p. ES-6 and p. 2-14.) A vote by the GCID Board of Directors is all it would take to reverse the internal commitment, a non-binding statement, and begin selling water at the 91,000 af per year threshold.

Annual Transfers

The DEIR fails to delineate the numerous transfers that have occurred in the recent past and those that are proposed outside the 10-Year Water Transfer Program. What should the public conclude from this glaring omission? GCID's failure to disclose their own repeated transfers and those from the region and Sacramento Valley is arbitrary and capricious.

The DEIR should disclose what level of monitoring has occurred during the past annual transfers. If monitoring transpired, was there comprehensive coordination of methods, data collection, and data analysis for both individual and all Sacramento Valley water transfers and are the products available to the public? This might shed light on the results of cumulative actions by numerous water sellers in the Sacramento Valley, including the lead agency, GCID. This material is not presented here nor is it in the public realm, to our knowledge.

---

[61] U.S. Bureau of Reclamation and San Luis Delta Mendota Water Authority, 2015. Final EIS/EIR 10-Year Water Transfer Program (aka Long Term Water Transfers) p. ES-12. http://www.usbr.gov/mp/nepa/nepa_projdetails.cfm?Project_ID=18361

[62] Id. p. 4-5.

As discussed above, the cumulative installation of well infrastructure, the repeated annual water transfers, participation in the 10-Year Water Transfer Program, and the increasing escalation of groundwater use by Sacramento Valley water districts involved in water sales do not exist in a vacuum. Instead, they are actually integrated, important parts of a broader program to develop regional surface and ground water resources into a conjunctive use system. GCID has planned for multiple decades to exploit groundwater, to "… integrate the Lower Tuscan Formation into the Central Valley water supply system…" and bank "…SWP and CVP contractual entitlements in the Lower Tuscan Formation…"[63]

The Project is also only one of several proposed and existing projects that affect the regional aquifers and surface waters. The existence of these numerous related projects makes an adequate analysis of cumulative impacts especially important.

IX. Additional Comments and Questions

Modeling

SacFEM has serious flaws yet is relied on exclusively for projections and impact analysis. Material produced for AquAlliance's comments on the 10-Year Water Transfer Program's EIS/EIR are equally relevant for the 10-Wells Project and is presented here. "One example of incorrect modeling assertions in the EIR/EIS is the characterization[1] of SacFEM2013 and its parent code MicroFEM as 'three-dimensional' and 'high-resolution'. In fact, the SacFEM2013 model provides only a linked set of two-dimensional analyses[2], and would more charitably be described as "two-and-a-half dimensional" instead of possessing a fully-3D modeling capability. This limitation is not an unimportant detail, as a general-purpose 3D groundwater model could be used to predict many important physical responses, e.g., the location of the phreatic surface within an unconfined aquifer. For the SacFEM2013 model, this prediction is part of the data instead of part of the computed solution, and hence SacFEM2013 apparently has no predictive capability for this all-important aquifer response."[64]

The relevant content from the *SACFEM2013: Sacramento Valley Finite Element Groundwater Flow Model User's Manual*[65] on this topic illustrates that the model is indeed being touted as having the capacity "[t]o generate a 3D surface defining the elevation of the base of fresh groundwater." (p. 3-5.) In addition, the DEIR states that, "SACFEM2013 was developed using the MicroFEM modeling code (MicroFEM, 2015), which is capable of simulating three-dimensional, transient, single-density groundwater flow in layered systems." (p. A-1.) Sadly, it is clear that the DEIR is relying on the very limited predictive capability of SacFEM for many of the most crucial conclusions for disclosing the significance of impacts from the 10-Wells Project.

This thin veneer is no substitute for actual, on the ground data from GCID's groundwater substitution transfers using the five existing wells. For example, "GCID pumped groundwater from July to September 2013 to make water available for transfer to the San Luis & Delta

---

[63] U.S. Bureau of Reclamation Assistance Agreement, 2006, p. 5.
[64] Mish, Kyran D., 2014. Comments for AquAlliance on Long-Term Water Transfers Draft EIR/EIS, p. 3.
[65] "A complete description of the construction and calibration of SACFEM2013 is provided in SACFEM2013: *Sacramento Valley Finite Element Groundwater Flow Model User's Manual* (CH2M HILL and MBK Engineers, Inc., 2015)." (DEIR p. A-1.)

Mendota Water Authority (SLDMWA). Groundwater was pumped in lieu of diverting surface water under its pre-1914 water right and its Settlement Contract No. 14-06-200-855A-R-1 with the United States Bureau of Reclamation (USBR)."[66] The results of the groundwater substitution transfer are poorly discussed in the report, regularly using vague numeric approximations such as "recovered to within a few feet" and "generally recovered." However the exhibits highlight the serious effects from pumping 5,000 af in 2013. When Figure D-7 is contrasted with Figure D-8, it is clear that impacts were occurring as far as 3-4 miles away across the Sacramento River in Butte County were still drawing water to the cone of depression six months later. The hydrograph figures illustrate some conditions that are not in the text and contradict some of the report, such as:

- Figure C- 2. Production well GCID 2 experienced a precipitous collapse of 240 feet at the end of the transfer period, but appears to have almost recovered in March 2014.
- Figure C-10 Monitoring well 21N02W04G002M dropped over 50 feet at the end of the transfer period and in March 2014 was still approximately 13 feet below the March 2013 starting measurement.
- Figure C-13. Monitoring well 22N02W01N001M dropped over 90 feet at the end of the transfer period and in March 2014 was still approximately 10 feet below the March 2013 starting measurement.
- Figure C-14. Monitoring well 22N02W15C002M dropped over 50 feet at the end of the transfer period and in March 2014 was still approximately15 feet below the March 2013 starting measurement.

Actual data with additional, unbiased professional analysis would have better informed the public than what is provided with the DIEIR's reliance on modeling. "MicroFEM is a poor choice for such large-scale modeling. It is an old code that apparently utilizes only the simplest (and least accurate) techniques for finite-element modeling of aquifer mechanics, and MicroFEM (and hence SacFEM2013) embed serious limitations into the model that compromise the accuracy of the computed results." [67]

<u>Maps must be provided to illustrate all wells in an expanded radius of the Project's wells</u>

There is a profound gap in understanding regarding the potential areas of impact from GCID's existing and proposed 10 wells. (See CEQA Guidelines § 15124(a).) There also are no maps in the DEIR that indicate the number of domestic and production wells even in the area of impact assumed by SacFEM. We argue that maps with this information must be provided in a recirculated Draft EIR and that the radius of potential impact must be expanded. Drawing from the scientific analysis completed by professors Todd Greene and Karin Hoover,[68] we find that, "The importance of this new information on the hydrostratigraphy around the GCID wells is that the generally symmetrical pattern of drawdown that resulted from the SACFEM2013 modeling effort may not reflect the predominance of coarser-grained, water-rich zones on the east side of the wells. The results of the SACFEM2013 model show that the total area of the pumping impacts and the outer distance to the no-impact boundary is greater to the west in Glenn County, than east in Butte

County. In fact, no wells in Butte or Tehama counties are proposed for monitoring in mitigation measures WR-1 and WR-2, and obviously are not included in the Glenn County BMO monitoring program. This lack of monitoring in Butte County, when that area may be a major source of the water pumped by GCID's wells, may allow for impacts that are inadequately recognized and thus improperly mitigated."[69]

Seismicity

The DEIR fails to discuss in any way the possible seismic risks from the 10-Wells Project. Not only does the construction of five new wells suggest a potential for seismic impacts, but there is also potential for seismic shaking because of subsidence from Project operations that in turn may cause additional stress to existing structures. Lack of disclosure in the DEIR necessarily leads to an absence of analysis of the potential effects from the Projects' construction and excessive groundwater pumping on the numerous known earthquake faults running through and about Northern California. As recently detailed in a paper published by a well-respected British scientific journal, "[u]plift and seismicity driven by groundwater depletion in central California," excessive pumping of groundwater from the Central Valley might be affecting the frequency of earthquakes along the San Andreas Fault, and raising the elevation of local mountain belts. The research posits that removal of groundwater lessens the weight and pressure on the Earth's upper crust, which allows the crust to move upward, releasing pressure on faults, and rendering them closure to failure. The 10-Wells Project and the cumulative water transfer projects impact the volume of groundwater extracted as farmers are able to pump and then forego surface water in exchange for money. The drought has exacerbated the demands from the water transfer market that is the major goal of the SVWMA, which is being implemented through the SVIRWMP and the 10-Year Water Transfer Program and has also depleted the natural regeneration of groundwater supply due to the scarcity of precipitation.

Detailed analyses of this seismicity and focal mechanisms indicate that active geologic structures include blind thrust and reverse faults and associated folds (e.g., Dunnigan Hills) within the Coast Ranges-Sierran Block ("CRSB") boundary zone on the western margin of the Sacramento Valley, the Willows and Corning faults in the valley interior, and reactivated portions of the Foothill fault system. Other possibly seismogenic faults include the Chico monocline fault in the Sierran foothills and the Paskenta, Elder Creek and Cold Fork faults on the northwestern margin of the Sacramento Valley.[70]

This deficiency must be corrected and included in a recirculated Draft EIR.

X. Conclusion

GCID's examination of the proposed Project fails to comply with the most essential review and disclosure requirements of CEQA, thereby depriving decision makers and the public of the ability to consider the relevant environmental issues in any meaningful way (details above). Rather,

[69] Custis, Kit, 2015. Comments and Recommendations on Draft Environmental Impact Report for Glenn Colusa Irrigation District's Groundwater Supplemental Supply Project, June 2015 for AquAlliance, p. 5.

[70] http://archives.datapages.com/data/pacific/data/088/088001/5_ps0880005.htm (Custis, Exhibit A 10-Year Water Transfer Program)

GCID has neglected to disclose significant information regarding the 10-Wells Project and cumulative impacts in violation of CEQA in what appears to be an ongoing effort to avoid disclosure of GCID's commitments to the SVWMA and implementation through the SVIRWM and the 10-Year Water Transfer Program. AquAlliance has demonstrated in 2010,[71] 2012,[72] 2013,[73] 2014,[74] and in 2015 that key questions have not been addressed, significant data gaps exist and the possible and very probable impacts are not disclosed, but summarily rejected without data and a scientific basis for the conclusions.

For the majority of the twentieth century, northern California supported family farming, healthy salmon runs, rich hydrologic watersheds, and a diverse environmental heritage. GCID members share in this heritage. We hope that GCID will not only recall the heritage of which it is a part, but actively participate in efforts to defend and restore the health of this region and its water legacy for future generations. That legacy continues to be in the crosshairs of water policies that have repeatedly failed in the San Fernando, Owens, and San Joaquin valleys of California. For all of the above-mentioned reasons, the 10-Wells Project should either be withdrawn or the DEIR should be withdrawn, revised, and recirculated after the release of the long-missing SVWMA programmatic EIR.

AquAlliance respectfully requests notification of any meetings that address this proposed GCID Project or any other GCID project that requires any consideration of CEQA. Please send AquAlliance any additional documents that pertain to this project, including a possible notice of determination through the U.S. Postal Service and e-mail.

Sincerely,

B. Vlamis

MEMORANDUM

To: Deputy Assistant Field Supervisor, Endangered Species Division,
Fish and Wildlife Office, Sacramento, California

From: Regional Resources Manager, Mid-Pacific Regional Office,
U.S. Bureau of Reclamation, Sacramento, California

Subject: Section 7 Endangered Species Act Consultation with U.S. Fish and Wildlife Service (USFWS) for 2012 "North-to-South" Water Transfers

RECEIVED
FEB 02 2012
SACRAMENTO FISH & WILDLIFE OFFICE

The Bureau of Reclamation is beginning the environmental compliance process for Central Valley Project (CVP) related water transfers in 2012. Based on the limited nature of north-to-south water transfers that may be proposed in 2012, Reclamation requests concurrence from the USFWS that 2012 water transfers may affect, but are not likely to adversely affect Federally listed species in the Sacramento and San Joaquin River Valleys.

As described below, water transfers in 2012 would be different in nature, and much less than, those evaluated in the 2010-2011 Water Transfer Program Environmental Assessment (EA) and Biological Assessment (BA) and would therefore have fewer effects, and potentially no effects, on listed species. The most notable difference for 2012 transfers is that no crop idling transfers would occur. If capacity in the Delta becomes available to pump transfer water south, groundwater substitution transfers would be the only water transfers considered by the purchasing agencies south of the Delta.

In 2010, Reclamation completed the EA/Finding of No Significant Impact and Endangered Species Act consultation for the 2010-2011 Water Transfer Program. USFWS issued the Biological Opinion (BO) for 2010-2011 water transfers on March 2, 2010. The EA and BO considered effects of groundwater substitution and cropland idling transfers from CVP contractors in the Sacramento Valley to purchasing agencies south of the Delta. Because of wet hydrologic conditions and limited export capacity, CVP contractors did not request any crop idling or groundwater substitution transfers in 2010 or 2011, and no water transfers were made under the 2010-2011 Water Transfer Program.

Reclamation is currently working with the San Luis & Delta-Mendota Water Authority on the Long-Term Water Transfers Environmental Impact Statement/Environmental Impact Report (EIS/EIR) that will provide environmental coverage for water transfers for 10 years, from 2013 through 2022. The EIS/EIR is on schedule to be completed, with a signed Record of Decision, by April 2013. Because of the proposed completion date in 2013, Reclamation must complete environmental documentation for the 2012 water transfer season.

Potential Water Transfers in 2012

For 2012 water transfers, Reclamation anticipates a maximum of approximately 76,000 acre-feet of water could be transferred. The 76,000 acre-feet of transfer water would be made available through groundwater substitution. The same mitigation measures that applied to groundwater substitution transfers would be implemented in 2012 as were provided in the 2010-2011 EA and BO.

Potential Effects to Species of 2012 Water Transfers

As stated above, Reclamation and water agencies did not make any water transfers in 2010 or 2011, and thus the water transfer program did not have any effect on the species in these two years. Additionally, giant garter snake populations would likely have benefitted from the amount of water available during the past two years. The proposed 2012 water transfers, if implemented to their full extent, would not result in any rice lands being idled, as none of the water would be generated through crop idling, and the environmental commitments for groundwater substitution in the 2010-2011 Water Transfer BO would be met. This would eliminate effects on giant garter snake habitat and the potential effects on individuals cited in the BO of stress, reduced growth, reduced reproductive success or mortality. Given that the program was not implemented in 2010 and 2011, there would be no cumulative effects on any listed species from the program carrying forward into 2012. Therefore, it is highly unlikely that the implementation of the proposed transfer program in 2012 would have any effect on giant garter snake populations.

The EA and BA also evaluated effects of water transfers to the listed San Joaquin kit fox. The BO concurred with Reclamation's conclusion in its BA that the 2010-2011 Water Transfer Program was likely to affect, but unlikely to adversely affect Federally-listed threatened San Joaquin kit fox, as the transfers would not result in the conversion of natural lands to annual crops or annual crops to permanent (woody) crops. Given the smaller amount of the proposed 2012 transfers, these conclusions would also be valid for the proposed program, and no adverse effects on San Joaquin kit fox would be anticipated.

For 2010-2011 water transfers, Reclamation included an environmental commitment to implement transfers within the operational parameters specified in the 2008 Biological Opinion for the Coordinated Operations of the Central Valley Project and State Water Project. Therefore, the effects of the 2010-2011 Water Transfer Program on federally-listed threatened Delta Smelt and its critical habitat were covered in the 2008 Biological Opinion. USFWS agreed to this conclusion in the 2010-2011 Water Transfer Program BO. Reclamation would meet this environmental commitment when implementing 2012 water transfers. Therefore, the conclusions in the EA and BO for 2010-2011 water transfers would also be valid for 2012 transfers and no adverse effects on Delta Smelt would be anticipated.

Groundwater Overdraft in California's Central Valley:
Updated CALVIN Modeling Using Recent CVHM and C2VSIM Representations

Acknowledgements

Many thanks to my advisor, Professor Jay Lund, for his guidance in this project and for his timely edits in helping me prepare this thesis. Thanks also to my committee members, Professor Tim Ginn and Professor Thomas Harter, for all of the thoughtful comments and edits that helped me finish this thesis.

Thanks to Josué Medellín-Azuara and Christina Buck for all of their technical and moral support. Josué and Christina dedicated much time to this project, always making themselves available for questions and providing assistance when possible.

Thanks to Prudentia Zikalala for all of her work and efforts in this project. The collaboration of our efforts and work was necessary to see this project through. Thanks also to Kent Ke, Eleanor Bartolomeo, Michelle Lent, and all fellow members of the research group for their help and support.

Thanks to Randy Hanson and Claudia Faunt at the United States Geological Survey for their help with CVHM. Thanks also to the California Department of Water Resources and the developers of C2VSIM for their assistance with model.

And finally, thanks to my family and close friends who have provided me with endless amounts of support and encouragement throughout this project.

Updates have been made to the CALVIN hydro-economic optimization model of California’s intertied water supply and delivery system. These updates better reflect water demands, groundwater availability, and local water management opportunities. This update project focused on improving groundwater representation in CALVIN, which included changing CALVIN groundwater parameters based on California Department of Water Resources’ (DWR) California Central Valley Groundwater-Surface Water Simulation Model (C2VSIM) and the United States Geological Survey (USGS) Central Valley Hydrologic Model (CVHM) model inputs and results. Using these models, a CALVIN model with updated groundwater representation now exists.

In updating CALVIN, a detailed comparison between C2VSIM and CVHM was conducted and the results are discussed in this thesis. The updated CALVIN model was used to study the effects of different cases of overdraft on Central Valley groundwater basins. When compared to the updated CALVIN model’s case of overdraft, ending overdraft in the entire Central Valley results in less available groundwater and higher economic scarcities in all regions, driving the model to use more surface water to try to meet demands and also to use more artificial recharge to even out variability in surface water availability.

CHAPTER 1

Introduction

This project included updating CALVIN's representation of Central Valley groundwater and revising some aspects of the CALVIN model framework to achieve more clarity in the terms representing groundwater conditions; this lays a streamlined framework for future CALVIN groundwater updates. With surface water reliability decreasing in California, groundwater continues to play a larger role in water supply. And because there is still much uncertainty in how much groundwater is actually available in California, this hydro-economic approach to modeling groundwater can be useful for water planners and managers. Using the updated model, several overdraft scenarios were examined to see how overdraft economically and physically affects Central Valley groundwater conditions and water users.

Groundwater in California

Groundwater provides about 30 percent of California's water demands in a normal year. In drought years and in the Central Valley, dependence on groundwater is even higher. An estimated 15 million acre-feet of water is pumped per year, which is more than what is being recharged, causing overdraft in some areas (Faunt et al. 2009; DWR 2003). Overdraft has negative effects on water quality, increases pumping costs, causes land subsidence, and eventually decreases groundwater availability. DWR estimates the overdraft in the state's groundwater basins to be one to two million acre-feet annually, mostly in the Tulare Basin. Even with substantial overdraft, there are no statewide regulations on groundwater pumping (DWR 2003). Groundwater availability in the Central Valley is particularly important for droughts, when the absence of surface water brings water users to pump more groundwater. The storage capacity in the Central Valley's aquifers is much larger than the water storage capacity of its surface water reservoirs, making groundwater pragmatic for long-term drought water storage.

CALVIN

CALVIN, the CALifornia Value Integrated Network model is an economic-engineering optimization model of California's water system. It covers 92% of California's population and 90% of the irrigated crop area (Howitt et al. 2012). The model uses a network flow optimization solver developed by the U.S. Army Corps of Engineers to provide results on surface and groundwater operations, and water use allocations based on maximizing statewide net economic benefit, or minimizing statewide water operations and scarcity costs. There are operating costs associated with infrastructure links in the system and scarcity costs are calculated from each area's water delivery demands. The current network consists of 41 urban demand areas, 25 agricultural demand areas, 44 reservoirs, 31 groundwater basins, and 1,767 links. Figure 1 shows the CALVIN coverage and network.

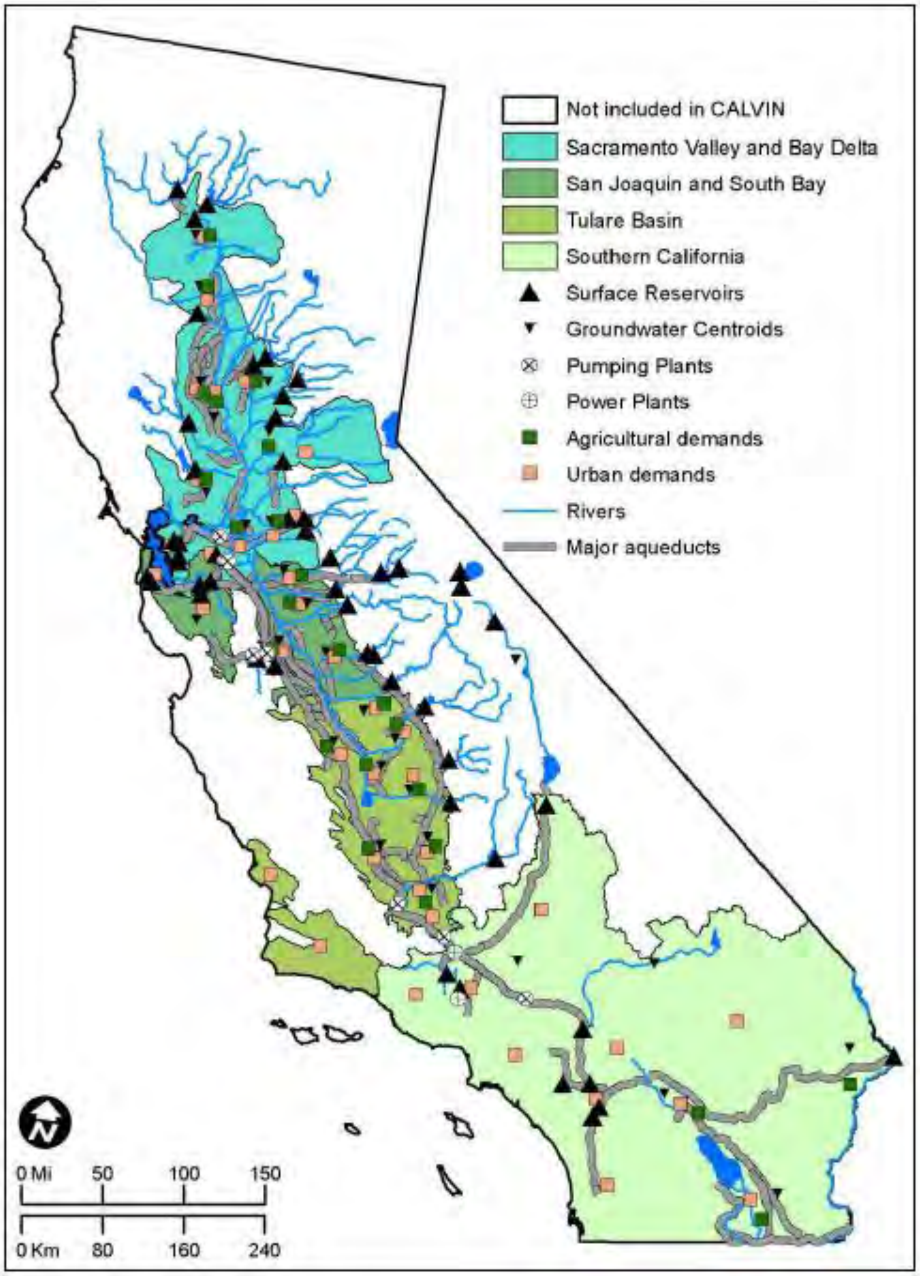

Figure 1.1: CALVIN Coverage Area and Network

Previous CALVIN Studies

CALVIN has been used to study a wide variety of different California water problems including infrastructure, water use, climate change, policy, and now–overdraft. These previous CALVIN studies are described in Table 1.1. This groundwater update project is the first major study of changes to CALVIN's Central Valley groundwater system since the model was developed in 2001.

18	Kaweah R. and Tule R. Area
19	Western Kern County
20	Eastern Kern County
21	Kern R. Area

Figure 1.2: Groundwater Basins Modeled in CALVIN

Since CALVIN is an optimization-based system engineering model, groundwater heads are not represented as in a groundwater model; changes in groundwater volumes are modeled instead (Draper et al. 2003). For each subregion, flows, volumes, and fractions have been extracted, calculated, and/or estimated from physical simulation groundwater models and inputted as parameters into CALVIN to represent the interactions within the subregions and storage volumes of these basins. These parameters are summarized in Table 1.2. More detailed descriptions of these terms and their calculations are found in Chapter 2 and Appendices 1, 2, and 4. Figure 1.3 describes the terms and how groundwater interacts in CALVIN.

Table 1.2: Groundwater Data Required by CALVIN for each GWSB

Item	Data for CALVIN	Data type
1	Agricultural return flow split (GW & SW)	Fraction (1a+1b=1)
2	Internal reuse	Amplitude (≥1)
3	Return flow of total applied water	Amplitude (<1)
4	External flows	Monthly time series
4-1	Inter-basin flows	Monthly time series
4-2	Deep percolation from streams and lakes	Monthly time series
4-3	Deep percolation from precipitation	Monthly time series
4-4	Boundary inflow	Monthly time series
4-5	Subsidence	Monthly time series

9	Storage capacity (maximum & minimum)	Number value
10	Calibration Flows	Monthly time series
11	Urban return flow	Amplitude (<1)

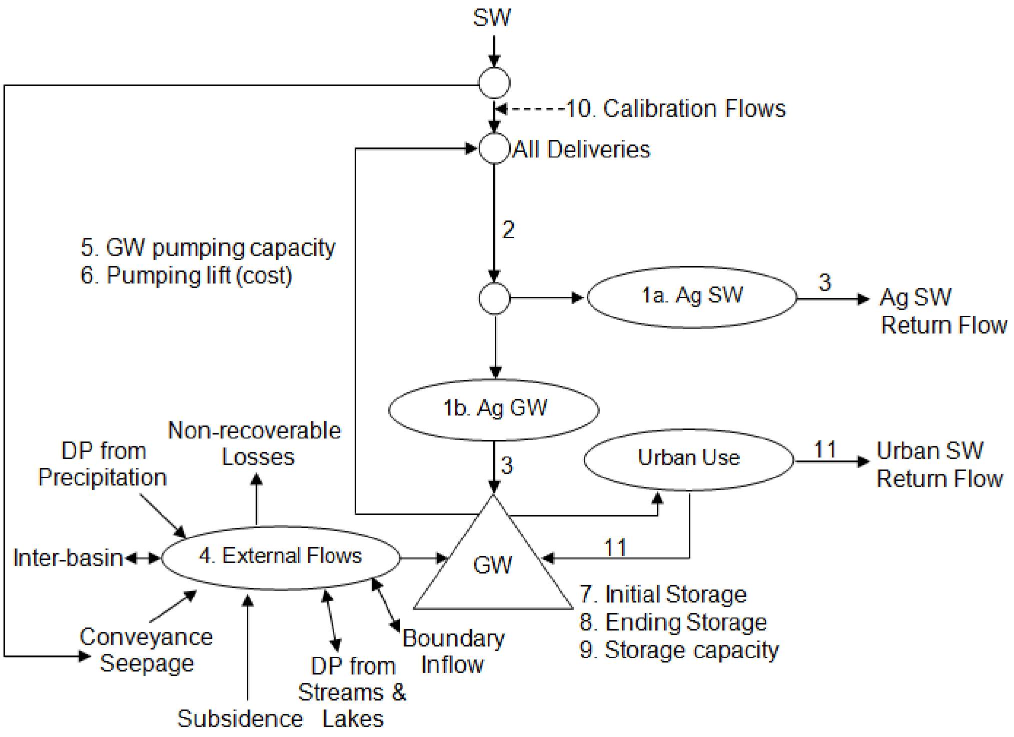

Figure 1.3: Flows and Interactions in CALVIN Groundwater Sub-basins

As seen in Figure 1.3, surface water and pumped groundwater come together at a node which represents all water deliveries to demand areas. These deliveries are then split between agricultural surface water and agricultural groundwater demands (term #1). A re-use amplitude (term #2) can be specified prior to this split. Following the water delivered to the surface water and groundwater demand areas, the return flow fraction (term #3) is the fraction of the water not used by the crops and is returned to groundwater or surface water. The external flows (term #4) include deep percolation from precipitation, inter-basin flows, boundary flows, stream leakage, subsidence, conveyance seepage, and non-recoverable losses (i.e. evapotranspiration and tile drain flows). Water pumped from the groundwater basin has capacity constraints (term #5) and also a pumping lift (term #6) to calculate pumping cost. The groundwater basin itself has initial, ending, minimum, and maximum storage constraints (terms #7-9). Any flows needed to maintain mass balance in the system or allow for feasible results are considered "Calibration flows" (term #10), which are added or removed prior to the delivery node to ensure that the appropriate amount of water can be delivered to the demand areas; calibration flows can be positive or negative. Such calibration flows also help reflect uncertainty in our understanding of California's hydrology. Urban return flow (term #11) is also represented as an amplitude, like term #3.

Previous CALVIN Groundwater Representation

Prior to this update project, CALVIN's groundwater representation was based on pre- and post-processing data and results from the Central Valley Ground Surface Water Model (CVGSM) 1997 No Action Alternative (NAA) run (USBR 1997). CVGSM is a special application of the Integrated Ground Surface Water Model (IGSM) to the Central Valley of California, used in the Central Valley Project Improvement Act (CVPIA) Programmatic Environmental Impact Statement (PEIS) of 1992. A description of CVGSM representation of CALVIN groundwater can be found in Jenkins et al. 2001 and Davis et al. 2001 (Appendix J).

Since CVGSM was used for CALVIN groundwater, new studies have shown that some of the old IGSM algorithms are very different from those used in MODFLOW, whose algorithms are widely tested and established, bringing some question in whether or not this version of IGSM's solutions are a good representation of the hydrologic system it is modeling (LaBolle et al. 2003). Considering that new and improved models like CVHM and C2VSIM (CVGSM's successor) have been developed, it was decided to update CALVIN groundwater based on one of the new, more detailed models. The groundwater terms calculated from the CVGSM model are compared with the new calculated terms from CVHM and C2VSIM in Chapter 3.

New California Groundwater Modeling Efforts

Several groundwater modeling efforts for California's Central Valley exist and are on-going. The Department of Water Resources (DWR) has developed and continues to update a groundwater model of California's Central Valley called the California Central Valley Groundwater-Surface Water Simulation Model (C2VSIM) using the Integrated Water Flow Model (IWFM) (Brush et al. 2008). In addition, the United States Geological Survey (USGS) also developed a groundwater model for the Central Valley using MODFLOW and published its development in Professional Paper 1766 in 2009 (Faunt et al. 2009). This model also continues to be developed. These two models have been studied extensively to draw data and results for improving CALVIN's groundwater representation. C2VSIM, CVHM, and CVGSM (old CALVIN) use the same subregion definitions (CVPM regions) for groundwater basins, allowing for direct comparisons of data and results.

Using MODFLOW and the FMP, CVHM simulates key groundwater and surface water processes in the Central Valley for the 21 water-balance regions for water years 1962 to 2003. The model is based on year 2000 land use. A Geographic Information System (GIS) was used to develop a geospatial database to manage the data. The model is divided horizontally into a square grid of 20,000 square mile cells, and vertically into 10 layers, ranging in thickness from 50-750 feet. A geologic texture model was developed for CVHM to better characterize the Central Valley aquifer system. More information on CVHM is in Chapter 2 and Faunt et al. 2009.

Using the 3-D finite element code IWFM, C2VSIM simulates groundwater flow and groundwater-surface water interactions for the 21 subregions on a monthly basis from water years 1921 to 2003. The model is represented by three layers of 1392 elements. More information on C2VSIM can be found in Brush et al. 2008.

Although there are similarities in the two models' hydrologic inputs, the models operate differently and the outputs and results are significantly different in some areas. Some differences and the effects of those differences on this application to CALVIN are discussed here. A detailed comparison of the theory, approaches, and features of the two models can be found in Dogrul et al. 2011.

Project Description

This CALVIN groundwater update had several steps. First, CALVIN groundwater parameters were identified. Data for these parameters was then estimated based on C2VSIM and CVHM inputs and outputs for use and comparison with the previous CALVIN model (CVGSM) estimates. Following comparisons of these parameter estimates, separate simplified CALVIN model runs were conducted using these parameter values from each groundwater model. These results were compared and the decision was made to primarily use C2VSIM for the final CALVIN groundwater representation mostly due to C2VSIM's longer historical modeling period. Next, calibration of the 72-year CALVIN model based on C2VSIM was done and a new CALVIN model with updated groundwater representation based on C2VSIM emerged. Finally, additional studies were done by adjusting the overdraft scenarios based on CVHM and other simulated scenarios.

The major steps in this groundwater update project are summarized as follows:

1. Estimate, calculate, and/or extract terms from CVHM and C2VSIM to use as parameters (Table 1.2) for CALVIN update
2. Compare CVHM and C2VSIM terms and methods with CALVIN representation to determine which parameters from which model are to be used for the final CALVIN Groundwater update. Options included: CVHM, C2VSIM, or a combination of CVHM and C2VSIM.
3. Run the CALVIN model
4. Calibration of CALVIN model to ensure feasible and reasonable results
5. Additional overdraft studies to test updated model

Overview of Thesis

This thesis work updated CALVIN groundwater representation in the Central Valley and also improved many aspects of the CALVIN model. Chapter 2 describes CALVIN groundwater input terms and the groundwater representation based on CVHM. Chapter 3 discusses and compares the groundwater input terms from C2VSIM, CVHM, and CVGSM. Chapter 4 presents the updated CALVIN model with Central Valley groundwater representation primarily based on C2VSIM and the calibration process that resulted in the final updated model from this research project. This chapter also presents a comparison between the updated CALVIN model with the version of the model prior to the update. Chapter 5 applies the updated model to investigate the economic and physical effects of different cases of overdraft in the Central Valley. Finally, Chapter 6 summarizes the results from this research project, discusses the limitations, and presents some ideas for future work on the CALVIN model.

CHAPTER 2

CALVIN Groundwater Representation Based on CVHM

This chapter discusses the CVHM model and how it was used to calculate the groundwater input terms for CALVIN. This chapter also provides a description of the groundwater terms used for CALVIN and the CVHM calculated term results. Although CVHM was ultimately not used as the primary basis for Central Valley groundwater representation in CALVIN, studying the CVHM calculation of the groundwater terms was very useful for understanding CALVIN groundwater and the CVHM results were used for comparisons during model calibration (discussed in Chapter 4).

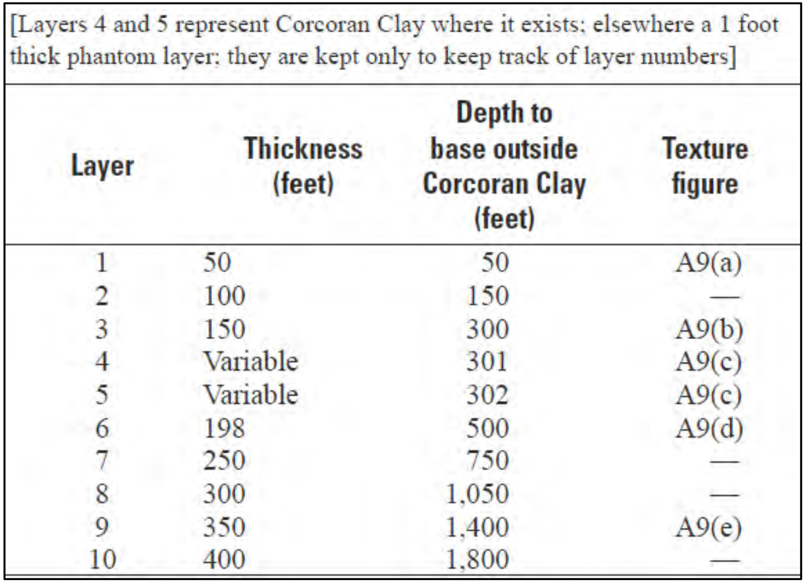
CVHM Description

CVHM was developed by the United States Geological Survey (USGS) to support a study assessing groundwater availability in California's Central Valley. This study, described in Faunt et al. 2009, had 3 major objectives:

1. To develop a better understanding of the freshwater-bearing deposits of the Central Valley; this objective was achieved by developing a new texture model.
2. To use improved water-budget analysis techniques to estimate water-budget components for the groundwater flow system in areas dominated by irrigated agriculture; this objective was achieved through the development of the Farm Process (FMP) to be used in conjunction with MODFLOW-2000 (MF2K).
3. To quantify the Central Valley's groundwater-flow system; this objective was accomplished by developing CVHM, which links the texture and landscape-process models with the groundwater-flow process model.

CVHM builds on many previous studies, but is primarily an update to the USGS Central Valley Regional Aquifer System and Analysis (CV-RASA), with the major update components being incorporating MODFLOW-2000 with the FMP into the model and spatial re-discretization of the model to finer spatial scales. Table 2.1 describes the model layer thicknesses and depths and Figure 2.1 shows a generalized vertical hydrogeologic cross section of the groundwater flow system. Figure 2.2 shows the farm process balance of the groundwater system. A detailed description of the CVHM development can be found in Faunt et al. 2009.

Table 2.1: CVHM layer thicknesses and depths (Table A3 from Faunt et al. 2009)



[Layers 4 and 5 represent Corcoran Clay where it exists; elsewhere a 1 foot thick phantom layer; they are kept only to keep track of layer numbers]

Layer	Thickness (feet)	Depth to base outside Corcoran Clay (feet)	Texture figure
1	50	50	A9(a)
2	100	150	—
3	150	300	A9(b)
4	Variable	301	A9(c)
5	Variable	302	A9(c)
6	198	500	A9(d)
7	250	750	—
8	300	1,050	—
9	350	1,400	A9(e)
10	400	1,800	—

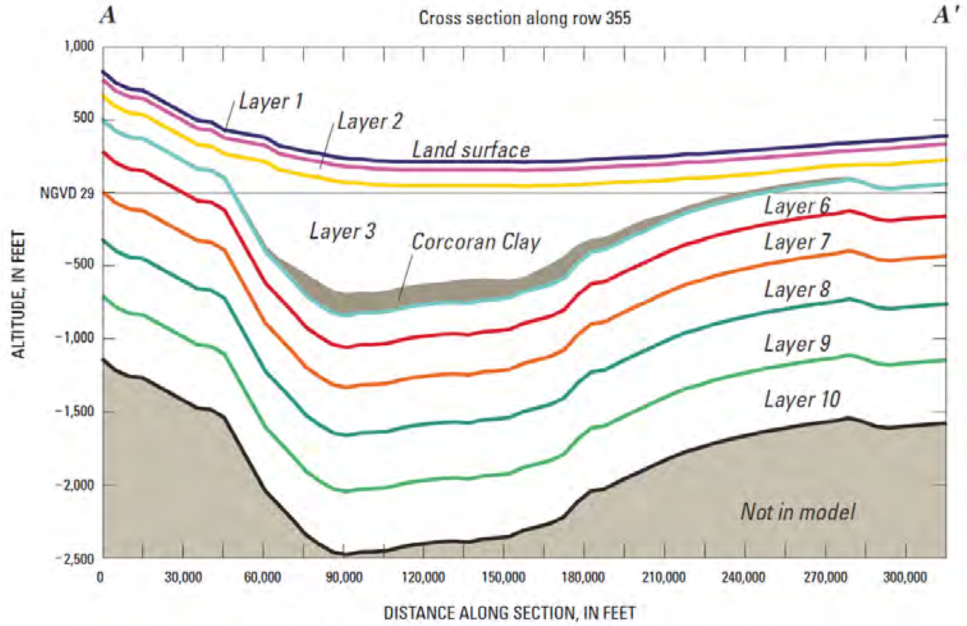


Figure 2.1: Generalized hydrogeologic section (A-A’) (Figure A11 from Faunt et al. 2009)

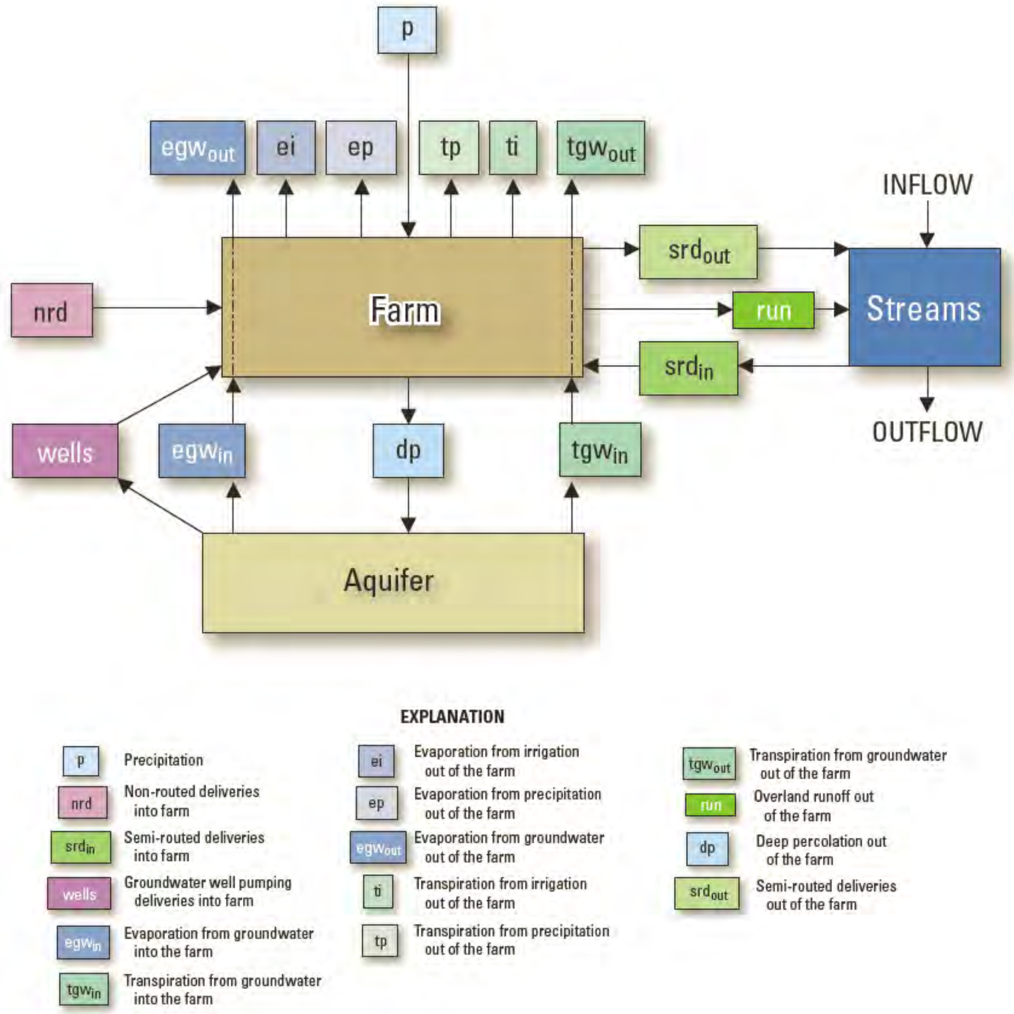

Figure 2.2: Inflows and outflows simulated by the FMP (Figure C5 from Faunt et al. 2009)

CVHM Datasets

Using pre- and post-processor results from CVHM, the parameters for CALVIN groundwater representation were calculated. The parameters were calculated for three different sets of data. The first set of data is based only on the data from 1980-2003 to focus on the time period after most major infrastructure changes in California (“CVHM Hist 1980-2003”). The second set of data is calculated from the entire historical time series (1961-2003) of the CVHM results (“CVHM Hist”). The third set of data is based on a CVHM run made with updated land use based on year 2000 (“CVHM 2000”). However, this run showed some obvious problems in Region 21 (in southern Tulare basin) and was ultimately not used, but its results were used for comparisons between the different CVHM datasets (Appendix 1).

Different approaches were taken when calculating the CALVIN groundwater parameters. The parameters summarized in this section will primarily be for calculations from results from the Zonebudget post-processor (“CVHM”), which estimates a mass balance for each region. Other versions of these calculations include results from FB_details.OUT and other input files, but these ultimately were not chosen to represent CVHM since it involved using terms from different post-processors that did not result in mass balance. However, these calculations still reflect reasonable methods to calculate these terms so some descriptions and results are summarized in Appendix 1. The calculations that were independent of these post-processors have the same results regardless of dataset. A summary of the different sets of CVHM data is shown in Table 2.2. This chapter presents and discusses the results used for CVHM to compare with C2VSIM and CVGSM.

Table 2.2: CVHM Datasets

Dataset name	Description
CVHM Historical (1980-2003) “CVHM Hist 1980-2003”	Based on historical CVHM run using a combination of FB_details.OUT and Zonebudget; averages are based on 1980-2003.
CVHM Historical (1961-2003) “CVHM Hist”	Based on historical CVHM run using a combination of FB_details.OUT and Zonebudget; averages are based on 1961-2003.
CVHM 2000 Land Use (1961-2003) “CVHM 2000”*	Based on an updated 2000 land use CVHM run using a combination of FB_details.OUT and Zonebudget; averages are based on 1961-2003.
CVHM Historical ZB (1980-1993) “CVHM”	Based on historical CVHM run using Zonebudget post-processor; averages based on 1980-1993. Used as final CVHM result for CALVIN comparisons with other groundwater models.

*Note that this run had obvious problems in some of the Tulare Basin regions so the results from this run were ultimately not used for any formal comparison.

CVHM Calculation of Terms

This section summarizes methods used to calculate the terms and the resulting values used for the final comparison between CVHM and the other models. For each term, there is a brief description followed by some tabulated results of calculated values. More details on these terms, alternative calculation methods, and a comparison of these terms’ results are in Appendix 1.

Agricultural Return Flow Split

The agricultural return flow split term represents the fate of applied water that is not consumed by crops or other consumptive uses. Return flow may return either to groundwater by deep percolation or to surface water. This term defines the fraction of agricultural use which returns to surface water (1a) and to groundwater (1b) as shown in Figure 1.3. Applied water is the amount of water used to meet demands.

Using the crop categories and properties in Table 2.3 and the corresponding subregion index data in the model input files, the splits to surface water and groundwater return flows were estimated. Based on the crop distribution file from the input files (a matrix of crop category numbers), the average of all the fractions of surface water runoff from irrigation for each subregion was taken. This results in the proportion of return flow to surface water. The proportion of return flow to groundwater is 1 minus this value. CALVIN takes only one fraction for surface water and one fraction for groundwater for each region over the model time period; these split fractions do not change over time in CALVIN. The results are shown in Table 2.4.

Table 2.3: Summary of Central Valley, California, crop categories and properties (from Table C4 from Faunt et al 2009)

Virtual crop category #	Land Use	Fraction of SW Runoff from Precipitation	Fraction of SW Runoff from Irrigation
1	Water	0.050	0.010
2	Urban	0.015	0.010
3	Native classes	0.207	0.010
4	Orchards, groves, and vineyards	0.102	0.010
5	Pasture/Hay	0.102	0.017
6	Row Crops	0.102	0.061
7	Small Grains	0.102	0.045
8	Idle/fallow	0.060	0.010
9	Truck, nursery, and berry crops	0.102	0.100
10	Citrus and subtropical	0.102	0.010
11	Field crops	0.102	0.077
12	Vineyards	0.013	0.012
13	Pasture	0.102	0.017
14	Grain and hay crops	0.102	0.045
15	Semiagricultural	0.323	0.350
16	Deciduous fruits and nuts	0.107	0.048
17	Rice	0.011	0.030
18	Cotton	0.102	0.102
19	Developed	0.102	0.078
20	Cropland and pasture	0.102	0.078
21	Cropland	0.102	0.078
22	Irrigated Row and Field Crops	0.102	0.068

Agricultural Reuse

CVHM does not explicitly "reuse" water locally for repeated irrigation. This might be included in future versions of the model, but is not in the version used here. As far as basic representation of this term using CVHM, 1 is used for all regions indicating no reuse, meaning water delivered to the region is the same as the applied (and re-applied) water in the region.

Return Flow of Total Applied Water

This term represents the return flow of total applied water, which applies to return flow to both surface water and groundwater. This term can be calculated by using given information on irrigation efficiencies (evapotranspiration of applied water, ETAW). In CVHM, the irrigation efficiencies are specified as a matrix of efficiencies for each subregion and each crop for each monthly stress period. The efficiencies vary from crop to crop for different subregions and they change through time. Table C6 from Faunt et al. 2009 gives the average area-weighted composite efficiency, by decade, for each subregion. Using the values from Table C6, the Return Flow of Total Applied Water is calculated as follows: Return Flow (%) = 1-ETAW (%). The composite efficiency and return flow of total applied water values for year 2000 are in columns 4 and 5 in Table 2.4.

Table 2.4: CVHM Agricultural Return Flow Splits, Composite Efficiencies, and Amplitudes of Return flow of Total Applied Water

Subregion	Agricultural Return Flow Split to GW	Agricultural Return Flow Split to SW	Composite Efficiency (fraction to ETAW)	Return Flow of Total AW
1	0.99	0.01	0.74	0.26
2	0.98	0.02	0.73	0.27
3	0.97	0.03	0.83	0.17

18	0.96	0.04	0.79	0.21
19	0.97	0.03	0.77	0.23
20	0.97	0.03	0.81	0.19
21	0.96	0.04	0.81	0.19

External Flows

The External Flows time series is the sum of several source flows into and out of the groundwater subregion, excluding pumping and recharge of agricultural applied water, which are represented separately in CALVIN. These flows include groundwater-surface water interactions (stream leakage), inter-basin groundwater flows, deep percolation from precipitation, boundary inflows, subsidence, and evapotranspiration/non-recoverable losses. The sum of these individual time series comprise the net external flows monthly time series that are used as input source flow in CALVIN.

Inter-basin flows represent the groundwater flow between subregions. For CVHM, these numbers were extracted from ZoneBudget output, “Inter-zone.” Positive values are flow into the groundwater subbasin and negative values are flows out of the basin to adjoining basins.

Stream leakage flows represent groundwater-surface water interaction within each region. These values are extracted from the ZoneBudget output, “Stream Leakage.” Positive values are flows into the groundwater subbasin and negative values are flows out of groundwater to surface water flow.

Deep percolation of precipitation is the volume of water percolating into groundwater from precipitation. This term was estimated using fractions calculated from the FB_details.OUT and applying those fractions to the Zonebudget “Farm Net Recharge” term. Using FB_details.OUT, the fraction ET_{precip} / (ET_{irrig} + ET_{precip}) was computed, where ET_{irrig} is the evapotranspiration from irrigation (applied water) and ET_{precip} is the evapotranspiration from precipitation (also called effective precipitation). This fraction was multiplied by the “Farm Net Recharge” term from Zonebudget to estimate the recharge from precipitation. The underlying assumption is that the relative contribution of precipitation to recharge is the same as that to evapotranspiration.

Boundary flow is the flow at each region’s boundary from either surface or basins from outside of the 21 subregions (not including inter-basin flow). For CVHM, only Region 9, the Delta, has boundary inflows. Positive values are flow into the groundwater subbasin and negative values are flows out of the subbasin.

Subsidence flows represent the effects of subsidence in each respective region on groundwater storage. For CVHM, subsidence flows are accounted for in the “Interbed Storage” term in ZoneBudget. Since this term had resulting values that were both positive and negative, it was evident that this term was not solely subsidence. However, the interbed storage flow would need to be accounted for in the CALVIN mass balance regardless of if it was solely subsidence or not, so this term was included in the External

Flows. Positive values are flow into the groundwater subbasin and negative values are flows out of the subbasin.

Evapotranspiration from groundwater is estimated by taking the negative irrigation recharge values from Zonebudget. This would be the fraction of Farm Net Recharge that is not recharge from precipitation and is negative, indicating a loss from the groundwater basin.

The average annual flows per region are summarized in Table 2.5. These flows are from the groundwater perspective; positive values are flows into the groundwater basin and negative values are flows out of the basin.

Table 2.5: Average Annual 1980-1993 CVHM-CALVIN External Flows (TAF/month)

Pumping Capacity

This term is the upper-bound constraint for groundwater pumping in CALVIN. These are estimated as the maximum values of pumping extracted from the ZoneBudget output, "Farm Wells" from 1980 to 1993. These capacities are shown in Table 2.6.

Pumping Lift

Depth to groundwater ("pumping depth" or "pumping lift") is used in CALVIN to determine agricultural pumping costs. CALVIN assumes a fixed cost per foot of lift and these calculated costs are used as model inputs (CALVIN Appendix G, 2001). Depth to Groundwater is essentially the ground surface elevation minus the water elevation. Taking these values from the input and output files for the original CVHM run for year 2000, the average lift per region was calculated. The head values used were from MODFLOW so they represent the average head for a 1 square mile cell, and not the water level in a well, which will typically be lower. This indicates that this value, in addition to all other assumptions, is likely to be an overestimate since the average head is likely to be a smaller value than the effective water level. These average lift values are summarized in Table 2.6.

Since DWR measured groundwater level data for year 2000 exists, it was decided that using measured data of groundwater heads would best represent pumping lift for these regions. Details of how these averages were calculated can be found in Appendix 2. These average lift values are also summarized in Table 2.6.

Table 2.6: CVHM Pumping Terms and DWR Measured Well Depths

Subregion	Pumping Capacity (TAF/mo)	CVHM 2000 Pumping Depth (ft)	DWR 2000 Average Measured Well Data (ft)
1	2.3	153	71

20	162.2	366	298
21	113.3	250	191

Storage

The maximum storage is the upper-bound constraint for groundwater storage capacity in CALVIN. The "Storage" term from the Zonebudget post-processor is used here. The data in Zonebudget represents change in storage. Effective storage is used for this term to represent the absolute maximum available water. Calculation is as follows:

1. Arbitrarily set the initial storage to a very large number ($1x10^9$) such that the created storage time series is never negative.
2. Once storage values are converted from change in storage to storage, the effective storage can be calculated: Absolute Maximum storage – Absolute Minimum Storage (note that the original arbitrarily high number is now cancelled out).

The initial storage was calculated to be the effective initial storage, the maximum amount of water available in September 2003. This was calculated: Storage in 2003- Absolute Minimum storage. The results are shown in Table 2.7 below. A more detailed discussion of the method can be found in Appendix 1.

Change in storage is also estimated directly from the Zonebudget storage change values. The totals of changes in storage per month for 1980-1993 are summed up by year and averaged to get the average annual change in storage. Then this yearly change in storage value is multiplied by 72 years to get an estimated storage change for 72 years. These storage changes are shown in the last column of Table 2.7. Positive values indicate overdraft and negative values indicate an increase in groundwater storage. The ending storage values were calculated from the initial storage minus the change in storage over 72 years. Additional overdraft scenarios and calculation methods will be discussed in Chapter 5.

Table 2.7: CVHM Storage Capacity, Initial & Ending Storage, and 1921-1993 Change in Storage (TAF)

Subregion	Maximum Storage Capacity	Initial Storage	Ending Storage	Change in Storage*

* Positive values indicate overdraft and negative values indicate an increase in groundwater storage.

Calibration Flow

For each groundwater basin, a mass balance could be achieved with a calibration flow to correct for the model error. To determine the mass balance, only the flows that directly flow in and out of the groundwater basin were considered: external flows, pumping, recharge from applied water, and changes in storage. Figure 2.3 shows these components and flow interactions. Recharge to groundwater, pumping, and storage changes ultimately will be modeled explicitly in final CALVIN, since these are actively managed as decision variables with associated management costs. But to check CVHM's representation of groundwater flows, the recharge flows and changes in storage are extracted and used here. As mentioned earlier, the change in storage is an output in the Zonebudget post-processor. The recharge flows are only the positive recharge flows from applied water (irrigation) because the recharge from precipitation and negative recharge terms are included in the external flows term. The mass balance results are summarized in Table 2.8. As seen in the results, the calibration flows to achieve the mass balance are rather small, which agrees with CVHM results presented in Faunt et al. 2009. In the overall CALVIN network, if the calibration flow was to be added or removed from the system, it would not be a direct interaction with the groundwater basin, as shown in Figure 1.3.

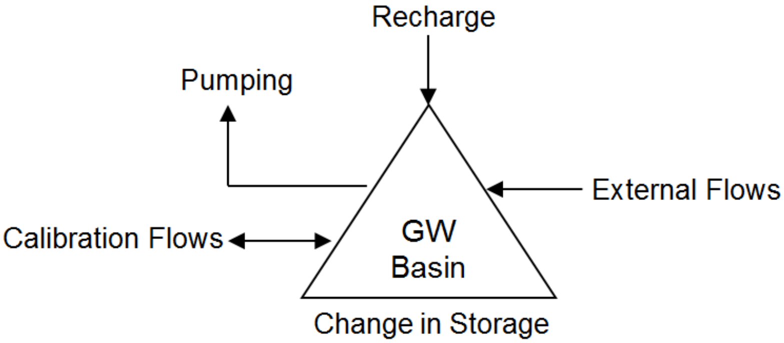

Figure 2.3: Groundwater Mass Balance Flows

Urban Return Flow

CVHM accounts for urban land use in its calculation of crop efficiencies; urban land use is considered a "virtual crop" as seen in Table 2.3 above. Specific fractions for just urban return flows were not separated for CVHM. Urban flows are generally small compared to agricultural flows so the return flows are also generally lower. CVGSM and C2VSIM do account for this term separately, and this is discussed in the next chapter, which compares the three models.

Discussion

This chapter focuses on how CVHM was summarized for the CALVIN update project. Although CVHM was ultimately not used as the groundwater basis for the updated CALVIN model, studying the model and calculating the terms provided useful insights during the calibration process and in the overdraft studies (Chapter 5). Future versions of CVHM will likely fit CALVIN purposes more closely and should be considered again when it is time for the next CALVIN groundwater update. The next chapter will present and compare the calculated terms for CALVIN from CVHM, C2VSIM, and CVGSM.

CHAPTER 3

Comparison of Models and Calculated Terms

This chapter discusses and compares the CALVIN calculated terms from C2VSIM, CVHM, and CVGSM. CVGSM was based on IGSM, a basin planning model that includes groundwater, surface water, groundwater quality and reservoir operation simulation routines (USBR 1997). C2VSIM is based on IWFM, whose precursor was the IGSM, but has been renamed to IWFM since many major changes and improvements were made. The calculated CALVIN terms show this similarity in the basis of the model's results in similar calculations and representations of some terms. CVHM is MODFLOW based with the Farm Process (FMP) package, which treats and represents many terms very differently than IWFM and IGSM, so some calculated terms differ greatly. However, some terms show strong agreement between CVHM and C2VSIM when compared with CVGSM, likely due to the more detailed discretization, calibration, and use of accepted and tested algorithms. IWFM and MODFLOW-FMP are newer models that address the physical and economic water balance in a watershed, allowing for simulations that account for both physical flow processes and water management practices. A detailed description and comparison of the theory, approaches, and features of the two models can be found in Dogrul et al. 2011. A comparison of IGSM and older versions of MODFLOW can be found in LaBolle et al. 2003.

Calculated Terms Comparison

The 21 groundwater subbasins (subregions) in all three models correspond with the CVPM regions used in CALVIN, allowing for direct comparisons. The same calculated terms for each model often account for additional flows or features that might be accounted for in a different term in the other model. Many different term calculation methods were used and the ultimate decision to use one method over others was based on trying to capture the term as best suited for representation in CALVIN, as a water management model, and looking at how the term compared with the other models and measured data. Different methods used in the calculations cause some differences in the calculated terms. Because C2VSIM output terms are similar to those of CVGSM, the calculations used for these two models were often more similar than the calculations used to calculate CALVIN terms from CVHM results. The effects of the differences in methods will be discussed in the sections below and the detailed descriptions of the terms can be found in Appendix J (Jenkins et al. 2001 and Davis et al. 2001), and Appendix 1 and 3 of this thesis. The various parameters representing groundwater in CALVIN are summarized in Table 1.2 and Figure 1.3. The comparison is structured by these sections below.

Agricultural Return Flow Splits

Table 3.1 shows some large differences for Agricultural Return Flow Splits between the models. The calculations for C2VSIM and CVGSM follow similar methods but result in very different splits. Detailed calculations and equations can be found in Appendix J and Appendix J-2 (II) (Zikalala et al. 2012). C2VSIM and CVGSM fractions are based on using model outputs and taking fractions of these to represent these splits. C2VSIM's fractions generally have higher return flows to groundwater, which agrees with CVHM, whose methods are based on taking the averages of fractions of surface water runoff from irrigation for each subregion from CVHM input files. Both newer groundwater models imply more irrigation return flow is to groundwater throughout the Central Valley.

Table 3.1: Agricultural Return Flow Splits to Groundwater

Subregion	C2VSIM	CVHM	CVGSM (1997)
	GW	GW	GW
1	0.28	0.99	0.45
2	1.00	0.98	0.69
3	0.60	0.97	0.60
4	0.99	0.96	0.12
5	0.72	0.97	0.59
6	0.98	0.97	0.37
7	1.00	0.98	0.42
8	0.93	0.98	0.14
9	1.00	0.96	0.74

14	1.00	0.92	1.00
15	1.00	0.94	0.30
16	0.84	0.98	0.13
17	1.00	0.97	0.42
18	1.00	0.96	0.99
19	1.00	0.97	1.00
20	0.82	0.97	0.59
21	1.00	0.96	0.94

Agricultural Reuse Amplitudes

As mentioned in Chapter 2, the non-reuse amplitude is 1 (no reuse) for all CVHM regions, neglecting local tailwater reuse. For CVGSM, the reuse fractions were a direct output in the model, but as seen in Table 3.2, amplitudes were quite high for reuse. When these amplitudes were used for the original CALVIN groundwater, they were some of the first to be adjusted (decreased significantly) during calibration, as discussed in the Chapter 4. In C2VSIM, the reuse amplitudes were calculated by summing the applied water and reused water and dividing that net sum by the applied water for the 1980 to 2003 time period. These values in Table 3.2 are significantly smaller than the earlier CVGSM values and seem fairly close to CVHM.

Table 3.2: Agricultural Reuse Amplitudes & Applied Water Return Flow Fractions

Subregion	Agricultural Reuse Amplitude			Agricultural Return Flow Fraction		
	C2VSIM	CVHM	CVGSM	C2VSIM	CVHM	CVGSM
1	1	1	1.32	0.47	0.26	0.39
2	1	1	1.26	0.14	0.27	0.29
3	1.086	1	1.28	0.20	0.17	0.35
4	1.001	1	1.21	0.14	0.21	0.35
5	1.049	1	1.283	0.21	0.2	0.37
6	1.001	1	1.08	0.06	0.23	0.28

21	1	1	1.25	0.10	0.19	0.32

Applied Water Return Flow Fractions

Table 3.2 shows that Agricultural Return Flow Fractions for CVHM and C2VSIM are generally lower than those of CVGSM. C2VSIM's fractions are calculated as the total applied water not consumptively used divided by the total applied water, where the terms used were determined following the calculations for Agricultural Return Flow Split. CVHM's values were determined by using the published composite efficiency values (evapotranspiration of applied water, ETAW) per region as discussed in Chapter 2 (Return Flow % = 1-ETAW %). CVGSM's return flow fractions are based on CVGSM NAA output data (Return Flow % = 1 – On-farm Efficiency %). DWR Bulletin 160-98 also had efficiencies published at the time, and they were generally higher than those from the CVGSM output, resulting in lower return flow fractions. So that was a primary basis for adjusting the CVGSM return flow fractions when calibrating the groundwater system in CALVIN in 2001. The calibration steps taken for the current update CALVIN are discussed in Chapter 4.

External Flows

External flows are entered into CALVIN for each subregion as a source time series. Some external flow terms were directly extracted from results files of the groundwater models, but a few required some calculations, as discussed below. Overall, the average annual external flows for C2VSIM and CVHM seem to follow a similar trend throughout the regions when comparing the 1980-1993 time period, which can be seen in Table 3.3 and Figure 3.1.

Table 3.3: Average Annual (1980-1993) Net External Flows (TAF/yr)

Subregion	C2VSIM[a]	CVHM[b]

[a] C2VSIM averages are based on adjusted flows for 1980-1993
[b] CVHM averages based on 1980-1993, same as Table 2.5

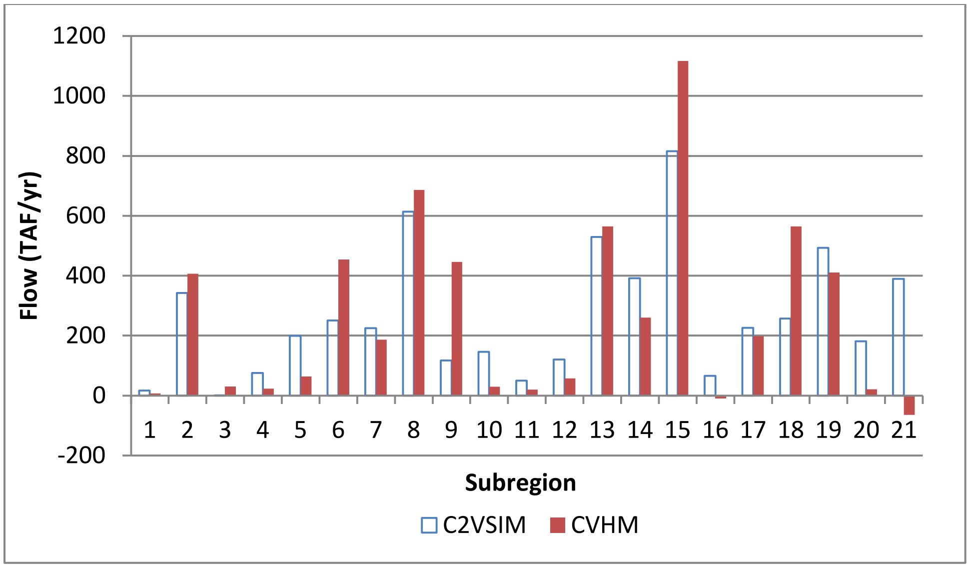

Figure 3.1: 1980-1993 Average Annual Net External Flows

The time period annual averages used to represent the models' external flows in CALVIN (1921-2009 for C2VSIM, 1980-1993 for CVHM, and 1921-1990 for CVGSM) are shown in Table 3.3a; these are the values that were input in CALVIN when comparing between models. These different time period-based external flows were used for each of the models because they were considered to be the best representation of updated land use and infrastructure. The CVGSM values are based on the entire time period of the CALVIN model run because that is what was used in the previous version of CALVIN. As seen in Table 3.3a, the average annual external flows for CVGSM are much larger than that of C2VSIM and CVHM. The newer models generally have more terms than CVGSM because the newer models break down the different terms more explicitly and it was decided to include all the time series terms to the external flow term so that a mass balance could be achieved. The breakdown yearly averages of each of the flows that comprise the net external flows averages are presented below in Tables 3.3b-d.

Table 3.3a: Average Annual Net External Flow Averages (TAF/yr)

Subregion	C2VSIM[a]	CVHM[b]	CVGSM[c]

[c] CVGSM averages based on 1921-1993

Table 3.3b shows the Interbasin and Boundary Flows. Both terms are direct time series output results from the models or their post-processors. CVGSM shows a major problem with the interbasin flows because the net sum of the terms is not zero. Since interbasin flows are only the flows between basins, and not flows from outside the model boundary, the net sum of interbasin flows between regions should equal zero if a proper mass balance is to be represented. Although C2VSIM and CVHM have significant differences in their representation of interbasin flows, their overall totals are zero. This is a good example of the differences that arise between C2VSIM and CVHM due to their different methods and assumptions, but still achieve a mass balance. The Boundary Flows show significant differences between the three models.

Table 3.3c shows groundwater-surface water (GW/SW) interaction from streams and lakes, and deep percolation of precipitation. GW/SW interaction from streams and lakes are direct outputs from the models or their post-processors. As can be seen in the table, CVHM does not represent GW/SW interaction from lakes (a small matter for the current Central Valley). Overall, the differences for GW/SW interaction from streams vary widely. And since this term is a direct output from the models, no adjustments were made here. This is another good example showing the differences between models and their representation of surface water and groundwater interaction.

The deep percolation from precipitation terms for C2VSIM and CVGSM are calculated in similar methods following the calculations for agricultural return flow splits. CVHM calculation of this term is based on the farm net recharge output and evapotranspiration splits. This term is significantly higher for CVHM than C2VSIM and CVGSM, likely largely due to the calculation method. The precipitation input data for C2VSIM and CVHM were compared and confirmed to be very similar. So this difference in deep percolation from precipitation between the two models is likely due to both the CALVIN term calculation methods and the methods in the groundwater models themselves. These differences are substantial, especially for the Sacramento Valley.

[c] CVGSM averages based on 1921-1993

Table 3.3d shows the subsidence, diversion losses to groundwater (gains to groundwater), and losses from groundwater. For C2VSIM and CVHM, subsidence results are directly from model outputs or from post-processors. There seems to be some trends between the two models for subsidence, but CVHM generally has more subsidence gains to the basin than C2VSIM. No subsidence term was used from CVGSM.

Diversion losses to groundwater, or conveyance seepage flows, are a loss from the surface water irrigation or conveyance system, which is a gain to the groundwater basin. CVHM does not explicitly represent this term but it is accounted for when calculating the crop efficiencies, which is discussed in Chapter 2 and in Appendix 1. This term is an input to CVGSM and is reported in C2VSIM's result post-processor. Estimated canal losses have decreased over time, as seen from time series data for the individual regions. It is unlikely that an up-to-date model like C2VSIM would suggest higher diversion losses over time so the likely reason there are more diversion losses from canals represented in C2VSIM than CVGSM could be that CVGSM was somehow underestimating diversion water that was being lost to the groundwater basins.

Tile drain outflow represents the practice of removing excess water from upper layers of some groundwater basins. Of the 3 models, this is only represented in C2VSIM and only in regions 10 and 14.

Evapotranspiration losses from groundwater are a time series output from CVHM (from FB_Details.OUT). This term is not included in external flows for CALVIN since the non-recoverable (and recoverable) losses are accounted for by an amplitude on the surface water side. This was necessary for CVHM due to the methods used to calculate some of the other terms in CVHM. Evapotranspiration losses needed to be subtracted in the net external flows for CVHM because terms like the deep percolation from precipitation have significantly higher flows to the groundwater basins because the evapotranspiration losses are accounted for separately as its own term, which does not seem to be the case for C2VSIM or CVGSM. CALVIN and C2VSIM represent evapotranspiration losses and conveyance losses as a fraction on the surface water side, and these are discussed and tabulated in Appendix 5. This is another reason CVHM was not ultimately used for the update project because trying to account for this difference would have required more changes to CALVIN's basic framework (CALVIN's surface water loss fractions would all need to be changed to 1 to indicate no non-recoverable or recoverable losses on the surface water side for CVHM). Although the loss on the surface water side is accounted for by the loss fraction in C2VSIM and CVGSM, the recoverable loss from the surface water as a gain to the groundwater side needs to be added back to the system. Since the CALVIN network does not represent this directly, the external flows term includes that recoverable loss from surface water as a gaining flow to the groundwater system.

*Positive values are flows into the groundwater basin and negative values are flows out of the basin.

[1] Subsidence for CVHM was actually the Interbed storage, which includes subsidence but is not entirely subsidence alone.

[a] C2VSIM averages are based on adjusted flows for1921-2009

[b] CVHM averages based on 1980-1993

[c] CVGSM averages based on 1921-1993

Although both C2VSIM and CVHM seem to represent Central Valley groundwater much better than the older CVGSM, there are still significant differences between the new, improved models, implying some level of uncertainty in the general understanding of Central Valley groundwater.

Pumping Terms

The pumping capacities and pumping depths are shown in Table 3.4. The pumping capacities for C2VSIM and CVHM are the maximum values of pumping for the period1980-1993. CVGSM capacities are the maximum monthly pumping for the period 1922-1990. If pumping volume is greater than 100 TAF, capacity is set to 110% of maximum value; otherwise, capacity is set to 105% of maximum value. The values shown in Table 3.4 do not include the correction factor.

The pumping depths for C2VSIM and CVHM were explicitly calculated using the heads from the input files. CVGSM depths to groundwater were not available for the previous CALVIN study so the depths to groundwater were pieced together from analyses for the Draft CVPIA PEIS (USBR 1997). Since there was some uncertainty in the C2VSIM and CVHM calculations and DWR measured groundwater level data exists, measured static water level was assumed to be the most appropriate and accurate set of data to be used for the CALVIN groundwater update (Appendix 2).

Table 3.4: Pumping Capacities and Depths

Subregion	Pumping Capacity (TAF/month)			Pumping Depth (ft)

* Average Measured Groundwater Level Data

Constraining a minimum pumping rate would ideally help represent parts of the Central Valley that exclusively depend on groundwater. However, none of the models seemed to have sufficiently detailed calibrations to provide such insights.

Storage Terms

Table 3.5 shows the storage related terms. The storage values for C2VSIM are output by the results post-processor. The maximum storage capacity was set by taking the maximum storage at any time from 1980-2003. For C2VSIM, the initial storage was set to be the storage at the end of 2005. CVHM's storage terms are calculated by using the maximum effective storage for the maximum capacity (maximum value minus minimum value for 1980-1993) and the effective storage based on September 2003 (September 2003 storage minus minimum value for 1980-1993). CVGSM storage capacities were extracted directly from the model output, as with C2VSIM.

Actual groundwater storage capacity in California is unknown and is not accurately measureable at this time. The California DWR Groundwater Bulletin 118 estimates that the groundwater storage capacity for the whole state can be anywhere between 850 million acre-feet (MAF) to 1.3 billion acre-feet. The C2VSIM results for maximum storage are a much larger estimate of groundwater storage, since the sum total for just the Central Valley exceeds the Bulletin's estimates for the whole state. CVHM's storage seems comparable to the estimates presented in the Groundwater Bulletin. It is important to have a reasonable initial storage since CALVIN does not model water levels, but change in storage; the initial storage is essentially a reference starting point. But ultimately, when considering CALVIN results, the change in storage results could be applied to any initial storage so long as there is still water available in the basin.

Overdraft is estimated directly from the change in storage values for CVHM and C2VSIM. The storage change per month is summed over a long time period and divided by the number of years in that time period to get the average annual storage change for that time period. C2VSIM's average was based on 1980-2009 (29 years) and CVHM's average was based on 1980-1993 (13 years). Then this yearly storage change value is multiplied by 72 years to estimate total change in storage for 72 years. Positive values indicate overdraft and negative values indicate recharge to groundwater. CVGSM storage change was estimated for Table 3.5 by subtracting the initial storage from the ending storage from the model output.

As seen in the change in storage region totals at the bottom of Table 3.5, the differences are large in the Sacramento region, with CVHM showing overall gain to the groundwater storage and C2VSIM showing 12 MAF of overdraft. The estimated overdraft for the San Joaquin region also differs widely between the three models, with CVGSM being 8 MAF less than CVHM, and CVHM 4 MAF less than C2VSIM. The total Central Valley modeled overdraft from 1921-1993 are close for C2VSIM and CVHM, at 80 MAF, which is significantly less in CVGSM, at about 28 MAF. The largest difference in magnitude of overdraft between the three models is the Tulare region. If only the San Joaquin and Tulare regions were totaled, CVHM would have 20 MAF more overdraft than C2VSIM, but with the addition of 8 MAF of groundwater inflow modeled in CVHM’s Sacramento region, C2VSIM and CVHM have very close total Central Valley estimated overdraft values. Given the variability in groundwater use and recharge, estimates of overdraft are also quite variable with different method used for long term averaging. Additional overdraft scenarios and calculation methods will be discussed in Chapter 5.

Table 3.5: Maximum Storage Capacity, Initial Storage, and Change in Storage (TAF)

Subregion	Maximum Storage Capacity			Initial Storage			Change in Storage from 1921-1993*

*Positive values represent overdraft and negative values represent gains to groundwater.

Urban Return Flow

As mentioned above, CVHM includes urban land use in the calculation of the farm efficiencies. C2VSIM and CVGSM include urban return flows separately so a return flow fraction can be calculated. C2VSIM simulates land use processes within the urban areas including groundwater pumping and surface water supply to meet urban demand, urban water supply shortage or surplus, and flow in excess of demand is returned to surface water bodies or to groundwater. In urban areas, a *Rootzone budget output* file tabulates monthly volumes of precipitation, runoff, applied water to urban regions, net return flow of applied water to surface water, and water that goes to the unsaturated zone as deep percolation. The algorithms for separating infiltration of applied water from the total monthly volume infiltrated and calculation of total return flows to SW and GW are similar to that described above. Calculated fractions show that for the Sacramento region, all water returned from urban regions returns to SW, whereas for the San Joaquin and Tulare regions all of the return flow infiltrates to GW. As seen in Table 3.6, C2VSIM representation of urban return flow fraction varies widely across all regions.

Table 3.6: Urban Return Flow Fractions

Conclusions

CVHM and C2VSIM are up-to-date groundwater models whose methods and results have been reviewed and confirmed to be significant improvements from previous Central Valley groundwater models (i.e., CVGSM). Both new groundwater models have been designed and built with added detail to represent Central Valley groundwater hydrology and management practices. Both models are also undergoing improvements and updates. Although there are many differences between the models' methods and results, both can be useful for water managers and planners. The benefits and drawbacks of each model are subjective to the users of the model and what the models are being used for. Dogrul et al. 2011 discusses the differences of the theory, approaches, and features of the two models. Schmid et al. 2011 compares the models using a common hypothetical example.

For this CALVIN groundwater representation update, C2VSIM was used primarily because the model period for C2VSIM (1921-2009) matches the model period for CALVIN (1921-1993). It would have been possible to use CVHM (1961-2003), but a thoroughly estimated hydrology match would have been needed to extend CVHM's data back to 1921 in order for CVHM results to be used for the CALVIN external flows term. Another benefit was that since C2VSIM is essentially an updated and improved version of CVGSM, many of the calculation methods used in the past remained relevant. C2VSIM also had all the terms previously represented in CALVIN plus some updates, whereas CVHM sometimes combined some representation of CALVIN required terms in other areas and there was some doubt associated with the methods used to split these back out to CALVIN terms. However, throughout this project, there was much valuable correspondence with USGS regarding the uses of CVHM for CALVIN and many of the components that were difficult to calculate or not present in this version of CVHM will be present in future versions. Future updates to CALVIN groundwater should re-visit the idea of using CVHM for groundwater representation. CVHM is based on the widely used MODFLOW and many of the results in the current version are comparable with other studies (i.e. storage results) and physical measurements. The CVHM calculated terms and results were largely considered when calibrating the C2VSIM inputs to updated CALVIN; Chapter 4 discusses some of these considerations and presents the results of the updated CALVIN model.

CHAPTER 4

CALVIN with Updated Groundwater Representation

As discussed in the last chapter, the updated CALVIN groundwater representation is based primarily on C2VSIM. Another update that affects groundwater management is Delta pumping constraints, which are updated based on CALSIM II 2009 results (DWR 2011). This chapter presents the final terms used in CALVIN, discusses the calibration process, shows CALVIN network improvements, and compares the updated CALVIN with the previous version.

Updated CALVIN

The previous chapter compared the input terms between the groundwater models. However, C2VSIM had additional components that were not directly accounted for in CVHM and/or CVGSM. Table 4.1 shows the C2VSIM terms required to achieve a mass balance and used for the updated CALVIN model. Figure 4.1 is a schematic of the flows and interactions of these terms in the groundwater system in the updated CALVIN network. This schematic is similar to the flow interaction diagram in Chapter 1, but has some differences and also includes the nodes and links as in the updated CALVIN network. The schematic shows the hidden nodes, which are used in the model to separate the shadow value of the diversion from the shadow value of the delivery. This schematic does not show the calibration flow term since calibration flows were small and ultimately were not included. This schematic also includes artificial recharge, which was not previously explicit in the CALVIN groundwater system. Along with artificial recharge, some network improvements and simplifications were made by adding a few hidden nodes, and these changes are shown in red in the schematic.

Table 4.1: Groundwater Data Required by Updated CALVIN

Item	Data for CALVIN	Data type
1	Agricultural return flow split (GW & SW)	Fraction (1a+1b=1)
2	Internal reuse	Amplitude (≥1)
3	Return flow of total applied water	Amplitude (<1)
4	External flows	Monthly time series
4-1	Inter-basin flows	Monthly time series
4-2	Deep percolation from streams & lakes	Monthly time series
4-3	Deep percolation from precipitation	Monthly time series
4-4	Boundary inflow	Monthly time series
4-5	Subsidence	Monthly time series
4-6	Gains from diversions (conveyance seepage)	Monthly time series
4-7	Non-recoverable losses	Monthly time series
5	Groundwater pumping capacity (maximum & minimum)	Number value
6	Pumping lift (for pumping cost)	Number value & Cost ($)
7	Initial Storage	Number value
8	Ending Storage	Number value
9	Storage capacity (maximum & minimum)	Number value
10	Artificial Recharge Operation Cost	Cost ($)
11	Artificial Recharge Rate	Amplitude (<1)
12	Urban return flow	Amplitude (<1)

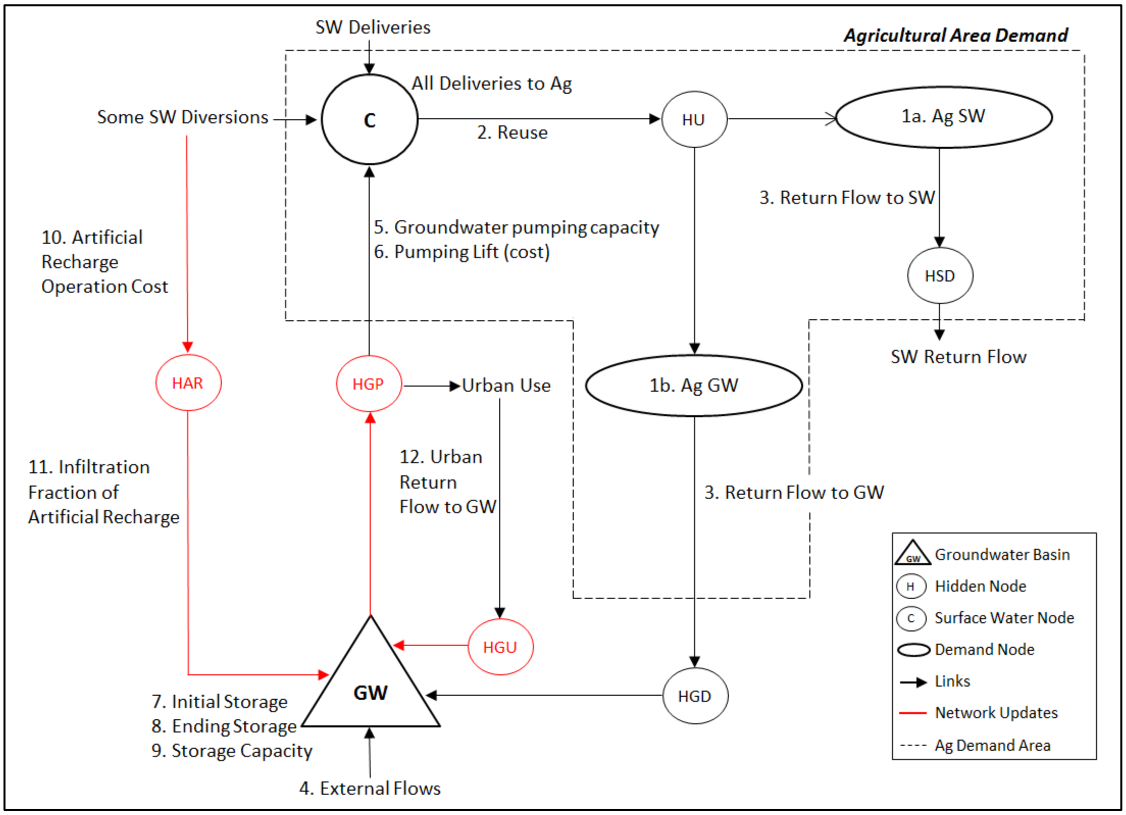

Figure 4.1 Updated CALVIN Groundwater Schematic

Network & Schematic Improvements

The schematic included the addition of the hidden nodes to simplify the direct groundwater interaction. The previous version of CALVIN had multiple pumping links and urban return flow links connected with the groundwater basins. Adding node "HGP" provides a link from groundwater which represents total pumping from the groundwater basin. From HGP, pumping is split between agricultural pumping and urban pumping. Similarly, the previous CALVIN had multiple urban return flows returning to the groundwater basin, and now combines return flows at "HGU" before returning to the aquifer. The link between HGU and the groundwater basin is the total urban return flow. Since C2VSIM represents artificial recharge for basins 13, 15-21, nodes and links for artificial recharge were added for those basins. A detailed description of the schematic updates is provided in Appendix 3.

Updated CALVIN & Old CALVIN Input Comparisons

The tables in this section compare the updated, calibrated CALVIN model and the CALVIN model prior to this groundwater update project. Table 4.2 shows the run numbers and a description of each run. Updated CALVIN will be referred to as "UPDATED CALVIN" and the previous version will be called "OLD CALVIN." These comparison tables will show and discuss the final values used for UPDATED CALVIN. A summary of the calibration process and reasons for some adjustments from the original C2VSIM inputs is discussed below.

Table 4.2: UPDATED CALVIN and OLD CALVIN

Run Name	Run Number	Description
"OLD CALVIN"	R17I03	The results from this run are discussed in Bartolomeo 2011. This is the "base" model for the groundwater update project.
"UPDATED CALVIN"	S07I14	This is the final calibrated run based primarily on C2VSIM groundwater terms and a hybrid CALSIM II-OLD CALVIN-based delta pumping & exports constraints.

Agricultural Return Flow, Reuse, and Total Applied Water Return Flow

Table 4.3 shows the Agricultural Return Flow to Groundwater fractions, the Reuse amplitudes, and the Total Applied Water Return Flow amplitudes. There are significant differences between old and UPDATED CALVIN for all three of these terms. UPDATED CALVIN has generally higher return flows to groundwater and lower reuse amplitudes. Many of the OLD CALVIN terms here were adjusted from the CVGSM based values in the groundwater calibration project from 2001. Details of why those earlier adjustments were made can be found in Appendix J and O (Jenkins 2001).

For the UPDATED CALVIN columns, the values adjusted during calibration are shown in bold italics and red. These particular values were adjusted based on comparisons with CVHM results and consideration of how reasonable the C2VSIM calculated value was. A summary of the calibration changes is in the calibration section below.

Table 4.3: UPDATED CALVIN Return Flow to Groundwater, Reuse, and Applied Water Return Flow

Subregion	Split Ag Return Flow to GW Fraction		Reuse Amplitude		Applied Water Return Flow Amplitude

* Red Bold Italics indicate values adjusted during calibration

External Flows

Table 4.4 shows the average annual net external flows for UPDATED CALVIN and OLD CALVIN, along with the original C2VSIM flow averages since this term was adjusted significantly for many basins. Specifically, the external flow time series term that was adjusted was groundwater-surface water interaction from streams. Differences in stream exchanges before and after 1951 are due to the change in aquifer levels and therefore changes in surface-groundwater interactions. Stream-aquifer connections have changed over time so streams that may have gained water from aquifers before 1951 have reversed to losing water to aquifers. If the historical time series of stream-aquifer flows was used, there would likely have been a million acre-feet per year of water that was not accounted for correctly in the Central Valley. As a result, streamflow exchanges before 1951 were adjusted based on if the annual average difference for subregions was above 50 TAF/yr. Adjusted subregions are 2, 4, 5, 6, 9, 11, 13, 15, 18, 19 and 21 (shown in bold italics and red in Table 4.4). To maintain mass balance of water available within the subregion, the difference between historical and adjusted stream inflows was accounted for in the depletion areas of respective subregions or as depletions or accretions to major streams in these subregions. A more detailed description of this adjustment is in Appendix 4.

Effectively, the C2VSIM external flow values are used; some of the water was just moved from the external flows term to the depletions and accretions to account for the changes in aquifer levels after 1951. Overall, UPDATED CALVIN has much less external flows entering the groundwater system than OLD CALVIN’s external flows entering the groundwater system. The individual flows that summed to be net external flows are discussed in Chapter 3.

As mentioned in the previous chapter, C2VSIM represents evapotranspiration losses as a surface water loss fraction so it is not accounted for in the external flows time series. More details on the C2VSIM surface loss fractions can be found in Appendix 5.

Pumping Terms

Table 4.5 shows the pumping related terms (capacity, depth, and unit costs) for CALVIN (UPDATED and OLD). The maximum pumping values from C2VSIM were used as pumping constraints except for a few regions (shown in bold italics and red). These exceptions were increased during calibration because it was found that the maximum pumping constraints were being hit often, and when comparing the C2VSIM maximum pumping capacities with CVHM, C2VSIM's maximum pumping values were significantly lower, indicating that the actual maximum could be larger.

Pumping depths and costs were not adjusted in the calibration phase. Since the data is based on average measured DWR groundwater level data, those pumping depths were used to calculate the pumping cost. Adjustments were made to the pumping costs to reflect year 2008 economic dollars. Details of the how pumping costs were calculated can be found in Appendix 2.

Storage Terms

The storage terms are shown in Table 4.6. The values in the table reflect the maximum, initial, ending, and average annual change in storage for the 72 year time period for water years 1921-1993.

For UPDATED CALVIN, the maximum storage constraint was not actually used in the final run since the initial and ending storages were set to simulate overdraft. The initial storage values were set based on C2VSIM initial storage values. The ending storages were set based on the calculated overdraft/change in storage discussed in Chapter 3, with some calibration adjustments. The change in storage calculated for the OLD CALVIN run was based on the initial storage minus the ending storage. The initial and ending storages for OLD CALVIN differ from the original groundwater calibration based on CVGSM, due to other CALVIN calibrations in the past 10 years.

As can be seen in the storage change numbers, there is some agreement that much more overdraft occurs in the Tulare basin than the other two Central Valley basins. The ending storages for UPDATED CALVIN that were adjusted from C2VSIM's calculated overdraft for the regions are shown in bold italics. Reasons behind this adjustment will be discussed in the next section.

In general, estimates of long-term overdraft vary widely, as such calculations are quite sensitive to the selection of periods, durations, and flows over wet and dry periods.

[1] Positive values represent overdraft and negative values represent gains to groundwater.

Artificial Recharge

In C2VSIM, subregions 13, and 15-21 manage their groundwater supplies with artificial recharge of imported or local surface water. Artificial recharge flows to groundwater are reported as C2VSIM diversions and are described in the simulation application's *CVdivspec.dat* file, which specifies diversions for spreading and destination subregions for infiltration facilities. In C2VSIM, spreading facilities have a recoverable fraction of 0.95 (an assumed infiltration rate). The groundwater budget output file has a "Recharge" term, which includes both diversion losses and water from spreading facilities. To separate artificial recharge volumes from the total recharge volume, an infiltration rate of 0.95 was applied to monthly diversion volumes for surface water diversions for spreading, where diversions for spreading are listed in Table 4.7. Monthly volumes of Diversion times 0.95 was taken as recharge from spreading facilities and was therefore separated from the total recharge term for subregions 13, and 15-21. Figure 4.1 shows the added nodes and links (in bold italics and red) that represent this artificial recharge addition to the CALVIN network. Artificial recharge was not explicitly represented in OLD CALVIN; historical artificial recharge was included in select inflows.

Table 4.7: Surface Water Diversion for Spreading

Table 4.8 shows the annual average historical artificial recharge per C2VSIM simulation and operation costs of artificial recharge facilities updated from OLD CALVIN artificial recharge costs. These are calculated to reflect operating costs for these agricultural groundwater recharge activities, which limit facility operations and the opportunity cost of land used for recharge basins.

Table 4.8: Artificial Recharge Operation Costs

[1] OLD CALVIN cost (5 $/AF) converted to 2008 dollars

Urban Return Flow

The urban return flow fractions used for UPDATED CALVIN are based on C2VSIM's representation of urban return flow, as discussed in Chapter 3 (Table 3.6). These can be compared with the urban return flow fractions for OLD CALVIN, which are from CVGSM (also shown in Table 3.6).

Agricultural Water Demands

Along with updating the input terms related to CALVIN groundwater, agricultural demands were also updated. Results from an improved and updated Statewide Agricultural Production Model – SWAP (Howitt et al. 2012) were used for UPDATED CALVIN's agricultural demands. Table 4.9 shows agricultural demands for OLD CALVIN and UPDATED CALVIN. The differences in the water delivery targets can be attributed to improvements made in SWAP crop production model in that some CVPM regions (3, 10, 14, 15, 19 and 21) were further discretized for better representation. A detailed description of SWAP is in Howitt et al. 2012.

Table 4.9 shows that overall net demand target for UPDATED CALVIN is slightly lower. Generally, this could imply that decreased shortages in deliveries can be expected in UPDATED CALVIN. The calibration steps were based primarily on determining if shortages reflected in the results of each run were "true" shortages or if a specific calculated input term caused the shortage, such as local capacity constraints, leading to scarcities even in very wet years. The calibration process to reduce these "untrue" shortages is discussed in the next section.

During the calibration phase of OLD CALVIN in 2001, it was found that there was too much excess water in the system, so a calibration outflow was needed for CALVIN to have reasonable results. These calibration outflows were constrained time series that dumped water from the C delivery node (shown in Figure 4.1) before reaching the demand nodes, effectively increasing water use. Table 4.10 shows these averaged annual calibration flows from the 2001 calibration. These calibration flows were a primary reason CALVIN needed to be updated.

Calibration Summary

The results presented in the sections above for UPDATED CALVIN reflect the already calibrated values (shown in bold italics). This section discusses and summarizes calibration adjustments made to the original C2VSIM inputs.

Calibration Steps

The previous section compared UPDATED CALVIN and OLD CALVIN. This calibration section discusses the key differences between these two successfully calibrated runs. Table 4.11 presents those runs, their numbers, and a description of the runs. Starting with OLD CALVIN as a base, the newly calculated C2VSIM-based input terms were used for the “UPDATED CALVIN C2VSIM Base” run. The model solves, but the shortages were quite high in unusual ways, indicating some possibly “untrue” localized scarcity. Calibration adjustments were made for different terms in runs S07I05-S07I08 to try to minimize unrealistic scarcity. Run S07I08 is called “UPDATED CALVIN Old Delta” since it is the successfully calibrated CALVIN run with updated groundwater representation based primarily on C2VSIM, but does not include the updated Delta term constraints. Calibration adjustments were made for Delta terms in runs S07I08-S07I14. UPDATED CALVIN represents the final, calibrated run with all updates, including the updated Delta terms.

Table 4.11: CALVIN Calibration Runs

Run Name	Run Number	Description
"UPDATED CALVIN C2VSIM Base"	S07I05	The results from this run are based primarily on C2VSIM inputs as originally calculated prior to any calibration changes (external flows adjustment is included). Delta terms are based on OLD CALVIN.
"UPDATED CALVIN Old Delta"	S07I08	This is the final calibrated run based primarily on C2VSIM groundwater terms with Delta terms based on OLD CALVIN.
"UPDATED CALVIN"	S07I14	This is the final calibrated run based primarily on C2VSIM groundwater terms and a hybrid CALSIM II-OLD CALVIN-based delta pumping & exports constraints.

The calibration process was essentially split into two parts: 1) the calibration of CALVIN based on C2VSIM input terms (from UPDATED CALVIN C2VSIM Base to UPDATED CALVIN Old Delta), and 2) the calibration of the new Delta exports and pumping constraints (from UPDATED CALVIN Old Delta to UPDATED CALVIN). The section below summarizes the changes made in the entire calibration process, discussing the base calibration first, then the Delta terms calibration. A detailed description of the entire calibration process can be found in Appendix J(2) (Zikalala et al. 2012).

UPDATED CALVIN C2VSIM Base Calibration

Table 4.12 shows the resulting annual average shortages (scarcities) for the major runs. As can be seen between the UPDATED CALVIN C2VSIM Base run and the UPDATED CALVIN Old Delta run, there are significant decreases in scarcities in regions 2, 4, 6, and 18. Small decreases occur in regions 9, 12, 13, 20, and 21. These reductions in shortages are due to adjusting surface water diversion capacities, amplitudes for return flows, maximum pumping capacities, and calculated overdraft. These adjustments were made based on examining the results from each run and determining what term or factor might be causing that region to have unrealistic shortages, particularly shortages in very wet years caused by localized capacity constraints and amplitudes. Dual values for node conveyances to the subregions were considered to assess if the capacities or upper bounds were realistic for the physical system. Values that were not believed to represent "true" groundwater or capacity conditions were adjusted; these adjustments were based on comparisons with CVHM results or measured data. The shortages for each run (S07I05-S07I08) and the changes made between runs are described in more detail in Appendix J(2).

*Note that OLD CALVIN had different SWAP targets

Since the surface water loss fractions were changed in this update, the surface water diversion capacities were examined more closely for the regions with significant shortages. Table 4.13 shows the changes made to the upper bound conveyance capacity for the surface water diversions and reasons for the adjustments. In most cases, the surface water loss amplitudes (discussed in Appendix 5) are lower for UPDATED CALVIN, indicating higher surface water losses so the upper bound capacities were increased to compensate for greater losses. The link that represents surface water diversion recoverable and non-recoverable losses comes after the link that the upper bound capacity is on in the CALVIN network. To better represent the "true" upper bound capacity, the upper bound capacities were increased so that when the flow reaches the link with the associated surface water loss, the original upper bound capacity could still be delivered.

Table 4.13: Surface Water Diversion Capacity Calibration Adjustments

Subregion	CALVIN SW Diversion Link	Upper Bound Capacity (TAF/month)		Source or Reason for Adjustment
		OLD CALVIN	UPDATED CALVIN	
2	D77-HSU2D77	12.7	29.7	USBR website
	C1-HSU2C1	1.8	1.98	Compensation for increased SW losses
	C11-HSU2C11	0.7	1.03	C2VSIM

	D624-HSU13D634	57.2	62.92	Compensation for increased SW losses
	D694-HSU13D694	0.5	0.55	Compensation for increased SW losses
18	C56-HSU18C56	179.6	197.56	Compensation for increased SW losses
	C58-HSU18C58	23.1	25.41	Compensation for increased SW losses

Calibration adjustments also were made to the C2VSIM calculated groundwater terms. Table 4.14 compares the final values used for UPDATED CALVIN and the original C2VSIM calculated values. These adjustments were not all made in just one run at one time; the changes were made throughout runs S07I05-S07I08 (discussed in detail in Appendix J(II) (Zikalala et al. 2012)).

The first column of Table 4.14 shows adjustments for total applied water return flow amplitudes. These amplitudes were increased to allow more water to return to the groundwater basins. The increases for this term were mostly justified based on comparisons with CVHM return flow amplitudes (Table 3.2).

The maximum pumping capacities were adjusted for regions 9 and 18. This was done because there were large shortages that seemed unreasonable for those regions. Additionally, maximum pumping was being reached even during normal water years and comparisons of the maximum pumping capacity for those regions with CVHM values indicated that they could be higher (Table 3.4).

Change in storage values were adjusted for regions 1, 18, and 21 because the C2VSIM-based calculations of storage change did not seem to reflect physically likely storage changes in those regions. Increased groundwater storage for regions 2 and 18 just did not seem realistic, so they were adjusted to have no storage change. Considering region 21's physical area, the C2VSIM calculated overdraft of 27,903 TAF seemed too high and unlikely to be true. So rather than eliminate region 18's recharge to groundwater, that addition of groundwater was accounted for in region 21 instead. Although this doesn't follow conventional calibration methods, regions 18 and 21 are both in the Tulare region, so making this adjustment seemed reasonable, from an overall Tulare basin perspective; the total overdraft for the Tulare region based on C2VSIM is not affected. Additionally, when compared with CVHM's region 21 calculated overdraft of 5,611 TAF, the UPDATED CALVIN value is much closer than the C2VSIM calculated value.

Table 4.14: Adjustments to Groundwater Terms

Subregion	Total Applied Water Return Flow Amplitude		Maximum Pumping Capacity (TAF/month)		Overdraft (TAF)	
	C2VSIM	UPDATED CALVIN	C2VSIM	UPDATED CALVIN	C2VSIM	UPDATED CALVIN
2	0.14	0.26	-	-	-990	0
6	0.06	0.12	-	-	-	-
9	0.09	0.10	43.9	50	-	-
12	0.16	0.18	-	-	-	-
13	0.12	0.13	-	-	-	-
18	-	-	238.4	300	-11063	0
21	-	-	-	-	27903	16840

Note that "-" just indicates that no changes were made for that term for that region.

The adjustments discussed above allowed for about an average annual 360 TAF of localized scarcities to be removed from the system, as seen in Table 4.12 when comparing shortages between UPDATED CALVIN C2VSIM Base and UPDATED CALVIN Old Delta. Adjustments were made until it was obvious that regardless of reasonable adjustments, the scarcities would remain, implying real scarcity in those regions not due to unrealistic local constraints. UPDATED CALVIN Old Delta was used as a base case for the next part of the update project – updates to Delta terms.

UPDATED CALVIN Delta Exports and Pumping Calibration

Table 4.15 compares the input constraints that affect the Delta. The major pumping plants for the Delta are Banks and Tracy Pumping Plants. For this update, the Tracy pumping upper-bound constraint was left as it was in OLD CALVIN; the CALSIM II Tracy pumping constraint had comparable maximums as the constraints used in OLD CALVIN. The Banks upper-bound pumping constraint used for UPDATED CALVIN is a hybrid of CALSIM II 2009 results (DWR 2011) and OLD CALVIN’s constraints. Although CALSIM’s complex Delta flow restrictions would be a better representation of real Delta exports than OLD CALVIN’s constraints, using CALSIM results alone as constraints would be too inflexible and would result in optimization infeasibilities. The hybrid version was used so that the final Banks pumping constraint is updated to be more comparable with CALSIM II 2009 results while still being able to achieve feasible results through CALVIN’s optimization methods.

A cumulative distribution was plotted for CALSIM II’s Banks pumping constraint and it was determined that the maximum of 465 TAF was a reasonable maximum to use for the new constraint. Then, in order to bring OLD CALVIN’s Banks upper-bound to a lower value, any value for pumping for OLD CALVIN that exceeded the 465 TAF maximum was set to 465 TAF. It appeared that every value was greater than 465 TAF so 465 TAF was used to be the Banks constraint, with adjustments for number of days per month.

The Required Delta Outflow is a constrained minimum flow in CALVIN. The constraint used for UPDATED CALVIN was based on both CALSIM II 2009 and OLD CALVIN. At every month, the maximum value for Delta Export Outflow between CALSIM II 2009 and OLD CALVIN was used as the constraint for UPDATED CALVIN. This results in UPDATED CALVIN having a larger annual average Delta Export Outflow constraint.

Table 4.15: Delta Pumping Constraints and Minimum Delta Outflow

Model	**Banks Pumping Upper-bound Constraint**		**Tracy Pumping Upper-bound Constraint**		**Total Delta Pumping Upper-bound Constraint**		**Minimum Delta Outflow**	
	Annual Average (TAF/yr)	Maximum (TAF/mo)	Annual Average (TAF/yr)	Maximum (TAF/mo)	Annual Average (TAF/yr)	Maximum (TAF/mo)	Annual Average (TAF/yr)	Maximum (TAF/mo)
UPDATED CALVIN	5475	465	2169	283	7644	748	6314	1713
CALSIM II 2009	2593	472	3331	283	5924	755	4944	1320
OLD CALVIN	6158	523	2169	283	8327	806	5593	1713

Table 4.12 shows that shortages for UPDATED CALVIN are higher than that of UPDATED CALVIN Old Delta. This is expected because in an attempt to have pumping capacity constraints and Delta exports be closer in comparison to CALSIM II 2009, there is less pumping and more required Delta outflow in UPDATED CALVIN than in OLD CALVIN (and UPDATED CALVIN Old Delta). As seen in the results, when the Delta terms were updated, there was more scarcity in the Sacramento region, which also agrees with the idea of more export outflow and lower pumping.

Table 4.16 shows the results from the CALVIN run for the Banks Pumping Plant and Tracy Pumping Plant. Although new constraints were used, the total annual average Delta pumping remained very close in comparison between the two models. This is interesting considering that UPDATED CALVIN has more Delta required outflow, and a tighter constraint for Banks pumping plant. This indicates that the upper bound constraint is reached more often in the Banks pumping plant in UPDATED CALVIN.

Table 4.16: Average Annual Delta Pumping Results (TAF/yr)

	UPDATED CALVIN	OLD CALVIN	CALSIM II 2009
Banks Pumping	4,383	4,906	2,984
Tracy Pumping	942	462	2,496
Total Delta Pumping	5,325	5,368	5,479

UPDATED CALVIN Results

This section presents and discusses the major run results for UPDATED CALVIN and compares them with OLD CALVIN's results.

Targets, Deliveries, and Scarcities

Table 4.17a shows the agricultural targets, deliveries and shortages for the model results. As mentioned before, the targets are different between the models because results from an updated version of SWAP were used to define water delivery targets for UPDATED CALVIN. One major problem with OLD CALVIN was that 2 million acre-feet of calibration flows out of the system were needed to have reasonable results, indicating that there was generally too much inflow in the system. With too much water in the system, scarcity is likely to be small, as seen in the last column of Table 4.17a. The scarcities for UPDATED CALVIN, though larger, are more reasonable and seem to better represent actual water scarcity, and omit the earlier 2 MAF/yr of calibration demands. The updated model has a much better physical basis.

Table 4.17a: UPDATED CALVIN and OLD CALVIN Agricultural Targets, Deliveries, and Scarcities (TAF/yr)

Central Valley Total	20670	20787	20246	20750	424	37

Table 4.17b shows the urban targets, deliveries, and scarcities. As seen in the table, there are no differences between OLD CALVIN and UPDATED CALVIN in the Central Valley. Slight differences between the models in deliveries and scarcities can be seen in Southern California. Since the differences in urban deliveries are very small in comparison to the agricultural deliveries, the rest of this chapter will focus on the differences that apply to the agricultural side of the models.

Table 4.17b: UPDATED CALVIN and OLD CALVIN Urban Targets, Deliveries, and Scarcities (TAF/yr)

CALVIN Delivery Region	**Target**		**Delivery**		**Scarcity**	
	UPDATED CALVIN	OLD CALVIN	UPDATED CALVIN	OLD CALVIN	UPDATED CALVIN	OLD CALVIN

Water Deliveries and Recharge

Total water deliveries include water pumped from the ground and surface water deliveries. The first two columns of Table 4.18 show the groundwater pumping and surface water deliveries. The targets are different between the two runs (as shown in Table 4.17), but it is still useful to compare the total pumping and total surface water deliveries. As seen in groundwater pumping column, UPDATED CALVIN pumps over 2 MAF less groundwater than OLD CALVIN. Similarly on the surface water side, UPDATED CALVIN uses over 2.5 MAF more surface water than OLD CALVIN. This is due mostly to the successful removal of 2 MAF/yr of calibration demands present in OLD CALVIN.

With smaller total deliveries, it could be expected that the groundwater return flow is also smaller for UPDATED CALVIN. However, UPDATED CALVIN has additional representation of artificial recharge in the Tulare region. Interestingly, when considering total recharge to the groundwater basins for UPDATED CALVIN, it sums to be more recharge than in OLD CALVIN.

Table 4.18: Average Annual Groundwater Pumping, Surface Water Deliveries, Groundwater Return Flow, and Artificial Recharge Results (TAF/yr)

Subregion	GW Pumping		SW Deliveries		GW Return Flow		Artificial Recharge

Change in Storage

CALVIN does not model actual storage capacities, but models the change in storage volume. The initial storage, as mentioned earlier, is an input term to CALVIN and is essentially just a reference starting point for the model. CALVIN outputs actual storage values, but they are relative to the set initial storage. For these models, change in storage has to be compared rather than the model output for storage since the initial storages differ between models. The changes in storage were calculated based on the model run output storage values for each region. Figures 4.2 - 4.4 show the change in storage by Central Valley region (Sacramento, San Joaquin, and Tulare) for UPDATED CALVIN and OLD CALVIN. Sacramento is the sum of Regions 1-9, San Joaquin is the sum of Regions 10-13, and Tulare is the sum of regions 14-21. Negative change in storage values indicate overdraft.

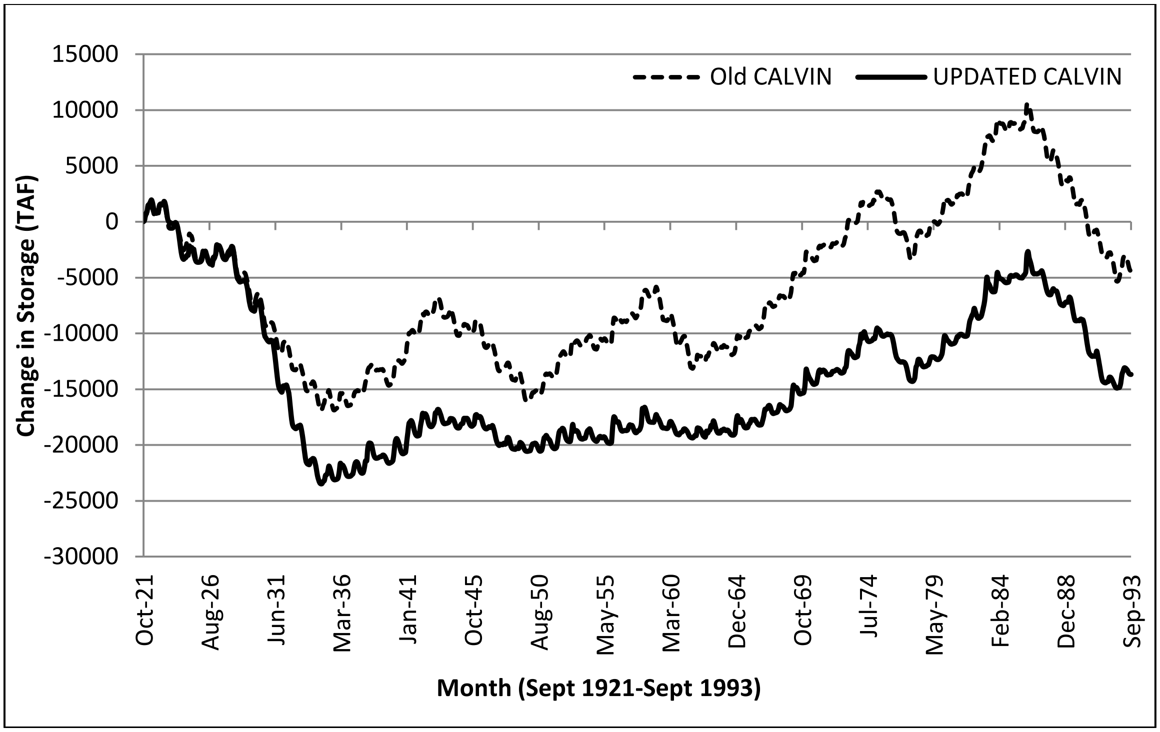

Figure 4.2: UPDATED CALVIN Sacramento Region (Basins 1-9) Change in Storage

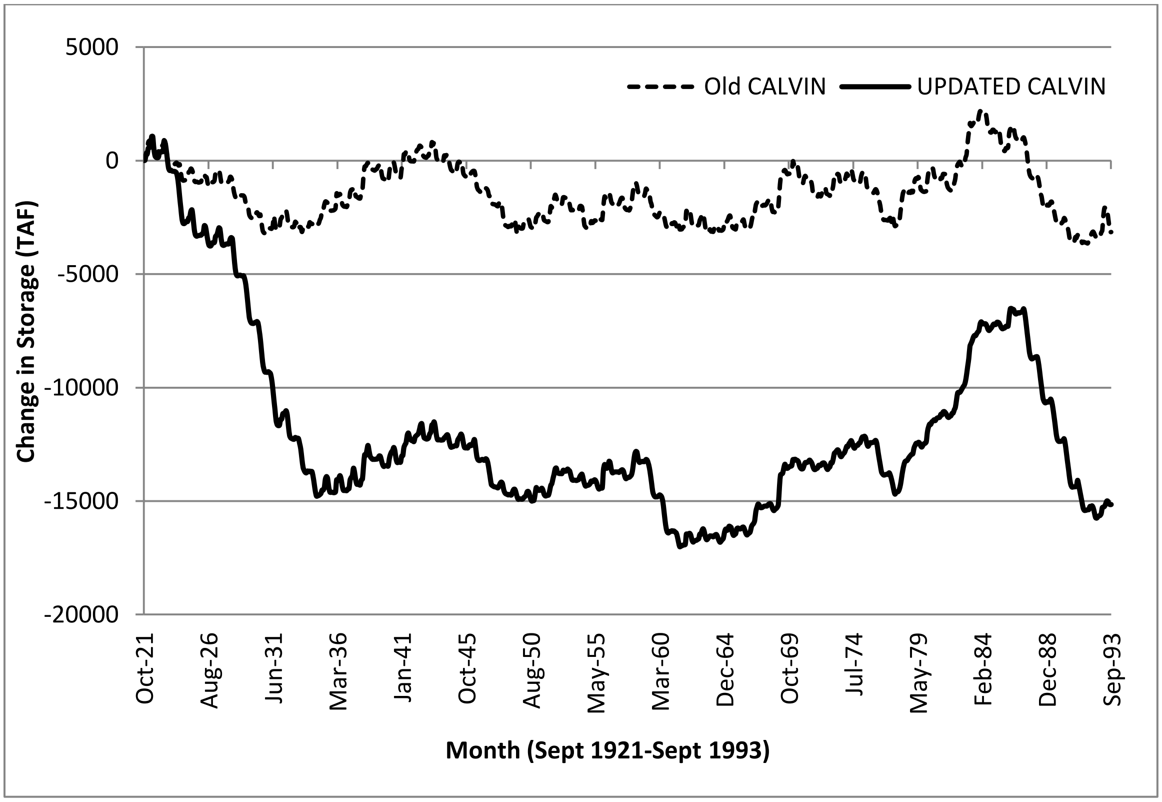

Figure 4.3: UPDATED CALVIN San Joaquin Region (Basins 10-13) Change in Storage

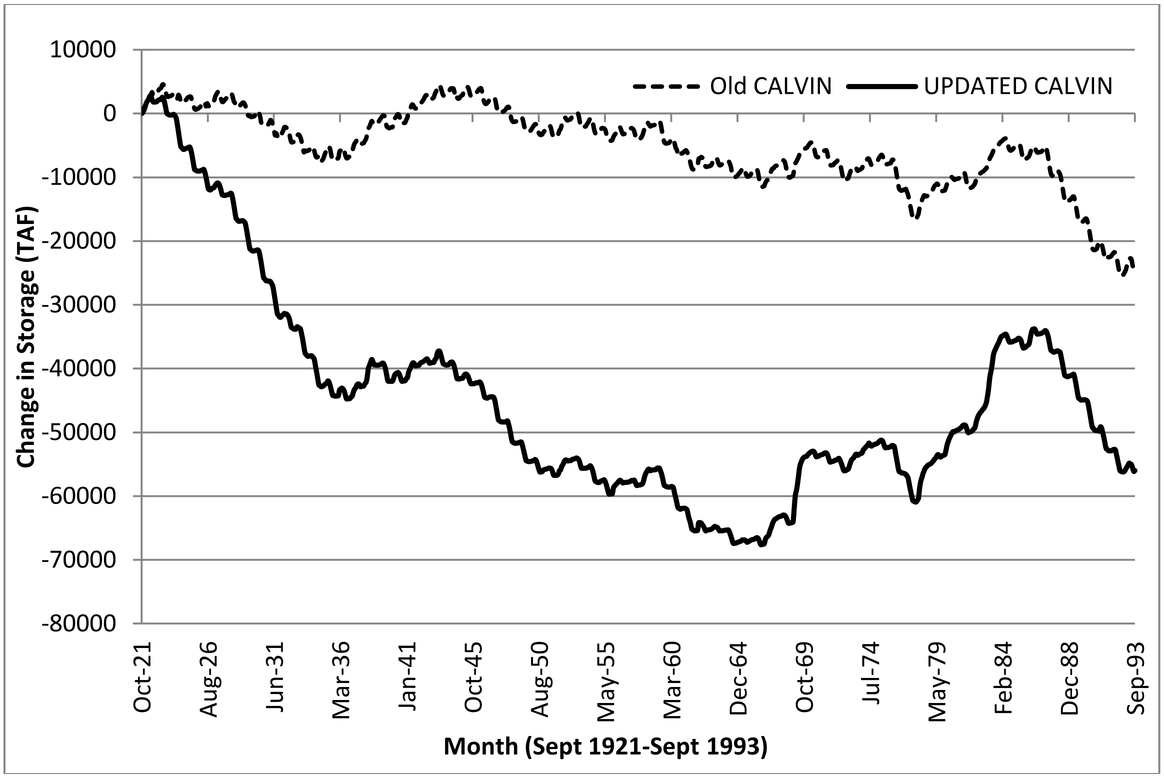

Figure 4.4: UPDATED CALVIN Tulare Region (Basins 14-21) Change in Storage

For all three Central Valley regions, UPDATED CALVIN has more overdraft overall than OLD CALVIN, agreeing more with both C2VSIM and CVHM. Change in Storage for both CALVIN models follow similar trends that agree with seasonal variations and year types, but UPDATED CALVIN's changes are greater and have more overdraft. These change in storage results help confirm the scarcity results in Table 4.16. Considering the Tulare region, scarcities were much higher for UPDATED CALVIN, and as can be seen in Figure 4.4, the overdraft difference is large. This also falls into line with the impression that OLD CALVIN had too much water in the system and its representation of groundwater was not always reasonable. The overdraft implied by UPDATED CALVIN agrees better with other studies on overdraft in the Central Valley, including CVHM's representation. Chapter 5 will discuss some different overdraft scenarios and their effects on the Central Valley.

System Costs

Many changes were made to UPDATED CALVIN, so the system's overall costs were affected. Table 4.19 shows the average annual system costs. The only changes to operating cost values for this update project were the groundwater pumping lift costs and the added artificial recharge costs; all other operating costs were not changed. These changes are reflected in the costs in the table. Scarcity costs are directly related to the scarcity estimates (Table 4.17), but follow seasonal patterns of demands and availability.

UPDATED CALVIN has overall lower pumping costs in the Central Valley, agreeing with Table 4.5, with lower pumping lifts and costs for UPDATED CALVIN. Surface water and other operating costs are not affected much. UPDATED CALVIN's artificial recharge adds an average annual $3 million/year in average costs. OLD CALVIN has much lower scarcity costs because there was much less scarcity in that version of CALVIN (Table 4.17). Overall, UPDATED CALVIN has about an annual average of $40 million (4%) less system costs than OLD CALVIN.

Table 4.19: Average Annual Central Valley System Costs ($millions/yr)

Costs	**UPDATED CALVIN**	**OLD CALVIN**
Groundwater Pumping	361	450
Surface Water Pumping	426	427
Artificial Recharge	3	0
Other[1]	294	264
Central Valley Operating Costs*	**$1,084**	**$1,141**
Scarcity Costs	21	4
Central Valley System Costs	**$1,105**	**$1,145**

[1] Other costs include: treatment, recycled water, and desalination.

*Total Operating Costs does not include hydropower benefits.

Results Summary

Table 4.20 summarizes the average annual results for the Central Valley (Regions 1-21) for UPDATED CALVIN. The percent differences from OLD CALVIN are also presented. Overall, UPDATED CALVIN has lower targets and lower deliveries; UPDATED CALVIN pumps 28 percent less groundwater and delivers14 percent more surface water than OLD CALVIN. This decreased pumping is a direct effect of the new input terms for UPDATED CALVIN. With the new groundwater representation, the scarcity for UDPATED CALVIN is 10 times that of OLD CALVIN, which better represents actual water scarcity in the Central Valley. Total Delta pumping is slightly lower in UPDATED CALVIN, but Tracy pumping for UPDATED CALVIN is more than two times that of OLD CALVIN; this increase in Tracy pumping is due to the lower Banks pumping constraint in UPDATED CALVIN. For total groundwater recharge, there is a 2 percent increase for UPDATED CALVIN, primarily due to the addition of artificial recharge representation. Total Central Valley overdraft for UPDATED CALVIN is nearly three times the amount of overdraft in OLD CALVIN; this new overdraft value is comparable with CVHM total overdraft ((Faunt et al. 2009) and DWR's Bulletin 118's estimated values (DWR 2003). Total system costs are 4% less for UPDATED CALVIN than OLD CALVIN.

Table 4.20: Updated CALVIN Summary – Average Annual Results

Results	OLD CALVIN	UPDATED CALVIN	
	Annual Average (TAF/yr)	Annual Average (TAF/yr)	% Difference
Total Central Valley Agricultural Target	20,787	20,670	-1%
Total Central Valley Agricultural Delivery	20,750	20,246	-2%
Agricultural GW Pumping	8,284	5,992	-28%
Agricultural SW Delivery	12,466	14,254	+14%
Total Central Valley Agricultural Scarcity	37	424	+1046%
Total Delta Pumping	5,368	5,325	-1%
Banks Pumping	4,906	4,383	-11%
Tracy Pumping	462	942	+104%
Total GW Recharge	3,267	3,338	+2%
Total Central Valley Return Flow	3,267	2,889	-12%
Total Central Valley Artificial Recharge	0	449	+100%
Total Central Valley Overdraft	394	1,160	+194%
Total Central Valley System Costs	$1,145	$1,105	-4%

Conclusions

This update project has greatly improved several aspects of CALVIN groundwater. First, schematic improvements were made to simplify the flows in and out of each CVPM groundwater basin. And overall, Central Valley groundwater representation in CALVIN has been greatly improved.

Many of the problems associated with OLD CALVIN's groundwater representation could be attributed to the problems with CVGSM (LaBolle 2003). Models like CALVIN can help inform water management decisions for a wide range of conditions. However, conditions are constantly changing so timely updates are needed to maintain the usefulness of the model. The inputs to CALVIN need to come from a trusted source or model that represents actual, or at least reasonable water and water use conditions. C2VSIM's groundwater representation is much more explicit and reasonable than the older CVGSM. However, C2VSIM results are not always close in comparison with other groundwater models (i.e. CVHM). With different representations and results, groundwater input terms to CALVIN can be very different and would overall represent groundwater very differently. It is important to remember this when considering UPDATED CALVIN results; errors and discrepancies in the C2VSIM groundwater model also carry over into CALVIN's groundwater representation. Nonetheless, this project provides a more accurate and up-to-date representation of Central Valley groundwater in CALVIN.

CHAPTER 5

Groundwater Overdraft in California's Central Valley

This chapter discusses an application of the updated CALVIN model to three groundwater overdraft cases in California's Central Valley. Overdraft is defined as a negative change in groundwater storage from the beginning to end of the model period. The comparison of study results shows potential effects of different levels of overdraft and confirms that the model is behaving well. All three model cases use the updated CALVIN model as a base and result in feasible solutions. Increasing Delta exports and surface water use are the primary adaptations to ending overdraft (aided by artificial recharge). Greater agricultural scarcity is the second adaptation.

Background

Groundwater overdraft occurs when groundwater extraction exceeds recharge over a long period. In California, few statewide regulations currently exist on groundwater extraction and water users commonly turn to groundwater use when demands cannot be met by surface water supplies. Continued overdraft of groundwater basins gradually depletes groundwater availability and can be environmentally detrimental (i.e. subsidence, increased nitrate leaching, and water quality degradation). Despite these negative consequences, some areas continue to pump groundwater at unsustainably high rates. Using a hydro-economic optimization model like CALVIN to study overdraft shows not only the basic, physical water system effects (i.e. effects on Delta pumping and recharge), but also some economic effects. CALVIN was previously used in a case study of the Tulare Basin that examined the economic effects of different management strategies to end overdraft in that basin (Harou and Lund 2007). Similar to the Tulare Basin case study, this overdraft study examines the economic effects of different overdraft scenarios. However, the 2007 Tulare Basin study had cases based on different management options for ending overdraft, whereas the study presented here uses different groundwater models' results to represent overdraft and compare those to a case without overdraft. This approach provides insight for managing overdraft in the Central Valley and also illustrates the consequences of remaining uncertainties in groundwater availability in the Central Valley.

Case Description

Of the three overdraft cases (Table 5.1), the first case is the "Base" updated CALVIN run with overdraft largely based on C2VSIM. In the "No Overdraft" case, no overdraft is allowed; all basin ending storage values were set to the basins' initial storage values. The "Higher Overdraft" case is a CVHM-C2VSIM-based overdraft scenario. Initially, there was a CVHM-based overdraft case, but since CVHM has major differences in groundwater representation of the Sacramento Valley (discussed in Chapter 3), there would not be a feasible CALVIN result based solely on CVHM overdraft results without new calibration. Instead, a semi-CVHM overdraft case was created using the updated CALVIN overdraft for subregions 1-9 (Sacramento region) and using the typically higher CVHM overdraft for subregions 10-21 (San Joaquin and Tulare regions).

Table 5.1: Overdraft Cases Description

Case Name	Run Number	Case Description
Base	S07I14	UPDATED CALVIN with overdraft based on C2VSIM with calibration adjustments. (1.2 MAF/yr Valley-wide).
No Overdraft	S07I14a	No overdraft (initial storage = ending storage).
Higher Overdraft	S07I14b	Overdraft for subregions 1-9 are the same as UPDATED CALVIN. Greater Overdraft for subregions 10-21 is based on CVHM. (1.45 MAF/yr Valley-wide).

Table 5.2 presents the total overdraft and average annual overdraft (1921-1993) per subregion for each case. Higher Overdraft is based on CVHM calculated overdraft for the San Joaquin and Tulare regions. CVHM has slightly less overdraft than the Base case in the San Joaquin region, but has significantly more overdraft in the Tulare region. Comparing the Central Valley totals with the Base run, the No Overdraft case has 84 MAF less groundwater available for use over the 72 years and the Higher Overdraft case allows 20 MAF more groundwater to be used over the 72 years. The results from these runs are presented and discussed below.

Table 5.2: 1921 – 1993 Overdraft Cases*

Subregion	Base		No Overdraft		Higher Overdraft

*Positive values represent a depletion of storage over time and negative values represent gains to groundwater over time.

CALVIN Study Results

This section discusses the results from this study. First, the average annual scarcities and water deliveries are presented, followed by a discussion of the recharge differences. Next, the time series for storages for each region are compared in plots, showing the differences in storage over time between the cases. Then the willingness-to-pay values, scarcity costs, and operating costs are tabulated and discussed. Finally, a summary table of the average annual results with the percent differences between the results for the different cases is presented.

Water Scarcity and Deliveries

Water scarcity is defined as the amount of target water delivery not supplied by the model to meet demands. These results are shown in Table 5.3. Ending overdraft increases water shortages statewide because there is not enough available surface water to meet all demands if groundwater is not overdrafted. As expected, the No Overdraft case has nearly double the water scarcity of the Base case and the Higher Overdraft case has less scarcity than the Base case.

Tulare	222	404	205
Central Valley Total	424	831	372

Table 5.4 compares the average annual Delta pumping for the three cases. Of the 1.2 MAF annual averaged reduction of overdraft in the No Overdraft case (compared to the Base case), approximately 0.4 MAF of that reduction becomes greater scarcity (Table 5.3) and the rest of the reduction is made up by higher Delta exports. For the system to maintain the Delta outflow requirement (discussed in Chapter 4) and have no reductions to southern California water supply, nearly 0.8 MAF/year more water is pumped from the Delta. So to account for the 1.2 MAF of water not available due to having no overdraft supplies in the No Overdraft case, there is 0.4 MAF of increased water scarcity in the Central Valley and 0.8 MAF increased Delta exports. And as expected, when comparing the Base case with the Higher Overdraft case, the increased supply from higher overdraft decreases Delta pumping and water scarcity.

Table 5.4: Overdraft Study Results – Average Annual Delta Exports (TAF/yr)

	Base	No Overdraft	Higher Overdraft
Banks Pumping	4,383	4,470	4,283
Tracy Pumping	942	1,614	726
Total Delta Pumping	5,325	6,084	5,009

Table 5.5 shows average annual groundwater pumping and surface water deliveries. The No Overdraft case significantly reduces average annual groundwater pumping and increases surface water deliveries. Even with the increased surface water use, there is still much scarcity. The Higher Overdraft case has more groundwater pumping, less surface water reliance, and less scarcity.

Table 5.5: Overdraft Study Results – Average Annual Agricultural Water Deliveries (TAF/yr)

Table 5.6 shows the average annual urban water deliveries and scarcities. Similar to the results comparison between OLD CALVIN and UPDATED CALVIN, the differences in overdraft cases do not affect urban deliveries in the Central Valley. Slight differences can be seen in the deliveries in Southern California. The No Overdraft case results in a higher scarcity total in Southern California whereas the higher overdraft case results in a slightly lower total scarcity in Southern California. Since differences in urban deliveries are non-existent in the Central Valley and small for Southern California, the rest of this chapter will focus on comparisons of agricultural related aspects of the models.

Table 5.6: Overdraft Study Results – Average Annual Urban Water Deliveries and Scarcities (TAF/yr)

CALVIN Delivery Region	Delivery			Scarcity		
	Base	No Overdraft	Higher Overdraft	Base	No Overdraft	Higher Overdraft
Sacramento	1609	1608	1608	0.3	0.3	0.3
San Joaquin	1571	1571	1571	0	0.0	0.0
Tulare	1279	1279	1279	5.1	5.1	5.1
Central Valley Total	4459	4458	4458	5.4	5.4	5.4
Southern California	6648	6645	6648	192.1	194.8	191.8

Recharge

Table 5.7 shows the average annual return flows and artificial recharge flows to groundwater for each region. Considering just groundwater return flow, the No Overdraft case has less return flow to groundwater and the Higher Overdraft case has slightly more return flow to groundwater. The smaller return flow to groundwater in the No Overdraft case is due to overall decreased delivered water to meet the agricultural demand (hence the increased scarcity); less water delivered proportionally reduces agricultural return flows to groundwater.

The artificial recharge result shows one way that overdraft is detrimental to the overall water system. The No Overdraft case increases use of artificial recharge, an action that should be encouraged and is effective in maintaining groundwater storage overtime. However, maintaining and using artificial recharge is generally more expensive in the short term. CALVIN has a link cost for using artificial recharge. The No Overdraft case drives the system to increase use of artificial recharge capabilities since there is a shortage of water and the no overdraft condition in the groundwater basins needs to be maintained. This conjunctive use approach helps allow more groundwater to be used because it is replenished artificially when surface water is abundant. This allows scarcity to be less than total reductions in available water supply due to the no overdraft constraint (met by increased surface water use and increased Delta exports). In contrast, the Higher Overdraft case reduces use of artificial recharge since it can meet more demands through pumping (the economically cheaper option) and is not required to maintain a condition of no overdraft. Considering that these artificial recharge facilities and capabilities are assumed to be in place for all three cases, general increased use of artificial recharge should be encouraged. This agrees with the results from Harou and Lund (2007), where ending overdraft significantly increases the economic value of additional recharge capacity and when there is overdraft, less artificial recharge occurs since maintaining groundwater storage levels is not a constraint. Adding artificial recharge capacity can help lower the cost of ending overdraft. However, if there is enough available supply from (over)pumping groundwater and nothing to require users to recharge water back to the groundwater basins, it is more economical in the short term to just pump more water and return less to the ground (in real practice and in the CALVIN model). Although it may be more economical in the short term to continue over-pumping groundwater, continued overdraft of groundwater basins will eventually increase pumping costs due to higher depths to groundwater as well as environmental problems. Increased pumping lift over time is not represented in CALVIN.

Considering total recharge to groundwater (groundwater return flow + artificial recharge), the No Overdraft case has the highest recharge of the three cases. In CALVIN, this higher recharge is needed to maintain the no overdraft constraint because the solver will do what satisfies constraints and results in the smallest overall cost, driven primarily by meeting demands since shortage costs are high. CALVIN will maximize the amount of water returned to the ground so that groundwater pumping can increase to levels that fall within the no overdraft constraint.

Table 5.7: Overdraft Study Results – Recharge flows to Groundwater (TAF/yr)

Total Central Valley	2,889	2,831	2,899	449	566	345	3,338	3,397	3,244

Storage

Figures 5.1 – 5.3 show the storages by Central Valley region (Sacramento, San Joaquin, and Tulare) for the three cases. All cases' storages follow similar trends that agree with seasonal variations and year types, but the no overdraft case ensures that the initial storage equals the ending storage. Comparing the Base case with the Higher Overdraft case, the Sacramento region is very similar since it has the same representation; the slight decreases in storage in the Sacramento region for the Higher Overdraft case can be attributed to some water from the north being sent to the south to supply demands.

As seen in Figure 5.2, the Higher Overdraft case actually has less overdraft in the San Joaquin region (it was called the Higher Overdraft case since overall Central Valley overdraft is higher). Figure 5.3 shows the large differences in the overdraft allowances in the Tulare region between the cases. All cases in each region have the same initial storage in the figures below.

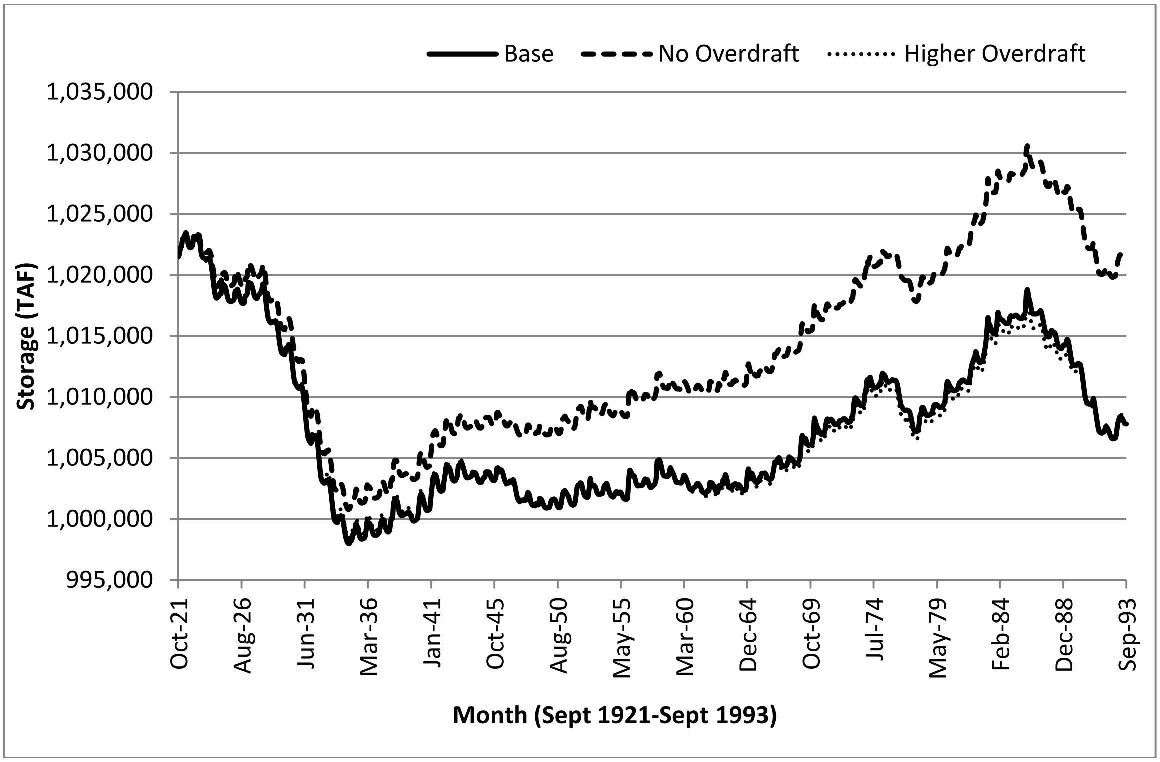

Figure 5.1: Overdraft Study Results – Sacramento Region (Basins 1-9) Storage

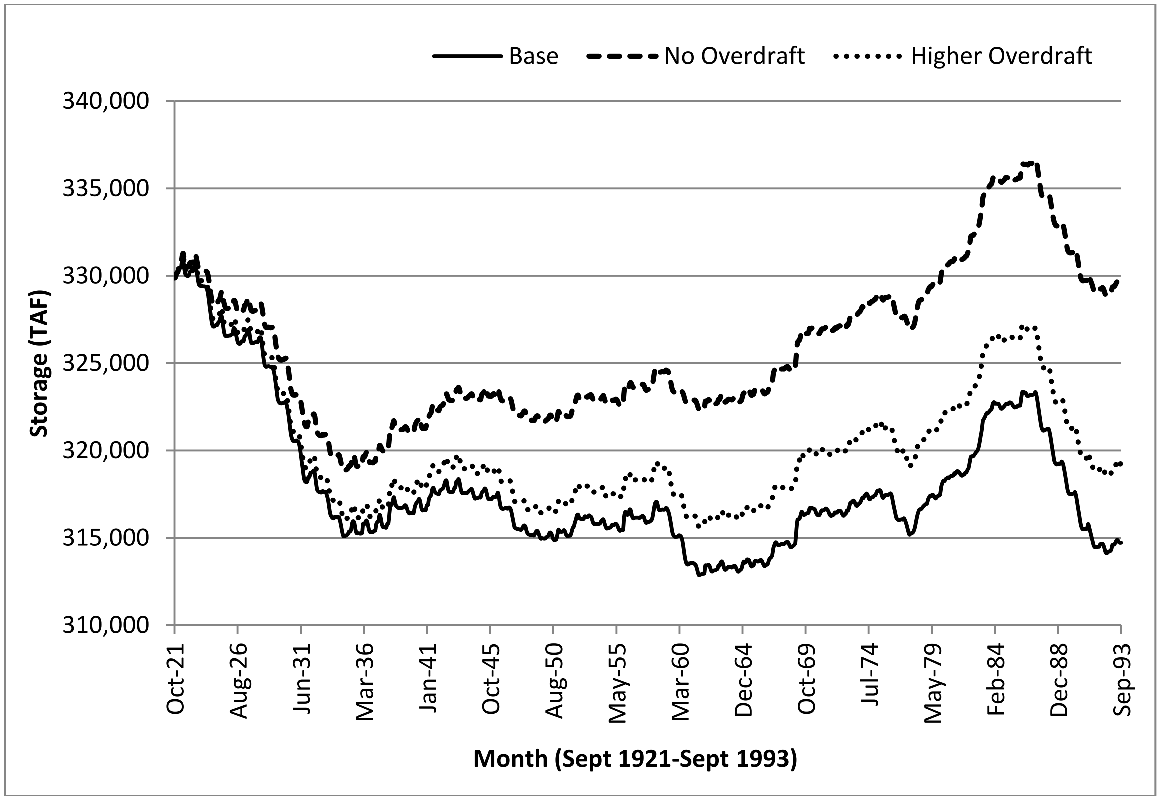

Figure 5.2: Overdraft Study Results – San Joaquin Region (Basins 10-13) Storage

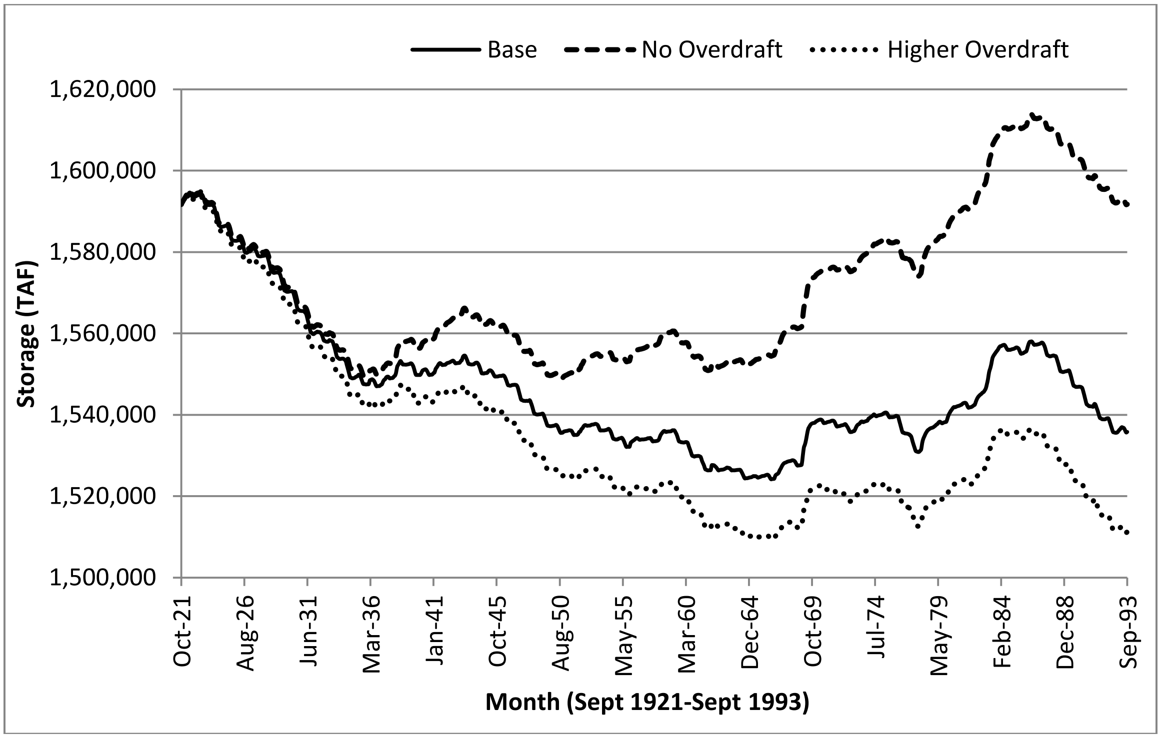

Figure 5.3: Overdraft Study Results –Tulare Region (Basins 14-21) Storage

Willingness-to-pay and Scarcity Costs

The average annual marginal willingness-to-pay (WTP) and scarcity costs are presented in Table 5.8. Marginal WTP reflects what demand areas with shortages would be willing to pay for an additional acre-foot of water; demand areas without scarcity, by definition, have no marginal WTP. Marginal WTP is estimated as the slope of the economic benefit function at the delivered water quantity. Each unit of water goes to the demand area with the highest WTP, if possible, ensuring that the highest value uses are supplied first when possible.

The No Overdraft case has a higher marginal WTP compared to the other two cases because less water is available, creating more scarcity. Comparing the two cases that allow overdraft, the Base case has a higher marginal WTP than the Higher Overdraft case since the Base case has higher scarcities with less available water, and would be willing to pay more for additional water.

Scarcity costs are directly related to the scarcity estimates (Table 5.3), but seasonal variations follow seasonal patterns of demands and availability. Overall, the No Overdraft case has the highest scarcity cost and the Higher Overdraft case has the lowest. The next section compares the Central Valley system costs, including operating costs.

Operating Costs

The different overdraft cases affect operating costs throughout the Central Valley. Table 5.9 shows the average annual operating costs and Central Valley system costs. The No Overdraft case has lower groundwater pumping costs than the other two cases. This is expected since there is less groundwater pumpage in the No Overdraft case (Table 5.5). The Higher Overdraft case has slightly higher groundwater pumping costs, not reflected in the table due to rounding. As expected, the No Overdraft case has higher surface water pumping costs than the Base case, and the Higher Overdraft case has less surface water pumping costs. Since there is little difference between the groundwater pumping costs of the Base case and the Higher overdraft case, the operating cost results indicate that pumping just a little more groundwater to meet demands is cheaper than using additional surface water. Artificial recharge costs are highest for the No Overdraft case and lowest for the Higher Overdraft case. Total operating costs are highest for the Base case, followed by the No Overdraft case, and then the Higher Overdraft case.

Overall, when also considering the scarcity costs, the No Overdraft case has the highest system costs. Although there are increases in the use of surface water and artificial recharge in the No Overdraft case, their capacities are unable to overcome all reductions in water availability, resulting in larger scarcities and thus larger scarcity costs. The Higher Overdraft case has the lowest system and operating costs, indicating that being able to pump more groundwater is still more economical than pumping less groundwater. If artificial recharge capacities could be increased or if there were higher costs for pumping groundwater (i.e. a tax, policy, or increased lifts represented), then pumping less and reducing overdraft might be economical. With no regulations on groundwater use and not considering the environmental and long-term effects of overdraft, CALVIN results show that it is more economically beneficial to overdraft groundwater to meet demands as best as possible, rather than pump less or end overdraft, if overdraft has no additional cost.

Comparing total Central Valley costs, the cost of ending overdraft in all Central Valley groundwater basins is at least $23 million/year, assuming that the Base case has good overdraft representation. Without economically-minded re-operation, the actual costs could be much higher. Completely ending overdraft in the Central Valley at one time is not possible, but taking steps towards having less reliance on over-pumping groundwater is. This can be done by improving efficiencies, promoting more recharge (artificial or natural), and conjunctive use, with a side-effect of increasing Delta exports unless agricultural deliveries are decreased. More discussion on viable management options for ending overdraft can be found in Harou and Lund 2007.

Table 5.9: Overdraft Study Results – Average Annual Central Valley System Costs ($millions/yr)

Costs	Base	No Overdraft	Higher Overdraft
Groundwater Pumping	361	315	361
Surface Water Pumping	426	460	416
Artificial Recharge	3	4	2
Other[1]	294	295	293
Total Operating Costs*	**$1,084**	**$1,074**	**$1,072**
Scarcity Costs	21	53	18
Total System Costs	**$1,105**	**$1,128**	**$1,090**

[1] Other costs include: treatment, recycled water, and desalination.
*Total Operating Costs does not include hydropower benefits.

Results Summary

Table 5.10 summarizes the average annual results for the entire Central Valley (Subregions 1-21) for this overdraft study and percent differences from the Base case. Overall, there is less total delivery in the No Overdraft case and more delivery in the Higher Overdraft case, with the largest factor for delivery differences being groundwater pumping. The No Overdraft case pumps 12 percent less groundwater than the base and increases surface water use by 2 percent and artificial recharge by 26 percent, but still nearly doubles scarcity. The Higher Overdraft case pumps more groundwater and uses less surface water, and has less overall scarcity. Delta pumping increases by 14% from the Base case to the No Overdraft case since there is less available groundwater in the No Overdraft case; the opposite effect happens for the Higher Overdraft case (decreased Delta pumping). More artificial recharge to groundwater occurs in the No Overdraft case to allow more use of surface water and even out water availability. The Higher Overdraft case has less artificial recharge since more groundwater is available in this case. Total system and operating costs are highest for the No Overdraft case and lowest for the Higher Overdraft case. The marginal willingness-to-pay for extra water and scarcity costs are highest for the No Overdraft case since that case has the most scarcity.

Table 5.10: Overdraft Study Summary – Average Annual Results

Result (TAF)	Base	No Overdraft		Higher Overdraft	
	Avg. Annual	Avg. Annual	% Difference	Avg. Annual	% Difference
Total Central Valley Overdraft (TAF/yr)	1,172	0	-100%	1,450	+24%
Total Central Valley Delivery (TAF/yr)	20,246	19,839	-2%	20,298	+0.3%

Total Delta Exports (TAF/yr)	5,325	6,084	+14%	5,009	-6%
Banks Pumping (TAF/yr)	4,383	4,470	+2%	4,283	-2%
Tracy Pumping (TAF/yr)	942	1,614	+71%	726	-23%
Total GW Recharge (TAF/yr)	3,338	3,397	+2%	3,244	-3%
Return Flow (TAF/yr)	2,889	2,831	-2%	2,899	+0.3%
Artificial Recharge (TAF/yr)	449	566	+26%	345	-23%
Total System Costs (million $/yr)	1,105	1,128	+2%	1,090	-1%
Operating Costs (million $/yr)	1,084	1,074	-0.9%	1,072	-1%
Scarcity Cost (million $/yr)	21	53	+152%	18	-14%
Maximum WTP ($/AF)	677	1,011	+49%	658	-3%

Conclusions

This overdraft study is just one of the many possible applications of the updated CALVIN model. Many other overdraft cases could be explored with Updated CALVIN, but some would require additional calibration. The cases chosen for this study did not need additional calibration and show some basic comparisons between the groundwater models (CVHM and C2VSIM) and a No Overdraft case, providing some policy and operations insights.

As discussed in Chapter 3, CVHM and C2VSIM have many significant differences in representing Central Valley groundwater. The Higher Overdraft case had only differences for Regions 10-21, but these differences affect the entire system, water diversions, and scarcities. This shows how different regional representations can affect system-wide results and how important it is to pick a model with reasonable results as a base.

The No Overdraft case provides some insight into how the system and system costs would change to end overdraft. It implies that an immediate switch to completely ending overdraft would raise costs, but the results also show that improving recharge and increasing Delta exports would reduce increases in water scarcity. Additional artificial recharge evens out surface water availability, allowing for more surface water to be used and for more consistent deliveries between wet and dry years. However, unless there are direct, immediate benefits to the water users or policies that require less over-pumping or more recharge, it is unlikely that water users will take it upon themselves to pay more for a benefit that they don’t immediately see.

Along with giving useful insights for overall groundwater management and policy, this study also confirmed that Updated CALVIN is behaving as it should and that its results make some practical sense.

CHAPTER 6

Conclusions

Integrated hydro-economic modeling is useful for examining the benefits and drawbacks of existing or proposed water policies, operations, and plans. However, water conditions, regulation, demands, and estimates are constantly changing, so timely updates are needed to maintain and improve the usefulness of models. New models with new data are constantly being developed, and incorporating newer data can make hydro-economic models, like CALVIN, more useful. In an effort to make the most of available resources and include a reasonable groundwater representation in CALVIN, C2VSIM was primarily used in this groundwater update project. This project provides a more accurate and up-to-date representation of Central Valley groundwater in CALVIN, which can lead to studies investigating the economic impacts of Central Valley groundwater use and provide an additional framework for groundwater policy discussions. The CALVIN improvements from this project are summarized below.

CALVIN Improvements

Many improvements were made to the CALVIN model. These include updating and improving the model's representation of Central Valley groundwater, updating the Delta pumping constraints to better reflect actual conditions, and improving the model network and schematic to be more explicit and include some artificial recharge. These improvements are summarized in Table 6.1.

Table 6.1: Improvements to CALVIN

Central Valley
Updated agricultural demands to match current SWAP estimates
Updated existing groundwater term inputs with new, more accurate values
Added some new groundwater terms for more detailed representation of the system
Eliminated 2 MAF of calibration outflows (from the previous version of CALVIN)
Added explicit representation of artificial recharge for some regions in the Tulare Basin
Delta Pumping
Updated Banks Pumping Plant constraint
Updated Delta Export Outflow
Network and Schematic
Added artificial recharge nodes and links for some regions in the Tulare Basin
Added hidden nodes and links for groundwater pumping
Added hidden nodes and links for urban groundwater return flow

Central Valley

The updated agricultural demands based on updated SWAP reduced demands by an average of 117 TAF/year. The changes to the agricultural return flow splits, internal reuse amplitudes, applied water return flow amplitudes, external flows, pumping capacities, pumping costs, storage constraints, and urban return flow amplitudes based primarily on C2VSIM significantly changed how CALVIN models water in the Central Valley. The elimination of 2 MAF of calibration outflows strengthens CALVIN because the model now has a tighter and more explicit representation of Central Valley mass balances of water, more reasonable results, and its groundwater interaction is balanced without the additional calibration flows. The addition of explicit artificial recharge representation allows for an important recharge practice to be represented in the model. The groundwater representation in the updated CALVIN model is more explicit and accurate, making the model more useful.

Delta Pumping

Updates to Delta pumping and outflow were made based on both CALSIM II 2009 and what was previously in CALVIN. Since CALVIN is an optimization model, its Delta pumping and outflows cannot be expected to be the same as a simulation-based model like CALSIM, but incorporating aspects of CALSIM into CALVIN makes CALVIN more relatable to CALSIM and real-life applications.

Network and Schematic

The improvements made to the CALVIN network simplify the direct interactions with the Central Valley groundwater subbasins. The urban and pumping hidden nodes result in fewer direct flows going in and out of each groundwater subbasin, allowing for easier comparisons of results and mass balances.

Conclusions from CALVIN Modeling

The updated CALVIN model was used to study how a few different overdraft cases could affect model results, as well as system economics and management. Three cases were examined: the base case, no overdraft, and higher overdraft. These three cases have significantly different results, as expected. With the no overdraft case, water scarcities were highest and drove the system to increase surface water use and artificial recharge to groundwater. Overall system and operating costs were lowest for the highest overdraft scenario, suggesting that being able to pump more groundwater is the more economical option, which agrees with current, real practices.

This study shows immediately ending overdraft in the Central Valley would have high costs and that including and increasing artificial recharge capacities can benefit the overall water system. Currently, overdrafting groundwater is common, with lower costs. However, with groundwater availability decreasing, pumping costs likely increasing, and environmental effects of overdraft worsening, overdraft will be an increasing problem in the future and may have other costs associated with it not included in CALVIN. Options to mitigate overdraft include: increasing recharge use and capacities (artificial and natural), increase in water reuse, more conjunctive use, more surface water use, and decrease in water use and demands. Although there are many possible solutions, many solutions have higher immediate costs and the long-term benefits are unclear or unknown. Unless policies require water users to follow these solutions, groundwater overdraft will likely continue to be a problem in the years to come.

Limitations and Further Work

“All models are wrong, but some are useful” said George Box (1979).

This CALVIN groundwater update project has improved Central Valley groundwater representation in CALVIN. However, CALVIN is just a model and the models used for this update are just models; they can all be useful, but are not exactly accurate. These models can help draw policy implications and present likely outcomes and effects, but as can be seen in comparisons with measured data and other similar models, there is still much uncertainty in many aspects of these models, albeit probably more accuracy and certainty than most model-free analysis.

Nonetheless, to maintain usefulness, these models should be kept up to date and continue to be improved. This project focused on updating the groundwater in the Central Valley, but CALVIN is a model of California’s entire water system and many more improvements can be made. To gain better understanding and insight to the Central Valley water system, the surface water side of CALVIN could use some updates to rim inflows and deliveries, particularly Valley floor accretions and depletions. Additionally, since the CALVIN network was built using software from the early 2000’s, new machines are having some problems with CALVIN’s network so some updates to the CALVIN software would also be very useful.

As it stands, CALVIN is a unique hydro-economic optimization model of California’s water system and has a variety of applications. Using this CALVIN with updated Central Valley groundwater representation for studies related to groundwater in California could provide some useful results. There have been many CALVIN climate change studies, but none that have updated Central Valley groundwater representation. This study examined just a few overdraft scenarios, but it would be interesting to see what the updated CALVIN model would show under more overdraft cases with added climate changes. Looking more into the economic aspects of climate change adaptation or overdraft mitigation in the Central Valley could also provide some useful results. There is always more research that can be done using CALVIN.

Appendix 1

CVHM Groundwater Term Calculations

This appendix presents some of the different approaches taken when calculating the CALVIN groundwater parameters. The parameters presented as "CVHM" (and in bold) are primarily calculations results from the Zonebudget post-processor; this was the version ultimately used to represent CVHM and the methods are described in Chapter 2. Other versions of these calculations include results from FB_details.OUT and other input files, but these were not chosen to represent CVHM since it involved using terms from different post-processors that did not result in mass balance. However, these calculations still reflect reasonable methods to calculate these terms so some descriptions and results are summarized below.

Table 2.2: CVHM Datasets (from Chapter 2)

Dataset name	Description
CVHM Historical ZB (1980-1993) "CVHM"	Based on historical CVHM run using Zonebudget post-processor; averages based on 1980-1993.
CVHM Historical (1980-2003) "CVHM Hist 1980-2003"	Based on historical CVHM run using a combination of FB_details.OUT and Zonebudget; averages are based on 1980-2003.
CVHM Historical (1961-2003) "CVHM Hist"	Based on historical CVHM run using a combination of FB_details.OUT and Zonebudget; averages are based on 1961-2003.
CVHM 2000 Land Use (1961-2003)* "CVHM 2000"	Based on an updated 2000 land use CVHM run using a combination of FB_details.OUT and Zonebudget; averages are based on 1961-2003.

*Note that this run had obvious problems in some of the Tulare Basin regions so the results from this run were ultimately not used for any formal comparison.

Agricultural Return Flow Split

Different approaches were explored to calculate this term. This was the original approach:

Fraction to SW= RUN/(RUN+DP)
Fraction to GW= DP/(RUN+DP)

Where RUN and DP are part of the Farm Balance found in FB_DETAILS.OUT.

RUN = Overland runoff out of the farm
DP = Deep percolation out of the farm

However, both RUN and DP include precipitation and applied water. CVHM does not separate precipitation out as a separate component to either runoff or deep percolation, as was previously done by the CVGSM model (Direct Runoff was runoff due to rainfall alone). So the above equation is not strictly agricultural return flows, but total return flow.

Since applied water and precipitation are outputs in the CVHM model, a ratio was used to estimate the runoff from applied water and runoff from precipitation.

Applied Water = NRD-in + SRD-in + WELLS-in

Consumptive Use = COMPOSITE EFFICIENCY (%) x Applied Water

Runoff from Applied Water = RUN x [Applied Water / (Applied Water + Precipitation)]

Deep percolation of Applied Water =
Applied Water – Consumptive Use – Runoff from Applied Water

Fraction of Agricultural Return Flow to GW =
Deep percolation of Applied Water / [Applied Water – Consumptive Use]

Fraction of Agricultural Return Flow to SW =
Runoff from Applied Water / [Applied Water – Consumptive Use]

NRD-in = Non-routed deliveries into the farm
SRD-in = Semi-routed deliveries into the farm
WELLS-in = Groundwater well pumping deliveries into the farm
COMPOSITE EFFICIENCY = see term #3 below

The results for return flow to groundwater and return flow to surface water are tabulated below. The "CVHM" set shown in bold is the dataset that was used in the final comparisons.

Table A1.1: Agricultural Return Flow Fractions to Groundwater and Surface Water

Subregion	**CVHM**		Hist CVHM (1980-2003)		Hist CVHM		CVHM 2000	
	GW	**SW**	GW	SW	GW	SW	GW	SW

Agricultural Reuse

This version of CVHM did not "reuse" water on a farm for repeated irrigation. 1 was used for all regions for this term, indicating no reuse.

Return Flow of Total Applied Water

External Flows: Deep Percolation from Precipitation

Many different approaches were taken to calculate this term. The final calculations were based on using ratios from output terms in FB_Details.OUT and applying them to the Zonebudget output “Farm Net Recharge.” The older calculations used the ratio from FB_details.OUT and applied it to FB_details.OUT’s DP-out.

Applied Water = NRD-in + SRD-in + WELLS-in

Precipitation = P-in

Deep Percolation = DP-out

Deep Percolation of Precipitation = DP-out x (P-in / (P-in + NRD-in + SRD-in + WELLS-in))

External Flows: Evapotranspiration / Non-recoverable losses

Some of the Agricultural Recharge terms calculated from the Farm Net Recharge terms in Zonebudget are negative. Rather than expressing negative recharge, the negative values were separated out to be the estimated ET losses from groundwater. This was the method used for the final CVHM terms. But the previous versions of the calculations took the time series of EGW-in and TGW-in from FB_Details.OUT, which are evaporation from groundwater and transpiration from groundwater to the farm. These estimated ET values are compared with the ones calculated from the Zonebudget in Table A1.7.

Representative depth to Groundwater (Pumping Lift)

Before it was decided that DWR 2000 average measured well data would be used to represent depth to groundwater, values were calculated based on CVHM using the following method:

Depth to Groundwater = Lift = GSE – Water Elevation

GSE = Ground surface elevation, used "cvr2_lay1_topm.txt" (from CVHM input, model_arrays folder)

Water Elevation = heads outputted in LIST file

NOTE: the head value given from MODFLOW is actually the average head, and not the effective water level. This would mean that head is actually an overestimate (this is in addition to all the other assumptions). So the calculated lift is an underestimate.

This method was based on using the well indices specified in the FMP file (a CVHM input file) that specifies, by element, where wells are located as of year 2000. For this calculation, an average of 2000 water year heads was used.

An alternative method involved using subregion indices from dwr_subregions file (CVHM input file) – to match, and then extract groundwater elevation at each element. However, this method involved sometimes using subregion elements where a well does not actually exist, or at least was not modeled in CVHM. Using the well indices file was determined to be a better representation since only elements with known, existing wells were used for the calculation.

An issue that arose was that GSE was less than Water Elevation in many elements. Elements where this occurred were excluded from the calculations.

Table A1.9: Groundwater Pumping Lift (feet)

Subregion	CVHM	CVHM 2000
1	153	154
2	43	43
3	63	63
4*	NA	NA
5	14	14
6	57	57

7	19	18
8	17	16
9	43	43
10	73	73
11	22	22
12	42	43
13	113	134
14	176	206
15	36	55
16	123	151
17	80	102
18	186	230
19	165	194
20	366	413
21	250	276

*For this region, all GSE values were less than the water elevation so no value for lift could be calculated.

Maximum Storage Capacity

The term “Storage” from the Zonebudget was used for all calculations here. Effective storage was calculated for this term to represent the absolute maximum available water. Calculation is as follows:

1. Arbitrarily set the initial storage to a very large number such that the created storage time series is never negative. Used $1x10^9$.
2. Once storage values are converted from change in storage to storage, the effective storage can be calculated: Absolute Maximum storage – Absolute Minimum Storage (note that the original arbitrarily high number is subtracted out by doing this).

Table A1.10: Maximum (Effective) Storage (TAF)

Initial & Ending Storage Capacity

The initial storage was calculated to be the effective initial storage, the maximum amount of water available in September 2003. This was calculated: Storage in 2003-Absolute Minimum storage. The results are shown in Table 14. The initial storage values used for CALVIN here are taken directly from CALVIN model inputs.

Table A1.11: Initial Storage (TAF)

Region	**CVHM Historical (1980-1993)**	CVHM Historical	CVHM 2000

Overdraft scenarios were not examined when initially calculating groundwater terms so the CVHM dataset ending storages were just set to the initial storages (no change in storage).

Appendix 2

Table A2.1 shows the summary calculation for pumping lift cost. The first column presents the DWR 2000 averaged well data. The Technical Note by Buck 2012 (below) describes how the pumping lift depths were determined. Column 2 shows drawdown values used in the previous version of CALVIN (Appendix J). Column 3 is the Pumping Head, which is estimated by summing the drawdown and the pumping lift. Column 4 shows the change in lift values that were used in the previous version of CALVIN, which are used to determine Total Dynamic Head in Column 5. Column 6 is the estimated pumping cost in year 2000 dollars ($.20af/ft). The 2000 costs are then hit with a multiplier (x1.296) to reflect 2008 costs (last column in the table).

Table A2.1: Estimated Agricultural Pumping Costs

Technical Note:

Pumping Lift from DWR Well Data

By: Christina R. Buck
September 20, 2011
Updated October 10, 2011

Introduction

An estimated pumping lift for each CVPM region is required for calculating pumping costs in CALVIN. Recent efforts to update the representation of groundwater in CALVIN have explored using the Central Valley Hydrologic Model (CVHM), developed by the United States Geological Survey (USGS), and the California Central Valley Simulation (C2VSIM) model, developed by the Department of Water Resources (DWR), to improve required terms. For estimating pumping lift in CALVIN, it was decided that using measured data of groundwater heads would be best.

The pumping lift is the length (often in feet) that water must be pumped from the water surface in the well to ground surface elevation. DWR monitors water levels throughout the Central Valley typically twice per year, once in the spring and then in the fall. This data provides a snapshot of the head in wells at the time of measurement. This is usually close to the start and end of the irrigation season. A variety of well types make up their monitoring network, including irrigation, domestic, stock, monitoring, industrial, observation, recreation wells and some that are no longer in use. Data from this monitoring effort is available online from the Water Data Library (http://www.water.ca.gov/waterdatalibrary/).

Method

In CALVIN, one number is used to represent typical pumping lifts in irrigation wells in each sub-region. Therefore, water level data was obtained (by Aaron King, UC Davis Center for Watershed Sciences, Graduate Student) from contacts at DWR. The full data set includes wells in CVPM regions 2 thru 21 from years 1990-2011. Data for CVPM region 1 was obtained separately. The year 2000 was chosen to establish a representative pumping lift.

Data was filtered by year (2000). Measurements were tagged as Spring or Fall measurements based on a cutoff of July (July and earlier being a spring measurement, August and later being a fall measurement). This allowed for calculating the average 2000 spring measurement and fall measurement independently. DWR data includes a number of columns: ground surface elevation, RPWS, GSWS, WSE, etc. Ground Surface Water Surface (GSWS) is the measured distance from the ground surface to the water level in the well. This was the data used to calculate a representative pumping lift.

There are a variety of well types in DWR’s monitoring network. Wells in the categories of irrigation, irrigation and domestic, stock, unused irrigation wells, observation, and undetermined were used in the calculation. This served to focus mainly on irrigation related wells while still including enough categories to maintain a good sample size. The distribution of wells with measurements taken in 2000 that were used for the calculation is shown in Figure A2.

Measured water levels indicate the piezometric head in the well and are dependent on the screened intervals of the well. This should be distinguished from the “depth to groundwater” which can refer to the distance below ground surface to the water table. Piezometric head in the wells can be higher or lower than the water table depending on the well screening and aquifer dynamics. For this effort, we want the average pumping lift for irrigation wells in each region, so averaging the GSWS measurements in each region to obtain a representative lift for that area assumes that the sample of measured wells is generally representative of wells in that region.

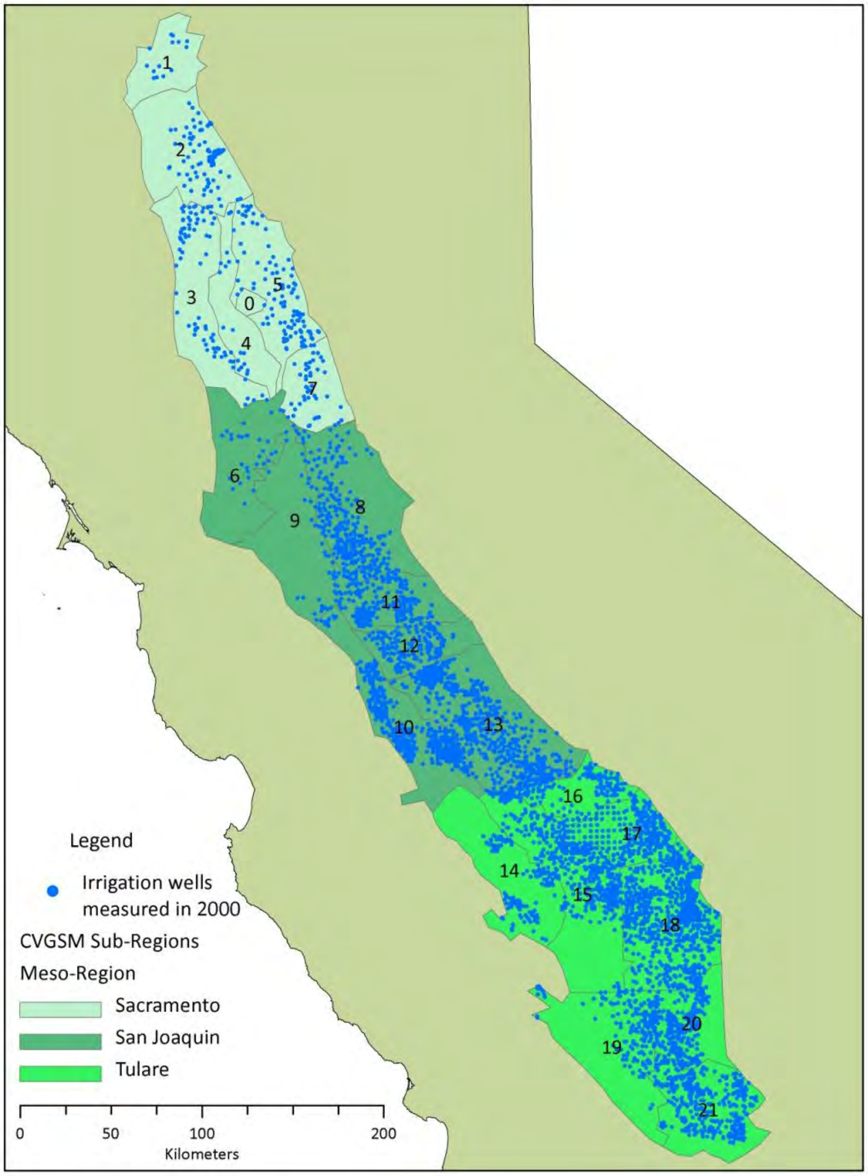

Figure A2: Distribution of wells measured in 2000 used for the estimate of pumping lift (courtesy of Aaron King)

Results

Table A1 presents averaged measurements taken any time during year 2000, average of fall and spring measurements, and the total number of measurements used for the year 2000 average (Count).

Table A1.2: Average GSWS (feet) for measurements taken in 2000, Fall 2000, Spring 2000 and the total count of measurements used for the Year 2000 average

CVPM region	GSWS (ft)			
	Year 2000	***Fall 2000***	***Spring 2000***	***Count****
1	71	70	73	31
2	40	45	38	529
3	27	33	23	258
4	16	19	13	221
5	27	29	26	294
6	25	26	23	155
7	40	39	42	210
8	90	99	84	589
9	24	27	22	104
10	17	77	16	439
11	47	45	48	319
12	68	#DIV/0!	68	177
13	75	#DIV/0!	75	641
14	235	245	150	136
15	93	140	92	377
16	57	#DIV/0!	57	145
17	34	#DIV/0!	34	271
18	80	#DIV/0!	80	857
19	139	#DIV/0!	139	179
20	298	178	298	282
21	191	#DIV/0!	191	379

*Measurement count for Year 2000

Cells that have #DIV/0! indicate that no data was available during that time or for that area. Spring values tend to be less than fall indicating that water levels in the spring and early summer are closer to the ground surface than by the end of irrigation season. This is due to winter recharge that "refills" the groundwater basin and summer extraction that draws water levels down. In some places where irrigation serves as a major source of recharge, fall levels can be higher than spring levels (example, region 20).

In reality, pumping lift is dynamic and changes between years and within a year. For the purposes of CALVIN, which uses a single number for all time and for each region, Year 2000 values were used because they approximate the overall average of available measured data for groundwater head in wells.

Appendix 3

CALVIN Schematic & Network Improvements

Updates to the CALVIN schematic were made to better accommodate components related to groundwater for the agricultural and urban sectors and to facilitate the calibration process. Hidden nodes and nodes for artificial recharge have been added to the PRMNetBuilder network. The following hidden nodes were added:

- Return flow of applied water to surface water from agricultural areas (HSD)
- Return flow of applied water to groundwater for urban areas (HGU)
- Infiltration of surface diversions allocated for spreading-Artificial Recharge (HAR)
- Pumping to all demand areas (HGP)

The added hidden nodes link to physical downstream and upstream nodes and carry amplitude functions that can represent losses. Hidden nodes for pumping (HGP) link groundwater to demand areas and have amplitudes of 1. It is assumed that pumps are located close to the demand areas so that no losses occur.

Hidden nodes for return flow (HGD and HGU) to groundwater for agricultural and urban areas link demand areas to groundwater and have a return flow amplitude representative of fraction of applied water that is returned to the ground. Artificial recharge nodes (HAR) consists of upstream and downstream links such that upstream links to surface water diversions allocated for spreading and carry amplitude that reflect fractions of diverted water that is lost to evaporation and the downstream link is artificial recharge flow to the groundwater basin. Hidden node for return flow to surface water (HSD) for agricultural and urban areas link demand areas to surface water and have return flow amplitude representative of fraction of applied water that is returned to surface water.

Figures A3.1 and A3.2 below show the updated, detailed schematic for agricultural and urban sectors, respectively.

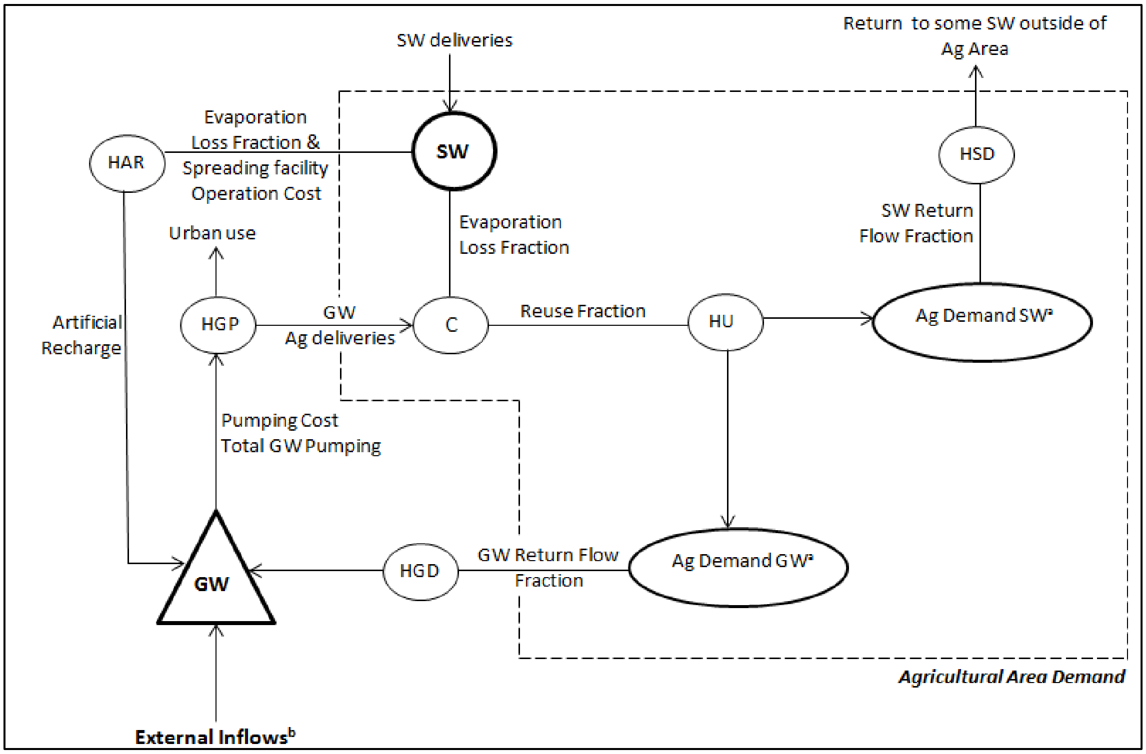

Figure A3.1: Updated CALVIN Schematic for Agricultural Sector

Notes: a) Ag Demand GW represents the non-consumptive use portion of irrigation water that deep percolates to groundwater, and Ag Demand SW represents the portion that returns to surface water systems as tailwater.
b) External Inflows represent net monthly time series inflows to groundwater from Streams, Lakes, Deep Percolation of Precipitation, Diversion losses, Boundary Inflows, Interbasin Inflows, Subsidence and Tile Drain Outflows

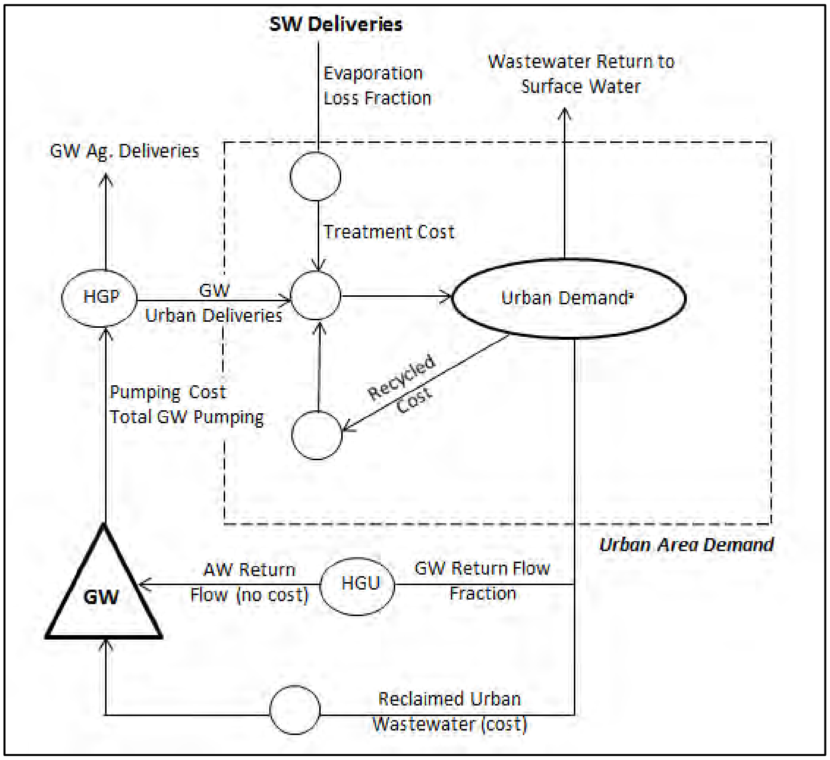

Figure A3.2: Updated CALVIN Schematic for Urban Sector

Notes: a) Urban Demands is represented in CALVIN as Int: CVPM, represent urban demands for water for indoor use and Ext: CVPM is demand for outdoor use, following Bartolomeo (2011).

Appendix 4

C2VSIM Streamflow Adjustments

Differences in streamflow exchange before and after 1951 could be due to the change in aquifer levels and changes in the interactions between surface-groundwater. There are changes in direction and magnitude of flow between groundwater basins and rivers over time so streams that may have been gaining streams before 1951 could have reversed to being losing stream after 1951 or vice versa. Another possibility is that less water goes from groundwater to streams after this time as a result of groundwater depletion and thus smaller stream-aquifer hydraulic connectivity. If the historical time series of streamflows were used, there would likely be a million acre-feet per year of water that may not be accounted for correctly in the Central Valley, which would result in some exaggerated availability of surface water or groundwater.

Because the possible inflated availability, streamflow exchanges before 1951 were adjusted using the annual average difference for subregions above 50 TAF/yr. Adjusted subregions are 2, 4, 5, 6, 9, 11, 13, 15, 18, 19 and 21. In order to maintain mass balance of water available within the subregions, the difference between historical and adjusted stream inflows were accounted for in the depletion areas of respective subregions or as depletions or accretions to major streams in these subregions. Table A4.1 shows monthly flows added or subtracted in the subregion depletion study areas: (-) add to depletion area and (+) subtract from depletion area. Details on depletion areas and how they are used in CALVIN are in the Appendix I (Draper et al. 2000). Table A4.1 also shows depletion and accretion areas and streams corresponding to subregions, as well as nodes per CALVIN network. Depletion and Accretion areas are listed in Appendix I and checked in CALVIN Schematic; stream information is as modeled in C2VSIM - version R356.

Table A4.1: Adjusted monthly flows to depletion and accretion areas in the Central Valley due to changes in historical streamflow exchanges before 1951

Subregion	Depletion Area or Stream	Nodes in CALVIN network	Adjusted monthly inflows (TAF/month)
2	10	D76a - DA10 Depletion	11.9

C2VSIM Surface Water Recoverable and Non-recoverable Losses

Table A5.1shows the C2VSIM surface water recoverable (primarily diversion) and non-recoverable (evaporation and transpiration) losses and how they correspond to CALVIN nodes and links. The 5th column shows the previous version of CALVIN's Recoverable and Non-recoverable loss amplitudes. Column 6 shows the new values used. If a parentheses ( ) is shown, that indicates that amplitude was adjusted to the value inside of the parentheses during the calibration process.

Table A5.1: Surface Water Recoverable & Non-Recoverable Loss Amplitudes

STATE OF CALIFORNIA – CALIFORNIA NATURAL RESOURCES AGENCY **EDMUND G. BROWN JR.,** *Governor*

DEPARTMENT OF WATER RESOURCES
NORTHERN REGION OFFICE
2440 MAIN STREET
RED BLUFF, CA 96080-2356

February 3, 2015

Glenn County Board of Supervisors
525 West Sycamore Street, Suite B1
Willows, California 95988

Glenn County Water Advisory Committee
Post Office Box 351
Willows, California 95988

Dear Supervisors and Committee members:

The purpose of this letter is to provide land subsidence results from the Global Positioning System (GPS) surveys performed in Glenn County. GPS surveys were performed to monitor changes in ground surface elevation to detect subsidence throughout the county and ultimately the entire Sacramento River Valley. The enclosed comparison showed two areas of the county exhibiting land subsidence.

The Glenn County subsidence network was installed and initially monitored in 2004. It consisted of 58 stations; about half were existing survey monuments, and the other half were installed as part of this project. Initial GPS surveying took place during March and April 2004. The network was resurveyed in spring 2008 as part of a larger Sacramento Valley GPS subsidence project.

The two surveys did not follow the same observation schedule and monitoring plan, and therefore, direct comparison was not possible at some locations within the county. By performing data analysis and review, the Northern Region Office of the Department of Water Resources (DWR) was able to develop the enclosed map showing the land surface change along the defined paths, or vectors, between the years of 2004 and 2008. The data analysis and review performed to complete the map included identifying and using similar vectors, where available, from both years. It also included using auto leveled monuments, where necessary, to be able to include the monuments that were relocated between the survey years. This was performed only when there was a direct relationship between the points in order to preserve the accuracy of the survey data.

Using the best methodologies available at the time, the GPS vertical accuracy, or threshold, for this monitoring effort was estimated to be 0.164 feet or approximately 2 inches. Any changes that show greater than the defined threshold are considered statistically significant and indicate possible ground movement.

In general, the analysis did not show that the county experienced widespread ground movement during this four-year time frame. However, two areas determined from the analysis indicate ground movement. The first area, to the south and east of Hamilton City, did exhibit a change in ground surface elevation that is statistically significant. The monument designated “WILD” on the enclosed figure showed an average change of 0.38 feet or about 4.5 inches when compared to the nearest monuments to the west. This monument is on the eastern edge of the Glenn County network and additional surveying would need to be performed comparing 2008 to current levels in a larger area of Glenn and Butte counties to determine if this is an ongoing concern or just an anomaly.

The second area is near Sunset Avenue and County Road E to the southwest of Orland. This area showed a change just below the level of being statistically significant at 0.125 feet or about 1.5 inches. This may have indicated an area of concern and warrant additional surveying to determine whether this is an onset of land subsidence or not.

Ideally, the entire Sacramento Valley GPS Subsidence Monitoring Network should be resurveyed and compared to the valley wide 2008 survey to determine changes caused by the increased groundwater pumping and the persistent drought impacts. It is possible to check small areas without resurveying the entire network as mentioned above. DWR will further investigate the opportunities to work with the Sacramento Valley counties to resurvey the Sacramento Valley GPS Subsidence Monitoring Network. As an intermediate step, DWR may resurvey the two local areas that showed subsidence in 2008 to investigate any additional land elevation changes.

A formal presentation of the results will be provided by DWR to the Glenn County Water Advisory Committee at a future date.

If you have any questions or need additional information, please contact me at (530) 528-7403, or Roy Hull, Engineering Geologist, at (530) 529-7337.

Sincerely,

Bill Ehorn, Chief
Groundwater and Geologic Investigations

for

Workshop #3
Analytical Tools for Evaluating the Water Supply,
Hydrodynamic, and Hydropower Effects of the Bay-Delta Plan
November 13 and 14, 2012

The State Water Resources Control Board called for workshops to receive information from and discuss with participating parties the scientific and technical bases for considering potential changes to the 200 Water Quality Control Plan for the San Francisco/Sacramento-San Joaquin Delta Estuary for Phase II of the Board's comprehensive review of this plan.

According to the State Board's public notice for these workshops, the prompts for Workshop 3 testimony are:

1. What types of analyses should be completed to estimate the water supply, hydrodynamic, and hydropower effects of potential changes to the Bay-Delta Plan?

2. What analytical tools should be used to evaluate these effects? What are the advantages, disadvantages and limitations of these tools?

Water Availability Analysis

Workshop 3 Testimony, Bay Delta Plan
Submitted by California Water Impact Network, California Sportfishing Protection Alliance, and AquAlliance

The California Water Impact Network, the California Sportfishing Protection Alliance, and AquAlliance (hereinafter, C-WIN) are pleased to submit this testimony to the State Water Resources Control Board. This testimony addresses the close linkage between the Board's public trust responsibilities on behalf of the State of California, its water quality control planning function, and its duty to regulate water rights in California. Water quality control planning efforts to date have led the Board to consider proportional tributary contributions needed to meet Delta inflow objectives from the Sacramento and San Joaquin River Basins to improve water quality and protect all beneficial uses, including fish and wildlife, in the Delta. The State Water Resources Control Board has authority over water rights in the Basins that would enable it to reallocate water usage and ensure compliance with the Board's new instream flow objectives.

Water availability analysis is an important method for modeling how the Board would implement new flow objectives. Our testimony illustrates the use of a planning-level water availability analysis for the Trinity River (much of whose flows are diverted to the Central Valley watershed of the Bay-Delta Estuary) and the major tributaries of the Sacramento and San Joaquin River Basins. We incorporate into the analysis the Basins' hydrologic variability, instream flow requirements based on the Board's 2010 public trust Delta flow determinations, and then operate publicly available water rights data and priorities on the divertable flows that remain in the system. We find that under public trust protective flow determinations, the promised water represented in water rights claims far exceed flow conditions available to these claims in most years.

We recommend for the Bay-Delta Plan's implementation program that the State Water Resources Control Board draw on its new flow determinations to increase the seasons during which rivers in the Bay-Delta Estuary's Central Valley watershed are fully appropriated, and push back the water rights priority date on which Term 91 curtailments are now based. Our water availability analysis suggests distinct parameters for both actions.

Finally, we conclude that the Board should use the Bay-Delta Plan process to tighten up its regulation of surplus water usage and export by the State Water Project and Central Valley Project to avoid permanently damaging Sacramento Valley groundwater resources. The Board's Delta flow determinations, coupled with comprehensive enforcement of water rights priorities, can help to protect both groundwater and surface water resources in the Sacramento Valley over the long term.

Government's Public Trust Responsibility

Governments have a permanent fiduciary responsibility and obligation to protect the public trust. In *National Audubon Society v. Superior Court* (1983) 33 Cal 3d 419, 441, the court held that "the public trust is more than an affirmation of state power to use public property for public purposes. It is an affirmation of the duty of the state to protect the people's common heritage of streams, lakes, marshlands and tidelands, surrendering that right of protection only in rare cases when the abandonment of that right is consistent with the purposes of the trust." The act of appropriating water is an acquisition of a property right from the waters of the state, an act that is therefore subject to regulation under the state's public trust responsibilities.

The State Water Resources Control Board has invoked its public trust responsibilities in regulating the waters of California and now acknowledges that the public trust is one of its ongoing regulatory responsibilities. Its most publicly prominent instance came in Water Rights Decision 1631 (D-1631) in 1994. In D-1631 the Board balanced the needs of the City of Los Angeles for water supply from the tributaries of Mono Lake with the lake's own needs for water to sustain its ecosystem. It required Los Angeles to make releases from each of its tributaries that would sustain riparian ecosystems and help restore fish populations to the tributaries by prescribing lake level targets in a specified time period (State Water Resources Control Board 1994 The Board has also adopted regulations governing how it treats the public trust in matters of the appropriation of water in California. (State Water Resources Control Board 2011b Article 14 Standard Permit Terms and Conditions)

The trial court in *United States v State Water Resources Control Board* (1986 18 Cal.App.3d 82 determined that the State Water Resources Control Board had the authority to modify an appropriative water right permit once it had been issued and that it could reduce the US Bureau of Reclamation's Central Valley Project permits to gain compliance from the Bureau. But the trial court held new fish and wildlife objectives the Board had approved in Water Rights Decision 1485 (D-1485 in 1978 to be invalid because the Board failed to identify the *source* of its authority. Justice John Racanelli, the author of the subsequent appellate court decision cited above, stated that the source of the Board's authority to issue and enforce new fish and wildlife objectives such as those contained in Water Rights Decision 148 (D-1485) was the Public Trust Doctrine:

> ...the state as trustee of the public trust retains supervisory control of the state's waters such that no party has a vested right to appropriate water in a manner harmful to the interests protected by the public trust. (18 Cal.App.3d 82 149)

Stevens (2005 summarizes the present range of coverage that American and California law gives the public trust doctrine:

1. It applies to all navigable streams.
2. It applies to ecological preservation.
3. It applies to wetland areas.
4. It applies underground (citing the Waiahole decision from Hawai'i).
5. It applies to artificially enlarged waters.
6. It applies to wild animals including fish.[1]

The Public Trust and Paper Water

In the next few years, the State Water Resources Control Board is expected to make several crucial decisions on California's water future. These decisions include:

---

[1] The California Constitution also provides an absolute right to fish among the fundamental declared rights it accords all California citizens. Article I, Section 25 states:

> ARTICLE 1 DECLARATION OF RIGHTS
>
> Section 25. The people shall have the right to fish upon and from the public lands of the State and in the waters thereof, excepting upon lands set aside for fish hatcheries, and no land owned by the State shall ever be sold or transferred without reserving in the people the absolute right to fish thereupon; and no law shall ever be passed making it a crime for the people to enter upon the public lands within this State for the purpose of fishing in any water containing fish that have been planted therein by the State; provided, that the legislature may by statute, provide for the season when and the conditions under which the different species of fish may be taken.

In combination with California Fish and Game Code Section 5937, which provides that owners of dams must preserve fish populations downstream in "good condition", preservation of this right logically should be construed as an important aspect of the public trust responsibilities of government. It retains meaning as a right only when there exist sufficient fish to catch sustainably.

- Determining how to provide sufficient flows from the Sacramento and San Joaquin River's major tributaries to the Bay-Delta Estuary.
- Updating its 200 Bay-Delta Water Quality Control Plan to include those new Sacramento and San Joaquin River flow and South Delta salinity objectives.
- Deciding whether to extend the water rights *permits* of the California State Water Project and the federal Central Valley Project, or instead *license* them at levels that represent reasonable and public trust protective water usage.
- Deciding whether and/or how to permit a "north Delta diversion"—a diversion that is now more familiarly known as the Peripheral Tunnels Project.
- Deciding whether and/or how to permit new reservoirs on the San Joaquin River and in the southwestern Sacramento Valley (and/or to raise existing dams to increase storage elsewhere) that would be added to the storage capacities of the Central Valley Project and the State Water Project.

As a regulatory agency, the State Water Resources Control Board is not known for making and holding to courageous or visionary decisions that protect beneficial uses of water throughout California. Their record of delay and incrementalism has contributed to the poor condition of the Bay Delta Estuary and the great rivers of its watershed, the great Sacramento and San Joaquin Rivers.

The State Water Resources Control Board has authority to make bold decisions and hold to them. (Cahill 2008)

The State Water Resources Control Board will need to balance protection of the public trust with other competing beneficial uses of water reliant on the Delta The Board has already determined the flows that fish and other aquatic species need (State Water Resources Control Board 2010: 114-123 In completing and implementing the Bay-Delta Plan the Board's next step is to evaluate the feasibility of measures needed to protect public trust resources fully. (California Supreme Court 1983 Kibe 2011 6 These steps will need to include determination of flow needs of public trust resources, water rights reallocation, flow modification benefit-cost analysis, and habitat restoration. In the process. key questions must be answered:

1. How does the State Water Resources Control Board intend to prioritize water use in terms of coequal goals of public trust balancing How does its long-established water rights priority system fit into this policy framework?

2. What does water supply reliability mean in an arid state where we have granted rights to far more water than actually exists? Should water supply reliability be conditioned upon specific requirements to maximize reclamation, reuse, conservation and development of alternative local sources of water?

3. Is the standard by which we measure water supply reliability the same for junior and senior appropriators? Do uses of water that require vast public subsidies have the same priority as uses that don't require subsidy or public funds Are uses that internalize adverse impacts equal in priority to uses that externalize them?

4. Should the worth of water be confined only to its economic value in use Or does water supply reliability apply to both public trust resource needs as well as consumptive uses (i.e. is legislation needed for better protection of public resources through water rights)?

5. Are statutory requirements to protect water quality and listed species equivalent to water supply reliability for lawns or surplus subsidized, and non-food crops? Are food crops more

important than non-food commodities when it comes to allocating water? Does health and safety take precedence over certain agricultural uses of water?

6. Does efficient use of water have higher priority over wasteful and inefficient use? Is protection of the Bay-Delta Estuary as a “national treasure” and one of the world’s great estuaries more valuable to society than irrigating impaired soils that by their nature when irrigated, discharge prodigious quantities of salt and toxic wastes back to our waterways and aquifers?

Answers to these questions are central to resolving California’s water problems.

The California Legislature consolidated the State of California’s water rights and water quality control responsibilities in the State Water Resources Control Board in 1967. Since that time, the Board has considerable authority to grapple with these questions and arrive at answers and solutions from them. The Board has authority to:

- Plan for water quality control.
- Receive, condition, and approve new water rights applications as permits.
- Regulate and license water rights permits specifying the point of diversion, diversion flows, place of use, and purpose of use for water.
- Investigate pre-1914 and riparian water rights to determine whether such claims to divert and use water are legal, including follow-up enforcement against illegal uses when determined (discussed below).
- Investigate and enforce the state’s prohibition of waste and unreasonable use and wasteful and unreasonable methods of diversion of water under the California Constitution, Article X, Section 2.
- Protect the public trust. As an agency of the state, the Board is charged with ensuring the state of California carries out its fiduciary responsibility to protect air, running water, the sea and the seashore, “these things that are common to all,” as stated originally in Roman law (the Institutes of Justinian).

California’s constitution promises water rights only up to what is a reasonable use. No one has a right in California to use water unreasonably, not even the federal government. (California Constitution, Article X, Section 2.) The Public Trust Doctrine provides that no one has a vested right to appropriate water in a manner harmful to the interests protected by the public trust. (*National Audubon Society v. Superior Court* 3 Cal.3d 419, 189 Cal.Rptr 346, 65 P.2d 709.) And the dictionary definition of usufructuary rights, of which both riparian and appropriative water rights are examples, indicates that a fundamental principle of usufruct is that it connotes only a right to *use* a resource like water, not to waste or use it unreasonably. The State Water Resources Control Board, in taking up all of the key questions we outline above, will be deciding whether and how California’s abundant legal authorities apply to the Bay-Delta Estuary’s Central Valley watershed.

The Public Trust and Proportional Delta Inflows

In mid-2009, the State Water Resources Control Board updated its review of the Water Quality Control Plan which its Water Right Decision 1641 (D-1641) implements. The Board took the position that to change its water quality and flow criteria it needed more scientific information about flows reasonably needed to protect fish and wildlife beneficial uses (State Water Resources Control Board, 2009, 17). Its impetus to consider making changes at that time included pronounced fisheries declines among both open water resident and migratory fish and the still-unfolding impacts of climate change and its impacts on the Bay-Delta estuarine system (State Water

Resources Control Board, 2009: 9) The California Department of Fish and Game sought to build a salmon survival model to assist the Board's need for additional information. (California Department of Fish and Game 2010)

Later in 2009, the California Legislature directed the State Water Resources Control Board to prepare a report on Delta flow criteria that would "develop new flow criteria for the Delta ecosystem necessary to protect public trust resources" and in so doing "use the best available scientific information." The Legislature directed the Board to gather the information as part of an "informational proceeding" rather than through an evidentiary hearing. And the Legislature charged the Board with including volume, quality and timing of water necessary for the Delta ecosystem under different conditions (California Water Code: Section 85086(c)).

The Board produced its Delta flow criteria report after taking detailed testimony on the best available science for key fish species and ecosystems. The report identified a set of broad flow regimes for upstream tributaries providing inflow to the Bay-Delta Estuary that fish need to survive and recover. They represent the Board's consideration of the best available fishery and hydrologic science it considered during 2010 addressing the question: what flows do fish need? The Board confirms this when it stated in a footnote, "...the flow criteria developed in this proceeding are intended to halt population decline and increase populations of certain species," and acknowledged that, "Recent Delta flows are insufficient to support native Delta fishes for today's habitats….Flow and physical habitat interact in many ways, but they are not interchangeable." (State Water Resources Control Board 2010: 5, 120)

The Board states that the flow criteria "must be considered" in context:

- The flow criteria do not consider any balancing of public trust resource protection with public interest needs for water.
- The State Water Board does not intend that the criteria should supersede requirements for health and safety such as the need to manage water for flood control.
- There is sufficient scientific information to support increased flows to protect public trust resources; ***while there is uncertainty regarding specific numeric criteria, scientific certainty is not the standard for agency decision making.*** (State Water Resources Control Board 2010: 4; emphasis added)

The Board's flow determinations are:

- 75 percent of unimpaired Delta outflow from January through June.
- 75 percent of unimpaired Sacramento River inflow from November through June.
- 60 percent of unimpaired San Joaquin River inflow from February through June.
- Increased fall Delta outflow in wet and above normal years.
- Fall pulse flows on the Sacramento and San Joaquin Rivers to stimulate migrating fish.
- Flow criteria in the Delta interior to help protect fish from mortality in the central and southern Delta caused by operations of the state and federal water export pumps.

In essence, these flow determinations represent the Board's answer to the question "what flows do fish need in the Central Valley watershed and the Bay-Delta Estuary?" The State Water Resources Control Board's 2010 Delta flow criteria report acknowledged that protective Delta outflows start with protective tributary inflows to the Delta. The Board's Delta inflow criteria rely on a percentage of unimpaired flow measure, which enables the flow criteria on the Sacramento and San Joaquin rivers to more closely mimic their natural hydrographs than now occurs.

Water Availability Analysis

Workshop 3 Testimony, Bay Delta Plan
Submitted by California Water Impact Network, California Sportfishing Protection Alliance, and AquAlliance

For the San Joaquin River, the State Water Resources Control Board approved its determination that 6 percent of unimpaired flow from February through June for the river basin would protect juvenile Chinook salmon during their peak emigration period. For the Sacramento River, the Board adopted the criterion of 7 percent of unimpaired flow from November through June. (This is because numerous runs of migratory salmon use the Sacramento River Basin for more of the year.) These constrained periods would also benefit the rearing period of juvenile salmon in the basin's major tributaries upstream. The Board also adopted in that report (2010) a fall season Delta inflow criterion calling for an average flow of 3,600 cubic feet per second for 10 days sometime during late October.

Nearly all scientists testifying to the Board in March 201 agreed that mimicking the natural hydrograph (in shape if not in magnitude and volume of flow) is necessary to improve conditions for native fish species, and to counter invasive species in the Delta. Existing Board water quality and flow objectives intended to protect fish and wildlife beneficial uses in the south Delta are not working, as shown in abundant evidence presented to the Board at its hearings for the Delta Flow Criteria report. The Board included much of that data in its report. (State Water Resources Control Board 2010.) C-WIN provides a brief evaluation of the Vernalis Adaptive Management Plan to supplement this record of failure in Appendix to this testimony.

In August 2010, the State Water Board approved these currently nonbinding Delta inflow determinations for the Sacramento and San Joaquin rivers. (State Water Resources Control Board 2010: 114-123.) The State Water Resources Control Board observed that using such flow criteria would mean that "to achieve the attributes of a natural hydrograph, the criteria are advanced as a percentage of unimpaired flow over a 14-day average, *to be achieved on a proportional basis from the tributaries to the San Joaquin River.*" (State Water Resources Control Board, 2010: 120, emphasis added.) The Board makes an important point that mimicking natural hydrograph and improving prospects for species recovery depends on achieving proportional flow allocations from all the major tributaries. Proportional tributary contributions would be needed to implement the Board's broader Delta inflow criteria. The Board will need to answer key questions including: what should those proportions be? how should responsibility for them be assigned? and who will be responsible for providing them? And when will the upper San Joaquin River be included by the Board in making these determinations? (Right now, the Board excludes the upper San Joaquin River from its Bay-Delta Estuary planning deliberations. C-WIN evaluates the Board's stance in Appendix B.)

The question for the Board is how to do proportional flows *legally*. Proportional tributary contributions from Delta inflow are not new. In 1992, the California Department of Fish and Game proposed a method to identify tributary contributions to Delta inflows based on the pro rata share of unimpaired runoff each tributary generates to the Delta, as identified in the California Department of Water Resource's Bulletin 12 each year (California Department of Fish and Game 1992). Other allocation methods could be devised as well, such as one based on reservoir storage on these same tributaries. The State Water Board in its Draft Water Right Decision 163 presented such a method, but which excluded contributions from the San Joaquin River above Mendota Pool (State Water Resources Control Board, 1992: Tables I and V).

Proportional tributary contributions needed to fulfill Delta inflow determinations from the Trinity River, and the major tributaries of the Sacramento and San Joaquin River Basins will require changes to the water rights of major water users in these Basins. The State Water Resources Control Board has authority over water rights to reallocate water usage and ensure compliance with the Board's Delta inflow objectives.

Paper Water Means Boundary Disputes and Clouded Titles

Property is often legally conceived as a bundle of rights representing “investment-backed expectations” of a future stream of benefits accruing to its owner, usually in the form of money. Water rights are a form of property, conveying to their owners rights to use water from a stream. Unlike real property in land however, we have a situation in which far more in rights to use water have been granted by the state or claimed by right holders than Nature and reality actually provide.

California’s modern water code and its body of water rights case law is the result of more than a hundred and sixty years of legislation and legal precedent. Riparian water rights are the most paramount rights, followed by pre-1914 appropriative rights and, lastly, post-191 appropriative rights, as determined by the seniority requirements of first-in-time-and-use.

But despite this accumulated legal tradition, human promises of water exceed Nature’s provisions. A shorthand description of this condition is “paper water.” The paper water problem in the area of water and rivers in California has close analogies in concepts like “clouded title,” and “boundary dispute” for a piece of real property (say, a house or a plot of land that has more than one owner claiming the same piece or portion of ground. Typically, boundary disputes are resolved by one or more disputants engaging the services of a surveyor to establish where the boundary is actually located. From there, the owners have a common set of facts on which they may agree to resolve their boundary dispute.

“Clouded title” has relevance here as well. A clouded title means the ownership of a title in water has some defect or potential defect arising from a competing claim for the same source of water.

One of the earliest recognitions of the problem of paper water in California occurred over a century ago and helps illustrate the clouded condition of paper water. In 1900, Frank Soulé, a professor of civil engineering at the University of California, was retained by the US Department of Agriculture’s Office of Irrigation Investigations to study water rights claims in the San Joaquin River basin. Soulé found that the San Joaquin River’s average winter and spring months flows were approximately 5,00 to 6,00 cubic feet per second. In drier late summer and fall months flows could get as low as 150 cubic feet per second. Soulé researched water rights claims to all tributaries of the San Joaquin River watershed to see how they matched up with flows in the river. Actual flows from the 1895-190 period averaged about 2.02 million acre-feet, according to state records. (State Water Resources Board 1951: Table 62) He visited the recorders’ offices for Stanislaus, Merced, and Fresno counties and itemized 31 claims to San Joaquin River waters totaling 36,571,471 miners inches of flow (there are 5 miners inches to a cubic foot per second). This converts to 731,42 cubic feet per second. Stretched out over a year (Soulé did not specify the seasons for which the claims were made), this translated into an annual claim of water rights of 529. million acre-feet of water, over 260 times greater than average flow of the San Joaquin River in that period. For an eight-month irrigation season of about 24 days, such flows would amount to 356. million acre-feet, nearly 180 times greater than San Joaquin River flows. These Soulé contended, were the “definite claims,” ones that had well-defined diversion points and amounts claimed. Six separate individuals claimed “all the water flowing in the San Joaquin River,” a definite claim is exaggerated. His summary for the San Joaquin did not include claims to the Fresno and Chowchilla rivers, which are much smaller watersheds, but the grandiosity continued there. On the Fresno River, some 670,79 miner’s inches were the subject of 5 claims (about 13,41 cubic feet per second or 9. million acre-feet a year), and on the Chowchilla just 1 claims aggregated to 31,00 cubic feet per second (or about 22.5 million acre-feet annually). (Soulé 1901: 222, 232)

Clouded titles in water have been allowed to fester since before Professor Soulé began studying the problem in 1900. Failure by the State of California to quiet titles to water since assuming authority for appropriative water rights in 191 contributes untold expectations for benefit streams that fuel controversy in California water resources planning and development ever since.

C-WIN is not lone contemporary voice on the problem of paper water. In September 2008, State Water Resources Control Board staff informed the Delta Vision Blue Ribbon Task Force about water rights, use, and flows in the Delta watershed. It stated in part:

- The "total face value of the approximately 6,300 active water right permits and licenses within the Delta managed by the State Water Board, including the already assigned portion of state filings is approximately 24 million AFA [acre-feet annually]." Our organizations note that this 245 million acre-feet of face value in water rights was permitted by the Board and its predecessors in the Central Valley watershed (including imports from watersheds like that of the Trinity River). (State Water Resources Control Board 2008)

- Face value "does not include pre-1914 and riparian water rights." Riparian water rights, in the absence of some form of watershed adjudication, are usually unquantified but nonetheless require real, wet water. (State Water Resources Control Board 2008) And,

- That "the total face value of the unassigned portion of state filings for consumptive use (excluding state filings for the beneficial use of power) within the Delta watershed is approximately 6 million [acre-feet annually]." These are claims the State has filed to reserve water for further expansion of the State Water Project. (State Water Resources Control Board 2008; see also Appendix C.)

Other matters exacerbate the paper water problem:

- The SWRCB does not know how much water is actually used (and by whom) since state law has yet to require full accounting of either surface or ground water use.

- The SWRCB does not know the extent of paramount riparian or senior pre-1914 water rights either.

- Climate change is likely to alter the timing and reduce the volume of runoff into California's rim dams and overall state and federal water systems. (Knowles and Cayan 2002) It is also likely to decrease natural groundwater recharge as well, which would further reduce runoff volumes where river reaches benefit from groundwater inflows.

- Increased cold water pools and groundwater support from gaining streams will be needed to maintain water temperatures below rim dams according to estimates by the SWRCB and Department of Fish and Game of the increased inflow and outflow necessary to protect rivers and the Delta public trust resources. (California Department of Fish and Game 2010: 51, Table 5)

Given these constraints, the obligation to achieve a public trust balancing of water supply reliability with fish and ecosystem survival cannot rest on maintenance of existing levels of supply from either Delta exports or the rim dams on all major Central Valley tributaries in the Delta watershed. The State Water Resources Control Board must use its water rights authority in the service of meeting these water quality challenges on behalf of public trust resources.

The Delta Watermaster acknowledges the problem of paper water in recent report on the State Water Resources Control Board's role in the Delta Stewardship Council's Delta Plan process (Wilson 2011). He expresses concern, however, that "the face value of water rights is not a sufficient measure of water that can be used to determine the over-allocation of water in the [Delta watershed." He cites four main reasons for his concern:

- The face value of many water rights are for nonconsumptive uses, such as hydropower.
    - **C-WIN Response:** As much as possible, water availability analysis should factor out water rights claims that are primarily devoted to nonconsumptive uses and hydropower generation in particular. C-WIN's analysis factors out all single-purpose hydropower generation water rights claims, whether pre- or post-1914. Where multiple purposes of use claims include hydropower generation, we assume these rights are still primarily consumptive use claims, especially when irrigation is one of the other purposes of use for which claims are made. Hydropower generation is considered incidental to the other consumptive uses.

- The face value represents a maximum possible water diversion, which is far greater than what is actually used;
    - **C-WIN Response:** We agree that face value often represents a maximum possible diversion (and/or storage amount). We also agree that it may be far greater than what is actually used in many cases. But C-WIN's review of water right claims shows that some rivers' claims far exceed maximum unimpaired flows and even reservoir capacity of that river. (The Trinity River is a good example of this.) This is less a criticism of face value than an acknowledgement of paper water by the Delta Watermaster. Nor does it justify continuation of the practice by the State Water Resources Control Board. Since the maximum possible flow (and use) can occur only relatively rarely in California's hydrology, C-WIN suggests that this extra increment of claims be eliminated because it will occur in the future with even less frequency than now occurs. Reliable rights are only meaningful when they can be exercised with relative frequency.

- Permit/license terms, such as those for protection of instream uses, further reduce below the face value the amount of water that can be diverted;
    - **C-WIN Response:** The State Water Resources Control Board needs to continue having some standard method for quantifying the value of water rights as property. This is the only way that increments of title to water as property can be described and titles cleared or quieted in the event of dispute. Moreover, quantified water rights are the only way to conduct reality-based water resources planning and development. This extends to employing a standard method for quantifying and measuring instream flows that benefit public trust resources. If the Board and Delta Watermaster are to enforce instream flows, they must quantify instream flow commitments and ensure that they are fulfilled *prior* to the exercise of permitted or licensed water rights claims.

- Water, when applied, is typically not consumed up to the full face value and the same water (return flow) is often used multiple times as it runs downstream.
    - **C-WIN Response:** While C-WIN acknowledges the reality of return flow in diversions of water for consumptive irrigation uses, there is no consistently available data that measures the volume and occurrence of return flow to rivers. Some estimates, both recent (California Department of Water Resources 2005 water balances for Sacramento and San Joaquin River Basins) and historical (Wiel 1928: 259) put return flow at between 6 and 6 percent of originally diverted volumes. Of course, the reality of return flow, however, means that river flow can decrease by as much as a third of diversion quantities each time it is applied; the more frequently water is diverted to consumptive use, the sooner surface flows are depleted in the immediate

> river reach downstream. Return flows do not reach the river from which they were diverted instantaneously. Once diverted there occurs a time lag between the diversion and its application, and when water actually returns to the river, and even then it may only reach the river in small increments, depending on the surface return flow and/or subsurface transmissivity getting back to the river. Meanwhile, the diverted water is gone from the river, thereby depleting its flow until some later time and lower location. If return flow is truly important to determining water availability and avoiding boundary disputes and clouded water titles, then California needs to invest in getting data from each watershed that quantifies the volume, timing, and duration of return flow, instead of ignoring it. (State Water Resources Control Board 1983, 9-10)

C-WIN's methodology recognizes each of these facets of "face value" or face amount of water rights. Unfortunately, the Delta Watermaster's remarks do not clarify whatever else it is that face value quantities in water rights are supposed to positively describe. If the quantities in water rights are not relevant to face value, then on what basis can separable, stable and reliable rights to water use be analyzed and judged? The Watermaster acknowledges that "while actual water use may be only a fraction of the face value of water rights, the state's water supplies have been over-allocated in many areas."[2] (Delta Watermaster 2011b, 5) C-WIN shows in this testimony that it is possible to use the "data" of water rights in combination with data on flows and diversions to generate a consistent and meaningful picture of the problem of overallocation of water supplies and rights in the San Joaquin River Basin. Our water availability analysis illustrates the usefulness of having *some idea* of the magnitude of the paper water problem as compared with having *no idea*. All of California needs better data on all facets of the problem of paper water.

Tables 1 and 2 provide static (snapshot) views of total water rights in the Trinity, San Joaquin River and Sacramento River Basins. Total water rights reported in these two tables are for consumptive uses. Hydropower generation water rights have been excluded from this analysis.

In Table 1, average annual unimpaired flow for the San Joaquin River Basin is about 6. million acre-feet compared with 32. million acre-feet of consumptive water rights claims. The ratio of total claims to average unimpaired flow for the San Joaquin Basin is 5. acre-feet of consumptive use claims to every acre-foot of unimpaired flow in the Basin. About 4 percent of total consumptive water claims are by riparian and pre-1914 claimants while 5 percent is by post-191 claimants (that is permits and licenses) regulated by the State Water Resources Control Board.

Specifically on the major tributaries of the San Joaquin River Basin the ratio of total consumptive use claims to unimpaired flow ranges from about 5. on the Stanislaus to 6. acre-feet of claims to every unimpaired acre-foot of flow on the San Joaquin River (including valley floor and upper watershed claims).

In Table 2, average annual unimpaired flow in the Sacramento Valley (essentially, average Sacramento River inflow to the Delta) is about 21.6 million acre-feet. Consumptive water rights claims are estimated at about 120. million acre-feet. The ratio of total consumptive use claims to averge unimpaired flow in the Sacramento River Basin is about 5. acre-feet of claims per acre-foot of unimpaired flow. Ratios of claims to unimpaired flow to range from 2. on the Yuba River to 6.8 on the Trinity River.

---

[2] The Delta Watermaster suggests that for the Delta the process for determination of fully appropriated streams from the Water Code Sections 1205 through 1207 be used (p. 5).

Table 1
Consumptive (Irrigation) Water Rights Summary for San Joaquin River Basin

Flows and Consumptive Water Rights	Thousands of Acre-Feet Stanislaus River	Tuolumne River	Merced River	San Joaquin	Basin Total
Average Annual Unimpaired Flow	957	1,851	956	1,728	6,181
Total Consumptive Water Right Claims	5,318	11,015	5,495	10,828	32,656
Ratio of Total Claims to Unimpaired Flow	5.56	5.95	5.75	6.27	5.28
Total Riparian & Pre-1914 Claims	1,401	8,185	4,525	2,014	16,125
Ratio of Riparian & Pre-1914 Claims to Unimpaired Flow	1.46	4.42	4.73	1.17	2.61
Total Post-1914 Claims	3,917	2,831	970	8,814	16,532
Ratio of Post-1914 Claims to Unimpaired Flow	4.09	1.53	1.01	5.10	2.67

Sources: State Water Resources Control Board (e-WRIMS); Public Records Act responses from various public water and irrigation districts; California Water Impact Network. Sum of major tributaries' unimpaired flow does not equal Valley total due to omission of other watersheds from the table.

Table 2
Consumptive (Irrigation) Water Rights Summary for Trinity and Sacramento River Basins

Flows and Consumptive Water Rights	Thousands of Acre-Feet Trinity River	Feather River	Yuba River	American River	Sacramento Valley Total
Average Annual Unimpaired Flow	1,283	4,370	2,287	2,621	21,619
Total Consumptive Water Right Claims	8,725	15,717	5,093	9,847	120,571
Ratio of Total Claims to Unimpaired Flow	6.80	3.60	2.23	3.76	5.58
Total Riparian & Pre-1914 Claims	134	3,855	92	286	47,883
Ratio of Riparian & Pre-1914 Claims to Unimpaired Flow	0.10	0.88	0.04	0.11	2.21
Total Post-1914 Claims	8,591	11,863	3,596	9,561	72,688
Ratio of Post-1914 Claims to Unimpaired Flow	6.70	2.71	1.57	3.65	3.36

Sources: California Department of Water Resources, 2007; State Water Resources Control Board (e-WRIMS); Public Record Act responses from various public water and irrigation districts; California Water Impact Network. Sum of major tributaries' unimpaired flow does not equal Valley total due to omission of other watersheds from the table. Trinity River is included because a large portion of its runoff is exported to the Sacramento River via federal Central Valley Project facilities.

On basin-wide basis riparian and pre-1914 water claims account for about 4 percent of total consumptive use claims of 120. million acre-feet, and post-191 claims (permits and licenses in the Sacramento River Basin amount to about 6 percent of total consumptive use claims.

The largest water claims on Sacramento River Basin tributaries belong to the Feather River and the American River. The mainstem Sacramento (which is incorporated into the total for the Valley) includes the Pit and McCloud rivers and numerous small creeks that enter it from the east and west. C-WIN estimates that the largest component of pre-1914 water rights claims is held by the Glenn-Colusa Irrigation District. This District claims 2 million acre-feet in rights to divert directly from the Sacramento, as well as another 1 million acre-feet in rights from west side creeks.

On the Trinity River, the U Bureau of Reclamation is significant claimant of post-1914 water rights, and given the small amount of riparian and pre-1914 water rights claims on the Trinity, the Bureau's Trinity River rights are reliable, as conditioned and limited by the Trinity River Record of Decision (U Department of the Interior 2000 The Trinity's ratio of total consumptive claims to average unimpaired flow is 6. acre-feet of claims to every acre-foot of unimpaired flow.

There is another, more dynamic approach that we also include in this testimony to characterize excess claims to water use relative to flows. This planning-level analysis of water availability incorporates into the model hydrologic variability, instream flow requirements and publicly available water rights priorities on the divertable flows that remain in the system.

Applying Water Availability Analysis

In Tables 3 and 3 and accompanying charts we present results of applying both diversion cap (derived from the State Board's 2010 Delta flow determinations) and the water rights priority system in the manner that the State Water Resources Control Board is legally authorized to proceed. The unimpaired flow hydrology for this analysis was obtained from the California Department of Water Resources (2007) This analysis proceeds from the basic water rights premises that:

1) Instream flows needed to meet water quality and flow objectives have top priority.
2) When applying water rights, riparian rights are paramount, followed by—
3) Pre-1914 water rights claim water based on seniority date, followed by—
4) Any water left over is provided to junior water rights holders in order of priority date (whether pre-1914 rights or post-1914 permits and licenses).

Detailed model results, water rights, and flow data employed in the analysis are found in Appendix D. Assumptions embedded in the method are itemized in Appendix of this report.

To apply the water rights priority system in the context of providing new Delta inflows from the major tributaries C-WIN's analysis builds in range of flows from the 10th through 90th percentiles of the 82-year unimpaired flow hydrology available from the California Department of Water Resources (2007). 25th 50th (median) and 75th percentile (quartile) flows are also considered. C-WIN's analysis summarizes total regulated period unimpaired flow, the Delta inflow contribution and calculates "diversion cap." (See Appendices D.1, D.2, and E.)

Water rights priorities are then assigned to allocate the diversion cap flows for the regulation period to paramount riparian and senior water right holders first. Detailed tables of our model results are provided in Appendix D.1 for the Trinity and the major Sacramento and San Joaquin River Basin tributaries On the major tributaries there are generally few significant water rights holders and relatively small bloc of riparians may be known and allocated flows prior to pre-1914

Table 3A
Summary of Water Availability Analysis Results Incorporating Water Right Claims for Major Tributaries of the San Joaquin River Basin

River/ Instream Flow Objective	Annual Total		
	Riparians and Senior Pre-191 Right Holders	**Major Water Right Claimants**	**Other Junior Major Claimants**
Stanislaus	**Various including Tuolumne Utilities District**	**Oakdale & South San Joaquin Irrigation Districts**	**US Bureau of Reclamation**
40% Diversion Cap	2 TAF in all percentile flows.	19 to 75 TAF in all percentile flows.	81 to 250 TAF in the 50th to 90th percentile flows.
Tuolumne	**Various including Tuolumne Utilities District**	**Turlock Irrigation District, Modesto Irrigation District**	**City and County of San Francisco**
40% Diversion Cap	2 TAF across all percentile flows.	40 to 1,66 TAF across all percentile flows.	95 TAF in only the 90th percentile flows.
Merced	**Various including Gallo interests**	**Merced Irrigation District**	**Not applicable**
40% Diversion Cap	218 to 283 TAF across all percentile flows.	to 59 TAF from 40th to 90th percentile flows, about 14% of all claims.	Not applicable
San Joaquin	**Below Friant Dam, and along Fresno Slough**	**San Joaquin River Exchange Contractors**	**US Bureau of Reclamation**
40% Diversion Cap	172 TAF in all percentile flows.	24 to 81 TAF in all percentile flows.	89 to 413 TAF in 75th to 90th percentile flows.

right holders Pre-1914 water right claims tend to comprise the majority, or in most cases exceed the unimpaired flows in most (and in some cases all decile flows reported in the analysis.

Table 3B
Summary of Water Availability Analysis Results Incorporating Water Rights Claims for the Trinity River and the Major Tributaries of the Sacramento River Basin

River/ Instream Flow Objective	Annual Total		
	Riparians and Senior Pre-1914 Right Holders	**Major Water Right Claimants**	**Other Junior Major Claimants**
Trinity	**Various small claimants**	**US Bureau of Reclamation**	**Not applicable**
25% Diversion Cap	13 TAF in all percentile flows.	7 to 454 TAF across all percentile flows.	Not applicable.
Sacramento River above Feather River Confluence	**Various including Anderson-Cottonwood ID and Glenn Colusa ID**	**Early Post-191 to early 1927 claimants**	**CVP and Feather River Project Filings from 1927 through 1961**
25% Diversion Cap	2,094 to 5,98 TAF ranging across all percentile flows.	0 TAF across range of all percentile flows.	0 TAF across range of all percentile flows.
Feather River	**Western Canal W and Joint Water Districts, adjudication decrees**	**South Feather and Thermalito 1920 Rights**	**DWR 1927, 1951, and 1956 Claims**
25% Diversion Cap	72 to 1,97 TAF ranging across all percentile flows.	4 to 3 TAF from 20th to 90th percentile flows.	7 to 23 TAF in all percentile flows.
Yuba River	**Various including Nevada ID, City of Nevada City**	**Nevada ID and Yuba C WD 1920 Rights**	**Yuba County Water Agency 1927 Claims**
25% Diversion Cap	25 to 1,00 TAF ranging across all percentile flows.	1 to 1 TAF only at 25th to 80th percentile flows.	2 to 8 TAF among 50th to 80th percentile flows.
Bear River	**Various including Nevada ID**	**Camp Far West and Nevada ID Claims**	**South Sutter Water District Claims**
25% Diversion Cap	2 to 9 TAF ranging across all percentile flows.	1 to 5 TAF across all percentile flows.	4 to 9 TAF from 50th to 90th percentile flows.
American River	**Various including San Juan Water District Nevada ID and City of Sacramento Post-1914 Claims**	**Georgetown Divide PUD and Placer County Water Agency**	**U Bureau of Reclamation**
25% Diversion Cap	29 to 1,00 TAF ranging across all percentile flows.	8 to 18 TAF from 50th from all percentile flows.	9 to 13 TAF in all percentile flows.

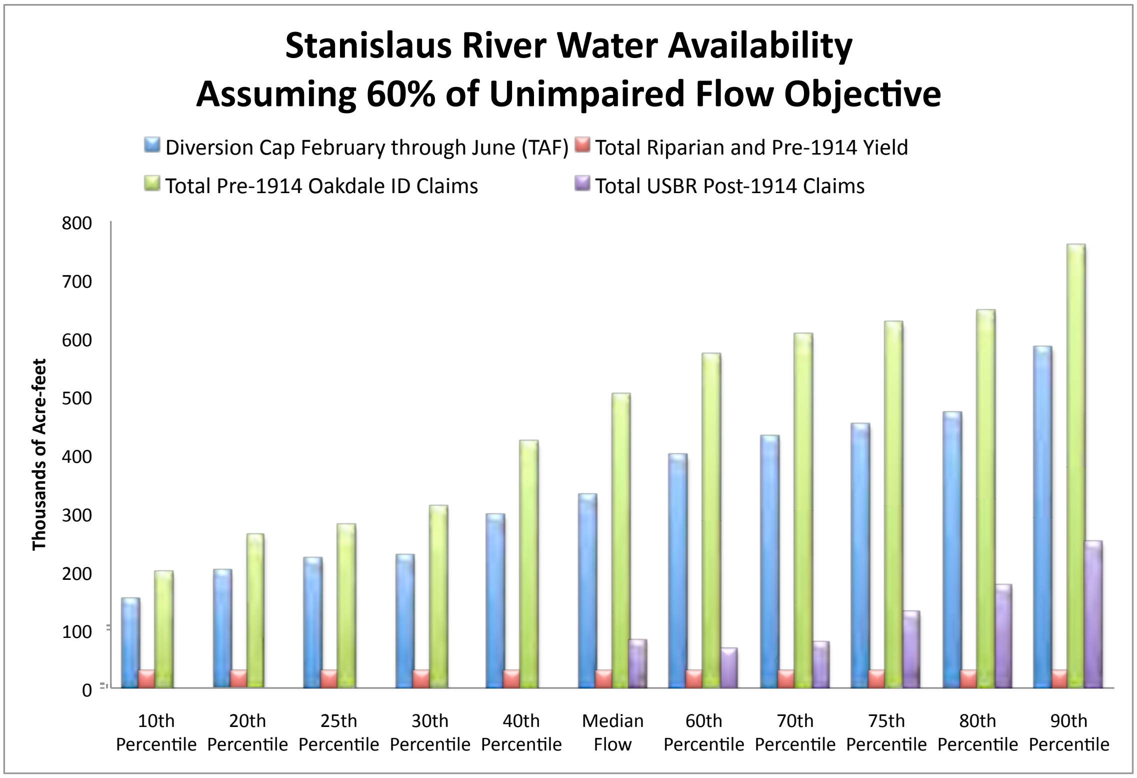

Figure 1, above. Figure 2, below.

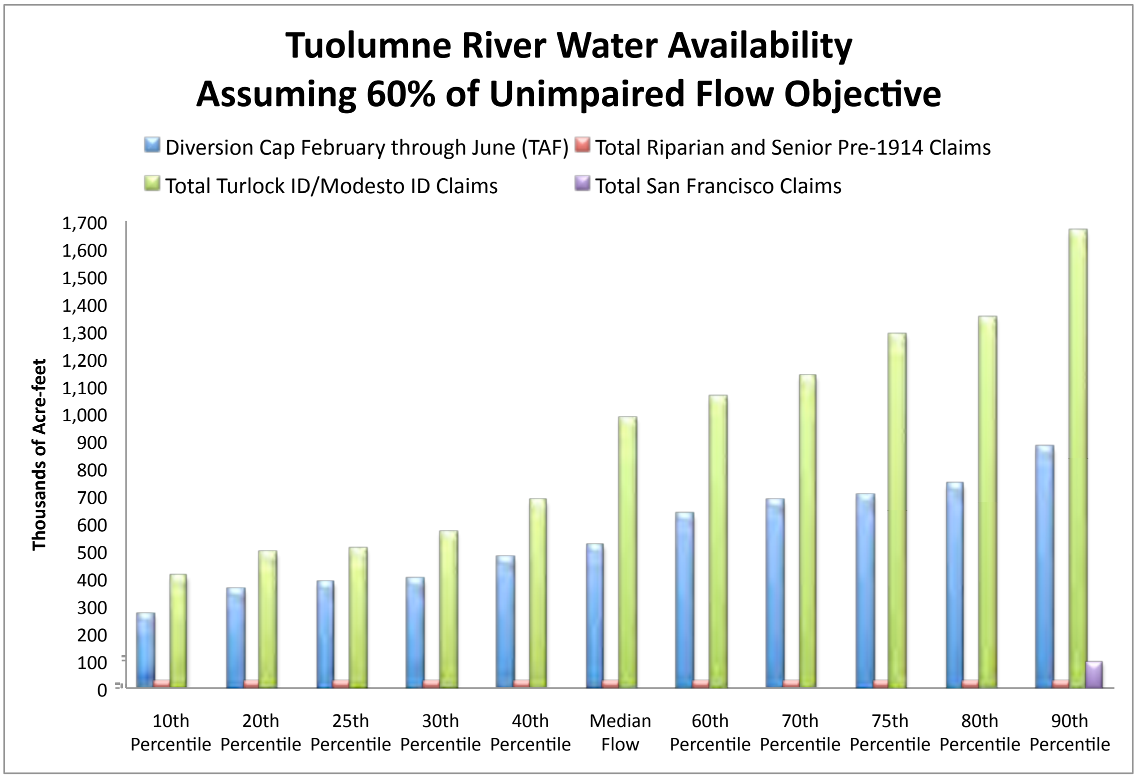

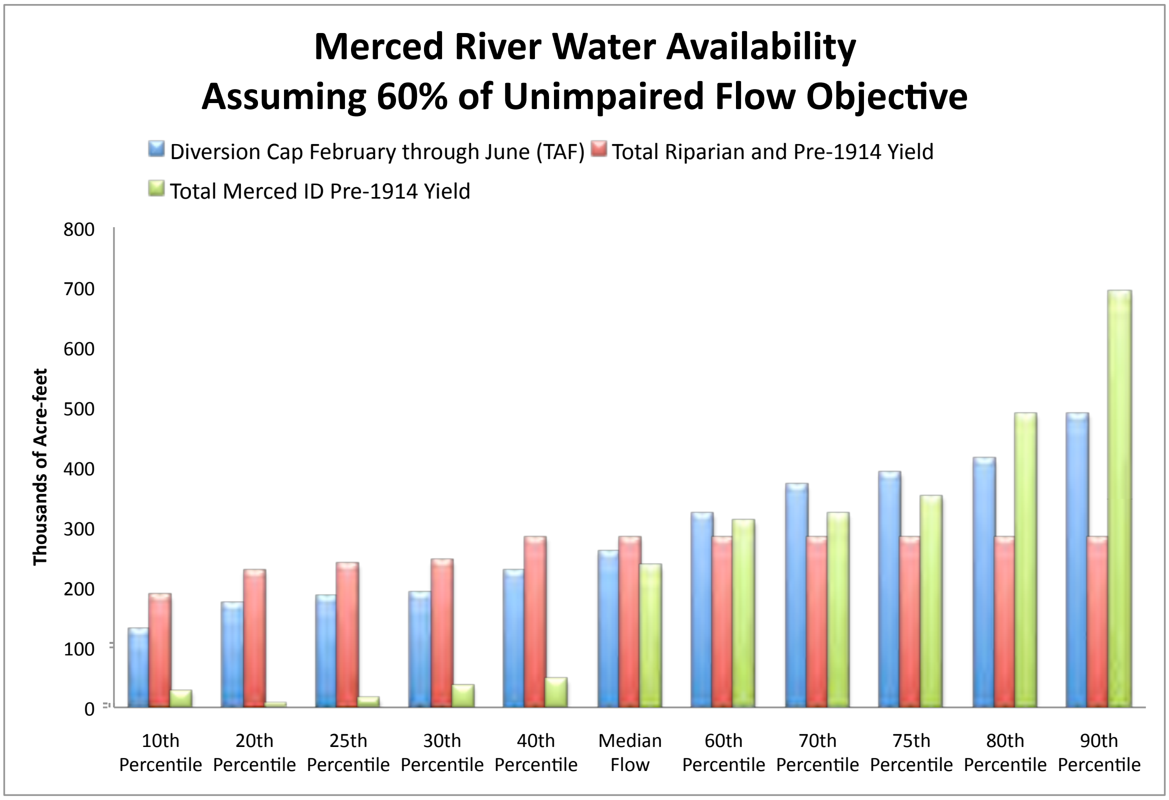

Figure 3, above. Figure 4, below.

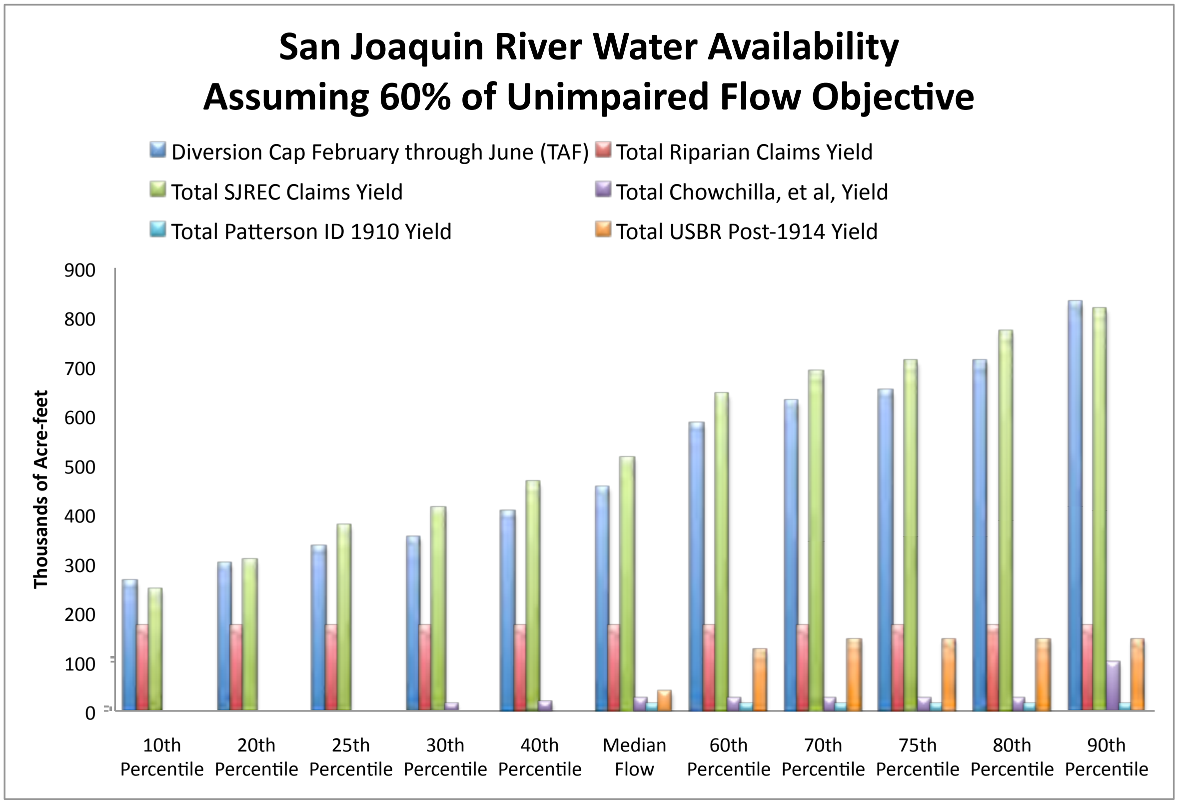

Stanislaus River (Figure 1)

Implications: Under strict application of both the 40 percent diversion cap and the water rights priority system in the Stanislaus River watershed, the US Bureau of Reclamation's water rights for New Melones Reservoir yield only a small fraction of Bureau claims in actual supplies.

Tuolumne River (Figure 2)

Implications: Under strict application of both the 40 percent diversion cap and the water rights priority system, the City and County of San Francisco would have reliable rights to water only in the wettest 10 percent of flows.

Merced River (Figure 3)

Implications: Under strict application of the water rights priority system to the 40 percent diversion cap, Merced Irrigation District's pre-1914 water rights exceed its post-1914 claims significantly, but are junior to a large amount of riparian and senior pre-1914 right holders.

San Joaquin River (Figure 4)

Implications: Only the small riparian allocations along the upper San Joaquin River would have fully reliable flows. The Exchange Contractors would have full claims on flows about 30 percent of the time (at the 70th percentile flows and above). The Bureau of Reclamation would not receive allocations except in the wettest 30 percent of years at all and would receive its full allocation no more than about 1 percent of the time.

Trinity River (Figure 5)

Implications: Riparian and pre-1914 water right holders on this river system are few. The Bureau's post-1914 water rights to develop Trinity Reservoir and Lewiston Dam, and the hydropower complex linked to Keswick Dam along Clear Creek are the dominant water rights on the Trinity River. As noted in Table 2, however, the consumptive use rights alone appear to be quite excessive relative to Trinity River's unimpaired flow hydrology.[3]

Sacramento River Above Feather River Confluence (Figure 6)

Implications: Because of large pre-1914 water rights claims by Glenn-Colusa Irrigation District along the Sacramento River, no water would be available to the US Bureau of Reclamation, except from Trinity River exports. Strict application of this pattern of water rights claims would dramatically reduce water available for export from the Sacramento River Basin and potentially undermine the San Joaquin River Exchange Contract.

---

[3] Our analysis applies to the Trinity the Board's 75 percent of unimpaired flow determination for November through June. This flow determination exceeds those of the 2000 Trinity Restoration Record of Decision. (US Department of the Interior 2000)

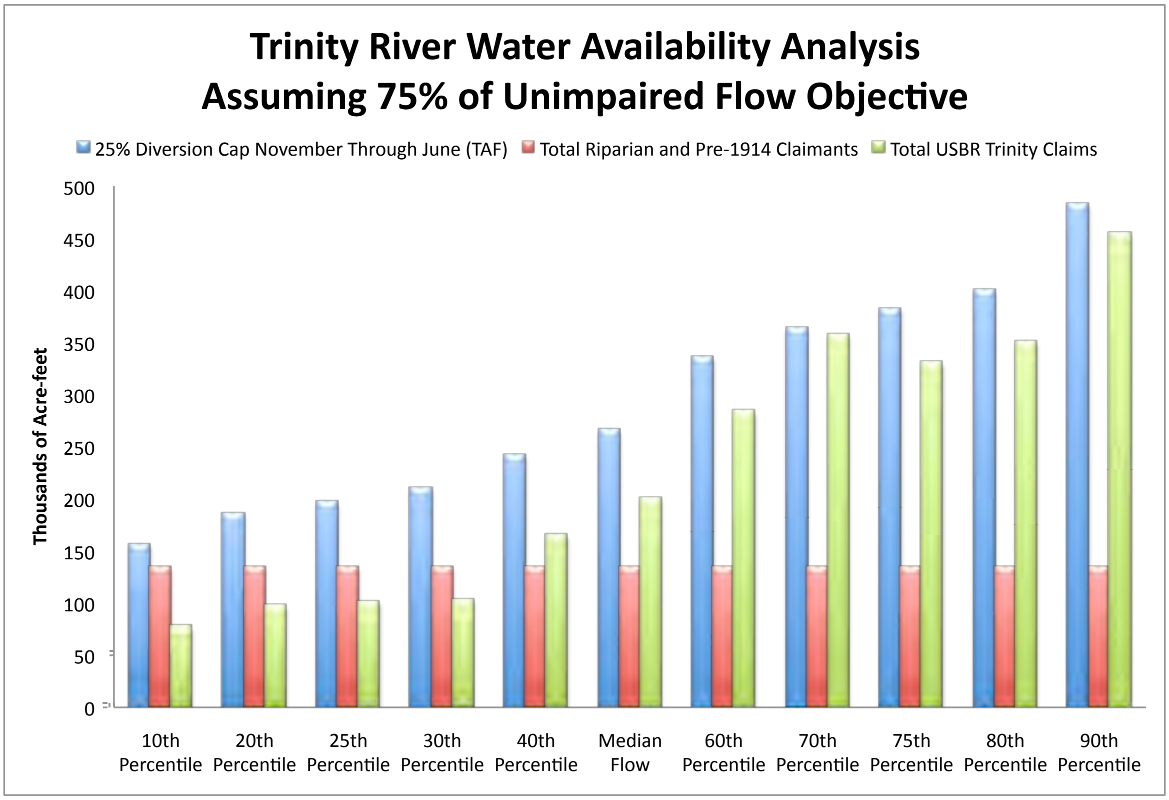

Figure 5, above. Figure 6, below.

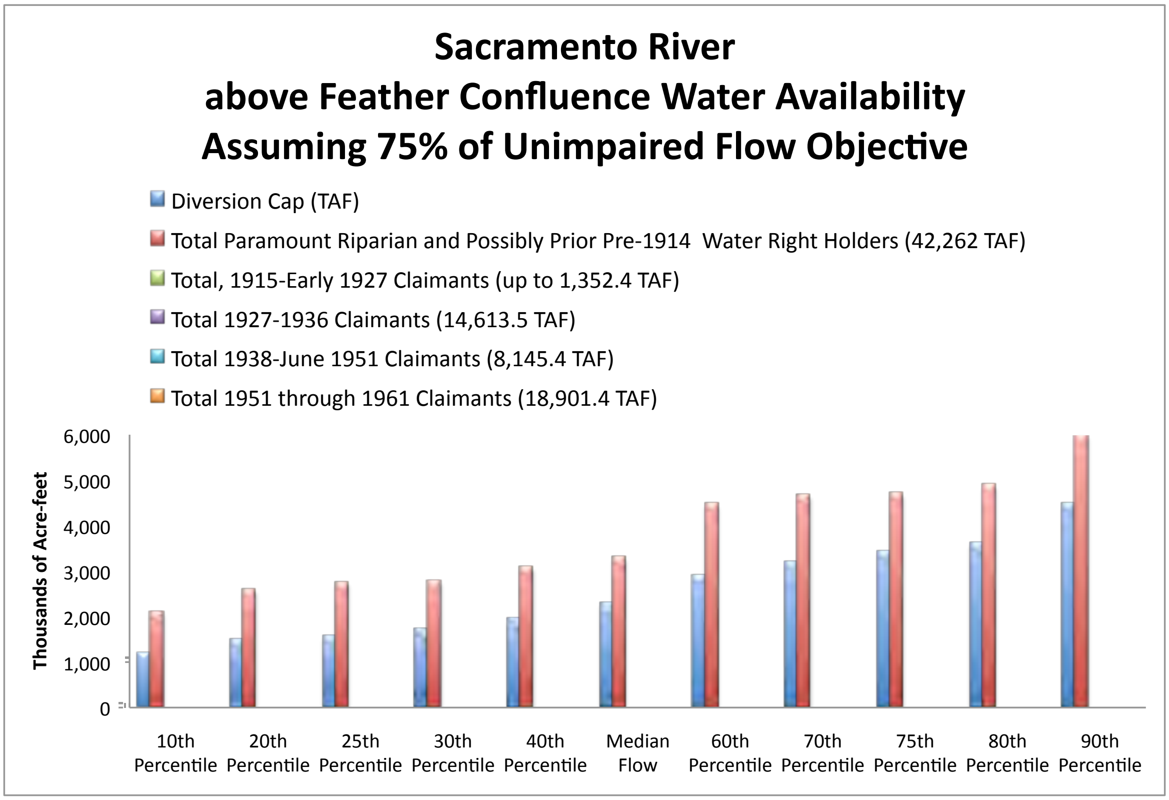

Feather River (Figure 7)

Implications The Department of Water Resources' 1927, 1951, and 195 water rights claims for the Feather River Project (now the State Water Project) would receive almost no water under a 25 percent diversion cap scenario. In drier years, even at relaxed diversion cap scenarios, DWR would receive only very small amounts. This is due to senior pre-1914 water rights claimants such as the Joint Water Districts[4] and Western Canal Water District, whose rights predate the cultivation of rice in the Butte County region, and were adjudicated in 1923. DWR's claims amount to about 10.4 million acre-feet (MAF) on the Feather River alone for consumptive uses.

Yuba River (Figure 8)

Implications Nevada Irrigation District and Yuba County Water District, through their pre-1914 claims and 1920s water rights claims, would have senior claims to Yuba River flows. Full operation of these claims would nearly eliminate Yuba County Water Agency diversions under a 2 percent diversion cap scenario.

Bear River (Figure 9)

Implications Because of senior water rights claims by Nevada Irrigation District and Camp Far West Irrigation District, South Sutter Water District would see its supplies reduced significantly relative to its claimed rights under a 2 percent diversion cap scenario.

American River (Figure 10)

Implications: The US Bureau of Reclamation's Central Valley Project facilities along the American River would receive very little water supplies from operation of the water rights priority system under a 2 percent diversion cap, despite having claimed up to 5.3 million acre-feet.

Discussion

Assuming that the State Water Board adopts the 7 percent unimpaired flow determination for the upstream tributaries of the Sacramento River Basin, the 6 percent of unimpaired flow determination for the San Joaquin River Basin, and that the water rights priority system is applied, it becomes evident that several significant water rights claimants that are junior in priority contribute dramatically to the problem of paper water: They have been promised water far in excess of flow conditions available to them in most years.

Table summarizes the major water rights claimants whose titles to water in the Central Valley watershed tributaries should be considered clouded, whose property "boundaries" are in dispute.

---

[4] The Joint Water Districts include Butte Water District, Biggs-West Gridley Water District, Richvale Irrigation District, and Sutter Extension Water District, the successors to pre-1914 water rights accumulated by the Sutter Butte Canal Company.

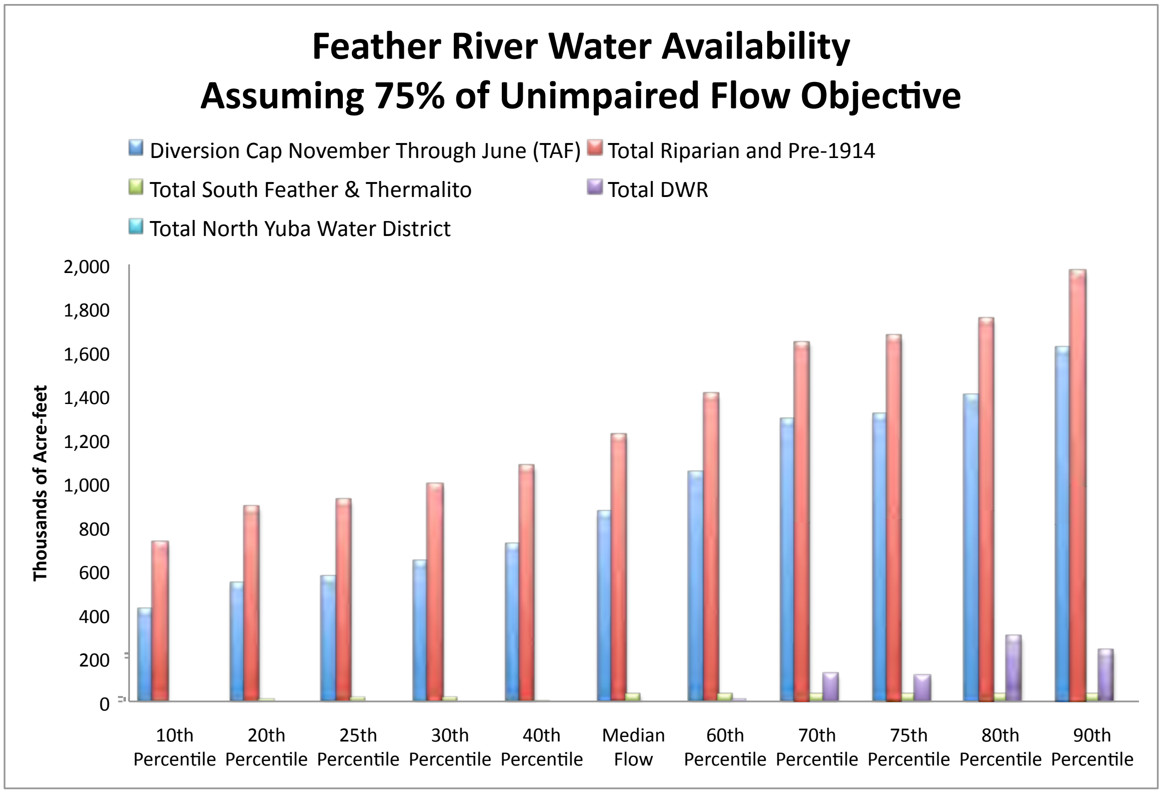

Figure 7, above. Figure 8, below.

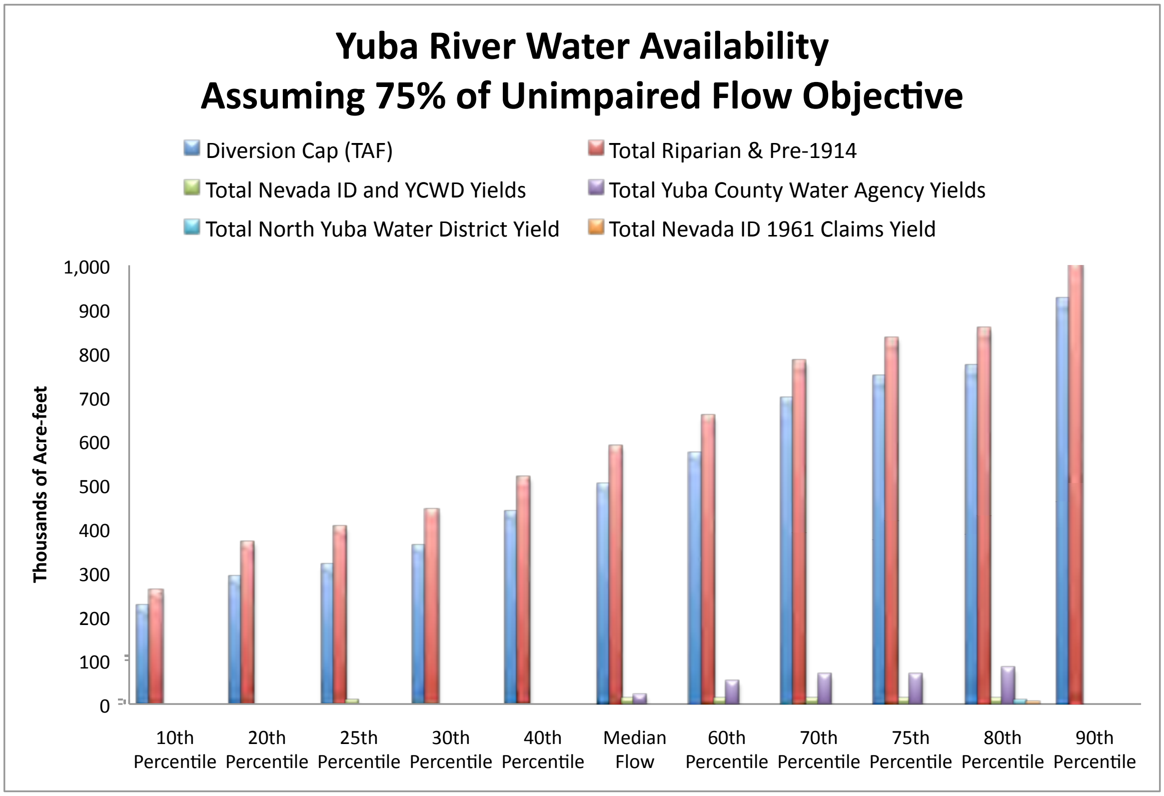

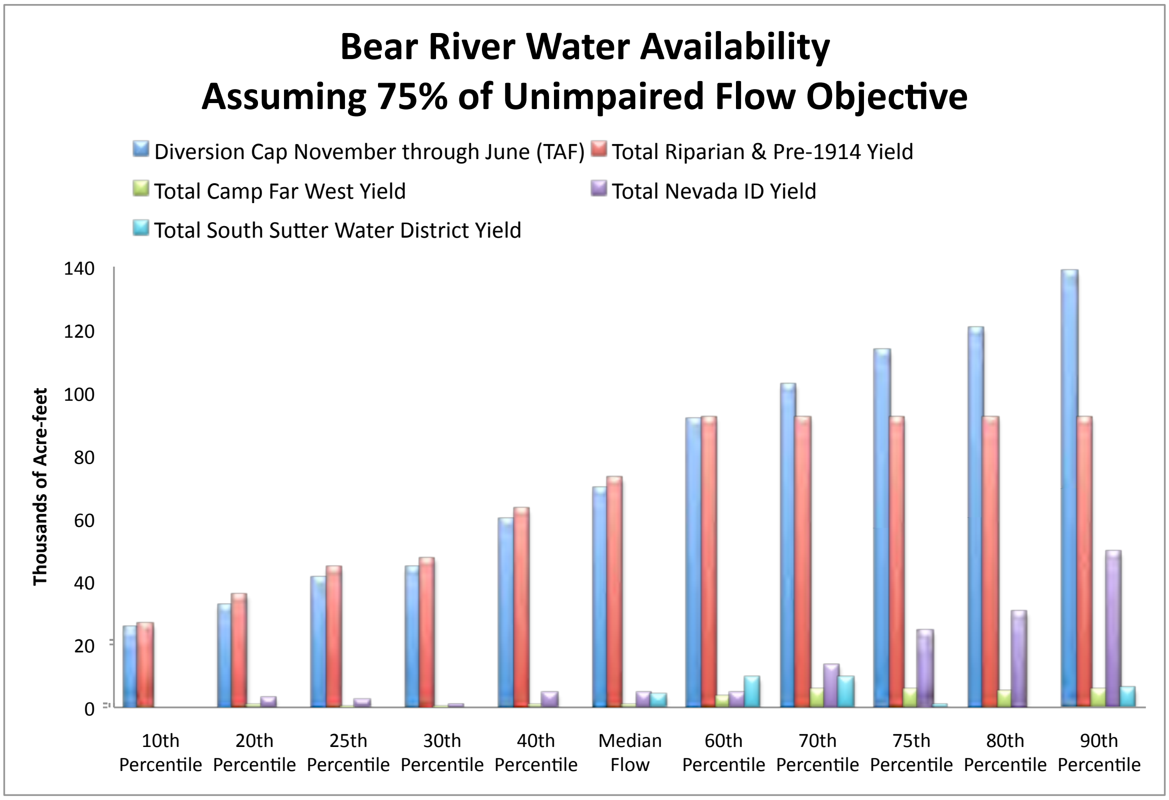

Figure 9, above. Figure 10, below.

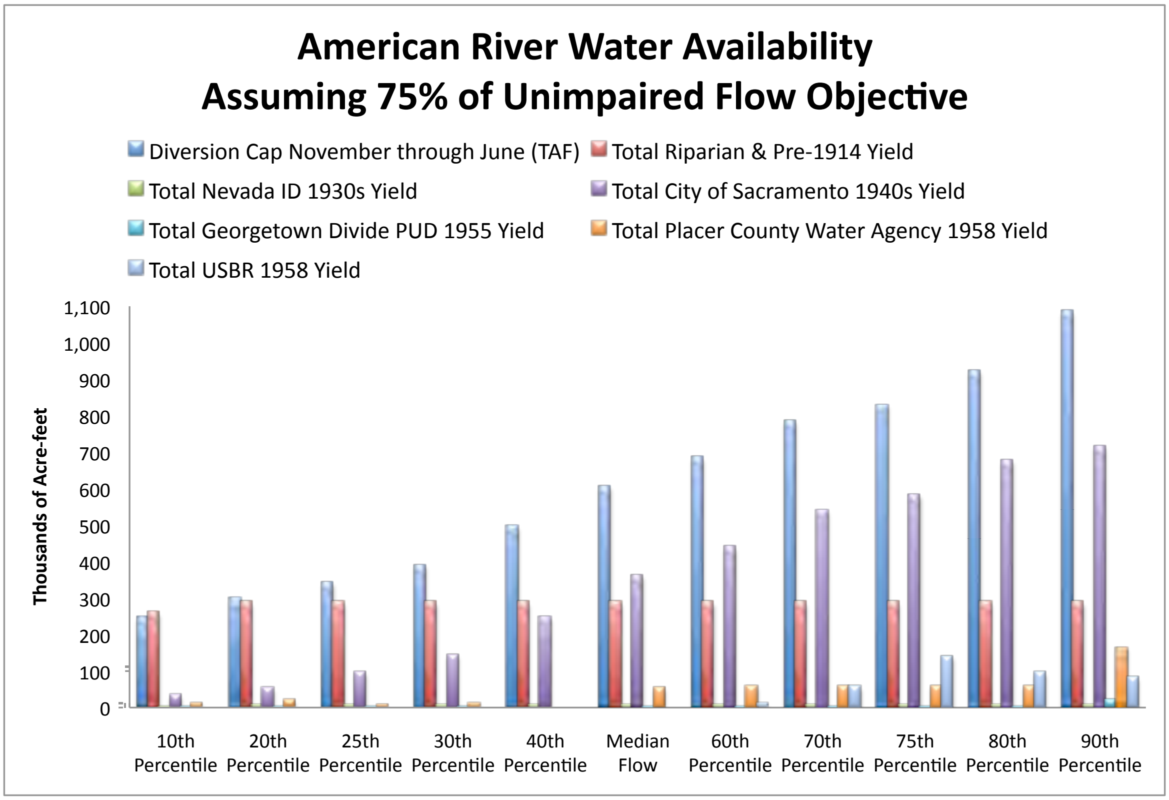

Table 4
Summary of Watershed Consumptive Water Rights Claimants by Reliability (Based on Legal Priority) of Claims

Watershed	Claimants with Highly Reliable Rights	Claimants with Potentially Clouded Title to Water
Stanislaus River	Various claimants covered by Stanislaus River decree of 1929; Oakdale ID, South San Joaquin ID	US Bureau of Reclamation (New Melones)
Tuolumne River	Tuolumne Utilities District, Turlock Irrigation District, Modesto Irrigation District	City and County of San Francisco (190 through 1911 rights)
Merced River	Gallo, various riparian and pre-1914 parties to early Merced River decrees	Merced Irrigation District (post-191 rights)
San Joaquin River	Paramount riparian claimants, San Joaquin River Exchange Contractors, Chowcilla WD, Tranquillity & James IDs, Patterson ID	US Bureau of Reclamation (post-191 rights)
Trinity River	Various small riparian and pre-1914 claimants US Bureau of Reclamation	US Bureau of Reclamation (has overstated water claims compared with actual basin hydrology)
Sacramento River (including west and east creeks, Pit and McCloud Rivers)	Various small riparian and pre-1914 claimants claimants among adjudicated watersheds in Pit River region, Anderson-Cottonwood Irrigation District, Glenn-Colusa Irrigation District	US Bureau of Reclamation (Shasta Lake)
Feather River	Upper watershed adjudicated claimants, Joint Water Districts, Western Canal WD	California Department of Water Resources (Lake Oroville)
Yuba River	Browns Valley ID, Nevada ID, Yuba County WD	Yuba County Water Agency (192 rights), Nevada ID (1930s rights), and North Yuba Water District (1958 rights)
Bear River	Nevada ID, Camp Far West ID	South Sutter Water District (195 and 1981 rights)
American River	City of Folsom, San Juan WD, Georgetown Divide PUD, El Dorado ID, Nevada ID, Placer County Water Agency, City of Sacramento	US Bureau of Reclamation (Folsom Lake), Foresthill PUD

By adopting its public trust Delta inflow determinations as flow objectives in the Bay-Delta Plan for each major tributary, and applying water rights priorities—in that order—the State Water Resources Control Board can use its authority to eliminate paper water (water claims that do not have a basis in water rights law) in the Bay-Delta Estuary's Central Valley watershed. The California Constitution reminds us that no one in California has a right to use or divert water wastefully or unreasonably. The state's public trust responsibility requires protection of the waters of the state for the benefit of all beneficial users, not just water rights holders. The state's water quality control planning obligations carry out this responsibility. It also helps the state meet its public trust obligations as well. The doctrine of prior appropriation requires that senior water right holders be served before junior water right holders. The water quality control planning process and the water rights priority system of the major tributaries of the Sacramento and San Joaquin River Basins should be used as tools for eliminating paper water—that is, for quieting water titles and ending trespasses and boundary disputes that compromise public trust resources—from the Bay-Delta Estuary's Central Valley watershed.

Paths for Aligning Water Rights with All Other Beneficial Uses and River Flows

We see three primary paths by which the State Water Resources Control Board can align water rights with all other beneficial uses and river flows:

- Water quality control plan implementation,
- Fully-appropriated streams declaration and Term 91, and
- Court adjudication.

Water Quality Control Plan Implementation. The State Water Resources Control Board has approved a Delta inflow determination for the San Joaquin River at Vernalis of 6 percent of unimpaired flow during the February through June period. For the Sacramento the Board approved a 75 percent of unimpaired flow determination for the November through June period. In doing so, the Board would implicitly place a cap on total diversions for each major tributary of 4 percent of unimpaired flow for the San Joaquin River and 2 percent of unimpaired flow for the Sacramento River Basin. These objectives would result in instream flows that are substantially greater in most years than current instream flow requirements now provide. In our water availability analysis, we also apply the Sacramento River Basin 7 percent objective rather than the Trinity Record of Decision flow objectives to the water availability analysis for the Trinity River. (US Department of the Interior 2000: 12)

Key water rights holders in these basins possess riparian and pre-1914 water rights that exist prior to the regulatory powers of the State Water Resources Control Board. On the question of implementing water quality control plans and adhering to state water rights law, the issue has arisen of the Board's jurisdiction over those water rights that the Board did not originally consent to.

Attorney Tim O'Laughlin, representing the San Joaquin River Group Authority (SJRGA), has asked the State Water Resources Control Board to "identify the legal theory or approach it will use at the implementation proceeding in order to obtain the necessary flows to meet the additional flow requirements identified" in the Board's flow studies. Without that legal theory or approach, O'Laughlin argues, the State Water Resources Control Board will be unable to complete economic or other impacts analysis in its Substitute Environmental Document on the San Joaquin River Flow and South Delta salinity objectives. He further contended in February 201 that the Board is operating according to *some* kind of theory since it

> blatantly **suggests** that additional flows will come from the Stanislaus, Tuolumne, and Merced Rivers. [State Water Resources Control Board 2011c, pp. 78 81, and 85-89. This foreshadowing demonstrates that the SWRCB not only believes that, regardless of the Vernalis flow alternative eventually adopted, it will be able to obtain flow from all the tributaries but that it intends to do so. That approach, however, completely ignores the existence of the water right priority system. (See, e.g. *Pleasant Valley Canal Company v. Borror* (1998) 6 Cal.App.4th 742, 770; *City of*

> *Barstow v. Mojave Water Agency* (2000) 23 Cal. 4th 1224, 1243; see also *El Dorado Irrigation District v. State Water Resources Control Board* (2006) 14 Cal. App.4th 937, 961.) As the SJRGA has pointed out to the SWRCB on numerous occasions, any approach to allocating responsibility for new Vernalis flow requirements must incorporate the water rights priority system. That said, the SJRGA recognizes that strict application of the water right priority system does not produce straightforward results such that the water required to meet the selected Vernalis flow alternative would come from a particular waterway or tributary, or that such water would roughly be divided equally or proportionally among such waterways and tributaries. (O'Laughlin 2011a, 1-2, emphasis in original)

O'Laughlin, on behalf of SJRGA, asserts that the Board has no jurisdiction to regulate pre-1914 appropriative water rights or riparian rights, regardless of any legal theory the Board intends to use in the implementation phase. If responsibility for new Vernalis flow requirements is determined solely based on the water rights priority system, writes O'Laughlin, "junior water right holders will be required to reduce or completely cease their water use before senior appropriators will be required to reduce theirs" as required in California's doctrine of prior appropriation. (O'Laughlin 2011a)

He wrote to the Board subsequently in June 201 about its jurisdiction in the Bay-Delta proceedings. There he stated, "It now appears that the [Substitute Environmental Document] is being prepared solely on the basis of percentage of natural flow, without regard to the nature or priority of the water rights affected, and will therefore be the subject of immediate litigation." (He is here apparently referring to the Board's proposed use of a percentage of unimpaired flow as the basis for limiting diversions.) O'Laughlin also reiterated in this letter to the Board that it

> does not have jurisdiction over pre-1914 appropriative water rights for any reason, including the implementation of water quality objectives adopted pursuant to the State Water Resources Control Board's authority under Porter-Cologne. Given the prevalence of pre-1914 appropriative rights held in the San Joaquin River Basin, and the scope of the percentage of natural flow that the [Board] is considering, it is almost certain that there will be times and conditions where the [Board] will not be able to implement a percentage of natural flow. It is arbitrary and capricious for the [Board] to continue to consider a percentage of natural flow as one of its objectives without knowing how often, if ever, it will be able to require such percentages be met. (O'Laughlin 2011b)

O'Laughlin argues that the Board's flow objective results may not be achievable if, for example, flow is 100 cfs and the Board applies a 6 percent instream flow criterion to this waterway while pre-1914 water right holders may claim 80 percent of the flow in the stream. In that case the Board, contends O'Laughlin, "would not be able to obtain the full 60 percent flow it desired." O'Laughlin contends that this not only renders the Delta flow criterion infeasible, it means that evaluation of criterion alternatives under the California Environmental Quality Act in the Substitute Environmental Document will also be infeasible and the SED thus inadequate.

Of course, contrary to the Racanelli decision, O'Laughlin elevates the water rights priority system to paramount status in California water and environmental law. It is plain from a review of state water case law that water rights priorities, while important, are not paramount considerations when the Board takes up the protection of beneficial uses of water. As Justice Racanelli stated, water quality control planning must concern itself with the regulation of *beneficial uses*, not water rights strictly speaking. Beneficial uses include, and go well beyond, water rights and their relative priorities. (See sidebar, page 26.) The Racanelli decision made clear that the State Water Resources Control Board has authority to implement its water quality control plan by regulating all beneficial uses. Adjusting quantities in water rights is within its authority.

Moreover, the Board retains authority to regulate pre-1914 water rights under its constitutional authority to prohibit waste and unreasonable use of water. The Legislature provided in the California Water Code key sections that do not limit the Board's authority to investigate rivers and streams in the service of the state's constitutional provisions (emphases added).

Beneficial Uses Served in the Bay-Delta Water Quality Control Plan:

- **Municipal and Domestic Supply**
- **Industrial Service Supply**
- **Industrial Process Supply**
- **Agricultural Supply**
- **Ground Water Recharge**
- **Navigation**
- **Water Contact Recreation**
- **Non-Contact Water Recreation**
- **Shellfish Harvesting**
- **Commercial and Sport Fishing**
- **Warm Freshwater Habitat**
- **Cold Freshwater Habitat**
- **Migration of Aquatic Organisms**
- **Spawning, Reproduction, and/or Early Development**
- **Estuarine Habitat**
- **Wildlife Habitat**
- **Rare, Threatened, or Endangered Species**

> ...
>
> 2501 Th board may determine, in th proceedings provided for i this chapter, al rights to water o a stream system whether base upo appropriation, riparian right, o other basi of right.

Nothin in thes section o th Water Code prevents th Board from investigating pre-1914 water rights an eliminatin illegal diversions shoul they b found. Water Code Sectio 275, appear to extend thi authorit o th Board to determining whether any water us i wasteful or unreasonable, o any metho of use o metho o diversion is wasteful o unreasonable.

Thes section provided authorit for th Board to investigate pre-1914 an riparia water rights in the Delta recently. I these investigations, the Board has issued water rights orders that in a least on instance adjusted the rights o a riparian water right holder. (Wilson 2012 Mr. O'Laughlin is surely aware o thi authority. O behal o th Sa Joaqui River Group Authority, his comment on the Board's 2008-201 strategic work pla helpe initiate th Delt water rights investigations in 2008 H cited California Water Code Section 182 to support the San Joaquin River Group Authority's recommendation tha th Board investigate Delt riparia an pre-1914 water rights. (San Joaquin River Group Authority 2008 64)

Whe the Board moves to adjus diversion amounts i th Delta's majo tributaries. Th Board should apply a diversion cap during the regulated period applicable to each tributary (including the Uppe Sa Joaqui River; se Appendix B an the allocate diversions according to water rights priority. C-WIN analyzes operation o th water rights priority system i the following river profiles.

Our testimony analyzes water availability usin water rights prioritie a way of identifyin the legal metho for allocatin responsibility for Delt inflows tha are fully protective o publi trust resources in the Delta.

Th Board announced i two notice (dated February 13 2009 an Apri 1, 2011, th latter containing revisions to the earlier Notice) its intent to revise the Bay Delta Water Quality Control Plan of 2006. This plan traces its lineage to the 199 Bay Delta Water Quality Control Plan an the Bay-Delta Accord. The Sa Joaqui River flow an Sout Delta salinit objective process i likely to b step i th right direction away from thes failed plans Th well-documented failures o this misguide loyalty include:

- Anadromous fishery decline throughout th Central Valley watershed o th Delt estuary.
- Declines o pelagi (open water) aquati ecosystem regimes throughout th Delta
- Continued listin o endangered species includin salmon steelhead, Delt smelt, longfi smelt, Sacramento splittail an green sturgeon.
- Chronic violation from 200 through 200 o sout Delta salinit objectives i bot the Bay-Delta Water Qualit Control Pla an Water Rights Decision 164 tha are intended to protect agricultural beneficial uses i this part of th Delta.

- Historic record Delta pumped exports between 200 and 2006 peaking at nearly 6. million acre-feet. (More recently, 2011 exports reached 6. million acre-feet.)

From the two NOPs, it appears the Board prepares to incorporate flow objectives for major tributaries of the San Joaquin River: the Stanislaus, the Tuolumne, and the Merced rivers. It appears to us the Board intends to require fair share flow contributions from each of these important rivers to flows of the mainstem San Joaquin as inflow to the Delta as measured at Vernalis. Our organizations welcome this prospect in concept, and support the Board's efforts toward this goal despite legal, ecological, and engineering challenges ahead.

The 198 Delta Water Cases decision (also named as the "Racanelli decision" for its author, presiding Justice John Racanelli of the Third District Court of Appeals in California) bears review because it defines the Board's water quality planning duties for the Delta and its watershed. (California Appeals Court, Third District 1986 When it comes to the Board's role in undertaking its duty to fulfill its water quality planning function, the Racanelli court stated:

> In its *water quality* role of setting the level of water quality protection, the Board's task is not to protect water rights, but to protect 'beneficial uses.' The Board is obligated to adopt a water quality control plan consistent with the overall statewide interest in water quality [citation to California Water Code §13240] which will ensure 'the reasonable protection of *beneficial uses*' (§13241 emphasis added) Its legislated mission is to protect the 'quality of all the waters of the state...for use and enjoyment by the people of the state.' (13000 1st para., emphasis added. (California Appeals Court, Third District 1986: 178)

Thus protection of beneficial uses must be the Board's paramount goal in this process. Beneficial uses make up "all competing demands for water" which must receive Board attention during public trust balancing and analysis. Water rights are among the Board's implementation tools for achieving the protection of beneficial uses in California's Central Valley watershed and Delta estuary, not strictly ends in themselves in this context.

Justice Racanelli wrote that the State Water Resources Control Board has a dual role of regulating both water quality and adjudicating water rights. The Racanelli court stated:

> In performing its dual role, including development of water quality objectives, the Board is directed to consider not only the availability of unappropriated water...but also *all* competing demands for water in determining what is a reasonable level of water quality protection. (California Appeals Court, Third District 1986: 179-180)

The Delta Water Cases came about because the Board construed its scope for water quality planning too narrowly, focusing on the major stakeholders in the Delta the Bureau, the Department of Water Resources, and their respective contractors. The Board erred in doing so, the Racanelli court stated.

> ...the Board must consider 'past, present, and probable future beneficial uses of water'...as well as 'water quality conditions that could reasonably be achieved through the coordinated control of *all* factors which affect water quality in the area' Unfortunately, the Board neglected to do so. (California Appeals Court, Third District 1986: 180)

That was 2 years ago As we will indicate below, C-WIN is deeply concerned that the Board may still neglect significant, realistic alternatives that will be essential to fulfilling its water quality planning role for solving problems in the Bay-Delta estuary and the larger Central Valley watershed.

Fortunately, the Board can avoid such neglect. Justice Racanelli wrote that the Board "need only take *the large view of the water resources* in arriving at a reasonable estimate of all water uses and activity well within its water rights function to determine the availability of unappropriated water." And he added "We think a similar *global perspective* is essential to fulfill the Board's water quality planning obligations." (California Appeals Court, Third District 1986, emphasis added) Justice Racanelli stated later that the Board compromised its role in previous water quality control plan when it defined its scope for action too narrowly "in terms of enforceable water rights. In fact," the judge wrote, "the Board's water quality obligations are not so limited."

> ...in order to fulfill adequately its water quality planning obligations, we believe the Board cannot ignore other actions which could be taken to achieve Delta water quality, such as remedial actions to curtail excess diversions and pollution by other water users. (California Appeals Court, Third District 1986, 182)

The Board's "paramount duty" remains to "provide 'reasonable protection' to beneficial uses considering all the demands made upon the water." Finally, Justice Racanelli concludes about the Board's water quality planning powers:

> Thus, we do not believe that difficulty in enforcement justifies a bypass of the legislative imperative to establish water quality objectives which in the judgment of the Board will ensure reasonable protection of beneficial uses. (California Appeals Court, Third District 1986, 182)

C-WIN believes that a credible water quality control plan for the Bay Delta estuary must take what Racanelli deemed the "global perspective" in order to redress the ecological collapse and cumulative salinization and pollution resulting from the Board's water quality planning efforts to date. The 1994 Bay-Delta Accord's water quality control planning pendulum swung too far in favor of water right holders and water contractors, and their respective beneficial uses. The Board's duty now is to credibly balance all of the beneficial uses of water in the estuary so that public trust resources are protected, and so that reasonable uses and methods of diversion of water are employed by all water users.

In addition to the water quality planning obligations that Justice Racanelli eloquently addressed, recent state legislation provides additional authority to the State Water Resources Control Board. Using this added authority, the Board can better protect water quality and beneficial uses in the Bay-Delta Estuary and the Central Valley watershed. We point to two new laws enacted in 2009.

The State Water Resources Control Board has already fulfilled its obligation under California Water Code Section 85086(c) and (e) to prepare a public trust assessment of the Bay-Delta flow criteria needed to protect fish and wildlife beneficial uses. While not a "balancing" analysis required under public trust doctrine, the Board's *Delta Flow Criteria Report* provides valuable scientific analysis and findings that must be used to help the Board fulfill its water quality planning responsibilities and achieve protective public trust resource outcomes in the Bay-Delta estuary. The report employed the best available science in arriving at its findings. (State Water Resources Control Board 2010b)

The same legislative package also changed the California Water Code to recognize the need to reduce reliance on the Delta as a source of water for California:

> 85021. The policy of the State of California is to reduce reliance on the Delta in meeting California's future water supply needs through a statewide strategy of investing in improved regional supplies, conservation, and water use efficiency. Each region that depends on water from the Delta watershed shall improve its regional self-reliance for water through investment

> in water use efficiency, water recycling, advanced water technologies, local and regional water supply projects, and improved regional coordination of local and regional water supply efforts.[5]

These new laws provide the Board with additional legal and political tools aiding the protection of all beneficial uses, particularly fish and wildlife beneficial uses whose protection has been neglected for decades.

The Water Code's Fully Appropriated Stream Provision and Term 91. The Board will need to revise its 199 water rights order concerning fully appropriated streams, and revisit its application of Term 9 curtailment of post-197 water rights permittees. Our water availability analysis helps show where key seasonal and priority thresholds may occur under the Board's new Delta inflow objectives.

California's Water Code implicitly acknowledges the potential for over-appropriation to occur and provides a process by which the State Water Resources Control Board may take steps to avoid or prevent excessive water promises. The Board can declare streams to be fully-appropriated on a month by month basis in every watershed of California under Section 120 through 1207. Its statutory language is reproduced in Appendix F to this testimony.

Section 1205(b) provides that a declaration that a stream system is fully appropriated shall contain a finding that the supply of water in the stream system is fully applied to beneficial use where the Board finds that previous water rights decisions have determined that no water remains available for appropriation. According to Section 1206(a), once a stream system is declared fully appropriated by the Board, the Board shall not accept for filing any application for a permit to appropriate water from the stream system described in the declaration, and may cancel any application pending on that date. Section 1206(b) states that the Board may provide for exceptions to application filing under specified conditions, which may limit the purpose of use, the instantaneous rate of diversion, the season of diversion, or the amount of water diverted annually.

Past State Water Resources Control Boards have declared fully-appropriated streams in California. (State Water Resources Control Board 1989, 1991, and 1998.) The Board's most recent 1998 declaration included major reaches of all tributaries to the Sacramento and San Joaquin River Basins as fully appropriated, including the Trinity River. (State Water Resources Control Board 1998, Exhibit A)

The Board has also designated as fully appropriated some rivers and streams that are adjudicated or have reaches designated for protection under state and federal wild and scenic river legislation. Major portions of the Trinity, Middle Fork of the Feather, the Tuolumne, and the Merced are designated as wild and scenic rivers. Wild and scenic rivers are off-limits to appropriations year-round. Other rivers and streams are fully-appropriated primarily during irrigation season. Appendix summarizes selected critical reaches of the Bay-Delta Estuary's Central Valley Watershed that are designated as fully-appropriated by the State Water Resources Control Board.

The Board's Full Appropriation Declaration blurs the distinction between water rights claims and water usage by claimants. Commendably, the Board has identified reaches of streams that are off-limits to new permanent applications to appropriate water. C-WIN identified several streams where it appears that the Board has excluded riparian and pre-1914 water rights in formulating its declaration. This appears to be the case of the Sacramento mainstem, the Tuolumne, the Merced, and the Yuba. On these rivers, substantial periods of the year are still officially open under the

---

[5] California Water Code §85021, passed November 2009.

Board's declaration to applications to appropriate. Substantial amounts of pre-1914 water rights do not appear to be considered in the Board's determination that a stream is fully appropriated.

Section 1205(b) does require that the Board's declaration "shall contain a finding that the supply of water in the stream system is being fully applied to *beneficial uses* where the board finds that previous water rights decisions have determined that no water remains available for appropriation." (For a list of all Bay-Delta beneficial uses see sidebar, page 26 above.) Note that the full-appropriation declaration legislation states that the supply of water is "being fully applied to beneficial uses and not merely to the claims of water right holders.

There is no explicit analysis in the 199 declaration by the State Water Resources Control Board of full application of water to beneficial uses as a direct consequence of citing its water rights decisions. This means that the full appropriation declarations are likely incomplete, albeit from a different standpoint. The Board may have construed Water Code Section 1205(b) as requiring the Board to rely on its archive of water rights decision, appropriately enough. But Water Code Section 1205(b) does not expressly limit the Board to use only water rights decisions, adjudications, and other determinative documents to justify these findings, as evidenced by the Board's additional reliance on wild and scenic river designations. Its approved 2010 flow objectives for the Sacramento and San Joaquin River basins (while legislated to be informational and predecisional in Water Code Section 85086(c)(1)) could also be used to support findings of full appropriation for the Sacramento River, the San Joaquin River, and their other major tributaries. Instream flows serve natural beneficial uses as surely as water rights claims serve economic uses. Accounting for these instream flows as part of full appropriation declarations would increase the period of full appropriation to include November through June throughout the Sacramento Basin and February through June in the San Joaquin Basin, given the magnitude of water rights claims we have identified.

Moreover, Board decisions like Water Rights Decision 1594 (D-1594) acknowledge the Board's duty to account for all beneficial uses, such as those protected by the Board's Delta water quality and flow objectives.

C-WIN's planning-level water availability analysis allocates unimpaired flow hydrology, among instream flow objectives first, followed by water rights in order of priority status for the Sacramento and San Joaquin River basins. This planning-level method of water availability analysis demonstrates that the waters of the Sacramento and San Joaquin River Basins, from a planning standpoint, should indeed be declared fully appropriated. The full spectrum of beneficial uses is fully accounted for in allocating the Basins' flows to full protection of instream beneficial uses as well as those of all water rights claimants in California's water rights priority system. Moreover, this water availability analysis uses instream flow determinations that the Board itself endorsed in 2010 as Delta protective of public trust resources. It also indicates which major claimants have either poorly reliable or no water rights once all beneficial uses are accounted for.

A problem with the State Water Resources Control Board's fully-appropriated declaration involves its reliance on Water Right Decision 1594 (D-1594) from 1984. D-1594 authorized the Board to place into permits (whose priority dates come after August 16, 1978) a new permit condition (called Term 91) notifying all permittees of its intent to curtail diversions of water right permittees. Curtailment occurs when flow and water quality conditions in the Delta demand that reservoir releases are needed to enable the California Department of Water Resources and the US Bureau of Reclamation to meet Delta water quality standards established by the Board. August 16, 1978, is significant as the date on which the Board adopted Water Right Decision 1485. This decision made the Bureau and the Department responsible for meeting water quality objectives in the Delta.

Water Availability Analysis

Workshop 3 Testimony, Bay Delta Plan

Submitted by California Water Impact Network, California Sportfishing Protection Alliance, and AquAlliance

D-1594 expressly addresses water availability for appropriation (diversion) in the Bay-Delta Estuary's Central Valley watershed by subordinating junior appropriative water rights to adherence to Delta water quality objectives. D-1594 is cited by the State Water Board as the water right decision authority for including the Sacramento-San Joaquin Delta in the 199 fully-appropriated streams water right order. This decision reaffirms the Board's reserved jurisdiction to revisit the season of diversion of water right permittees in the Bay-Delta Estuary watershed, and it establishes with standard permit Term 91 its authority to curtail diversions by post-1978 diverters so that storage releases by the Bureau and the Department can meet Delta water quality objectives.

In this decision, the Board states:

> The availability of water for appropriative water right permittees is affected by the quantity needed to satisfy holders of prior rights and the quantity necessary for protection of other beneficial uses. (State Water Resources Control Board 1983: 2)

In the process leading up to D-1594, the Board initiated a process to conduct a planning-level water availability analysis. Unfortunately, it abandoned that analysis:

> Staff had originally proposed a comprehensive analysis of water supply and demand which attempted to identify and quantify water usage by all diverters below the foothill reservoirs within the Delta watershed. [SWRCB Exhibit. 1, pp. 19-20] This approach was discontinued [apparently in April 1983, according to reporter's transcript dated April 11, 1983, p. 14, lines 16-20] due to the lack of adequate data for factors such as return flow, groundwater accretions, unmeasured tributary inflow, riparian use, appropriative use, and Delta consumptive use. (State Water Resources Control Board 1983: 9-10)

D-1594 states at least twice that application of Term 91 to post-1978 permittees is an "interim solution" or an "interim measure." Nearly 3 years later, the Board still employs Term 91's method of calculating water availability. D-1594 commits the Board to occasionally requiring the post-1978 permittees in the Delta's extensive watershed to curtail deliveries when flows are insufficient to meet Delta water quality objectives and protect the Delta's beneficial uses.

Our planning-level water availability analysis focuses on water rights claims compared to historical hydrology. As we earlier showed, it finds there are far more water right diversion claims than there are flows in the Bay-Delta Estuary's Central Valley watershed (including the Trinity River claims of the Bureau). Our water availability analysis incorporates Board-approved instream flow determinations the Board approved as fully protective of public trust resources in the Bay-Delta Estuary and its watershed. Its results suggest that *making Delta water quality and flow objectives fully protective of public trust resources will require moving the priority date of Term 8 permittees far earlier than 197 for determining when and for whom Term 9 diversion curtailment would occur*. This is necessary because the State Water Resources Control Board (2010) found that current Delta flow objectives on the mainstem and tributaries of the two basins, including the Vernalis Adaptive Management Plan on the San Joaquin River, are insufficiently protective of the Delta's fish and wildlife beneficial uses (State Water Resources Control Board 2010: 9-10). Conversely, this means that Term 91 *currently* applies Delta water quality objectives that are well known to be ineffective at protecting public trust resources in the Delta.

C-WIN believes it will be necessary for the State Water Resources Control Board to revisit Term 91 and D-1594's method of estimating water availability in the Bay-Delta Estuary's Central Valley watershed when implementing new Delta inflow (instream flow) objectives for the Sacramento and San Joaquin River Basins and their major tributaries upstream of the Delta. For the same reason, the Board's 199 water rights order must also be revisited to update and expand the seasons where appropriations would be prohibited as a matter of protecting all beneficial uses in compliance with Water Code Sections 1205 through 1207. The Board should include these actions in the Bay-Delta Plan's implementation program.

In sum: the Board has acknowledged that existing Delta water quality and flow objectives for the Bay-Delta Estuary are inadequate. (State Water Resources Control Board 2000 5 However, the Board *assumes* these water quality and flow objectives when it enforces Term 9 on post-197 water rights permittees. Improving these objectives will mean the Board must curtail diversions by water right permittees (also probably licensees with priority dates *earlier* than August 16, 1978, in order for Board-required Delta water quality and flow objectives to perform their functions protecting Delta watershed public trust resources. As part of its Phase II process to implement the Bay-Delta Plan the Board must take testimony on how to determine this earlier priority date.

In all types of hydrology and using the Sacramento River Basin flow determination of 7 percent of unimpaired flow from November through June C-WIN's water availability analysis suggests that for the Sacramento River Basin above the Feather River confluence and the Feather River basin itself the earliest date for curtailment should be December 19 1914 On the Yuba and the Bear Rivers, the date of curtailment could be somewhat later, ranging from 192 on the Yuba to 194 on the Bear. On the American River, the earliest date should coincide with the priority date of Placer County Water Agency's 1958 water rights.

In all types of hydrology and applying the San Joaquin River Basin flow determination of 6 percent of unimpaired flow from February through June, C-WIN's water availability analysis suggests that for the Stanislaus and Merced Rivers, the Term 9 curtailment date should be December 19 1914. On the Tuolumne River, the Term 91 curtailment date should be 1871. On the upper San Joaquin River, our analysis suggests that Term 9 curtailment dates should be on or before the dates of the Bureau of Reclamation's permits for Friant Dam and Millerton Lake in 1916. (See Appendix D.1 for Water Availability Analysis model results.)

The Board has acknowledged that current Delta water quality and flow objectives do not protect Delta fish and wildlife beneficial uses adequately. The Board must decrease the seasons of diversion for the Delta and its major tributaries of the Sacramento and San Joaquin River Basin watersheds, because the Board is obligated under the Public Trust Doctrine to protect all beneficial uses in the Delta To implement this obligation, the Board must also revisit its Fully-Appropriated Streams Declaration and push back the priority date used to conduct diversion curtailments under Term 91.

Court Adjudication Still another path that may be used is that of adjudication by a court of competing water rights claims in a watershed. It may take years of painstaking testimony and argumentation by attorneys and (usually) engineers But the present situation of extreme uncertainty and unreliability, clouded water titles, trespassing on the public trust, and related boundary disputes of many surface and groundwater water rights throughout the Bay-Delta Estuary's Central Valley watershed argues for its consideration.

In the 1930s and 1940s, staff within the Department of the Interior and the old State Water Rights Board advocated an adjudication of water rights prior to construction of the Central Valley Project. Both Governor Earl Warren and State Water Rights Board Chairman Henry Holsinger testified during the Clair Engle's Congressional hearing in 195 that a complete adjudication of water rights on the Sacramento River should have occurred prior to the completion of the Central Valley Project. In fact, the Engle committee concluded that, "[t]hat for all practical purposes the developed water supplies on the Sacramento River are overcommitted and oversubscribed." This was prior to approval and construction of the State Water Project. That project was predicated on obtaining some 5,000,00 acre- feet of water annually from north coastal streams (Figure 11) With the exception of about million acre-feet of Trinity River flows to the Central Valley Project service area, this "surplus" of surface water to the Delta system never arrived. Adjustments to the State Water Project should have been made earlier, but were not. The logical result is that the Delta's native aquatic ecosystems have collapsed.

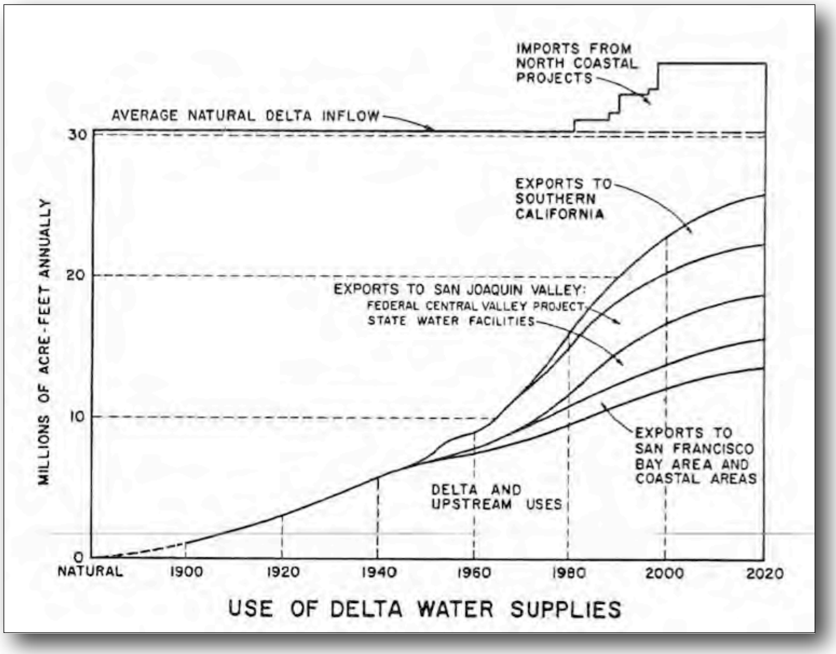

Figure 11
Source: California Department of Water Resources, 1960: 13.

A reliable source of surplus water for the State Water Project and the Central Valley Project eluded the Department and the Bureau, so far. Because surface water imports from north coast watersheds were precluded by wild and scenic river designations the Department and the Bureau have instead tried to establish a "water market" to transfer water from northern California across the Delta as an interim strategy for increasing water supplies in dry years for low-priority water service contractors south of the Delta. C-WIN, CSPA and AquAlliance see this as a grave threat to the regional aquifers of the Sacramento Valley from the Delta to Redding.

This threat is manifest in "groundwater substitution transfers." In such water transfers, surface water rights are transferred by "willing sellers" to the Department or the Bureau. The agencies facilitate the transportation of the water in the deal to the buyer south of the Delta using their export pumps near Tracy. To continue producing their crop however, the seller replaces or substitutes the surface water supply with water pumped from underground. The seller is thus able to achieve a net profit from the gross revenues from selling surface water rights, less the cost of pumping water from below ground, and still can sell a crop after harvest.

Such transactions however assume that groundwater may be treated simply as an individual's property under their land. Such a legal theory runs straight into the reality of groundwater in the Central Valley watershed being a regional commons, a shared resource, particularly among all individual landowners of the Sacramento Valley who overlie its extensive aquifers. One landowner or a set of landowners in one general location may cause a region-wide cone of depression by pumping a lot of groundwater to replace surface water they sold to someone south of the Delta. Such intensive pumping can damage the wells of neighbors near to and far from the scene of the original pumping. Many of the Valley's rivers are well known as "gaining" streams—that is, surface flows are actually enhanced upslope by accretions from groundwater sources. Too much groundwater pumping lower down in the aquifers for the "surplus" benefitting only the State Water Project and the Central Valley Project could drastically lower water tables upslope and reduce river flow permanently if allowed to become "the new normal." Potentially permanent injuries to many beneficial users of water in the Sacramento Valley would result.

glimpse of this prospect occurred in 199 when the Department sponsored a drought water bank program. The program resulted in damage to municipal well and to individual wells in Durham and Cherokee areas of Butte County. More recently, the Department and the Bureau have since 2002 repeatedly sought "willing sellers to offer surface water among the numerous public and private Sacramento Valley water right holders in Sacramento, Yolo, Sutter, Butte, Glenn and Colusa counties The State Water Resources Control Board in 1996 engaged in proceedings to determine the responsibility of Sacramento River Basin diverters to meet water quality standards in the Bay-Delta Estuary. The Board had completed phase through of the proceeding that led in 200 to adoption of Water Rights Decision 164 (D-1641). Phase of that proceeding was to focus on the Sacramento River and its tributaries In Phase 8, the Department of Water Resources and the Bureau of Reclamation, as operators of the state and federal export projects, claimed that certain water right holders in the Sacramento Valley must cease diversions or release water from storage to help meet water quality standards in the Delta. Sacramento Valley water users claimed that their water use had not contributed to any water quality problems in the delta and as senior water right holders and water users within the watershed and counties of origin they are not responsible for meeting these standards. To avoid both litigation and independent regulatory action by the State Water Resources Control Board, water diverters throughout the Sacramento River Basin executed an agreement in April 2001 (Northern California Water Association, 2001 As a result of the Sacramento Valley Water Management Agreement, the Phase process was dismissed by the State Water Resources Control Board. (State Water Resources Control Board 2001)

The Department and the Bureau have encouraged planning approaches to regional water management to facilitate water transfers, such as those in this partial list:

- The Department of Water Resources undertook draft and final Program Environmental Impact Report in 199 of drought water bank but to our knowledge has never certified this document.
- The Sacramento Valley Water Management Agreement, signed in 2002 but which ten years on still lacks a programmatic environmental review document. It expired December 31 2010.
- The 200 Governor's Advisory Drought Planning Panel Report, Critical Water Shortage Contingency Plan, which also promised program environmental document of drought response water transfer program, but was never undertaken.
- The Sacramento Valley Integrated Regional Water Management Plan of 2006 overseen by a joint powers authority of numerous water agencies in the Valley.
- DWR's last Drought Water Bank in 200 sought authorization for over 100,00 acre-feet of temporary transfers of water, though only 16,000 acre-feet were eventually supplied to Southern California buyers.
- The Northern Sacramento Valley Integrated Regional Water Management Plan now in development.
- The Delta Stewardship Council's Delta Plan, whose planning scope includes the entire Sacramento Valley and assumes groundwater surplus is necessary for meeting Delta export water demands The Council has also expressed support for water transfers using groundwater substitution.
- The Bay Delta Conservation Plan which would provide coverage from 50-year habitat conservation plan for Governor Brown's recently announced Peripheral Tunnels Project. This project has no identified water source, other than acknowledgement by the Bureau of Reclamation that it would reroute existing surface flows around the Delta from the Sacramento River Basin (Vlamis et al 2012)

C-WIN, CSPA, AquAlliance, and other knowledgeable experts are concerned that long term impacts of regional use of groundwater to substitute for transferred surface supplies will accelerate the depletion of the Valley's groundwater supplies. There are significant gaps in scientists' grasp of how the aquifer system recharges; how surface flows and groundwater systems interact in the Valley's creeks and rivers; how supplies contained within upper and lower aquifers interact; how the aquifers respond in the long-term to increasingly intense demand on them even during wetter years. And the regional effect of declines in groundwater levels on river and creek flows and riparian corridor species and wetland ecosystems has never been adequately explored. These are beneficial uses upstream along the major tributaries of the Sacramento River Basin that must also be considered part of the public trust responsibilities of the State Water Resources Control Board in its Bay-Delta Plan. (Vlamis et al. 2012)

State and federal water planners assume that surface and groundwater flows will always be there to support this hoped-for surplus. Based on that assumption they continue each winter and spring to plan the next water transfer program that relies on and encourages groundwater substitution transfers. This assumption has been built into the Department and the Bureau's chief water supply and operations planning tool, CalSIM II. When surface water supplies for riparian and appropriative water right holders are exhausted in model runs through CalSIM II the model's automatic response is to add pumped groundwater to make up for any deficit to water demands in the model. (Draper and Bourez 2004, slide 20; Close et al. 2003: 26-27; California Department of Water Resources and U.S. Bureau of Reclamation 2004, Appendix A) Sacramento Valley groundwater activity is explicitly modeled to include "minimum groundwater pumping" for those land uses that rely exclusively on groundwater in the Valley. (California Department of Water Resources and U.S. Bureau of Reclamation et al. 2004: Appendix A) San Joaquin Valley groundwater is not modeled. (Close et al. 2003) This can result in low estimates of salinity reaching the south Delta. (San Joaquin Valley CalSIM II External Review 2006: 45) Upper bounds on potential pumping from aquifers in the Sacramento Valley are undefined. According to Close et al.:

> This does not represent reality, since if CalSIM II is used for statewide planning, it would allow pumping of vast quantities of water for export to southern parts of the state, something which agency staff [i.e. California Bay-Delta Authority Science Program and the Association of Bay Area Governments] claim is unrealistic. Realistic upper bounds to pumping from any of the aquifers represented in the model need to be developed and implemented. (Close et al. 2003: 26-27)

The Department and the Bureau responded that CalSIM II does explicitly model the "impact on groundwater storage of each sub-basin." They state that CalSIM II runs that result in groundwater pumping over and above the natural and artificial recharge and which cause depletion of the basin will cause CalSIM II to no longer run. They also state, however, that CalSIM II "does not include local ground water inventories" but instead relies on a historically-modeled calibration of approximated inventories. They state further that "no groundwater is exported from the overlying watershed (except in the form of surface water return flow or tailwater that results from irrigation using groundwater)." (California Department of Water Resources and U.S. Bureau of Reclamation 2004: A-1) Thus, CalSIM II assumes that groundwater "backstops"surface water rights holders and their needs for supplies when in reality groundwater now backstops river flows (and all associated beneficial uses associated with those flows). It is small comfort that CalSIM II ceases to work when a basin is depleted from the program's operations; more to the point, it fails to assume let alone build in a rational groundwater management strategy of sustained yield.

CalSIM II's reliance on groundwater to meet overall water demand when surface supplies must not be the de facto water supply development strategy for the state of California when supplies run low. When supplies run low—as they are forecasted to as climate change affects the American West—the state and its responsible and lead agencies must increase other means of stretching water supplies. This can be done through water recycling, reuse, conservation, and a range of urban, industrial and agricultural efficiency measures.

Attorney for Petitioners

SUPERIOR COURT OF CALIFORNIA

COUNTY OF SACRAMENTO

California Water Impact Network, a non-profit Corporation, California Sportfishing Protection Alliance, a non-profit Corporation, and AquAlliance, a public benefit Corporation, Petitioners, vs. The California State Water Resources Control Board, The California Department of Water Resources, and DOES 1-100, Respondents The United States Bureau of Reclamation, Real Party in Interest	Case No.: 34-2010-80000653 **SECOND AMENDED COMPLAINT FOR DECLARATORY AND INJUNCTIVE RELIEF AND PETITION FOR WRIT OF ADMINISTRATIVE MANDATE (Code of Civ. Proc. §§ 526, 1060, 1094.5)** Judge: Hon. Michael P. Kenny Action Filed: September 3, 2010

INTRODUCTION

1. Petitioners California Water Impact Network (hereinafter "C-WIN"), the California Sportfishing Protection Alliance (hereinafter "CSPA"), and AquAlliance (collectively "Petitioners"), by and through their counsel, hereby allege on information and belief that the California Department of Water Resources (hereinafter "DWR"), is operating in violation of the Public Trust; Article X, Section Two of the California Constitution; the 1995 Water Quality Control Plan narrative standard for salmon; and State Water Resources Control Board Decision 1641 (hereinafter "D-1641"), all of which have led to the continuing and ongoing degradation of fish and wildlife.

2. Petitioners further allege that the State Water Resources Control Board (hereinafter "Board" or "SWRCB"), has failed to enforce permit and licensing conditions of the Porter-Cologne Act and D-1641 against DWR, thereby allowing DWR to cause extensive damage to the Bay-Delta estuary and the fish and wildlife that live therein.

3. Petitioners request a writ of administrative mandate challenging the approval by Respondent SWRCB of WR Order 2010-0002, which modified the Cease and Desist Order of WR Order 2006-0006 on January 5, 2010, and request that the Court set aside Board WR Order 2010-0002 and reinstate the Cease and Desist Order in WR Order 2006-0006 that required Respondent DWR to comply with interior Delta salinity standards by July of 2009.

4. Petitioners seek declaratory relief against DWR for violations of the Public Trust; Article X, Section Two of the California Constitution; the 1995 Water Quality Control Plan narrative standard for salmon; and D-1641 and seek an injunction to further pumping by DWR at the Banks Pumping Facility until DWR can comply with the law.

PARTIES

5. Petitioner C-WIN is a California non-profit public benefit organization with its principal place of business in Santa Barbara, California. C-WIN's organizational purpose is the protection and restoration of fish and wildlife resources, scenery, water quality, recreational opportunities, agricultural uses, and other natural environmental resources and uses of the rivers and streams of California, including the Bay-Delta, its watershed and its underlying groundwater

resources. Members of C-WIN reside in, use, and enjoy the Bay-Delta and inhabit and use its watershed. They use the rivers of the Central Valley and the Bay-Delta for nature study, recreation, and aesthetic enjoyment. Harm to the pelagic and anadromous fishery in the Bay-Delta and its watershed harms the California Water Impact Network and its members by threatening impairment of their use and enjoyment of these species and their habitat.

6. Petitioner CSPA is a California non-profit public benefit organization with its principal place of business in Stockton, California. CSPA's organization purpose is the protection, preservation, and enhancement of fisheries and associated aquatic and riparian ecosystems of California's waterways, including Central Valley rivers leading into the Bay-Delta. This mission is implemented through active participation in water rights and water quality processes, education and organization of the fishing community, restoration efforts, and vigorous enforcement of environmental laws enacted to protect fisheries, habitat and water quality. Members of CSPA reside along the Central Valley watershed and in the Bay-Delta where they view, enjoy, and routinely use the Delta ecosystem for boating, fishing, and wildlife viewing. Petitioner's members derive significant and ongoing use and enjoyment from the aesthetic, recreational, and conservation benefits of the Bay-Delta ecosystem. Harm to the Bay-Delta fisheries has had, and continues to have, a substantial negative impact on Petitioners' organizational members use and enjoyment of the Bay-Delta.

7. Petitioner AquAlliance is a California public benefit corporation organized to protect Northern California's waters to sustain family farms, recreation opportunities, vernal pools, creeks, rivers, and the Bay-Delta estuary. Currently, AquAlliance is a fiscally sponsored project of the Rose Foundation. Members and officers of AquAlliance are being affected by the over-pumping of the Bay-Delta and by the over-appropriation of water for excess water delivery south of the Bay-Delta. Mismanagement of water resources in the Bay-Delta deplete local lakes, and harm salmonids that travel through the lakes and streams used and enjoyed by AquAlliance members.

8. Respondent DWR is a state agency responsible for the State of California's management and regulation of water usage. DWR operates the State Water Project ("SWP"), a

water storage and delivery system of reservoirs, aqueducts, power plants and pumping plants, including the Oroville Reservoir and dam, the Clifton Court Forebay, the John E. Skinner Delta Fish Protective Facility, and the Harvey O. Banks Pumping Plant.

9. Respondent SWRCB the governing board that performs both adjudicatory and regulatory functions of the state in allocating water rights and ensuring water quality pursuant to the California Water Code. The Board has broad authority to carry out these functions, including the authority to hold hearings and conduct investigations in any part of the state necessary to carry out the powers vested in it. It also may require a state or local agency to investigate or report on technical factors, or comply with waste discharge requirements involved in water quality control. The Board may subject water rights to terms and conditions the board finds necessary to carry out a water quality control plan, and a water quality control plan may require changes to water rights, and it may reserve its jurisdiction to enforce these terms and conditions over time. The Board may hold an adjudicative proceeding to consider any changes to water rights to implement the plan.

10. Real Party in Interest the United States Bureau of Reclamation (hereinafter "Bureau" or "USBR"), is a federal agency required to comply with state laws relating to the control, appropriation, use, or distribution of water by the Reclamation Act of 1902. The Bureau operates the Central Valley Project (hereinafter "CVP" of "Project"), which reaches from the Cascade Mountains near Redding in the north some 500 miles to the Tehachapi Mountains near Bakersfield in the south. The Project is one of the world's largest water storage and transport systemscomprised of 20 dams and reservoirs, 11 power plants, and 500 miles of major canal as well as conduits, tunnels, and related facilities.

11. The true names and capacities of Respondents sued in the Petition under the fictitious names of DOES 1 through 100, inclusive, are unknown to Petitioners who therefore sue such Respondents by such fictitious names.

12. Whenever reference is made in this complaint to any act of Respondents, such allegation shall mean that each Respondent acted individually and jointly with the other Respondents named in that cause of action.

13. At all relevant times, each of the Respondents has acted as an agent, representative, or employee of each of the other Respondents and has acted within the course and scope of said agency or representation or employment with respect to the causes of action in this complaint.

14. At all relevant times, each Respondent has committed the acts, caused others to commit the acts, or permitted others to commit the acts referred to in this complaint and has made, caused, or permitted others to ignore the legal obligations referred to in this complaint.

JURISDICTION AND VENUE

15. Pursuant to Public Resources Code §§ 21168 and 21168.5, and Code of Civil Procedure section 1094.5, this Court has jurisdiction to hear this matter.

16. Venue is appropriate in this judicial district in accordance with Code of Civil Procedure §§ 401 and 393 because the respondents SWRCB and DWR are both located in Sacramento.

PROCEDURAL BACKGROUND

17. Violations of state permit and license requirements by DWR, and the Board's failure to enforce permit conditions, water quality standards, and its own decisions and order are causing, and continue to cause, extensive and irreparable damage to the Bay-Delta estuary and the public trust resources therein.

18. In 2000, the SWRCB adopted Decision D-1641, which established water quality objectives for the interior southern delta and conditioned DWR's pumping and export activities on meeting those standards.

19. On February 15, 2006, after DWR had repeatedly failed to meet the D-1641 standards, the SWRCB adopted WR Order 2006-0006, holding DWR responsible for meeting the water quality objectives described in D-1641 and imposing a time schedule requiring DWR to obviate the threat of non-compliance by no later than July 1, 2009. The order specifically rejected the possibility of any time extensions for compliance, stating "considering that the objectives were first adopted in the Water quality control plan in 1978… the State Water Board

will not extend the date for removing the threat of non-compliance beyond July 1, 2009."[1] WR Order 2006-0006 included a cease and desist order ("CDO") mandating DWR to cease and desist pumping and export activities if it failed to obviate the threat of non-compliance by July 1, 2009. DWR chose, as their preferred method of compliance, to build gates, known as permanent operable barriers.

20. In May of 2007, DWR informed the SWRCB that it would be unable to construct the permanent operable barriers that it planned to use to meet the D-1641 standards by the July 1, 2009 deadline, and requested an extension until July 1, 2011. No evidentiary hearing on the request to extend the compliance deadline was set by the Board at that time.

21. By June of 2009, one month before the CDO deadline, DWR had not begun construction on the proposed operable barriers to comply with the requirements of WR Order 2006-0006. That same month, a biological opinion from the National Marine Fisheries Service (NOAA Fisheries) was published that specifically prohibited construction of the proposed operable gates as a part of the South Delta Improvements Program (SDIP).

22. Therefore, on June 5, 2009 the Board issued public notice of an evidentiary hearing on whether the CDO in WR Order 2006-0006 should be extended. The Board asserted that the evidentiary hearing was noticed in response to DWR's May 2007 request to extend the compliance deadline. In late June of 2009 the SWRCB held an evidentiary hearing on potential modifications to the CDO in WR Order 2006-0006. The Board later adopted WR Order 2010-0002 on January 5, 2010, which modified the CDO and extended DWR's compliance deadline for complying with D-1641 standards to an uncertain future date, thereby allowing DWR to continue operating its pumps despite the continuing and ongoing degradation of fish and wildlife in the Delta.

23. In February of 2011, the Board officially denied Petitioner's Petition for Reconsideration of WR Order 2010-0002. Petitioners have therefore exhausted all available administrative remedies.

---

[1] WR Order 2006-0006, p. 27, ¶ 5

STATEMENT OF FACTS

24. The Bay-Delta is the largest estuary on the west coast of the Americas, and serves as one of California's most environmentally important and economically valuable ecosystems. Millions of Californians depend upon the Bay-Delta Estuary as one of the sources of their drinking water. Still more use the Bay-Delta as a recreational resource, making it a major recreation and tourist destination. Of the Delta's approximate 738,000 acres, roughly two-thirds support agriculture. More than 500,000 acres of the Delta currently are in agricultural production.

25. In addition to supplying drinking water and serving agricultural interests, the Bay-Delta but is home to approximately 750 plant and animal species, including 130 species of fish. The Delta serves as a critical fishery habitat as it supports an estimated twenty-five percent (25%) of all warm water and anadromous sport-fishing species, and eighty percent (80%) of California's entire commercial fishery habitat.

26. An extraordinary variety of wildlife, including several species which cannot be found anywhere else, live in the Bay-Delta. Many other species depend upon the Bay-Delta for migratory corridor habitat, and numerous commercial and sport fisheries depend upon the Bay-Delta for their continued existence.

27. The Bay-Delta provides critical habitat for a number of species that are protected by the Endangered Species Act ("ESA"), including the Sacramento winter-run Chinook salmon, Central Valley spring-run Chinook salmon (*Onchorhynchus tschawytscha*), Central Valley steelhead (*Onchorhynchus mykiss*), and Delta smelt (*Hypomesus transpacificus*, collectively, the "Listed-Species").

28. Since 1993, the National Marine Fisheries Service ("NMFS") has listed the several fish in the Bay-Delta as "threatened" or "endangered," including the Sacramento River winter-run Chinook salmon and the Central Valley spring-run Chinook salmon.

29. In September of 1999 the National Marine Fisheries Service listed the Central Valley spring-run Chinook salmon as a threatened species, with a population of only 500.

30. The NMFS has also officially listed the Bay-Delta as critical habitat for the aforementioned threatened and endangered fish. As such, the Bay-Delta Estuary is one of California's most threatened ecosystems. The SWRCB designated the Delta's channels, the Sacramento and San Joaquin Rivers, and areas throughout the Bay as water-quality-limited water bodies, yet violations of water quality standards in the Delta are chronic.

31. Many of the Bay-Delta's fish are threatened with extinction. In the last three (3) years several populations of previously healthy species have also suffered catastrophic declines. Still others, including plankton and other food organisms that underpin the Bay-Delta's entire food chain, are in similarly poor health.

32. The collapse of the California salmon run has triggered severe fishing restrictions that have resulted in the near-complete closure of commercial and recreational salmon fishing in California for the 2008, 2009, and 2010 fishing seasons. The number of Chinook or King salmon returning from the Pacific Ocean to spawn in the Sacramento River and its tributaries dropped 67 percent from a poor year earlier. Restoration of California's anadromous fish populations is mandated by the Salmon, Steelhead, and Anadromous Fisheries Program Act of 1988 which states that it is the policy of the State to significantly increase the natural production of salmon and steelhead by the end of the 20th century.

33. Pursuant to the California Water Code, the SWRCB has a duty to protect the waterways of California by the imposition and enforcement of certain requirements to permits and licenses that regulate water quality in the State.[2]

34. Under California law, the SWRCB has an affirmative duty to take the public trust into account in the planning and allocation of water resources, and to protect public trust uses whenever feasible.[3]

---

[2] See, Wat. Code § 100: "…The right to water or to the use or flow of water in or from any natural stream or watercourse in this State is and shall be limited to such water as *__shall__* be reasonably required for the beneficial use to be served, and such right does not and shall not extend to the waste or unreasonable use or unreasonable method of use or unreasonable method of diversion of water" (*__emphasis added__*); and Wat. Code § 275: "The department and board *__shall__* take all appropriate proceedings or actions before executive, legislative, or judicial agencies to prevent waste, unreasonable use, unreasonable method of use, or unreasonable method of diversion of water in this state" (*__emphasis added__*).

35. The SWRCB is also charged with complying with California Constitution Article X, Section 2, which requires that any right to the use or divert water from any natural stream or water in the State shall be reasonable.

36. The SWRCB has adopted several orders that, if enforced, would be protective of fish and wildlife in the Bay-Delta estuary. For example, the Porter Cologne Act required the Board to adopt the 1995 Water Quality Control Plan which includes a Narrative Standard for Fish and Wildlife (hereinafter “the narrative standard”). This narrative standard requires that water flow, water quality, and appropriate temperature conditions are sufficient to achieve a doubling of natural production of Chinook salmon from the average production of 1967-1991.

37. Consistent with the Clean Water Act, the Porter-Cologne Act requires the SWRCB to create and enforce a water quality control plan that includes water quality standards and objectives, which resulted in the SWRCB adopting D-1641.

38. Decision 1641, adopted by the SWRCB on December 29, 1999, establishes water quality objectives for the Bay-Delta Estuary as a part of the Board’s implementation of the 1995 Bay-Delta Water Quality Control Plan. D-1641 also imposes a series of restrictions on the use of export pumps to protect fish and wildlife and assigned responsibilities to the persons or entities holding water rights permits to meet specific flow objectives to protect fish and wildlife. One such restriction requires that water quality objectives must be met at four different monitoring stations in the Bay-Delta before DWR pumping activities can continue. D-1641 holds DWR specifically responsible for meeting these flow objectives.

39. The Board has consistently assigned DWR responsibility for meeting salinity objectives in the Bay-Delta, including those objectives described in D-1641.

40. The SWRCB found that export pumping under the conditions imposed by D-1641 would not unreasonably affect or substantially injure any legal user of water, and would not unreasonably affect fish, wildlife, or other in-stream beneficial uses of water.

---

[3] See *National Audubon Society v. Superior Court* (1983) 33 Cal.3d 419.

41. Contrary to the findings and conditions of D-1641, the SWRCB continuously fails to enforce its own Basin Plan standards, allowing DWR to continue pumping activities leading to the dramatic decline in the health and viability of the Bay-Delta estuary and the public trust recourses therein.

42. In spite of D-1641 Respondent DWR, with the tacit approval of the SWRCB, has increased its water exports by 53% percent since 2000. This increase exceeds the average of 2.1 million acre-feet that was exported during the 1990s, resulting in the dramatic decline of Delta fisheries. Meanwhile, Delta fish populations of salmon, striped bass, Delta smelt, and other listed and unlisted species collapsed.

43. DWR exports water that it claims is excess or surplus under Article 21 of the amended State Water Project contracts. The exported water is used largely to further development, water banking, and water transfers. Despite the recent and dramatic further decline in the health of the Bay-Delta estuary, DWR has continued to export increasing amounts of water in violation of D-1641, causing some substantial fish declines between the years of 2000 and 2010 with the approval of the SWRCB.

44. In 2008, 2009, and 2010 the populations of various California salmon runs have dramatically declined, resulting in the complete closure of commercial and sport-fishing salmon fishing in California for the 2008 and 2009 fishing seasons, and a substantial reduction in fishing in 2010. The number of Chinook or King salmon returning from the Pacific Ocean to spawn in the Sacramento River and its tributaries this fall dropped 67 percent from a year earlier.

45. Every scientific study done in the last decade (CalFed ROD, IEP Science Reviews, OCAP Biological Opinions on Delta smelt and listed salmonids) has found that exports from the Bay-Delta are largely to blame for the current fish and wildlife declines in the Delta.

46. The fish protection conditions of D-1641, when they are not enforced and allow increased export pumping, are not protective of the Bay-Delta fisheries. The lack of protection has resulted in a serious decline in the health of those fisheries and in their habitat. Increased SWP pumping necessarily decreases in-stream flow and Delta outflow, thereby increasing the concentration of pesticides, herbicides, and other toxins in the Bay-Delta waterways. Increased

export pumping by the SWP since 2000 has had a significant, negative impact on the survival of juvenile Chinook salmon emigrating through the Delta, particularly in the November through June period.

47. Numerous scientific studies, including the SWRCB's recent report to the State Legislature, indicate that increasing flows from the SWP to the Delta in the spring would protect marine wildlife habitat and the threatened water ecosystem. Increased flows in the San Joaquin River correlate to increased numbers of adult fall-run Chinook salmon, and spring flow coincides with the spawning season of a number of estuarine species, such as delta smelt, Sacramento split-tail, Green sturgeon, and striped bass.

48. The SWRCB has a duty of continuing supervision over the taking and use of appropriated water, and must allocate water resources in light of current knowledge and current needs. In the face of mounting evidence that water exports are harming fish and wildlife since 2000, the Board has refused to reduce DWR's water rights and export permits and has failed to evaluate permit conditions that would protect fish and wildlife and would reflect changed environmental circumstances in the Bay-Delta.

49. The SWRCB has continuously refused to act on public trust complaints against DWR and its activities at the Banks pumping plant, and has rejected Petitioners' attempts to address the allegations contained herein through administrative proceedings.

50. On January 5, 2010 the SWRCB modified WR Order 2006-0006 and the related Cease and Desist Order (CDO) against DWR for threatened violation of their permit/license requirements to meet the 0.7 EC standard in the interior southern Delta. Petitioners had strongly opposed the modification of the CDO, which had required complete compliance with the permit and license requirements by July of 2009. In its decision to modify the CDO in WR Order 2006-0006, the Board largely dismissed fish and wildlife concerns under the public trust, and failed to enforce Article X, Section 2 of the California Constitution.

51. By approving WR Order 2010-0002, the SWRCB has allowed Respondent DWR to violate the conditions of their permits, the agricultural water quality standards in the Bay-

Delta, D-641, and the CDO (WR Order 2006-0006), and has failed to exercise its duty to protect the public trust and guard against waste and unreasonable use.

FIRST CAUSE OF ACTION
Violation of the California Public Trust Doctrine

52. Petitioners restate and re-allege and incorporate all of the preceding paragraphs as if fully set forth herein.

53. Respondent DWR has increasing annual pumping in violation of the Public Trust Doctrine since 2000, despite the increasingly perilous collapse of Delta fish populations of salmon, striped bass, Delta smelt, and other listed and unlisted species.

54. Respondent DWR's decision to continue pumping despite the obvious damage to public trust resources has caused there to be a substantial decline in the food web, in fish numbers, in water quality, and in hydrologic changes which have caused injury to the ecosystem and to members of the public, including Petitioners. Present ecological conditions in the Bay-Delta have contributed to the closure of the commercial and sport-fishing fishing seasons off the California Coast, resulting in the near complete loss of recreational fishing opportunities for anglers.

55. On information and belief, unless the DWR is enjoined by this court, it will continue to violate the Public Trust, as described above, and Petitioners will suffer irreparable injury for which there is no adequate remedy at law.

56. An actual controversy exists between Petitioners and Respondent DWR. Specifically, Petitioners contend and Respondent DWR denies that its pumping methods constitute a violation of the California Public Trust doctrine or that its failure to abide by salinity standards set by their water rights permits violates the Public Trust and injures Petitioners. As an actual controversy exists, Petitioners are entitled to and hereby seek a declaration that Respondent DWR has violated the Public Trust.

/

/

/

SECOND CAUSE OF ACTION
Violation of Article 10, Section 2 of the California Constitution: Unreasonable Method of Diversion

57. Petitioners restate and re-allege and incorporate all of the preceding paragraphs as if fully set forth herein.

58. Article X, Section Two of the California Constitution states that "the right to water or to the use or flow of water in or from any natural stream or water course in this State is and shall be limited to such water as shall be reasonably required for the beneficial use to be served, and such right does not and shall not extend to the waste or unreasonable use or unreasonable method of use or unreasonable method of diversion of water."

59. Water levels in several Delta channels are reduced to unacceptably low levels by Respondent DWR's operation of the State Water Project pumps, harming fish and riparian diverters in the process. At present export levels, DWR's Method of Diversion from the Bay-Delta at the export pumps is unreasonable and has overwhelmingly contributed to the pelagic fish decline and the listing of several species as threatened or endangered.

60. Over the years and continuing to the present time, Respondent DWR's methods of diversion caused there to be insufficient in-stream flow and Delta outflow to support the environmental needs of the estuary which has caused injury to the ecosystem and to members of the public, including Petitioners.

61. Over the years and continuing to the present time, Respondent DWR has used an unreasonable method of diversion of water from their facilities in the Bay-Delta in violation of Article 10, Section Two of the California Constitution by continuing to increase volumes of water drawn from the Bay-Delta ecosystem, and limiting and ignoring research and information that indicated this method of diversion is causing a collapse in the Pelagic fisheries in the Bay-Delta and harm to the listed salmonids and other fish and wildlife.

62. On information and belief, unless enjoined Respondent DWR will continue to violate the California Constitution, as described above.

63. In light of the Respondent DWR's failure to comply with the California Constitution, and the significant likelihood of repeated violations in the future, Respondent DWR

must be permanently enjoined from continuing to divert water from the Bay-Delta until they comply with Article X, Section Two of the California Constitution. If Respondent DWR is not so enjoined, Petitioners will suffer irreparable injury for which there is no adequate remedy at law.

64. An actual controversy exists between Petitioners on the one hand and Respondent DWR on the other. Specifically, Petitioners contend and Respondent DWR denies that its pumping methods constitute a violation of Article 10, Section Two of the California Constitution for unreasonable use methods of diversion, causing injury to Petitioners. As an actual controversy exists, Petitioners are entitled to, and hereby seek, a ruling that Respondent DWR has violated Article X, Section 2 of the California Constitution for unreasonable method of diversions.

THIRD CAUSE OF ACTION

Violation of Article X, Section 2 of the California Constitution: Unreasonable Use

65. Petitioners restate and re-allege and incorporate all of the preceding paragraphs as if fully set forth herein.

66. Article X, Section Two of the California Constitution states that, due to the conditions prevailing in the State "the general welfare requires that the water resources of the State be put to beneficial use to the fullest extent of which they are capable, and that the waste or unreasonable use or unreasonable method of use of water be prevented, and that the conservation of such waters is to be exercised with a view to the reasonable and beneficial use thereof in the interest of the people and for the public welfare."

67. Further, Article X, Section Two specifically states that "the right to water or to the use or flow of water in or from any natural stream or water course in this State is and shall be limited to such water as shall be reasonably required for the beneficial use to be served, and such right does not and shall not extend to the waste or unreasonable use or unreasonable method of use or unreasonable method of diversion of water."

68. SWP export pumping from the Delta for water banking and resale by Respondent DWR at the current levels is an unreasonable use of the water resources of this State. Export pumping adversely effects fish and wildlife resources in the Delta, including spring-run Chinook

salmon (listed as threatened under the CESA and ESA) and winter-run Chinook salmon (listed as endangered under the CESA and ESA). The adverse impacts to fish include decreases in salmon smolt survival during outmigration from changes in hydrologic patterns in the Delta (increases in net reverse flows), entrainment at the export pumps, and increased predation at the pumps. On information and belief, unless enjoined Respondent DWR will continue to violate the California Constitution, as described above.

69. In light of the Respondent DWR's failure to comply with the California Constitution, and the significant likelihood of repeated violations in the future, Respondent DWR must be permanently enjoined from continuing to divert water from the Bay-Delta until they can comply with all applicable water quality standards and fish protection mechanisms, including appropriate screening of diversions. If Respondent DWR is not so enjoined, Petitioners will suffer irreparable injury for which there is no adequate remedy at law.

70. An actual controversy exists between Petitioners on the one hand and Respondent DWR on the other. Specifically, Petitioners contend and Respondent DWR denies that its operation of the SWP violates Article X, Section Two of the California Constitution and injures Petitioners. As an actual controversy exists, Petitioners are entitled to, and hereby seek, a ruling that Respondent DWR has violated Article X, Section 2 of the California Constitution by failing to use water reasonably.

FOURTH CAUSE OF ACTION
Violation of the 1995 Water Quality Control Plan Narrative Standard for Fish and Wildlife

71. Petitioners restate and re-allege and incorporate herein the foregoing paragraphs of this Complaint.

72. In accordance with the SWRCB 1995 Water Quality Control Plan, the Board adopted a narrative standard for fish and wildlife to double the natural production of salmon from the average number of fish in the Bay-Delta between the years 1967-1991. Due to the dramatic decline in salmon populations, Respondent DWR has failed to comply with the narrative salmon doubling standard as required by law.

73. In light of Respondent DWR's violation of the standard, and considering the significant likelihood of repeated violations in the future, Respondent DWR must be enjoined from export pumping at the Banks pumping facility in the Delta until such a time as DWR can operate in compliance with the narrative standard for fish and wildlife. If Respondent DWR is not so enjoined, Petitioners will suffer irreparable injury for which there is no adequate remedy at law.

74. An actual controversy exists between Petitioners on the one hand and Respondent DWR on the other. Specifically, Petitioners contend and Respondent DWR denies that it is violation of the 1995 Narrative standard. As an actual controversy exists, Petitioners are entitled to, and hereby seek, a ruling that Respondent DWR has violated the 1995 Water Quality Control Plan Narrative Standard for Fish and Wildlife.

FIFTH CAUSE OF ACTION
Violation of and Failure to Enforce State Board Decision 1641

75. Petitioners restate and re-allege and incorporate herein the foregoing paragraphs of this Complaint.

76. Board decision 1641 implemented flow objectives for the Bay-Delta Estuary that Respondent DWR was specifically charged with meeting. Respondent DWR has repeatedly failed to meet the flow objectives in the Bay-Delta.

77. Respondent Board has a statutory duty to comply with its own water quality control plan, and has failed to enforce the flow objectives against Respondent DWR as set out in D-1641.

78. DWR has an affirmative duty to meet the interior southern Delta salinity objectives established pursuant to D-1641, yet the Board's approval of WR Order 2010-0002 obviates DWR's mandatory compliance with those standards until an undisclosed, future date.

79. In light of the Respondents DWR's failure to comply with Decision 1641, Respondent Board's failure to enforce D-1641 as required by law, and the significant likelihood of repeated violations in the future, Respondent DWR must be permanently enjoined from continuing to export water from the Bay-Delta until such a time as they fully comply with the

requirements of D-1641. If Respondent is not so enjoined, Petitioners will suffer irreparable injury for which there is no adequate remedy at law.

80. An actual controversy exists between Petitioners on the one hand and Respondent DWR on the other regarding the extent to which their export pumping violates the conditions of D-1641, and Respondent Board's duty to enforce D-1641 as against DWR. Specifically, Petitioners contend and Respondent DWR denies that they are in violation of D-1641 by their export pumping in the Bay-Delta. Petitioners further contend and Respondent Board denies that they decided WR Order 2010-0002 without substantial evidence on the record and that their decision was arbitrary and capricious. As an actual controversy exists, Petitioners are entitled to, and hereby seek, a ruling that Respondent DWR is in violation of D-1641 and that Respondent Board decided WR Order 2010-0002 without substantial evidence in the record thereby rendering their decision arbitrary and capricious.

SIXTH CAUSE OF ACTION

Failure to Enforce Requirements of the Porter-Cologne Act

81. Petitioners restate and re-allege and incorporate herein the foregoing paragraphs of this Complaint.

82. Respondent SWRCB's actions in WR Order 2010-0002 constituted a prejudicial abuse of discretion, in that Respondent SWRCB did not proceed in the manner required by the Porter-Cologne Act, and substantial evidence does not support their Findings, as set forth below.

83. WR Order 2010-0002 fails to adequately analyze the reasonably foreseeable adverse effects of continued exceedence of the interior southern Delta salinity standards would have on fish and wildlife, water quality, and Delta agriculture in the Bay-Delta.

84. Respondent DWR has violated, and continues to violate, the interior southern Delta salinity standards required by D-1641. The SWRCB refuses to hold DWR to the water quality standards required by D-1641 and the Porter-Cologne Act, and the significant likelihood that DWR will continue to violate these standards in the future, demands that Respondent SWRCB must be required to set aside WR Order 2010-0002 and hold DWR to the requirements of Order WR 2006-0006. If Respondent DWR is allowed to continue pumping at the Banks

pumping facility in violation of the water quality standards, Petitioners will suffer irreparable injury for which there is no adequate remedy at law.

85. An actual controversy exists between Petitioners and SWRCB. Specifically, SWRCB denies Petitioners' contention that the Board is in violation of the Porter-Cologne Act. Petitioners allege that the SWRCB's method of "enforcing" DWR's permit conditions is not enforcement at all, and the adoption WR Order 2010-0002 is not based on substantial evidence. As an actual controversy exists, Petitioners are entitled to seek, and hereby do seek, a declaratory ruling that Respondent DWR is pumping in violation of the water quality standards of D-1641 with the SWRCB's permission in violation of the Porter-Cologne Act. Petitioner's further request a writ of administrative mandate requiring Respondent SWRCB to enforce the Porter-Cologne Act as required by law.

PRAYER FOR RELIEF

WHEREFORE, Petitioners respectfully request that the Court enter judgment as follows:

1. For a declaration that Respondent DWR's operations have violated the California Public Trust in the Bay-Delta;

2. For a declaration that Respondent DWR's operations are an unreasonable method of diversion in violation of Article X, Section 2 of the California Constitution;

3. For a declaration that Respondent DWR's operations are an unreasonable method of use in violation of Article X, Section 2 of the California Constitution;

4. For a declaration that Respondent DWR's operations have violated the 1995 Water Quality Control Plan narrative standard for salmon in that Respondent DWR has failed to meet the required doubling of the salmon population under the 1995 Water Quality Control Plan;

5. For a declaration that Respondent SWRCB has failed to enforce, and Respondent DWR's operations have violated, Decision 1641 in that Respondent DWR has failed to meet flow objectives necessary to protect beneficial uses in the Bay-Delta;

6. For a declaration that Respondent SWRCB has failed to enforce DWR's permit and license conditions under the Bay-Delta Water Quality Control Plan in accordance with the Porter-Cologne Act;

7. That the Court enjoin Respondent DWR from diverting water from the Bay-Delta until such a time as Respondent DWR's operations conform with the law;

8. That the Court enjoin Respondent SWRCB from allowing operation of state water export projects until such a time that Respondent DWR come into compliance with the law;

9. That the Court direct Respondents to remedy their violations of the California Public Trust, Article X, Section 2 of the California Constitution, the Porter-Cologne Act, the 1995 Water Quality Control Plan, and Decision 1641 within a reasonable time;

10. That the Court issue a writ of administrative mandate vacating and setting aside WR Order 2010-0002;

11. That the Court retain jurisdiction over this matter until such time as Respondents have fully complied with the law;

12. That the Court award Petitioners their costs of litigation pursuant to California Code of Civil Procedure § 1021.5; and

13. That the Court grant Petitioners such other further relief, including injunctive relief, as the Court may deem just and proper.

Dated: April 21, 2011

VERIFICATION

I, Michael B. Jackson, am the attorney for Petitioners herein and am authorized to execute this on their behalf. I have read the foregoing Petition for Writ of Mandate and Complaint for Injunctive and Declaratory Relief and am informed and believe, and thereon allege, that the matters stated therein are true and correct. I sign this verification on behalf of Petitioners pursuant to Code of Civil Procedure § 446, as Petitioners are located outside the county in which my office is located.

I declare under penalty of perjury under the laws of the State of California that the foregoing is true and correct and that this verification was executed on April 21, 2011 in Quincy, California.

Executive Summary

The US Bureau of Reclamations and San Luis & Delta-Mendota Water Authority released the Public Draft of the *Long-Term Water Transfers Draft Environmental Impact Statement/Environmental Impact Report* (LTWT) in September 2014. The purpose of the LTWT, as we understand, is to evaluate the potential impacts of three proposed water-transfer alternatives, as well as a no action alternative. AquAlliance asked ECONorthwest to critique and provide written comments on the LTWT.

In general, the analysis described in the LTWT suffers from significant omissions and errors. These omissions and errors matter. As written the report provides stakeholders and decisions makers with a biased and incomplete description of the environmental and economic consequences of water transfers. In the following sections of this report we describe our critiques in detail. Our major critiques include the following.

The LTWT ignores relevant background information about the affected environment that would have helped inform the analysis. The LTWT provides a cursory description of the relevant affected environment that paints an incomplete picture of the context within which water transfers would happen. A more complete, accurate and up-to-date description would have included, for example: information from the many recent reports on California's climate and groundwater conditions; current data on water transfers; and, a market analysis of water prices, prices for agricultural commodities and how price changes influence the number and volumes of water transfers. As such, the deficient description is the shaky foundation upon which a lacking analysis rests. The resulting effort yields questionable results regarding the likely future frequency and amounts of water transfers and their environmental and economic consequences.

The LTWT relies on outdated and incomplete data. The analysis described in the LTWT relies on obsolete data for certain key variables and ignored other relevant data and information. For example, the analysis assumes a price for water that bears no resemblance to the current reality. It also ignored relevant research results on the impacts of groundwater pumping on stream flow depletion and the current status of groundwater levels as provided by monitoring wells. The water transfers at issue in the LTWT would not happen in an economic vacuum. Growers and water sellers and buyers react to changing prices and market conditions. The analysis described in the LTWT, however, is silent on these forces and how they would influence water transfers.

The LTWT underestimates negative impacts on the regional economy in the sellers area. The LTWT acknowledges that negative economic impacts would be worse if water transfers happen over consecutive years. The analysis, however, estimates impacts for single-year transfers, ignoring the data on the frequency of recent consecutive-year transfers. The analysis also fails to address the extent to which water transfers cause economic harm to water-based recreational activities.

The LTWT finds significant negative effects but the vague and incomplete proposed monitoring and mitigation plans would not address these effects. The LTWT proposed both a monitoring and mitigation program for significant negative impacts. Implementing these programs would take planning, effort and financial resources on the part of sellers, injured third parties, and regulatory agencies. The LTWT does not include these costs. The monitoring program is vague and depends on potential sellers implementing the program. This conflict of interest pits financial gain from water sales against complete and impartial monitoring efforts. This opens the door to lax, biased, or incomplete monitoring, which could lead to negative environmental and economic consequences for third parties. The monitoring program includes monitoring subsidence, however, the program is vague on requirements and what amount of subsidence would trigger a halt in water transfers. Injured third parties would bear the costs of bringing to the sellers' attention harm caused by groundwater pumping. The analysis described in the LTWT assumes that disagreements regarding third-party damages would be settled cooperatively between third parties and sellers, without presenting evidence substantiating such an optimistic assumption. The LTWT is silent on the economic consequences of sellers and injured third parties not cooperatively agreeing on harm and compensation.

The LTWT ignores the environmental externalities and economic subsidies that water transfers support. The LTWT lists Westlands Water District as one of the CVP contractors expressing interest in purchasing transfer water. The environmental externalities caused by agricultural production on Westlands are well documented, as are the economic subsidies that support this production. To the extent that the water transfers at issue in the LTWT facilitate agricultural production on Westlands, they also contribute to the environmental externalities and economic subsidies of that production. The LTWT is silent on these environmental and economic consequences of the water transfers.

The LTWT underestimates the cumulative effects of water transfers. Cumulative effects analyses under NEPA and CEQA are intended to identify impacts that materialize or are compounded when the proposed action is implemented at the same time as or in conjunction with other actions. The LTWT addresses cumulative effects for each resource area and provides a global description of the methods and actions considered for analysis in each resource area. The analysis, however, provides cursory discussion of potential cumulative effects for the regional economy, and ignores the full range of possible cumulative outcomes associated with the proposed transfer

1 Introduction and Context

The US Bureau of Reclamations (BOR) and San Luis & Delta-Mendota Water Authority (SLDMWA) released the public draft of the *Long-Term Water Transfers Draft Environmental Impact Statement/Environmental Impact Report* (LTWT) in September 2014. The LTWT covers water transfers that would happen between 2015 through 2024. Because the transfers would use federal and state infrastructure, the LTWT must comply with NEPA and CEQA guidelines. BOR is the lead agency regarding NEPA requirements, and SLDMWA is the lead agency for CEQA requirements.[1]

The premise underlying the proposed water transfers is that sellers, mostly in the Sacramento Valley, would idle cropland, switch to less water-intensive crops, and/or substitute groundwater for surface water, and send the surface water they would other wise have used through the Bay Delta to buyers in the south.

The proposed transfers would happen within a context of environmental conditions that both highlight the increasing demand for water throughout California and raise concerns regarding the environmental and economic effects of the water transfers at issue in the LTWT. These conditions include:

- Current drought conditions of historic proportion coming on the heals of consecutive dry years.
- Increasing concerns over the demands on groundwater and groundwater conditions throughout the state, including in the Sacramento Valley.
- Increasing competition for water from all user groups including agricultural, municipal and industrial users, and environmental requirements that help protect habitats and water quality.

Within this context, regulatory agencies face increasing demands from stakeholders for transparent decisions that rely on the best available science and information when balancing competing demands. For example, the relevant NEPA requirements for the LTWT analysis include:

> "Rigorous exploration and objective evaluation of all reasonable alternatives, …"[2]

AquAlliance asked ECONorthwest to review the LTWT and provide comments on the extent to which the analysis described in the report fulfills the NEPA requirement. We describe the results of our initial review and critique of the document in this report. The relatively short

---

[1] LTWT, page 1-1, 2-1.

[2] LTWT page 2-1.

public comment period limited the extent of our review. Should the comment period be extended or reopened, we may expand and revise our comments.

The remainder of our report is as follows. In the next section, Section 2, we comment on the LTWT's incomplete description of the affected environment within which the water transfers would happen. We cite sources with relevant information that if included would yield a more complete and comprehensive description of the affected environment.

In Section 3 we highlight deficiencies in the data and analysis described in the LTWT. For example, we note that the model relies on outdated prices for water and agricultural commodities—two central components of the analysis. The analysis also estimates that water transfers would happen in a static environment where water prices and commodity prices remain fixed. These conditions do not reflect the dynamic reality of water demands and use.

In Section 4 we note instances in which the analysis described in the LTWT underestimates the impacts of water transfers on the regional economy in the source-water areas.

In Section 5 we draw attention to some of the deficiencies of the proposed monitoring and mitigation programs that the LTWT's authors claim will adequately address any negative effects of the transfers. These deficiencies include the inherent conflicts of interests in the programs, excluding the costs of the programs, and vague and ill-defined critical components of the programs.

In Section 6 we describe some of the environmental and economic externalities associated with the use of the transferred water.

In Section 7, we list some of the deficiencies in the analysis of cumulative effects. For example, the analysis ignores the impacts of transfers that would happen in addition to those at issue in the LTWT.

2 The LTWT ignores relevant background information about the affected environment that would have helped inform the analysis

The LTWT provides a cursory description of the relevant affected environment that paints an incomplete picture of the context within which water transfers would happen. A more complete, accurate and up-to-date description would have included, for example: information from the many recent reports on California's climate and groundwater conditions; current data on water transfers; and, a market analysis of water prices, prices for agricultural commodities and how price changes influence the number and volumes of water transfers. As such, the deficient description is the shaky foundation upon which a lacking analysis rests. The resulting effort yields questionable results regarding the likely future frequency and amounts of water transfers and their environmental and economic consequences.

Specific concerns regarding the LTWT's incomplete description of the affected environment in the Sacramento Valley include the following.

Incomplete description of current climate conditions

According to the California Department of Water Resources (DWR), 2013 was the driest year on record for many parts of the state.[3] Such drought conditions are one reason given for why growers and municipal and industrial (M&I) users in the south would purchase water from other parts of California. The analysis described in the LTWT fails to acknowledge, however, that other parts of the state, including the Sacramento Valley, also feel the effects of drought. How agricultural and M&I water users in the north respond to recent drought conditions would affect water transfers. The authors of the LTWT exclude these factors from their analysis.

For example, in a recent letter to the BOR, the Glenn-Colusa Irrigation District (GCID) indicated they were developing a groundwater supplemental supply program and that developing this program takes priority over participating in water transfers as described in the LTWT.

> "GCID's position is that it will pursue, as a priority, the proposed Groundwater Supplemental Supply Program over any proposed transfer program within the region, including Reclamation's Long-Term Water Transfer Program (LTWTP)."

---

[3] California Department of Water Resources (DWR). 2014a. *Public Update for Drought Response Groundwater Basins with Potential Water Shortages and Gaps in Groundwater Monitoring*. April 30. Page ii.

> "… It is important to underscore that GCID would prioritize pumping during dry and critically dry water years for use in the Groundwater Supplemental Supply Program, and thus wells used under that program would not otherwise be available for USBR's LTWTP."[4]

GCID's focus on its own groundwater program over BOR water transfers is notable because the LTWT lists GCID as a potential seller with the largest volume of water for sale, 91,000 af.[5] GCID's reasons for pursuing its groundwater supply program include concerns over water availability during dry years.

> "The primary objective is to develop a reliable supplemental water source for GCID during dry and critically dry years. The proposed goals are as follows:
>
> - Increase system reliability and flexibility
> - Offset reductions in Sacramento River diversions by GCIS during drought years to replace supplies for crops and habitat
> - Periodically reduce Sacramento River diversions to accommodate fishery and restoration flows
> - Protect agricultural production"[6]

A related point is that the LTWT fails to discuss the possibility that current climate and water conditions may represent a new benchmark rather than a deviation from past trends. The increasing number of years with water transfers (described below), and reports on climate change and its impacts on water conditions, are two arguments in support of exploring this point. For example, according to a report commissioned by the Northern California Water Association (NCWA),

> "This year [2014] we face unprecedented drought conditions, following a decade of relatively dry years and increased demands on our groundwater resources. These increased demands have two principal causes. The reduced availability of surface water during dry years brings a predictable shift towards greater use of groundwater. The second is expanding and intensifying agricultural land use within the Sacramento Valley, together with increasing urban water demands, leading to increased reliance on groundwater even in 'normal' years."[7]

Fails to consider concerns regarding the oversubscription of water resources

The analysis described in the LTWT fails to acknowledge the problem of supporting water transfers using "paper water," or oversubscribed water in the Sacramento Valley. A report on water transfer issues in California describes one aspect of this problem.

> "The inability of interested parties to agree on the volume of transferable water associated with the short-term fallowing of agricultural lands has caused substantial controversy and delays in approving certain water transfer proposals. The primary issue for interested parties is whether a fallowing-based transfer proposal would actually increase the burden on the CVP and SWP to maintain water quality and flow conditions in downstream portions of the Sacramento River and Delta because upstream transfer proponents were allowed to transfer what might prove to be 'paper' water."[8]

Stakeholders in the Sacramento Valley concerned about this problem researched the extent of paper water and found that rights to water significantly exceed available supply. Testimony by the California Water Impact Network submitted to the State Water Resources Control Board concluded that, "The ratio of total consumptive use claims to average unimpaired flow in the Sacramento River Basin is about 5.6 acre-feet of claims per acre-foot of unimpaired flow."[9] Thus, claims on water in the Sacramento Valley significantly exceed the available supply.

Incomplete description of current groundwater conditions

The LTWT excluded current information on groundwater conditions in the Sacramento Valley. This information includes concerns regarding historically low groundwater levels in certain areas of the Sacramento Valley, related concerns over subsidence caused by depleted groundwater, and a lack of groundwater monitoring information.

According to the DWR, groundwater levels are decreasing through out California, including in the Sacramento Valley. Groundwater levels decreased since the spring of 2013, and "notably" since the spring of 2010.[10] A related point, according to the DWR, is that there are "significant" gaps in groundwater monitoring data for areas throughout the state, including the Sacramento Valley.[11] There's also a lack of understanding

California Water Impact Network. For Workshop #3 Analytical Tools for Evaluating the water Supply, Hydrodynamic, and Hydropower Effects of the Bay-Delta Plan November 13 and 14, 2012. Page 11.

[10] DWR, 2014a, page ii.

[11] DWR, 2014a, page ii.

regarding groundwater recharge and interactions between surface and groundwater in the Sacramento Valley. According to the NCWA report,

> "[G]roundwater changes can take many years to become apparent, and we have not yet been able to measure with certainty the long-term impacts of the current level of groundwater use as it affects our measures of sustainability."
>
> "Persistently declining groundwater levels in many areas of the Sacramento Valley over the past decade reveal that groundwater discharge exceeds recharge. Simply put: if the objective is to stem or reverse the trend, the groundwater balance must be adjusted either by putting more water into the ground or taking less out."[12]

According to the DWR, the Sacramento River hydrologic region has 23 groundwater basins ranked "high" or "medium" as described by the CASGEM groundwater basin prioritization study. These rankings describe a groundwater basin's importance in meeting demands for urban and agricultural water use. The San Joaquin River hydrologic region has nine "high," or "medium" ranked basins.[13]

A recent report from Glenn County indicates that current groundwater levels in the county are at the lowest levels recorded going back to the start of record keeping in the 1920s.

> "Data in reference to groundwater levels has been collected from both private and dedicated monitoring wells located within Glenn County, in some cases dating as far back as the 1920's. The lowest levels in these wells were most frequently associated with measurements from the 1976-77 monitoring period, which coincided with one of the more severe droughts in California's history. In the years following the 76-77 drought, groundwater levels often approached these historic lows but rarely fell below them. However, recent (2012-13) data indicate levels in many wells have declined below those historic thresholds and are now at the lowest levels observed since monitoring began."[14]
>
> "Readily available monitoring data obtained through DWR's California Statewide Groundwater Elevation Monitoring (CASGEM) is available for 100 wells, and of those 100, 21 still show their lowest levels as occurring in 1977, while 21 had an all-time low water surface elevation level in 2013, and an

> additional 15 wells reached their lowest point in 2009-2012. Therefore, one out of every five monitored wells in the area was at its lowest-ever recorded level in 2013, and one out of every three wells monitored in the area was at its lowest-ever recorded level between 2009 and 2013."[15]

Regarding the limited groundwater modeling described in the LTWT, consulting hydrologist Kit Custis comments,

> "Because the groundwater modeling effort [described in the LTWT] didn't include the most recent 11 years record, it appears to have missed simulating the most recent periods of groundwater substitution transfer pumping and other groundwater impacting events, such as recent changes in groundwater elevations and groundwater storage [citation omitted], and the reduced recharge due to the recent periods of drought. Without taking the hydrologic conditions during the recent 11 years into account, the results of the SACFEM2013 model simulation may not accurately depict current conditions or predict the effects from the proposed groundwater substitution transfer pumping during the next 10 years."[16]

The DWR reports that areas of the Sacramento Valley are at risk for subsidence from depleted groundwater. Most of the groundwater basins susceptible to future subsidence are also ranked "high" and "medium" priority by the CASGEM groundwater basin prioritization analysis. According to the DWR and based on data from 2008 through 2014, approximately 36 percent of long-term wells surveyed in the Sacramento Valley are at or below the historical spring low levels. Another measure indicates that 50 percent of groundwater levels in 18 groundwater basins in the Sacramento Valley are at or below historical spring low levels.[17] A white paper by a consulting engineer on groundwater use and subsidence in the Sacramento Valley noted that subsidence may happen years after groundwater pumping and that real-time monitoring of groundwater pumping "will generally tend to underestimate the long-term settlement of the ground surface."[18]

Subsidence can cause substantial economic harm. According to a report by consulting engineers studying subsidence in California,

> "Land subsidence has been discovered in many areas of the state, causing billions of dollars of damage. Impacts from subsidence fall into the following categories:
>
> - Loss of conveyance capacity in canals, streams and rivers, and flood bypass channels;
> - Diminished effectiveness of levees;
> - Damage to roads, bridges, building foundations, pipelines, and other surface and subsurface infrastructure; and
> - Development of earth fissures, which can damage surface and subsurface structures and allow for contamination at the land surface to enter shallow aquifers."[19]

Subsidence in Colusa, Yolo and Solano counties in the Sacramento Valley during the 1976-77 drought caused widespread well casing damages, which made some wells unusable.[20] A recent series of reports by the Stanford Woods Institute for the Environment and the Bill Lane Center for the American West at the Water in the West center at Stanford University describe the subsidence concerns regarding groundwater pumping in California, including the Sacramento Valley.[21] Custis notes the types of infrastructure in the Sacramento Valley susceptible to damage from subsidence,

> "There are a number of critical structures in the Sacramento Valley that may be susceptible to settlement and lateral movement. These include natural gas pipelines, gas transfer and storage facilities, gas wells, railroads bridges, water and sewer pipelines, water wells, canals, levees, other industrial facilities."[22]

In response to concerns over groundwater use and related issues, the California legislature recently passed, and Governor Brown signed into law, the Sustainable Groundwater Management Act (Act).[23] The Act will affect groundwater users including those supplying water transfers. The LTWT makes no mention of how the Act could affect the context within which water transfers would happen, or the transfers themselves. This is a significant omission.

Carriage Water Costs

The LTWT assumes that required carriage water component of water transfers from the Sacramento River will account for 20 percent of transferred water.

> "Transfers from the Sacramento Rive assume a 20 percent carriage water adjustment to maintain Delta salinity."[24]

Recent data on the percentage of required carriage water are higher than the 20-percent assumption in the LTWT. For example, the DWR describes a recent carriage water percentage of 30.

> "Another cost related to transferring water is carriage water. … For the Sacramento River, this has generally been about 20 percent of the transfer water … It is worth noting, however, that in 2012 and 2013 carriage water losses for the Sacramento River were as high as 30 percent of transfer water."[25]

To the extent that carriage water requirements exceed 20 percent, the LTWT overestimates the amount of water delivered south through the Bay Delta to water purchasers, and thus the economic benefits of these transfers.

Data and modeling ignore recent trends in water transfers

Using water data from 1970 through 2003, the LTWT estimates that future water transfers will happen on average 12 out of 33 years.[26] Twelve of 33 years is a transfer probability of approximately 36 percent. By ignoring water data for years after 2003, the analysis excludes relevant information on the more recent dry trend and current historical drought. For example, Table 1-3 on page 1-17 of the LTWT lists years and amounts of water transfers from 2000 through 2014. This data shows that water transfers happened in 9 of the previous 15 years, or a transfer probability of 60 percent, almost double that used in the LTWT. For years after 2003, transfers happened in eight out of 11 years, for a transfer percent of approximately 73.

Other sources of data on the frequency of water transfers do not support the LTWT's water-transfer results. For example, a report by the Western Canal Water District (WCWD) includes a table showing water transfers from the Sacramento Valley through the Bay Delta from 2001 through projected 2010. The information in this table shows transfers happening in eight out of ten years.[27] A similar report by WCWD in 2014

---

[24] LTWT page B-18.

[25] California Department of Water Resources. 2013. California Water Plan 2013 Update. Bulletin 160-13. Volume 3 Resource Management Strategies. Pages 8-9.

[26] LTWT, page 3.3-60 and -61.

[27] Western Canal Water District (WCWD). 2009. *Initial Study and Proposed Negative Declaration for Western Canal Water District 2010 Water Transfer Program*. Western Canal Water District, Richvale, California. January. Page 25.

included a table of water transfers for years 2006 through projected 2014. The data in that table shows transfers happening during seven of nine years.[28] Taken together, these two reports show water transfers from the Sacramento Valley south through the Bay Delta in 11 out of 14 years between 2001 through 2014. This works out to a transfer probability of approximately 79 percent.

These results demonstrate two important points. First, using a transfer probability of 36 percent greatly underestimates the actual years that transfers happened post-2003, the last year of data in the LTWT analysis. Underestimating transfers leads to underestimating the environmental and economic effects of the transfers.

Second, the data upon which conclusions in the LTWT rest do not depict actual conditions post-2003. That is, by relying on flawed or incomplete data, models that use this data produce flawed or biased results. The estimated transfer frequency (36 percent of years), does not match the recent actual transfer frequency (60, 73, or 79 percent, depending on the source and years included).

At an October 21st, 2014 public hearing in Chico, California on the LTWT, a consultant working with BOR on the LTWT commented on the water model and the 1970 through 2003 data upon which the model relies. In response to questions about why the model did not include data from the previous ten years, or why the period of analysis was not extended out to the current drought situation, the consultant replied that the modeling tools "are not up-to-date."[29]

According to resource agencies in California, variable, even extreme climate and rainfall conditions are the norm. Climate change is projected to make these trends worse and increase prediction uncertainties. The recent Bay Delta Conservation Plan describes this uncertainty,

> "Variability and uncertainty are the dominant characteristics of California's water resources."[30]
>
> "Precipitation is the source of 97% of California's water supply. It varies greatly from year to year, by season, and by where it falls geographically in the state.

> With climate change, the state’s precipitation is expected to become even more unpredictable.”[31]
>
> “However, the total volume of water the state receives can vary dramatically between dry and wet years. California may receive less than 100 MAF of water during a dry year and more than 300 MAF in a wet year (Western Regional Climate Center 2011).”[32]
>
> “The geographic variation and the unpredictability in precipitation that California receives make it challenging to manage the available runoff that can be diverted or captured in storage to meet urban and agricultural water needs.”[33]
>
> “Historically, precipitation in most of California has been dominated by extreme variability seasonally, annually, and over decade time scales; in the context of climate change, projections of future precipitation are even more uncertain than projections for temperature. Uncertainty regarding precipitation projections is greatest in the northern part of the state, and a stronger tendency toward drying is indicated in the southern part of the state.”[34]

Consultants working for the BOR admit that the water model and data upon which the LTWT analysis and conclusions rest are not up to date. We note above the model’s unreliability and poor projection capabilities regarding water transfers post-2003. The DWR concludes that variability and extremes characterize the state’s weather and rainfall conditions, and that climate change is increasing this variability and uncertainty. Taken together, these facts raise questions regarding the veracity of the projected water transfers described in the LTWT, and the estimated environmental and economic consequences of those transfers.

The analysis does not adequately take into account recent trends in agricultural production

Not included in the LTWT’s description of current conditions are recent trends in agricultural production that affect groundwater use and conditions in the Sacramento Valley. For example, according to a recent report, approximately half the increase in irrigated acres in the Sacramento Valley since 2008 (approximately 200,000 acres), happened on lands not served by surface water suppliers. Irrigating these lands takes approximately 300,000 acre-feet (af) of groundwater per year. [35]

---

[31] DWR, 2013. Page 5-2.

[32] DWR, 2013, page 5-2.

[33] DWR, 2013, page 5-2.

[34] DWR, 2013, page 5-2.

[35] DMW, 2014, page 7.

A related point is the lack of discussion or analysis in the LTWT of trends in prices for agricultural goods produced with surface and groundwater, trends in prices for water, and how these factors affect grower decisions. For example, the analysis fails to address the extent to which historically high prices for water (discussed below) increase groundwater mining and sale in the Sacramento Valley, and how this affects water transfers and their environmental and economic consequences.

Another agricultural trend not discussed in the LTWT, but which has implications for water transfers and their consequences, is the increasing use of pressurized irrigation methods in the Sacramento Valley. Pressurized irrigation reduces groundwater recharge by limiting water percolation. Some growers supply their pressurized irrigation systems using groundwater, even when they have access to surface water. According to the report commissioned by the NCWA,

> "The increasing use of pressurized irrigation systems using groundwater is likely to be an increasingly important factor in the overall management of groundwater and surface water in the Sacramento Valley as a whole, particularly as such system displace the use of available surface water."[36]

In response to the recent trend in high prices for almonds, olives, walnuts and other tree crops, growers in the San Joaquin *and* Sacramento Valleys planted more acres of these tress and other permanent-type crops, and less acres of lower valued annual crops. Such a change increases and "hardens" demand for water in both valleys because growers no longer have the flexibility of idling these acres in response to drought.[37] Thus, one of the arguments in support of water transfers—that growers south of the Bay Delta planted increased acres of tree crops that have higher water demands—also affects growers and water use and demands north of the Bay Delta.

The LTWT is silent on these trends or how they would influence future water transfers from the Sacramento Valley.

[37] DMW, 2014, page 7.

3 The LTWT relies on outdated and incomplete data

In addition to the deficiencies described in previous sections, the analysis described in the LTWT relies on obsolete data for certain key variables. The analysis also ignored other relevant data and information. These shortcomings include the following.

The LTWT assumes a price for water that bears no resemblance to the current reality

The analysis described in the LTWT assumes a price of water of $225 per af of water.[38] This amount drastically underestimates the current price for water. Dollar amounts for water trades are not readily available to the public. However, information on the current price of water from news articles and other sources reveals a range of current prices that exceed $225 by a significant amount.

A report by Bloomberg News on the impacts of drought on water prices reports water prices of $1,000 to $2,000 per af. The article also quotes a spokesman for the BOR,

> "The rising prices are 'a function of supply and demand in a very dry year and the fact that there are a lot of competing uses for water in California,' said Mat Maucieri, a spokesman for the Bureau of Reclamation."[39]

An article in the Sacramento Bee on water transfers noted that one buyer was paying "in the neighborhood of $500 to $600 an acre-foot."[40] The Glenn-Colusa Irrigation District commenting on the LTWT noted that the $225 per af price used in the analysis was the price paid for water over eight years ago.[41]

Water users, sellers and buyers would surely respond differently to a market price of water of $1,000 to $2,000 per af, than they would to a price of $225. As such, the extent to which growers idle cropland, switch to less water intensive crops, and substitute groundwater for surface water in the LTWT likely does not reflect this difference. As we note below, missing from the LTWT analysis is an assessment of the economics of water markets, how sellers and buyers respond to changing water prices, and how this affects the type and amount of water transfers.

Ignored impacts on tax revenues to local governments from IMPLAN results

The LTWT describes estimating impacts of water transfers on employment, labor income and total value of output using IMPLAN.[42] IMPLAN is a commonly used software and data package that helps analysts estimate economic impacts of policy changes or compare economic impacts of allocation alternatives, e.g., alternative logging proposals or alternative water-transfer amounts. According to the IMPLAN website, IMPLAN "… allows an analyst to trace spending through an economy and measure the cumulative effects of that spending."[43] IMPLAN traces the economic benefits of increased spending as it works its way through an economy, or, when spending decreases, the negative economic impacts of decreased spending. From our own experience using IMPLAN, and from information on the IMPLAN website, in addition to the employment, labor income and total value of output reported in the LTWT, IMPLAN also quantifies the impacts of alternatives on *government finances and tax revenues*.[44] For example, the IMPLAN website describes how the software can estimate state, local, and federal tax amounts collected (or lost) as a result of a change in an economy, such as reduced agricultural activity.[45]

Even though IMPLAN calculates impacts of alternatives on local government finances and tax revenues, the analysis described in the LTWT does not report these results. That is, the authors apparently choose not to report the output from IMPLAN on how the transfer alternatives would affect the dollar amounts of tax revenues to local governments as a result of the reduced agricultural activity and spending. Instead, the report notes that impacts "to local government finances, including tax revenues and costs, are described *qualitatively*." [emphasis added][46] The report does not explain why the analysts chose to address impacts on local tax revenues of the water-transfer alternatives qualitatively, rather than rely on the estimates of tax impacts produced by IMPLAN.

Ignored own research results on stream flow depletion factors

The LTWT makes no mention of the results from studies of the impacts of groundwater pumping in support of water transfers on stream flow depletion. A technical memo on the impacts of groundwater pumping on stream flow depletion describes the analysis and concludes that,

---

[44] IMPLAN. https://implan.com/index.php?option=com_content&view=article&id=532:532&catid=233:KB16.

[45] IMPLAN. https://implan.com/index.php?option=com_content&view=article&id=532:532&catid=233:KB16.

[46] LTWT, page 3.10-24.

> "The effect of groundwater substitution transfer pumping on stream flow, when considered as a percent of the groundwater pumped for the program, is significant."[47]

> "The three scenarios presented here estimated effects of transfer pumping on stream flow when dry, normal, and wet conditions followed transfer pumping. Estimated stream flow losses in the five-year period following each scenario were 44, 39, and 19 percent of the amount of groundwater pumped during the four-month transfer period."[48]

In spite of these results, information distributed by the DWR and BOR to those interested in making water transfers in 2014, cites a stream flow depletion factor of 12 percent.[49] It's not clear how BOR justifies using a 12-percent depletion factor when analyses conducted by their contractors found depletion factors of 44, 39 and 19 percent.

We understand that the same SACFEM model that produced other results in the LTWT also produced the stream flow depletion factors.[50] Yet, while the LTWT reports other results from SACFEM, it makes no mention of these results. It also ignores the assumed 12-percent depletion factor cited by DWR and BOR. Instead, it states that stream flow depletion will be studied at a later date.[51] This approach ignores their own modeling results on stream flow depletion.

Incomplete and selective use of information from groundwater monitoring wells

The LTWT omits a significant concluding passage when describing results from a groundwater monitoring well in the Sacramento Valley.

For well 21N03W33A004M, the LTWT states,

> "Water levels at well 21N03W33A004M generally declined during the 1970s and prior to import of surface water conveyed by the Tehama-Colusa Canal. During the 1980s, groundwater levels recovered due to import and use of surface water supply and because of the 1982 to 1984 wet water years [citation omitted]."[52]

---

[47] Lawson, P. 2010. Technical Memorandum. Groundwater Substitution Transfer Impact Analysis, Sacramento Valley. CH2MHill. March 29. Page 8.

[48] Lawson, 2010, Page 8.

[49] DWR and BOR, 2014. Addendum to DRAFT Technical Information for Preparing Water Transfer Proposals. Information to Parties Interested in making Water Available for water Transfers in 2014. January. Page 33.

[50] LTWT, page 3.3-60.

[51] LTWT, page 3.1-21.

[52] LTWT, page 3.3-22.

The document cites a DWR report from 2014 on drought response and gaps in groundwater monitoring.[53] The description in the DWR report, however, includes this additional concluding passage that the LTWT authors excluded,

> "Water levels declined again in the 2008 drought period, followed by a brief recovery during 2010 to 2011, and *then returning to 2008 levels (which are notably lower than the 1977-79 drought levels)."*[54] [emphasis added]

The omission matters as it completely changes the conclusion regarding current groundwater conditions as reported by the well.

The description in the LTWT of results from well 15N03W01N001M match those from the DWR source document. That description concludes,

> "… After the 2008-2009 drought, water levels declined to historical lows. Water levels recovered quickly during 2010 and 2011, *then after returned to the trend of long-term decline*."[55] [emphasis added]

Taken together these results indicate a long-term trend in declining groundwater levels in areas around the wells. The LTWT discounts or ignores these results instead favoring results from other wells. On this point, consulting hydrologist Custis describes other relevant data on groundwater monitoring,

> "The Draft EIS/EIR doesn't provide maps showing groundwater elevations, or depth to groundwater, for groundwater substitution transfer seller areas in Sutter, Yolo, Yuba, and Sacramento counties.
>
> The DWR provides on a web site a number of additional groundwater level and depth to groundwater maps at: [website omitted]."[56]

Custis notes other deficiencies of the groundwater monitoring as described in the LTWT.

> "…[T]he Draft EIS/EIR provides only limited information on the wells to be used in the groundwater substitution transfers [citation omitted], and no information on the non-participating wells that may be impacted."[57]

Custis goes on to list other recommended groundwater monitoring information that the LTWT does not include.[58]

---

[53] LTWT, page 3.3-22.

[54] DWR, 2014a, page 24.

[55] LTWT, page 3.3-22.

[56] Custis 2014, pages 9-10.

[57] Custis 2014, page 2.

A related point is the available monitoring data from past water transfers. DWR and BOR apparently already collect information on the impacts of groundwater pumping in support of water transfers on groundwater levels.[59] The LTWT makes no mention of this data or how it could help inform the analysis of impacts of water transfers at issue in the LTWT on groundwater levels and related concerns. It would seem that BOR has available data relevant to its analysis described in the LTWT but makes no use of this data. On this point Custis notes,

> "The BoR should already have monitoring and mitigation plans and evaluation reports based on the requirements of the DTIPWTP for past groundwater substitution transfers, which likely were undertaken by some of the same sellers as the proposed 10-year transfer project."[60]

The analysis relies on outdated prices for agricultural commodities

The analysis described in the LTWT uses outdated prices for agricultural commodities to estimate the volume and value of water transfers. The analysis relies on prices for rice, processing tomatoes, corn and alfalfa from 2006 through 2010.[61] The analysis compares the price of water, which as we note above bears no resemblance to current prices, with prices for agricultural commodities to estimate cases in which selling water is more profitable than producing crops. Using outdated commodity prices compounds the error of using water prices that greatly underestimate actual prices. The combined effect is misleading results and conclusions regarding the degree of participation by growers in the water transfer program.

No mention of how prices for water and agricultural commodities could impact the affected environment, water transfers and their environmental and economic consequences

The water transfers at issue in the LTWT would not happen in an economic vacuum. Growers and water sellers and buyers react to changing price and market conditions. The LTWT, however, is silent on these forces and how they would influence water transfers.

The analysis depicted in the LTWT assumes a static water price of $225 per af and prices for agricultural commodities as they existed in 2006 through 2010.[62] Such a static analysis

---

[58] Custis 2014, page 2.

[60] Custis 2014, page 24.

[61] LTWT, page 3.10-27, -28.

[62] LTWT, page 3.10-27.

provides a single estimate, or a snapshot view, of estimated water transfers. A more informative and useful analysis would have described how changing water and commodity prices influence the conclusions re the number and volumes of water transfers. Such a sensitivity analysis would allow readers to better compare current or expected future prices with prices in the analysis to see how these conditions affect results.

The LTWT is also silent on likely transaction costs and how they influence water transfers. Water transactions, particularly out-of-basin and cross-Delta, would require a diverse and substantial set of transaction costs that are not quantitatively included in the analysis. Omitting these transaction costs either overestimates the benefit potential to buyers and sellers of these transactions, or implies that these transaction costs will be borne by the public. Communication, information, and contracting costs have long inhibited water markets in California, and while mechanisms for overcoming these challenges have improved, they do have real costs, particularly across diverse regions and incorporating farmers using differing operations.[63] Transaction costs are hurdles to transactions, functionally a third party that must be satisfied before the buyer and seller can find opportunities to both be made better off by the transaction. For example, if a seller is willing to sell water at $250 per af, and a buyer is willing to pay $300 per af, if there are $60 per af in transaction costs, the transaction cannot efficiently take place.

Cross-Delta transaction would also impose a number of costs on the Delta conveyance system. Pumping costs at Banks and Jones Pumping Plants should be incorporated into transaction costs. Transactions could also affect congestion and overall capacity for these plants and the SWP and CVP systems overall. Energy, management, staffing, delays, and other costs and impositions could arise that would either require compensation by the buyers and sellers, or externalities on other parties.

Permitting, liability, and long-term protection of water rights all contribute to additional concerns for buyers and sellers that functionally generate additional forms of transaction costs. If these are incorporated into willingness-to-pay for buyers and willingness-to-accept for sellers, the transactions become less desirable. Alternatively, if these costs are borne by public agencies, as with the variety of other transaction costs mentioned above and referenced qualitatively throughout the LTWT, the burden for taxpayers could be substantial. These public contributions require demonstration of benefits to the public as a whole. The LTWT does not demonstrate benefits to portions of the public that are not party to transactions. On this point Custis notes,

> "Because the spatial limits of groundwater substitution pumping impacts are controlled by hydrogeology, hydrology, and rates, durations and seasons of pumping, the impacts may not be limited to the boundaries of each seller's service area, GMPs [groundwater

---

[63] Haddad, B. M. 2000. *Rivers of Gold: Designing Markets to Allocate Water in California*. Island Press.

> management plan], or County. There is a possibility that a seller's groundwater substitution area of impact will occur in multiple local jurisdictions, which should results [sic] in project requirements coming from multiple local as well as state and federal agencies. The Draft EIS/EIR doesn't discuss which of the multiple local agencies would be the lead agency, how an agreement between agencies would be reached, or how the requirements of the other agencies will be enforced."[64]

Overall, the estimates of benefits and costs of transactions, as well as identification of efficient transactions, do not include the diverse and substantial set of transaction costs that cross-Delta transfers would require. Therefore the analysis either overestimates the benefits of the LTWT, or hides public costs to manage and overcome these transaction costs.

---

[64] Custis 2014, page 9.

4 The LTWT underestimates negative impacts on the regional economy in the sellers area

In this section we describe our comments on the analysis of regional economic effects in the LTWT.

Underestimates economic effects on regional economy in sellers area

In the sections above, we describe omissions and errors regarding the estimated number and volumes of water transfers. Some of these errors could lead to underestimating the number and volume of water transfers, some could have the opposite effect. In this subsection we focus on additional examples of how the LTWT likely underestimates the number and volume of water transfers that will happen in the future. By underestimating the water transfers the LTWT also underestimates the negative impacts of the transfers on the regional economy in the sellers area.

The negative economic effects listed in the LTWT include:

- Approximately 500 lost jobs in Glenn, Colusa, Yolo, Sutter, Butte and Solano counties.
- Over $20 million in lost labor income and over $61 million in lost economic output in these same counties.
- Unquantified but increased pumping costs for water users in areas where groundwater levels decline.
- Unquantified but negative affects on other local economic effects.
- Unquantified but negative affects on tenant farmers.[65]

The LTWT analysis of some regional economic effects assumes non-consecutive years of water transfers. If water transfers happen in consecutive years, impacts would be greater than reported in the LTWT.

> "Local effects would be more adverse if cropland idling transfers occurred in consecutive years. Business owners would likely be able to recover from reduced sales in a single year, but it would be more difficult if sales remained low for multiple years."[66]

As shown in LTWT Table 1-3 on page 1-17, from 2004 through 2014, there have been eight water-transfer years out of 11, and 5 cases of consecutive transfer years. Given these recent

---

[65] LTWT, page 3.10-45 and -46.

[66] LTWT, page 3.10-33.

conditions, it is likely that consecutive years of water transfers will happen more frequently than assumed in the LTWT.

Incomplete description of impacts on pumping costs

The LTWT reports that farmers in the Sacramento and San Joaquin Valleys pay water-pumping costs of approximately $0.32 per af.[67] The LTWT analysis estimates that as a result of groundwater-substitution transfers, pumping costs for "many growers" would increase by $0.32 to $1.60 per af.[68] This represents a non-trivial increase of 100 to 500 percent. In some cases, cost increases could be $6.40 to $8.00 per af.[69] Expressed on a percentage basis these amounts are increases of 2,000 to 2,500 percent. The LTWT describes these increases in pumping costs as "adverse." The analysis, however, does not report a total estimated increase in pumping costs or describe the increase as a percentage of current costs, either of which would have helped the reader better understand the significance of the increase.[70] A related point is that the analysis of pumping costs in the LTWT relies on results from the water modeling, the deficiencies of which we describe above and elsewhere in this report.

It's also not clear from the description of the analysis if the "adverse" effects on pumping costs apply only to those participating in water transfers, or also affect third parties that will not benefit from the transfers.

No mention of costs of deepening or installing new wells

The LTWT makes no mention of increased costs of deepening or installing new wells as a result of the impacts of groundwater pumping on groundwater levels. As we note above in section 2 under the description of current groundwater conditions, the CASGEM groundwater basin prioritization study lists 23 basins in the Sacramento Valley ranked "high" or "medium" dependent on groundwater. These basins support private residential wells, public water supply wells, and irrigation wells.[71] Recent news reports describe the intensity of well drilling operations in California's Central Valley.[72] To the extent that groundwater pumping in support of water transfers lowers groundwater levels, some

current water users depending on groundwater may face increased costs of deepening or installing new wells. The analysis described in the LTWT does not address these costs.

Underestimates the significance of impacts on unemployment rates

Any negative impacts of water transfers on agricultural production and related unemployment effects, would take place against a backdrop of already hurting economies. As Figure 3.10-7 illustrates, current unemployment rates in the seller counties runs between approximately 8 and 18 percent. The LTWT analysis estimates that water transfers will idle approximately 500 workers in the Sacramento Valley. The analysis assumes that impacts of transfers on unemployment would be temporary.

> "Reductions in employment associated with cropland idling transfers would contribute to unemployment in the region. However, cropland idling effects are temporary and under the Proposed Action, cropland idling transfers would not occur each year over the 10-year period."[73]

As we note above, however, data on the frequency of recent water transfers do not support the LTWT assumptions regarding infrequent future water-transfer years. Thus, the LTWT analysis likely underestimated the negative impacts of the plan on unemployment in the Sacramento Valley.

No mention of economic harm to local economies from lost water-based recreational activities

The analysis of regional economic effects in the LTWT focuses on impacts of water transfers on agricultural production and related businesses. The LTWT ignores other negative impacts on the regional economy. For example, the LTWT is silent on the impacts of water transfers on reservoirs such as Lake Oroville and others in the sellers area, and the related impacts on the region's water-based recreational economy. In their letter commenting on the LTWT, the Butte County Board of Supervisors noted their concerns that the LTWT "… failed to take into account the reduction in stream flows and the lowering of Lake Oroville that will harm the local economy."[74] In an earlier letter to Governor Brown commenting on the BDCP, the Butte County Board of Supervisors noted the importance of the lake to the region's economy, and the fact that the State of California has not fulfilled commitments made regarding developments at Lake Oroville.[75] Ignoring the potential impacts of water transfers on Lake Oroville and the associated economic impacts compounds the negative effects of the State's failure to fulfill past commitments at the lake.

Arbitrary limits on crop idling

The analysis in the LTWT relies on arbitrary limits on crop idling as a means of avoiding negative economic impacts. The DWR and BOR document that provides technical guidance for those interested in making water transfers describes the possibility of negative economic effects of crop idling, however, the guidelines for the amount of idling that would cause economic harm appear arbitrary. The relevant passage from the document states,

> "Cropland idling/crop shifting transfers have the potential to affect the local economy. Parties that depend on farming-related activities can experience decreases in business if land idling becomes extensive. Limiting cropland idling to 20 percent of the total irrigable land in a county *should* limit economic effects."[76] [emphasis added]

While the statement may be true, it lacks the analytical rigor that would satisfy NEPA requirements for, "Rigorous exploration and objective evaluation of all reasonable alternatives, …"[77] As such, the guidelines on crop idling seem arbitrary rather than the result of rigorous and objective analysis.

Table 3.10-22 lists the total number of acres affected by cropland idling in the analysis described in the LTWT. As shown in this table, approximately 60,000 acres could be idled in Glenn, Colusa, Yolo, Sutter, and Butte counties.[78] In the table below, we show the total number of acres of irrigable land in each county, and 20 percent of these acres. According to the guidelines noted above, up to 257,000 acres could be idled in these counties without significant economic effects. This seems doubtful. Rather than relying on arbitrary rules of thumb and assumed limited economic effects of idling, a more complete and transparent assessment of the economic effects of water transfers would take an analytical and quantified approach.

Table 1: Acres of Cropland, by County, 2011.

County	Acres of Cropland	20 Percent of Acres
Butte	224,592	47,969
Colusa	291,435	56,246
Glenn	250,493	50,099
Sutter	239,846	58,287
Yolo	281,228	44,918
Total	1,287,594	257,519

5 The LTWT finds significant negative effects but the vague and incomplete proposed monitoring and mitigation plans would not address these effects

The LTWT concludes that water transfers will have some significantly negative impacts on groundwater resources. As we note in earlier sections of this report, the analysis described in the LTWT likely underestimates the negative effects of water transfers. For example, the analysis likely underestimates the frequency of water-transfer years, and so the negative effects of the transfers. The analysis also ignores negative impacts on water-based recreational activities and the associated negative economic consequences. The monitoring and mitigation plans focus only on the negative effects listed in the LTWT. Thus, they would address only a subset of the likely total negative economic consequences of the water transfers. In addition, the vague and incomplete proposed monitoring and mitigation plans would not adequately address those negative effects listed in the LTWT. Concerns regarding these plans include the following.

The LTWT ignored the costs of monitoring and mitigation

The LTWT proposes both a monitoring and mitigation program for significant negative impacts of water transfers on groundwater resources. Implementing these programs would take planning, effort and financial resources. The LTWT, however, does not include these costs in their analysis of alternatives. For example, water sellers would be required to monitor and record groundwater conditions and coordinate with regulators regarding the impacts of their groundwater pumping on groundwater levels. Water seller will incur costs monitoring, measuring, recording, and reporting the necessary information. The LTWT excludes these and related costs from the analysis.

Likewise, the mitigation of negative groundwater consequences would also require time, effort, and costs to water sellers, third parties negatively affected by groundwater pumping, and regulators. LTWT excludes these costs as well.

The monitoring and mitigation programs include inherent conflicts of interests

The monitoring program as described in the LTWT is vague and depends on sellers implementing the program. This conflict of interest pits financial gain from water sales against complete and impartial monitoring efforts. This opens the door to lax, biased, or incomplete monitoring, which could lead to negative environmental and economic consequences for third parties not part of the water transfers.

The monitoring program includes provisions for a coordination plan that would share information among "well operators and other decision makers."[79] Such confidential results would keep other stakeholders in the dark regarding the impacts of water transfers. Given the fact that multiple wells belonging to multiple property owners can access the same groundwater aquifer, and that groundwater pumping can affect flows of surface water, such a confidential program seems counter to the wellbeing of the regional economy in the sellers area. An open monitoring program with public results would better communicate the potential environmental and economic risks of groundwater pumping in support of water transfers.

If the seller's monitoring program finds that water sales are causing "substantial adverse impacts"[80] the seller will be responsible for implementing a mitigation program. The conflict of interest is obvious.

One method of avoiding the obvious conflicts of interests is requiring monitoring by independent third parties not involved with or affected by groundwater pumping in support of water transfers. Such monitoring could be detailed, transparent and public, which would alleviate concerns over the risks and consequences of negative environmental and economic effects of groundwater pumping. Mitigation decisions and requirements should likewise be detailed, transparent and public for the same reasons.

Insufficient monitoring period

As described in the LTWT, groundwater levels would be monitored through March of the year following a transfer. It's not clear that this limited monitoring period is sufficiently long enough to track potential impacts on groundwater of water transfers. For example, the report cited above for the NCWA states,

> "…[G]roundwater changes can take many years to become apparent, and we have not yet been able to measure with certainty the long-term impacts of the current level of groundwater use as it affects our measures of sustainability."[81]

An insufficient monitoring period could underestimate the impacts of groundwater pumping on groundwater levels and impacts on stream flow depletions. Lowering groundwater level and increasing stream flow depletions would generate negative environmental and economic impacts. The monitoring period in the LTWT may cause analysts to underestimate the environmental and economic effects of the water-transfers alternatives.

---

[79] LTWT, page 3.3-89.

[80] LTWT, page 3.3-90.

[81] DMW, 2014, page 10.

Insufficient monitoring for land subsidence

The monitoring program includes monitoring subsidence, however, the program is vague on monitoring requirements and what amount of subsidence would trigger a halt in water transfers. Custis describes a number of technical deficiencies in the proposed mitigation plan.

> "The Draft EIS/EIR should be able to provide the specific thresholds of subsidence that will trigger the need for additional extensometer monitoring, continuous GPS monitoring, or extensive land-elevation benchmark surveys by a licensed surveyor as required by GW-1. The Draft EIS/EIR should also specify in mitigation measure GW-1, the frequency and methods of collecting and reporting subsidence measurements, and discuss how the non-participating landowners and the public can obtain this information in a timely manner. In addition, the Draft EIS/EIR should provide a discussion of the thresholds that will trigger implementation of the reimbursement mitigation measure required by GW-1 for repair or modifications to infrastructure damaged by non-reversible subsidence, and the procedures for seeking monetary recovery from subsidence damage [citation omitted]."
>
> "Specific 'strategic' subsidence monitoring locations should be given in mitigation measure GW-1 based on analysis of the susceptible infrastructure locations and the potential subsidence areas."[82]

Implementing the Custis recommendations will take time and financial resources for water sellers, local jurisdictions and third parties negatively affected by groundwater pumping. The LTWT does not include the costs of these measures in the analysis. Thus, the costs of the water transfers described in the LTWT underestimate the true costs of the program.

Vague significance criteria

The mitigation program includes a number of vague descriptions of critical components. Relevant missing descriptions include details on:

- How regulators and stakeholders would define "substantial adverse impacts" from groundwater pumping.
- What constitutes a "significant" increase in pumping costs suffered by injured third parties.
- Required modifications to damaged third-party infrastructure or the installation of new infrastructure.

---

[82] Custis 2014, page 28.

- The procedure that injured third parties would use when making claims against a seller.
- The procedure that regulators and stakeholders would use when investigating third-party claims.
- What constitutes "legitimate significant effects" on third parties.[83]

A vague and ill-defined mitigation program increases risks of environmental and economic harm, and shifts the costs of such harm from water sellers to third parties and society in general. The analysis described in the LWTW does not identify, describe or quantify these risks, costs and consequences. A related point is that the LTWT makes no mention of BOR addressing these or similar issues as part of reviewing past annual water transfers. Including such information from past water transfers—if BOR considered these effects—in the LWTW could help illustrate or describe the uncertainties listed above.

The mitigation plan puts costs on to injured third parties

Injured third parties bear the costs of bringing to the sellers' attention harm caused by groundwater pumping. Also, the LTWT states that proposed mitigation options would be developed "in cooperation"[84] with injured third parties. This approach places costs on injured third parties rather than on sellers. That is, those who would not benefit financially from the program bear the costs of bringing negative impacts to the sellers' attention. They also would incur costs of documenting and presenting their damages in the context of an ill-defined mitigation program. This raises equity concerns that those suffering costs of the program bear the additional costs of identifying, describing and calling attention to their costs. The analysis described in the LTWT further assumes that disagreements regarding third-party damages would be settled cooperatively, without presenting evidence substantiating such an optimistic assumption. The LTWT is silent on the economic consequences of sellers and injured third parties not cooperatively agreeing on harm and compensation.

As we note above, information the BOR collected from past water transfers may help inform the types and amounts of costs that injured third parties could incur as a result of the water transfers at issue in the LTWT.

BOR's role in monitoring and mitigation

The LTWT describes a substantive role for BOR in the monitoring and mitigation program, without specifics of how BOR would implement its responsibilities. Topic not addressed include:

---

[83] LTWT, page 3.3-88 through -91.

[84] LTWT, page 3.3-91.

- The costs to BOR of monitoring and mitigation.
- The details of interactions between sellers, injured third parties, and BOR staff regarding the details of monitoring and mitigation.
- The details of collecting, organizing and publishing relevant details of monitoring and mitigation.
- The details of decision making processes that affect monitoring and mitigation.
- The details of interactions between BOR and other federal or state agencies, and BOR and local jurisdictions.

Lead CEQA agency

SLDMWA is the lead state agency regarding CEQA compliance. It is also one of three potential buyers for the transferred water.[85] This arrangement creates a conflict of interest in that the lead CEQA agency also has a self interest in facilitating the water transfers. As described on their website, SLDMWA delivers approximately 3 million af of water to member agencies.[86] SLDMWA has a financial and operational interest in delivering water to its members. Thus, SLDMWA is not an impartial agent.

The LTWT provides no information on why SLDMWA is the lead state agency and not the California Department of Water Resources.

---

[85] LTWT EIS/EIR, Table 1-2, page 1-5. The other two buyers are Contra Costa Water District and the East Bay Municipal Utility District.

[86] SLDMWA web site, www.sldmwa.org/learn-more/about-us/.

6 The LTWT ignores the economic costs of environmental externalities and subsidies that water transfers support

The LTWT lists Westlands Water District as one of the CVP contractors expressing interest in purchasing transfer water.[87] The environmental externalities caused by agricultural production in Westlands are well documented, as are the economic subsidies that support this production. To the extent that the water transfers at issue in the LTWT facilitate agricultural production in Westlands, they also contribute to the environmental externalities and economic subsidies of that production. The LTWT is silent on these environmental and economic consequences of the water transfers.

In this section we summarize recent information on the environmental externalities and economic subsidies of agricultural production on Westlands that water transfers would support.

The environmental and economic externalities of Westlands have a long history

For decades, high levels of selenium have posed a serious environmental threat to drinking water, soil quality, and agriculture in the Westlands Water District.[88] This naturally occurring element leaches into soil and drinking water when irrigation water is applied and when significant levels accumulate, has been known to cause deformities and death in wildlife and human beings.[89] The most extreme example of this type of degradation occurred from 1981-1986 during the Kesterson Disaster, when the federally operated San Luis Unit diverted selenium-rich wastewater into the Kesterson National Wildlife Refuge, killing over one thousand birds and causing severe birth defects.[90]

Menlo Park, California.

Current environmental concerns

Since the Kesterson Disaster, the Westlands has followed a "no-discharge policy" where irrigated wastewater is reused on agricultural land or stored in groundwater aquifers.[91] In spite of the well-documented concerns regarding selenium contaminated runoff from Westlands, as yet there is no official monitoring of selenium levels in the district.[92] The San Luis Act (1960) gives the BOR, not the Westlands Water District, responsibility for disposing of Westland Water,[93] but as of yet neither entity has implemented any meaningful solution. This failure prompted the Westlands District to bring a lawsuit against the BOR in 1995, which was finally brought to the Ninth Circuit Court of Appeals in 2000.[94] The court upheld a lower court's decision to force the BOR to provide drainage to the district but allowed that solutions other than a drain might be considered.[95]

At first, it seemed that large-scale retirement of farmland was the solution favored by both the Westlands and the federal government.[96] In 2001, the District released a fact sheet entitled "Why Land Retirement Makes Sense for the Westlands Water District" advocating for a possible deal with the federal government that would retire up to 200,000 acres of agricultural land. According to the federal government's National Economic Development analysis, this option would result in an economic gain of $3.6 million per year excluding any additional savings as a result of reduced crop subsidies.[97] Instead, after more than a decade of negotiations, the federal

government and the Westlands Water District finally signed an agreement in 2014 which lifts the federal government's obligation to provide drainage to the district, forgives the nearly $400 million the district owes to the federal government for its part in the construction of the Central Valley Project (CVP), assures the district almost 900,000 acre-feet of water per year from the CVP, and requires only 100,000 acres of land be retired.[98] This leaves over 100,000 more acres of selenium-degraded land that the Westlands Water District will now need to decide how to drain in the years to come.[99] In addition, while the BOR's Environmental Assessment found that there would be no significant environmental impact as a result of the interim renewal contracts with the Westlands and other CVP districts, several environmental groups have criticized the study as violating federal environmental requirements, including the National Environmental Policy Act of 1969.[100]

Economic subsides to the Westlands water district

As the largest water district in California and the largest recipient of water under the Central Valley Project, the Westlands Water District receives significant crop, water, and power subsidies to supplement its agricultural activities. According to a report by the Environmental Working Group, between 2005 and 2009, the federal government issued almost $55 million of counter cyclical and direct crop subsidies to 356 individuals in the district.[101] The district's 350 farms networks are entitled to over 1.1 million acre-feet of water per year, more than twice the allocation of the City of Los Angeles.[102] In 2002, the group estimated that the federal

government paid $110 million per year in water subsidies, making its water drastically less expensive than that allocated to urban households.[103]

In 2002, the Westlands Water District received more than $70 million in power subsidies Although the Westlands receives 25% of all water from the CVP, it consumes 60% of the electricity required to deliver water to all districts and 60% of all government granted power subsidies to the CVP.[104]

As mentioned above, the federal government has subsidized the Central Valley Project since its construction. While farmers were meant to pay $1 billion of the $3.6 billion project cost fifty years after its completion, it's estimated that by 2008, only 20% of that debt had been repaid.[105]

7 The LTWT underestimates the cumulative effects of water transfers

Cumulative effects analyses under NEPA and CEQA are intended to identify impacts that materialize or are compounded when the proposed action is implemented at the same time as or in conjunction with other actions. In Chapters 3 and 4, the LTWT addresses cumulative effects for each resource area and provides a global description of the methods and actions considered for analysis in each resource area. Section 3.10 provides a cursory discussion of potential cumulative effects for the regional economy, but ignores the full range of possible cumulative outcomes associated with the proposed action.

According to NEPA and CEQA requirements, cumulative effects analysis must examine the possibility of effects occurring across several dimensions. When multiple projects produce effects within the same geographic and temporal range, they may:

- Expand or contract the set of possible impacts.
- Increase or decrease the likelihood of specific potential impacts.
- Accelerate or decelerate the timing of specific potential impacts.
- Change the trajectory of potential impacts.
- Increase or decrease the economic importance of specific potential impacts.
- Shift the distribution of uncertainty or risk borne by different groups.

Cumulative effects may arise as multiple projects interact in a linear fashion, resulting in impacts that are additive. Interactions might also be non-linear, either offsetting each other to be less than additive, or exacerbating each other to be greater than additive.

The LTWT does not adequately consider cumulative effects within this framework, so misses important interactions that could result in significant impacts beyond those identified for the project alone.

One of the greatest potential sources of cumulative impacts is non-CVP water transfers. Although transfers under the SWP were considered, the possibility of other transfers occurring was not. Additional transfers would have similar impacts in the sellers' region, and may also lead to net effects that exceed sustainable thresholds and have a larger impact than each would individually. For example, the analysis

- Ignores cumulative effects of additional water transfers on water prices, and fails to examine the effects of price on the decisions and behaviors of farmers in the context of other water transfers.
- Ignores effects resulting from additional water transfers that have the potential to influence agricultural prices, and how those agricultural prices influence decisions about water transfers.

- Treats effects as “temporary” and thus not significant, and thereby fails to adequately account for potential thresholds in the local agricultural economy where short-term effects would become long-term effects.
- Assumes mitigation for groundwater effects of the proposed action would make farmers whole, so fails to properly account for potential threshold effects in groundwater resources, and associated costs to farmers.
- Ignores the possibility that increased uncertainty related to groundwater levels, agricultural market conditions, etc. from the proposed action, in conjunction with other actions, would adversely affect farmers.
- Ignores the cumulative effects of additional water transfers on environmental resources and conditions including aquatic, riparian, terrestrial and avian species and habitats.

WATER RIGHTS WITHIN THE BAY/DELTA WATERSHED
STATE WATER RESOURCES CONTROL BOARD

The water right permit system administered by the State Water Resources Control Board (State Water Board) applies to surface water bodies and to a narrow classification of groundwater, “subterranean streams flowing in known and definite channels.” (Wat. Code, § 1200.) Aquifers that are not part of a subterranean stream are classified as “percolating groundwater.” There are two basic categories of surface water rights: post-1914 appropriative; and pre-1914 appropriative and riparian. The State Water Board has very limited information on water use for either of these classes of water rights, and the little information it does have has not been synthesized and is not maintained electronically. The State Water Board has no information on groundwater use in the Delta watershed.

Post-1914 Appropriative Water Rights

The State Water Board has permitting and licensing authority over surface water diversions associated with post-1914 appropriative water rights within the legal Delta and within the Delta watershed. December 19, 1914 is the effective date of the Water Commission Act that established the modern procedures to regulate surface water appropriation. Surface water appropriations established prior to this date are not bound by these procedures. The State Water Board maintains paper and electronic files for post-1914 permitted and licensed water rights, pending water right applications, and also state filings, which are state filed water right applications reserved for future use by individuals and entities in the areas where water originates. The information in its files includes the holder of the water right, point of water diversion, limitations on the rate, amount, and season of diversion, the place and purpose of use of the water, and any other terms or conditions placed on the water right. These limitations on rate, amount, and season of use are used to determine the “face value” of the water right, defined as the total annual amount of diversion authorized for direct diversion or storage by a permit or license. The term is primarily used in the calculation of water right fees and does not take into account water availability, bypass requirements, or other conditions that may have a practical effect of limiting diversions. Further, the State Water Board has continuing authority to change existing water rights, following formal notice and opportunity for hearing, in order to protect the public trust and water quality and to prevent the waste, unreasonable use, and unreasonable method of use or diversion of water.

Water right permit and license holders are required to file progress reports with the State Water Board, and to report their water diversion and use amounts (Cal. Code of Regs, tit. 23, § 847). These reports are to be completed annually for water right permit holders and triennially for water right license holders. Approximately 68 percent of permit and license holders submit completed water use reports to the State Water Board. The Water Code does not contain specific enforcement provisions that would allow the State Water Board to enforce against the lack of reporting. Use information reported to the State Water Board is stored in paper files and there has been no verification of the quality of this information except as part of limited enforcement actions. Summary information is therefore not available to compare face value of water rights to actual use. Some water users who hold multiple rights report the same use information for all of their rights. For instance, a right holder may use 2500 acre-feet per year of water under three different water rights. If that user reports a use of 2500 acre-feet for each of the three rights, a cursory review might lead the reviewer to conclude that 7500 acre-feet of water is being used, although this is not the case.

Pre-1914 Appropriative and Riparian Water Rights

The State Water Board does not have permitting and licensing authority over Pre-1914 appropriative or riparian water rights. The State Water Board does however collect Statements of Water Diversion and Use (Statements) from water diverters claiming riparian and pre-1914 water rights. (Wat. Code, § 5100 et seq.) The State Water Board has approximately 5,500 Statements of Water Diversion and Use on file for pre-1914 and riparian rights in waters tributary to the Delta. These Statements, however, do not provide complete information about riparian and pre-1914 water diversions in California. Of particular significance in the Delta, certain diverters are statutorily exempt from filing Statements; Water Code section 5101 exempts diversions that are reported by the Department of Water Resources (Department) in its hydrologic data bulletins or that are included in the consumptive use data for the Delta lowlands published by the Department in its bulletins. (*Id.*, § 5101, subds. (e)-(f).) The State Water Board estimates that there are approximately 1,600 unreported Pre-1914 and riparian diversions in the Delta. Additionally, even if a water diverter is statutorily required to file a Statement, there is no penalty for failure to file a report. (*Id*., § 5108.)

Groundwater

Percolating groundwater is not subject to the State Water Board's permitting system and, in most of the state, is not regulated by any other public agency. When considering a proposed appropriation of groundwater, or determining whether an unpermitted diversion in close proximity to a stream is an unauthorized diversion, the State Water Board must evaluate the legal classification of the groundwater from which the water is being appropriated to determine whether it is a subterranean stream, which is under the jurisdiction of the State Water Board, or percolating groundwater, which is not. (See *North Gualala Water Co. v. State Water Resources Control Board* (2006) 139 Cal.App.4th 1577 [43 Cal.Rptr.3d 821] [upholding State Water Board's use of four-part test in determining legal classification of groundwater].) To the extent groundwater is classified as a subterranean stream, it is managed as surface water. (See also Wat. Code, § 2500 [statutory adjudication procedures, under which all rights in a stream system are determined, apply to surface waters and subterranean streams, not percolating groundwater]. The State Water Board has no legal authority to require users of percolating groundwater to report their uses of water, other than in four southern California counties. The State Water Board does not therefore maintain information on extraction of percolating groundwater within the Delta watershed.

Water Use versus Water Rights

The mean annual unimpaired or full natural flow in the Delta Watershed between 1921 and 2003 was 29 million acre-feet per annum (AFA), with a maximum of 73 million AFA in 1983.[1] Unimpaired flow is flow that would be expected in the Delta watershed in the absence of storage and other human developments. In contrast, the total face value of the approximately 6,300 active water right permits and licenses within the Delta managed by the State Water Board, including the already assigned portion of state filings, is approximately 245 million AFA. There are 100 rights with a face value of 500,000 AFA, or more that account for 84% of the total face value of the water rights within the Delta watershed. The Central Valley Project and State Water Project hold 75 permits and licenses within the Delta watershed that account for 53% of the total face value of the water rights within the watershed. The total face value of the unassigned portion of state filings for consumptive use (excluding state filings for the beneficial use of power) within the Delta watershed is approximately 60 million AFA. This does not mean that this 60 million AFA is hydrologically available for appropriation. Prior to assignment of a state filing, the State Water Board will require that an applicant provide evidence that water is available to support the assignment. Clearly, actual use must be only a small fraction of the face value of these water rights, particularly since face value does not include pre-1914 and riparian water rights. There are three primary reasons why the face value of water rights is greater than actual diversions:

1. When approving a water right application, the State Water Board has to find that water is available for appropriation for the project being proposed. In making that determination, the State Water Board looks at both the demand characteristics associated with the proposed use and the likelihood that supply will be adequate to supply that demand. The State Water Board is required to maximize the beneficial use of water. Historically, the State Water Board has approved permits for agricultural projects if water is available in 50 percent of years, under the condition that water cannot be diverted in years in which there is insufficient supply to satisfy prior vested rights.
2. Water rights are issued based on the maximum rate of diversion (for direct diversion projects) and the maximum annual diversion to storage (for reservoirs and other impoundments). For large storage projects, the maximum annual diversion to storage generally only occurs in the year in which the project initially fills. Most modern water rights include a bypass condition which can limit diversion amounts below the "face value" amount in many years. Some water rights include a condition that limits the amount of water that can be diverted in combination with other water rights. This information is difficult to capture in a database format.
3. Some projects are covered by multiple rights for the same molecules of water. The State Water Board's regulations require that separate water rights be obtained for non-consumptive and consumptive uses of water. Large multi-use reservoirs will have at least two permits as a result, one that allows non-consumptive uses like recreation at and below the reservoir and one that allows consumptive uses such as municipal and irrigation uses. Similarly, the same molecule of water may be diverted several times by several different water right holders as it works its way down a river. If the water is not consumptively used,

---

[1] DWR, Bay Delta Office, California Central Valley Unimpaired Flow Data, Fourth Edition Draft, May 2007

or lost to deep groundwater recharge, it likely returns to a river and is rediverted downstream.

Actual use under existing water rights is clearly a better metric to compare with unimpaired flows than is face value but the State Water Board has limited information on actual use. Comprehensive review and synthesis of the State Water Board's paper files would however provide only a crude estimate of actual historic and current use because of gaps in reporting and unreliability of the data already collected. Finally, there is a linkage between water availability in many surface waters and groundwater pumping but the State Water Board has no information on percolating groundwater pumping in the Delta watershed.

RE: COMPLAINT: Against SWRCB, USBR and DWR for Violations of Bay-Delta Plan, D-1641 Bay-Delta Plan Requirements, Clean Water Act, Endangered Species Act, Public Trust Doctrine and California Constitution

Dear Mr. Howard and Ms. Evoy:

The California Sportfishing Protection Alliance (CSPA) hereby submits a complaint against the State Water Resources Control Board (SWRCB), United States Bureau of Reclamation (USBR) and California Department of Water Resources (DWR) for violations of the Water Quality Control Plan for the San Francisco Bay/Sacramento-San Delta Estuary (Bay-Delta Plan) and violations of D-1641 implementing requirements of water quality standards, Clean Water Act (CWA), Endangered Species Act (ESA), Public Trust Doctrine and the California Constitution.

Specifically, CSPA alleges that the SWRCB's sequential weakening of D-1641 requirements violates the federal CWA and represents a de facto change in the standards themselves, that the SWRCB has failed to enforce Bay-Delta water quality standards and has failed to enforce its 2010 Cease & Desist Order against USBR and DWR for violations of southern Delta salinity standards, that USBR and DWR are presently violating water quality standards protecting fish & wildlife and agricultural beneficial uses, and that USBR and DWR have failed to comply with the SWRCB 2010 Cease & Desist Order. CSPA additionally alleges that the SWRCB, USBR and DWR have failed to comply with their respective responsibilities and obligations under the ESA, Public Trust Doctrine and Article X of the California Constitution.

We incorporate by reference the protests, objections, exhibits and workshop comments and presentations that CSPA et al., the Bay Institute, Restore the Delta and Sequoia Forestkeeper et al. have previously made during the 2014 and 2015 SWRCB proceedings regarding USBR and DWR's Temporary Urgency Change Petitions (TUCPs) for the operation of the State Water Project and Central Valley Project.

Given the impending extinction of Delta smelt and possibly several other species, we ask the SWRCB to act expeditiously in responding and requiring USBR and DWR to respond to the allegations herein and to immediately reestablish D-1641's critical year requirements for the protection of fish and wildlife.

Dr. Peter Moyle has been publicly quoted as predicting the imminent demise of Delta smelt. Agency biologists have privately told us "they're gone." Should Delta smelt perish, it will not be the drought that sent them into extinction: it will be the failure of the SWRCB to comply with and enforce minimal standards for drought sequences that it adopted to prevent such catastrophe. Fallowed fields will be replanted when the drought is over; extinct species are forever lost. It would be tragic if the SWRCB's legacy were that its failure to comply with the law sent species that evolved and prospered over millennia into extinction. And longfin smelt are next in line.

Violations of Bay-Delta Standards & D-1641 Requirements

The federal CWA requires the adoption of water quality standards consisting of the designated uses of navigable waters and the water quality criteria or objectives necessary to protect those designated uses. Antidegradation requirements are an integral part of water quality standards.

The current water quality objectives in the 2006 Bay-Delta Plan for the San Francisco Bay/Sacramento-San Delta Estuary are the same as those in the 1995 Water Quality Control Plan. Many of those objectives were also in the 1978 Bay-Delta Plan.

The SWRCB's Decision 1641, issued in 2000, is the current implementation plan for Bay-Delta water quality standards. Implementation plans that do not protect the designated use of the waters do not comply with applicable water quality standards. D-1641 contains objectives to protect fish and wildlife, agricultural, municipal and recreational designated beneficial uses of the Bay-Delta estuary. Those objectives are expressed as narrative, concentration and or flow.

There is continuing disagreement between the SWRCB and U.S. Environmental Protection Agency (USEPA) concerning whether the CWA regulates the quantity of water or flow. However, flow and constituent concentration are flip sides of the same coin. Reductions in flow increase the concentration of pollutants. The U.S. Supreme Court observed that a lowering of quantity or flow could destroy all of the beneficial uses of a river, and specifically that "… there is recognition in the Clean Water Act itself that reduced stream flow, *i.e.*, diminishment of water quantity, can constitute water pollution." *PUD No. 1 of Jefferson County v. Washington Department of Ecology,* (1994), 511 U.S. 700, 17.

This complaint addresses violations of agricultural objectives, expressed as concentration, and fish and wildlife objectives, expressed as both flow and concentration. For example, fish and wildlife objectives are expressed as both minimum Delta outflow and salinity concentration. However, the preferred habitat of estuarine species like Delta and longfin smelt is predicated on the concentration of salinity. A key to Delta smelt abundance, X2, is determined by the concentration of salinity and not by flow.

In an effort to avoid having to secure USEPA approval, the SWRCB suggests that it only modified the implementation of water quality objectives and not the objectives themselves. However, the sequential or serial weakening of standards and refusal to enforce violations of standards constitutes a de facto change in the standards themselves, especially when the serial weakening of and failure to enforce standards is replicated over decades in similar situations.

In 2013, the SWRCB Executive Director allowed USBR and DWR to operate to critical year criteria, without being subject to enforcement, instead of to the prevailing dry year criteria. In 2014, the Executive Director issued a series of TUCP Orders substantially weakening and extending the modifications of water quality objectives and requirements on 31 January, 7 February, 14 February, 28 February, 18 March, 9 April, 11 April, 18 April, 2 May and 7 October. The SWRCB denied multiple objections and petitions for reconsideration of the TUCP Orders on 24 September 2014. So far in 2015, the Executive Director has issued a series of TUCP Orders modifying and weakening water quality objectives and requirements on 3 February, 5 March, 6 April and 3 July.

Beyond the SWRCB's de facto weakening of Bay-Delta water quality objectives, the USBR and DWR have failed to comply with even the modified objectives. Violations of salinity standards at Threemile Slough and Jersey Point have occurred in 2015 and are continuing. Additionally, the sequential Cease & Desist Order compliance schedules adopted by the SWRCB in WR Orders 2006-0006 and 2010-0002 that allowed USBR and DWR to avoid actual compliance with southern Delta salinity objectives have expired and USBR and DWR are now in violation of WR Order 2010-0002 and the southern Delta salinity objectives at Old River Near Tracy, Old River near Middle River and San Joaquin River at Brandt Bridge. Further, the Vernalis salinity objective was violated on 5 days in July 2015.

This pattern and practice has replicated itself over decades. For example, during the 1987-1992 drought, D-1485 Bay-Delta standards were violated 246 times in the period from 1988 through 1991, and the SWRCB declined to take enforcement action. In 1992, the SWRCB, citing an effort to preserve sufficient cold water in Shasta Reservoir to meet temperature requirements for spawning salmon, weakened Suisun Marsh salinity and Rock Creek chloride requirements in WR Order 92-02. Of particular note, the SWRCB, referencing WR Order 90-05, stated in WR 92-02 at page 9:

> The State Water Board also has advised the USBR that decisions on water deliveries are subject to the availability of water, and that water should not be considered available for delivery if it is needed as carryover to maintain an adequate cold water pool for the fishery.

However, the USBR and DWR have ignored that advice and have continued to maximize water deliveries in the initial years of drought sequences and failed to maintain sufficient carryover storage to protect fisheries and public trust resources. The pattern and practice of delivering near normal water supplies in the early years of drought, depleting carryover storage and then relying on the SWRCB to weaken water quality standards has been extensively discussed and documented in previous protests, objections and SWRCB TUCP workshops and is incorporated by reference and need not be repeated here.

Violations of Bay-Delta Agricultural Salinity Objectives

Water quality objectives contained in the Bay-Delta Plan include salinity standards to protect agricultural beneficial uses. Table 2 objectives include electrical conductivity (EC) requirements of 2.78 mmhos/cm in the Sacramento River at Emmaton between 1 April and 15 August of critical dry years; EC requirements of 2.20 mmhos/cm in the San Joaquin River at Jersey Point between 1 April and 15 August of critical dry years and EC requirements of 0.7 mmhos/cm (April-August) and 1.0 mmhos/cm (September-March) at four locations in the South Delta (Vernalis, Brandt Bridge, Old River near Middle River and Old River at Tracy Road) in all years.

On 6 April 2015, the SWRCB Executive Director approved a Temporary Urgency Change Petition submitted by USBR and DWR to move the Emmaton EC compliance location to Threemile Slough from April through June. On 30 June 2015, the Executive Director provided interim approval of a subsequent TUCP, and, on 3 July he issued an order approving an extension of the relocated Emmaton objective to Threemile Slough until 15 August 2015. This action was similar to an action in the 2014 TUCP Order by the Executive Officer that moved the compliance point to Threemile Slough.

Had the SWRCB Executive Director not relocated the Emmaton compliance point, EC would have violated objectives on or about 1 May 2015, when the 14-day running average EC was 2.81 mmhos/cm, and would be ongoing in the present. As of 16 July 2015, 14-day running average EC at Emmaton was 5.26 mmhos/cm. During 2014, the Emmaton objective was exceeded on or about 26 May, and exceedances continued through 23 July.

Beginning on 7 July 2015, the EC objective of 2.78 mmhos/cm at the relocated Threemile Slough compliance point has been violated. The 14-day running average EC concentrations stated respectively for each day were 2.85, 2.94, 3.03, 3.09, 3.11, 3.15, 3.18, 3.20, 3.21, 3.21, 3.18, 3.14, 3.01, 2.91 and 2.84 mmhos/cm from 7 through 21 July. The 15-minute EC data from the DWR gage at Threemile Slough is included in Attachment A. As of this writing, violations are continuing.

Beginning on 8 July 2015, the EC objective of 2.20 mmhos/cm at Jersey Point has been violated. The 14-day running average EC concentrations stated respectively for each day were 2.204, 2.234, 2.242, 2.233, 2.250, 2.239 and 2.238 and 2.231, 2.219 and 2.207 mmhos/cm from 8 through 17 July. The 15-minute EC data from the USBR gage at Jersey Point is included in Attachment A.

USBR and DWR have not requested changes regarding salinity objectives at compliance stations in the South Delta in any of their 2014 and 2015 TUCPs and no changes or variances have been granted. D-1641 included a 5-year time schedule to meet the southern Delta 0.7 mmhos/cm EC objective. The objective became effective on 1 April 2005. Violations occurred. The SWRCB, in Order 2006-0006, issued a Cease & Desist Order that required USBR and DWR to take corrective actions in accordance with another time schedule in order to obviate violations of water quality objectives for EC by 1 July 2009. Violations continued. The SWRCB extended the compliance deadline yet again in Order 2010-0002. CSPA and South Delta Water Agency petitioned for reconsideration of Order 2010-0002 but the SWRCB denied both petitions.

Order 2010-0002 required USBR and DWR to implement measures to obviate the threat of non-compliance with South Delta EC objectives and to submit a detailed plan and completion dates for actions that would ensure compliance. Order 2010-0002 extended the timeline for compliance to allow the SWRCB time to consider the possibility of modifying the responsibilities of USBR and DWR for meeting the objective, as part of its 2006 review of the 2006 Bay-Delta Plan. However, Order 2010-0002 explicitly states that *"the pending proceeding to consider changes to the interior southern Delta salinity objectives and associated program of implementation and any subsequent water right proceeding shall be deemed to have been completed if the State Water Board has not issued a final order in the water right proceeding by January 1, 2013, unless the Deputy Director for Water Rights determines that the water right proceeding has been initiated, is proceeding as expeditiously as reasonably possible, and will be completed no later than October 1, 2014."* Emphasis added.

After three consecutive compliance deadlines have expired, violations of southern Delta EC objectives continue. Pursuant to the 2010-0002 Cease & Desist Order, the "compliance schedule" concluded on 1 January 2013 because a 2006 Bay-Delta Plan water rights proceeding was not underway and could not be successfully concluded by October 2014. The USBR and DWR have failed to provide a detailed plan and completion date for coming into compliance with salinity objectives and are presently violating those objectives. We have documented more than 1,400 days of violations of the 1.0 or 0.7 mmhos/cm EC objective at the Old River at Tracy Road compliance site alone since April of 2007, including every day this year. In fact, between 10 June and 15 July 2015, all three southern Delta locations have violated the 30-day running average EC objective everyday and the EC objective at Vernalis was violated 7-9 July.

In summary, from 1 January through the end of 14 July 2015, legally promulgated water quality criteria in Table 2 of the Bay-Delta Plan to protect agricultural beneficial uses was exceeded numerous times: specifically, Emmaton salinity criterion was exceeded at least 79 days; Old River Near Tracy salinity criterion was exceeded at least 199 days; San Joaquin River at Brandt Bridge salinity criterion was exceeded at least 96; days and Old River near Middle River salinity criterion was exceeded at least 40 days. In July 2015, the modified 14-day running average salinity criterion at Threemile Slough was exceeded 7 July and continues to be exceeded, the 14-day salinity criterion at Jersey Point was exceeded 8 July through 17 July and the 30-day salinity criterion at Vernalis on the San Joaquin River was exceeded 7 - 11 July. The USBR and DWR have failed to provide a plan and date for achieving compliance with southern Delta salinity criteria and, consequently, have been violating the SWRCB's Cease & Desist Order since 1 January 2013 (566 days, as of 20 July 2015).

Violations of Bay-Delta Fish and Wildlife Salinity Objectives

Table 3 of the Bay-Delta Plan contains Delta outflow requirements, several of which are also expressed as salinity concentration. For critically dry years, the requirements mandate a minimum monthly average Net Delta Outflow Index (NDOI) of 7,100 cubic feet per second (cfs) or a daily average or 14-day running average of EC less or equal to 2.64 mmhos/cm at

Collinsville. For July, August, September and October of critically dry years, the requirements are an NDOI of 4,000, 3,000, 4,000 and 3,000 cfs, respectively. During dry years, the July, August, September and October requirements are 5,000, 3,500, 4,000 and 4,500 cfs, respectively.

As noted above, so far in 2015, the Executive Director has issued a series of TUCP Orders modifying and weakening water quality objectives and requirements on 3 February, 5 March, 6 April and 3 July. The 2 February TUCP Order reduced NDOI requirements and salinity objectives from 7,100 cfs/2.64 mmhos/cm requirements to 4,000 cfs, increased allowable exports when the 7,100 cfs objective wasn't being met, allowed the Delta Cross Channel Gates to be opened under certain circumstances and reduce San Joaquin River flow requirements from 710/1,140 to 500 cfs.

The 5 March TUCP Order exempted water transfers from export provisions and increased exports when outflow was between 5,500 and 7,100 cfs. The 6 April extended outflow/salinity and export requirements through June, shifted the time period and reduced the volume of the San Joaquin pulse flow from 3,110 to 710 cfs, reduced minimum San Joaquin River outflow requirements to 300 cfs in May and 200 cfs in June and moved the Western Delta salinity compliance point on the Sacramento River at Emmaton to Threemile Slough.

The 3 July TUCP Order reduced Delta outflow requirements in July from 4,000 to 3,000 cfs, with a 7-day running average of no less than 2,000 cfs, reduced the minimum Sacramento River flow requirements at Rio Vista from 3,000 cfs (September, October) and 3,500 cfs in November to a monthly average of no less than 2,500 cfs, with a 7-day average of no less than 2,000 cfs and extended the change in the salinity compliance point from Emmaton to Threemile Slough on the Sacramento River through 15 August.

From 1 January through the end of June 2015, legally promulgated water quality criteria in Table 3 of the Bay-Delta Plan to protect fish and wildlife beneficial uses were exceeded numerous times. Specifically, Delta outflow criterion was exceeded approximately 124 days, Collinsville salinity criterion was exceeded at least 146 days and San Joaquin River flow criterion was exceeded approximately 112 days.

Violations of the Public Trust and Article X of the California Constitution

Article X, Section 2 of the California Constitution provides that:

> The right to water or to the use of the flow of water in or from any natural stream or water course in this state is and shall be limited to such water as shall be reasonably required for the beneficial use to be served, and such right does not and shall not extend to the waste or unreasonable use or unreasonable method of use or unreasonable method of diversion of water.

Because of this Constitutional requirement, the SWRCB must consider the reasonableness of a particular method of diversion of water when evaluating (or reevaluating) all permitted uses of water and the requirements controlling those uses. "The limitations of Art. X, Section 2 … apply to all water users of the state and serve as a limitation on every water right and method of diversion." See *Yuba River D-1644* at p. 29. Both USBR and DWR are water users subject to Article X, Section 2 in the operation of their respective projects in the Central Valley.

Considering the conditions of drought which are described in the "drought emergency" declared by Governor Brown - the curtailments of water rights, the waiver of D-1641 standards to protect fish and wildlife and water quality in the Delta watershed - it is time for the SWRCB to declare flood irrigation by agriculture during the drought emergency a waste and unreasonable use until the emergency is over.

If the SWRCB can require urban conservation, it can also require conservation in agriculture. Flood irrigation in the Sacramento Valley in particular is unreasonable when the endangered salmon are facing extirpation. Increased evaporation from spreading water on the ground alone likely uses more stored water than that needed to save the fishery.

Alfalfa and irrigated pasture alone consumes 8.6 MAF of water in California and provides low net revenue and few jobs. The SWRCB can and must reduce the quantity of water allocated to irrigated pasture and low-value crops like alfalfa that use prodigious amounts of water during the drought emergency. To continue this use is unreasonable and a waste of water and must be stopped or reduced until the drought emergency is declared over.

The continued killing of threatened and endangered species by obsolete and non-protective export pumping facilities simply because the state and federal water contractors refuse to pay for new state-of-the-art fish screens is an unreasonable method of diversion. This is especially true when water diverted through those facilities deprives listed species of water and primary production necessary for survival. The SWRCB can and must curtail south Delta exports during the drought emergency until D-1641 water quality standards are met.

The SWRCB must also consider public trust issues in proceedings that concern water rights and water quality based on reserved jurisdiction or under the doctrine of reasonable use. The SWRCB may also modify permits of "the projects" that require the appropriator to reduce the quantity of exports. *United States v. SWRCB* (1986) 182 Cal.App. 3d 82, 124-131. The SWRCB has a complaint procedure that can exercise authority over both federal and state water projects by virtue of having state water rights permits issued by the Board.

The State's management responsibilities include broad discretion to promote trust uses, such as the continued survival of the Bay/Delta estuary and dependent endangered species, provided the discretion is exercised consistent with constitutional and statutory constraints. *People v. California Fish Co.* (1913) 166 Cal. 576, 597. While the State has discretion to promote trust issues, the SWRCB has "an affirmative duty" to protect trust resources. See *Illinois Central Railroad v. Illinois,* 146 U.S. 387; and *National Audubon Society v. Superior Court* (1983) 33 Cal.3d 419 (The state may not abdicate its supervisory role any more than the state may abdicate its police power); see also Stevens, The Public Trust: *A Sovereign's Ancient Prerogative Becomes the People's Environmental Right*, 14 U.C. Davis Law Review 195, 223.

Fish and wildlife are natural resources unequivocally protected by state sovereignty, whereby ownership of the resource is reserved to the states. *Geer v. Connecticut*, (1896) 161 U.S. 519.

The court in *Audubon v. Superior Court*, (1983) 33 Cal.3d. 419 held that "no one may obtain a vested right to undertake an act that is harmful to the trust." See also *SWRCB D-1644* (Yuba River) at page 29. The supremacy of the public trust over private individuals is reflected in a "judicial presumption against state or legislative alienation of trust resources." *People v. California Fish*; see also *Illinois Central v. Illinois* (1892) 146 U.S. 387; *Montana v. U.S.*, (1981) 450 U.S.544. Historically, state sovereign ownership was limited to "the traditional triad of uses" – commerce, navigation, and fishing.

However, in 1971 the California Supreme Court expanded the protected uses to cover the environment generally. *Marks v. Whitney* (1971) 6 Cal 3d. 251, 259-260. State sovereign ownership imposes restraints on the state's discretion regarding the use of navigable waters. The use of trust resources must be consistent with the general trust purposes or it is invalid. *State of California v. Superior Court* (Lyon) (1981) 29 Cal 3d. 210, 220-230; *Marks v. Whitney*, supra; *City of Long Beach v. Mansell*, (1970) 3 Cal 3d. 462, 482-485. Preservation of a public trust resource such as the San Francisco Bay/Delta estuary is a legitimate disposition of the public trust resource, and is consistent with general trust purposes. Thus, tidelands and water may be burdened with a negative easement against any active use or disposition of the trust reserve. Id; *National Audubon*, supra; *State of California v. Superior Court* (Fogerty), (1981) 29 Cal 3d. 240, 249-250.

Consequently, the SWRCB has both the authority and responsibility under its reserved jurisdiction in the permits and licenses of the USBR and DWR, and under its continuing authority and responsibilities pursuant to the public trust and reasonableness doctrine to protect fisheries, public trust resources and beneficial uses. To protect those resources and uses, it established minimum water quality objectives and requirements for critical dry years in the Bay-Delta Plan and D-1641.

USBR and DWR's pattern and practice of delivering near normal water supplies in the early years of drought, depleting carryover storage and then relying on the SWRCB to weaken water quality standards established to protect public trust resources as successive dry years occur has been amply documented in multiple documents and TUCP proceedings over the last several years. The SWRCB has failed to establish minimum reservoir storage levels that ensure compliance with water quality standards protective of public trust resources. When successive dry years occur, it then routinely weakens those standards, with little regard to its public trust and constitutional obligations.

To weaken those water quality objectives and requirements simply because USBR and DWR recklessly delivered water that was otherwise necessary to maintain sufficient carryover storage to comply with water quality objectives and to protect public trust resources and agricultural beneficial uses in the Delta is a violation of Public Trust Doctrine and the California Constitution. To send fisheries into extinction while continuing to supply water for low value crops like pasture and alfalfa is an unreasonable use of water.

It is not the SWRCB's responsibility or legal right to sacrifice public trust resources and Delta beneficial uses in order to absolve USBR and DWR of the consequences of their egregious mismanagement. If customers of water contractors are now suffering because USBR and DWR failed to exercise prudence and due diligence in water management and rashly delivered near normal water supplies in initial drought years with little thought that another dry year might occur, it is USBR and DWR and not the SWRCB that have the responsibility to alleviate the suffering they caused.

The SWRCB has failed to balance the public trust. The California Legislature, in the Sacramento-San Joaquin Delta Reform Act of 2009, mandated the SWRCB to develop new flow criteria for the Delta ecosystem that are necessary to protect public trust resources. Following an extensive public proceeding, the SWRCB prepared a report titled "*Development of Flow Criteria for the Sacramento-San Joaquin Delta Ecosystem.*" The SWRCB's 2010 Report stated: "Recent Delta flows are insufficient to support native Delta fishes for today's habitats" and recommended 75% of unimpaired Delta outflow from January through June, 75% of unimpaired Sacramento River inflow from November through June and 60% of unimpaired San Joaquin River inflow from February through June as necessary to protect public trust resources. While the flow report did not balance the public trust against other beneficial uses or consider economics, it did conclusively establish that present flows are seriously insufficient to protect public trust resources.

The Legislature also mandated the California Department of Fish and Wildlife (DFW) to develop *Quantifiable Biological Objectives and Flow Criteria for Aquatic and Terrestrial Species of Concern Dependent on the Delta.* Following an extensive public proceedings throughout 2010, the DFW's report mirrored the conclusions and recommendations contained in the SWRCB flow report.

Five years after those reports were issued, the SWRCB has not begun to balance the public trust. It has, however, significantly weakened water quality standards and Delta flows. Fisheries have continued to decline and we are now faced with the imminent likelihood that one or more native species will become extinct.

An example of the SWRCB's egregious failure to even attempt to balance the public trust is demonstrated in the paucity of flows allocated to protect water quality and fisheries in July 2015. Releases from upstream-of-Delta rim reservoirs (Keswick, Whiskey Town, Oroville, Bullards Bar, Folsom, Camanche, New Hogan, New Melones, Don Pedro, New Exchequer and Friant) averaged 22,039 cfs or 43,703 AF daily 1 July through 19 July. Delta outflow for the same period averaged 2,990 cfs or 5,928 AF, most of which was necessary to allow operation of the state and federal project export pumps. In other words, under the most favorable light, only 13.6% of reservoir releases were allocated to protect fish and wildlife and Delta agricultural beneficial uses. The situation is even more bizarre on the San Joaquin River. Between 1 and 19 July, only 2.9% of flows released from New Melones, Don Pedro, New Exchequer and Friant reached the Delta. Whatever represents a reasonable public trust balancing, it is not 2.9% or 13.6% of flow, as water quality standards are violated and listed fish species plunge toward extinction.

Another example of the disregard for the public trust was provided in SWRCB staff's presentation on Sacramento-San Joaquin Watershed Use at the SWRCB 20 May 2015 Workshop on the TUCP, Emergency Drought Barrier, and Water Right Curtailments. Staff revealed that the 2015 TUCP Orders had reduced regulatory outflow by 78% to allow export pumping to increase by 46%. Increasing water exports is apparently a higher priority to the SWRCB than protecting water quality, critical habitat for listed species and public trust resources.

Violations Are Likely to Cause or Contribute to Extinction of Species

Since DWR's State Water Project began exporting water from the Delta, the DFW Fall Midwater Trawl indices for striped bass, Delta smelt, longfin smelt, American shad, splittail and threadfin shad have declined by 99.7, 97.8, 99.9, 91.9, 98.5 and 97.8 percent, respectively. The U.S. Fish & Wildlife Service's (USFWS) Anadromous Fisheries Restoration Program (AFRP) documents that, since 1967, in-river natural production of Sacramento winter-run Chinook salmon and spring-run Chinook salmon have decline by 98.2 and 99.3 percent, respectively, and are only at 5.5 and 1.2 percent, respectively, of doubling levels mandated by the Central Valley Project Improvement Act, California Water Code and California Fish & Game Code. Numerous species have been listed pursuant to state and federal endangered species acts.[1]

Populations of Bay-Delta fisheries plummeted during the 1987-1992 period and have never recovered from the impacts resulting from the serial violations of water quality objectives. Winter-run Chinook salmon were listed as threatened under the federal ESA emergency interim rule and endangered under the California Endangered Species Act (CESA) in 1989. Delta smelt were listed as threatened under both state and federal endangered species in 1993. Many of the noxious invasive species that have been identified as adversely impacting native fisheries became established and/or entrenched during that period.

The estuary's pelagic and anadromous fisheries have continued to decline since the 1987-1992 period. And now, the further weakening of water quality standards in 2013-2015 threatens to catapult several species into extinction.

For example, the 2014 Fall Midwater Trawl, 2015 Spring Kodiak Trawl and Summer Townet Delta smelt indices were the lowest in history. The Summer Townet index for Delta smelt was 0.0. Trawl #8 of the 20-mm Survey, conducted in late June, found only a single Delta smelt in Sacramento River at Threemile Slough, no longfin smelt and few striped bass. Compared to 2012, the 2015 trawl #8 of the 20-mm Survey catch-per-unit-effort of Delta smelt, striped bass and longfin smelt were down 98.9, 98.0 and 100 percent, respectively. Perhaps most alarmingly, the Survey identified no Delta smelt in Cache Slough and the Sacramento Deep-Water Ship

---

[1] Southern DPS green sturgeon (*Acipenser medirostris*), federal threatened, candidate for federal endangered; Delta smelt (*Hypomesus transpacificus*), state endangered, federal threatened, Longfin smelt (*Spirinchus thaleichthys*), state threatened; Central Valley steelhead (Oncorhynchus mykiss), federal threatened; Sacramento winter-run Chinook salmon (Oncorhynchus tshawytscha), state endangered, federal endangered; Central Valley spring-run Chinook salmon (Oncorhynchus tshawytscha), state threatened, federal threatened; Central Valley fall/late-fall-run Chinook salmon (*Oncorhynchus tshawytscha*), federal species of concern, state species of special concern; Sacramento splittail (*Pogonichthys macrolepedotus*), state species of special concern; Pacific lamprey (*Entosphenus tridentate*), federal species of concern and river lamprey (*Lampetra ayresi*), state species of special concern. The state and federal Project also have the potential to adversely affect Killer whales or Orcas (Southern Resident DPS) (*Orcinus orca*), federally listed as endangered because they are dependent upon Chinook salmon for 70% of diet and reduced quantity and quality of diet is one of the major identified causes of their decline.

Channel and trawl #9 found only one. The northern population of Delta smelt seems to have, as expected, succumbed to excessive temperature.

Delta smelt are at extreme risk of imminent extinction. There are multiple threats to the Delta Smelt population that contribute to its vulnerability and risk of extinction. Chief among these threats are reductions in freshwater inflow to the estuary; loss of larval, juvenile and adult fish at the state and federal Delta export facilities and urban and agricultural water diversions; direct and indirect impacts of the Delta Smelt's planktonic food supply and habitat; and lethal and sub-lethal effects of warm water and toxic chemicals in Delta open-water habitats.

Weakened water quality objectives and failure to enforce objectives have significantly reduced Delta outflow, increased Delta salinity and moved the Low Salinity Zone further upstream (eastward) into the Delta, thereby increasing the degree of each of these threats. Presently, remnants of the population are confined to a small area of the Low Salinity Zone where water temperatures have been significantly above levels identified in the literature as highly stressful and barely below the lethal endpoint.

The continued violations of Bay-Delta Plan and D-1641 objectives and requirements are an obvious and direct threat to the remnants of Delta smelt living in the Low Salinity Zone. Allowing these "weakened standards" to be violated is a direct disregard for the remaining population, placing them under extraordinary risk by bringing them further into the zone of water diversions, degrading their habitat into the lethal range of water temperature, further degrading their already depleted food supply, and increasing the concentrations of toxic chemicals being discharged into the Delta.

The various Biological Reviews, agency concurrence letters and the SWRCB's TUCP Orders acknowledge the manifold threats to Delta smelt and other estuarine species but dismiss them and disregard the consequences of further weakening of already inadequate standards.

USBR's March Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September, submitted to the SWRCB and fish agencies, acknowledged that the Delta smelt population had plunged to an all time low. It observed that drought impacts Delta smelt by reducing the area of low salinity habitat and food availability, impacting reproductive potential impairing fecundity, and reducing turbidity, thereby limiting predator avoidance. It pointed out that warm, slow-moving water promotes conditions in which parasites and toxic *Microcystis* blooms thrive, and that non-native Delta smelt predators, like black bass, and food competitors, like *Corbicula*, have increased during the present drought. It admitted that Delta smelt have a strong positive association with the position of X2 and that under the TUCP Delta smelt would not be in areas optimal for growth and survival because X2 would move further upstream.

With respect to longfin smelt, the USBR biological review observed that the TUCP will reduce outflow and that increased outflow is one of the best predictors of longfin smelt year class strength. Consequently, it is likely that the TUCP will exacerbate poor longfin smelt recruitment and survival and that longfin smelt larvae will have an increased risk of entrainment into the south Delta where they are not expected to survive warming water temperatures.

Despite knowing that smelt were already at historically low abundances, that the drought had increased already deleterious conditions, and that further reductions in outflow would exacerbate impacts, the USBR and DWR proposed the TUCP on 24 March 2015 and requested agency concurrence. Incredibly and inexplicably, the USFWS and CDFW, acutely aware that subsequent fish surveys had revealed a catastrophic collapse in population abundance and knowing that the Biological Opinions assumed compliance with D-1641 criteria and that there were significant "uncertainties" in the conclusions of the Biological Review, issued brief, cursory three-page concurrence letters three days latter, on 27 March, that claimed that reducing Delta outflow by 25 to 40% below D-1641 critical dry year criteria would not jeopardize the continued existence of smelt.

Of course, senior agency supervisors made these decisions. And we know, from private discussions with fishery agency staff, that the senior agency supervisors, many of whom participate in the secret weekly meetings of the Real-Time Drought Operations Management Team (RTDOT), ignored and rejected the recommendations and pleas from biological and technical staff that the TUCPs posed a threat to the continued existence of these species. Over the last several years, we have consistently told the SWRCB what would occur should they approve the various TUCPs. Sadly, the results from subsequent fish surveys and trawls establish that we were right and the SWRCB, USBR, DWR and fishery agencies were wrong!

The SWRCB was acutely aware of the adverse consequences of approving the recent TUCP. The 3 July 2015 TUCP Order acknowledges on pages 12 and 13:

> "The extreme drought conditions that have been occurring for the last four years are having significant impacts on fish and wildlife," Delta smelt indices "…*are at record low numbers*," "*Delta smelt have a strong positive relationship with a specific location in the low salinity zone (LSZ) referred to as X2*…" and "*...habitat quality and quantity diminish the more frequently and further the LSZ movers upstream*…" It points out that "…*there are likely to be few adult Delta smelt that live through the summer*…" and "…it *appears fish density has become so low that the SKT (Spring Kodiak Trawl) has reached or gone below its minimum effective detection ability*," and that in supplemental USFWS in sampling in the lower San Joaquin River "catch of *adult Delta smelt declined precipitously to zero in the final month of sampling*." Emphasis added.

The 3 July 2015 TUCP Order, discussing the biological reviews, observes on page 14:

> The proposed TUCP changes will have effects on physical habitat and water quality which may affect Delta smelt. The changes *will add to the already unfavorable conditions* related to the dry conditions. The Biological Review finds that reductions in inflows and outflows associated with the changes to Delta outflow, Western Delta agricultural salinity and Sacramento River flows may *reduce the general quality of habitat conditions throughout the Delta*. Further, survival of Delta smelt that are currently in the interior and North Delta may be *reduced through increased exposure to degraded habitat and predators and increased travel time for migrating fish*. In the lower San Joaquin River, the upstream relocation of X2 may result in a greater proportion of the

> available habitat encompassing areas of high semi-aquatic vegetation and associated low turbidities. This could result in lower prey availability and higher predation rates on juvenile Delta smelt. Further constraining Delta Smelt closer to the upstream spawning areas in the lower Sacramento River, San Joaquin River, and the Cache Slough Complex/SDWSC *will increase Delta smelt exposure to less favorable conditions.* Conditions in these regions are generally warmer in the summer than locations further west due to prolonged heat waves and less marine influence. Juvenile Delta smelt may be able to reside in thermal refugia to reduce these effects, but *it is not clear how long that cool water refugia will be available this summer*. In addition, due to the more upstream location of X2, it is also likely that summer *Delta smelt distributions will not be in areas for optimal growth and survival* further west in Suisun Bay. Reduced inflows and outflows may also *affect Delta smelt's ability to move downstream to cooler habitats* with more food resources. These effects could *pose additional risks to the persistence of local populations.* Emphasis added.

With respect to estuarine habitat and species, the 3 July 2015 TUCP Order on page 15 observed:

> The Biological Review focused on species listed under ESA and CESA, but the proposed action is *also likely to have adverse effects on other beneficial uses protected under D-1641*," "Since most of these species are not afforded the protections of ESA and CESA, *many have undergone population declines over the history of water development in the Bay-Delta*" and "*...decreasing Delta out flow constrains habitat by moving X2 and the LSZ inland* from the shallow, more favorable habitats of Suisun Bay to the deeper, channelized, and less hospitable habitats of the lower Sacramento and San Joaquin Rivers and their confluence. This reduction in habitat quantity and quality *will also likely result in lower survival and recruitment of several other estuarine dependent species*. Emphasis added.

Despite the serious risks of extinction of Delta smelt and other estuarine species, the SWRCB issued the TUCP Order on 3 July 2015. Apparently, the determination to deliver large quantities of water to Sacramento Settlement Contractors similar to the quantities they received over the last several years outweighs the potential extinction of species. In other words, the irrigation of vast tracts of pasture, alfalfa and other low value crops in the Sacramento Valley is more important than the continued existence of species that evolved and prospered over millennia.

Violations of the Federal Clean Water Act

The Code of Federal Regulations, at 40 CFR §131.20 states that the "State shall from time to time, but at least once every three years, hold public hearings for the purpose of reviewing applicable water quality standards and, as appropriate, modifying and adopting standards." The State is required to submit the results of the review to USEPA for review and approval.

Over the last 20 years since adoption of the present standards in 1995, the SWRCB has reviewed the water quality standards pertaining to the Delta only once, in 2006. In the 2006 review, no changes were made in the 1995 standards despite the continued decline of the estuary's pelagic and anadromous fisheries. The present proceeding to review Bay-Delta standards is years away from completion. The SWRCB is in violation of the federal CWA.

Following disapproval of the results from the state's 1991 proceeding to revise the 1978 Water Quality Control Plan, USEPA promulgated specific water quality standards for the Delta. The federal standards are significantly more protective of the ecosystem than present state standards. Even though the SWRCB subsequently issued its present standards in late 1995, the federal standards remain at 40 CFR §131.37. The SWRCB has refused to acknowledge or comply with the federal standards. Consequently, the SWRCB is in violation of the federal CWA.

The SWRCB has failed to comply with state and federal antidegradation requirements in lowering water quality. At a minimum, antidegradation requirements require that water quality standards must protect "fishable" beneficial uses. The SWRCB has undertaken no analysis of the impacts to beneficial uses and the trade-offs or costs between a temporary loss of water to state and federal water contractors to irrigate low value crops like pasture and alfalfa and the decline of fisheries and likely extinction of species. Nor is there any analysis of the relative benefits of weakening water quality standards in order to provide water to state and federal water contractors at the cost of depriving Delta farmers of water and water quality.

USBR and DWR's pattern and practice of delivering near normal water supplies in the early years of drought, depleting carryover storage and then relying on the SWRCB to weaken water quality standards as successive dry years occur has been amply documented in multiple documents and TUCP proceedings over the last several years. The SWRCB has failed to establish minimum reservoir storage levels that ensure compliance with water quality standards in the event of successive dry years and then routinely weakens those standards when droughts occur.

The numerous violations of water quality criteria enumerated above, the serial weakening of water quality criteria and implementation requirements, the refusal to enforce violations of water quality criteria, the failure to timely review water quality criteria and the approval of the pattern and practice of creating conditions that prevent water quality criteria from being met in sequential dry years constitute violations of the CWA. Consequently, the SWRCB, USBR and DWR have violated the CWA.

Violations of the Endangered Species Act

In enacting ESA, Congress stated that the purpose of the ESA is "to provide a means whereby the ecosystems upon which endangered species and threatened species depend may be conserved." 16 U.S.C. § 1531(b). As part of conserving endangered or threatened species, ESA prohibits the "taking" of any such listed species. 16 U.S.C. § 1538(a)(1)(B). A "take" is defined as "to harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, or collect, or to attempt to engage in any such conduct." 16 U.S.C. § 1532(9). To "harm" a listed species in the context of a "take" includes "[any] act which actually kills or injures wildlife. Such act may include significant habitat modification or degradation where it actually kills or injures wildlife by significantly impairing essential behavioral patterns, including breeding, feeding, or sheltering." 50 C.F.R. § 17.3 (1994). An indirect injury to a listed species through habitat modification also constitutes a “take.” *Babbitt v. Sweet Home Chapter of Communities for A Great Oregon*, 515 U.S. 687 (1995). The 9th Circuit Court of Appeals ruled that “under Sweet Home, a habitat modification which significantly impairs the breeding and sheltering of a protected species amounts to ‘harm’ under the ESA.” *Marbled Murrelet v Pacific Lumber Company*, 83 F.3d 1060 (9th Cir. 1996).

USBR and DWR have operated to a pattern and practice of delivering near normal water supplies in the early years of drought, depleting carryover storage and then relying on the SWRCB to weaken water quality standards. The SWRCB has operated to a pattern and practice of weakening water quality standards and thereby significantly degrading the habitat and impairing essential behavioral patterns, breeding, feeding, or sheltering of listed species. The SWRCB, USBR and DWR are in violation of the ESA.

Delta smelt and other estuarine species’ abundances have plummeted over the last few years to the point where they are facing the likelihood of imminent extinction. Over this period, the SWRCB has acceded to multiple requests by USBR and DWR to weaken basic minimum standards adopted to protect listed species and their habitats. These serial actions by the SWRCB have seriously modified and degraded the habitat and impaired the breeding and sheltering of listed species to the point of impending extinction.

The fact that USFWS, NMFS and CDFW have routinely issued concurrence letters in response to the TUCPs, frequently within hours or several days of receiving Reinitiation of Consultation requests, cannot be a valid excuse or defense. Since initial listings under EWA or CESA, abundances of listed species have continued to plummet. USFWS, NMFS and CDFW have essentially defined themselves as “capture agencies” and chaperoned listed species on their road to extinction.

Notwithstanding the letters of concurrence from USFWS, NMFS and CDFW that claim these actions are consistent with existing Biological Opinions, nothing in the ESA legally allows or justifies the SWRCB, USBR or DWR to further degrade the habitats of species lingering on the precipice of extinction. Collectively, the excuses, justifications and serial weakening of water quality criteria emanating from the secret RTDOT meetings while the fishery agencies remain embraced in denial as fisheries plummet toward extinction, surely constitute one of the saddest and most wretched spectacles we’ve ever witnessed and could be easily construed as an illegal conspiracy to defraud the public of public trust resources to the benefit of special interests.

A Final Thought

It is not simply water quality, fisheries and public trust resources that have been sent to the scaffold: it is also the public’s security. With the exception of Shasta, water storage in all of the rim reservoirs is significantly below this time last year. Several are already below 1976-1977 levels and others are headed toward historic lows. As of 20 July, storage in the rim reservoirs totaled 5,632,522 AF and was being depleted by 43,703 AF daily or 1,354,796 AF monthly.

Historically, El Nino years have had an equal chance of being dry or wet. Should California experience another dry year, the impacts will be far greater than those endured this year. The

SWRCB's failure to establish minimum reservoir storage levels and its inability to protect the public and public trust resources by saying no to special interests in sequential dry years has placed the state in grave jeopardy. California deserves better.

In Conclusion

We request that the SWRCB immediately use its public trust, constitutional and water rights authorities to require USBR and DWR to comply with D-1641 critically dry year water quality objectives, reduce water deliveries to low value crops in order to meet Bay-Delta objectives and to ensure sufficient reservoir storage to comply with temperature and other water quality objectives, and issue sanctions against USBR and DWR for their willful disregard for public trust resources and Delta beneficial uses. We also request that the SWRCB accelerate the present review of Bay-Delta standards, including a comprehensive balancing of the public trust with competing uses, and provide us a response to our 13 August 2014 complaint regarding illegal diversion by DWR and USBR and petition to adjudicate Central Valley waters.

Thank you for considering these comments and responding to this complaint. If you have questions or require clarification, please don't hesitate to contact us.

Sincerely,

Bill Jennings

RE: COMPLAINT: Against SWRCB and USBR for Violations of Central Valley Basin Plan, WR Order 90-05, Clean Water Act, Endangered Species Act, Public Trust Doctrine and California Constitution

Dear Mr. Howard and Ms. Evoy:

The California Sportfishing Protection Alliance (CSPA) hereby submits a complaint against the State Water Resources Control Board (SWRCB) and United States Bureau of Reclamation (USBR) for violations of the Water Quality Control Plan for the Sacramento River and San Joaquin River Basins (Basin Plan), violations of WR Order 90-05 and Sacramento River temperature requirements and for violations of the Clean Water Act (CWA), Endangered Species Act (ESA), Public Trust Doctrine and the California Constitution.

Specifically, CSPA alleges that the SWRCB has failed to implement crucial Basin Plan water temperature criteria and CWA requirements protecting water quality and fish and wildlife beneficial uses with respect to USBR’s water rights permits and licenses and has failed to take enforcement actions against USBR’s habitual violations of the Basin Plan, CWA and WR Order 90-05 temperature criteria and requirements. CSPA alleges that USBR has failed to comply with explicit temperature criteria protecting fish and wildlife beneficial uses contained in the Basin Plan, CWA and WR Order 90-05. CSPA additionally alleges that the SWRCB and USBR have failed to comply with their respective responsibilities and obligations under the ESA, Public Trust Doctrine and Article X of the California Constitution.

CSPA incorporates by reference the comments, protests, objections (including exhibits) and workshop presentations submitted and presented over the last two years in the SWRCB drought proceedings related to Temporary Urgency Change Petitions (TUCP) and SWRCB TUCP Orders by CSPA et al., Bay Institute, Sequoia Forestkeeper and Restore the Delta. Those documents can be found on the SWRCB’s State Water Project and Central Valley Project Temporary

Urgency Change Petition webpage under the headings *Comments/Objections/Protests/Petitions for Reconsideration* and *Temporary Urgency Change Petitions and Drought Workshops.*

We file this complaint in the wake of poor natural production of the 2013 brood year of Sacramento River winter-run, spring-run and fall-run Chinook salmon and the destruction of the 2014 year classes. Given the presence of lethal temperatures in the Sacramento River this year that threaten a repeat of last year's disaster, CSPA asks the SWRCB to act expeditiously in responding and in requiring USBR to respond to the allegations herein. CSPA requests that the SWRCB immediately re-establish protective, non-lethal temperature criteria at the Clear Creek compliance point and that the SWRCB require USBR to reduce water deliveries in order to preserve what's left of cold water reserves in Shasta Reservoir. CSPA further requests the SWRCB to issue sanctions against USBR for failure to comply with the Basin Plan, CWA and ESA.

WR Order 90-05 and the initial listing of winter-run Chinook salmon came on the heels of myriad exceedances of temperature criteria and alarming salmon population declines following the drought of 1976-1977 and the initial years of the 1987-1992 drought. Subsequent droughts brought similar population declines followed by only partial rebounds in wetter years that show a parallel long-term decline in anadromous fisheries. Failure to adopt and enforce defensible temperature criteria has been a key factor in the continued decline of Sacramento Chinook salmon to the point where winter-run and spring-run are now threatened with extinction and California's commercial salmon fishery is wholly dependent on grow-and-truck hatchery production for survival.

As discussed more fully below, the Central Valley Regional Water Quality Control Board (Regional Board) established temperature criteria in the Sacramento River, pursuant to the CWA and the SWRCB implemented the temperature criteria in USBR's permits and licenses in WR Order 90-05. In doing so, the SWRCB implemented temperature criteria based on average daily temperatures without determining whether average daily temperatures were protective of aquatic life and, additionally, exempted almost 43% of identified fish spawning habitat from temperature requirements. The SWRCB then ignored the Basin Plan's Controllable Factors Policy and it's own admonition to USBR that water necessary to meet water quality criteria was not available for delivery. When the National Marine Fisheries Service (NMFS) listed winter-run Chinook salmon as threatened under the ESA, the SWRCB ignored the presence of other species and relocated the temperature compliance point further upstream.

Over the next 23 years, the SWRCB participated in back-room temperature management group meetings that recommended ever-changing temperature compliance points, based upon the quantities of water USBR had remaining in storage after deliveries to its water contractors. The SWRCB subsequently approved the recommendations of the temperature management group of which it is a participating member. These approvals generally relocated temperature compliance points further and further upstream, often eliminating as much as 90% or more of spawning habitat protected by the Basin Plan. And despite these yearly concessions, USBR has violated temperature criteria in nearly every year without a single enforcement sanction being issued by the SWRCB.

The SWRCB has ignored USBR's failure to comply with the National Marine Fisheries Service's (NMFS) OCAP Biological Opinion's (BO) Reasonable and Prudent Action (RPA) performance measures regarding end of September carryover storage at Shasta Reservoir and the percentages-of-time USBR is required to meet temperature criteria at specific compliance points. It has sidestepped the BO's RPA drought exception procedures when end of September Shasta storage is projected to be less that 1.9 million acre-feet (MAF). It refuses to address the conflict that exists under these conditions, between USBR delivering "nondiscretionary" water to Sacramento Settlement Contractors and achieving compliance with temperature objectives, despite the fact that the BO observes that these poor conditions "… could be catastrophic to the species, potentially leading to a significant reduction in the viability of winter-run."

The SWRCB is aware that USBR lacks the legal authority to curtail "nondiscretionary" contract water deliveries to Sacramento Settlement Contractors to meet ESA requirements. Despite being notified of a likely conflict between the delivery of this "nondiscretionary" water and compliance with temperature requirements, the SWRCB refused to use its authorities to reduce water deliveries in order to retain sufficient cold water storage necessary to meet temperature criteria. The BO does not address ESA section 7(a)(2) compliance for individual water supply contracts and, consequently, delivery of water that is "nondiscretionary" for the purposes of the ESA is not exempt from ESA section 9 take prohibitions. In effect, the SWRCB has sanctioned the illegal "take" of endangered species by the USBR and Sacramento Settlement Contractors.

USBR's delivery of 1.3 MAF of water to Sacramento River contractors in 2014 depleted limited cold water reserves in Shasta Reservoir leading to significant exceedances of water temperature criterion. The 2014 year classes of Sacramento winter-run, spring-run and fall-run Chinook salmon were virtually destroyed. Although the SWRCB acknowledged that it had made a serious mistake last year, it has inexplicably elected to repeat the mistake in 2015.

Rejecting the politically unpalatable option of reducing water deliveries to Sacramento Settlement Contractors to ensure compliance with temperature criteria, the SWRCB has instead approved USBR's request to increase the temperature compliance target from a daily average of 56ºF to 58ºF. This despite the fact that the NMFS pointed out in April that an increase to 58ºF would result in adverse impacts to incubating winter-run eggs and alevin in redds and that 58ºF was identified in the scientific literature as lethal to incubating salmon eggs and emerging fry. The subsequent concurrence by NMFS because "the plan provides a ***reasonable possibility*** that there will be ***some juvenile winter-run survival*** this year" is an unacceptable and illegal standard of compliance with the BO and ESA. [Emphasis added.]

The SWRCB justified the higher temperature criterion as necessary to preserve cold water in Shasta to avoid depletion of the cold water pool and more devastating impacts later in the year. However, the urgent need to preserve cold water was apparently unimportant to the SWRCB as USBR delivered 366,794 acre-feet (AF) of water in April and May to Sacramento River water contractors while exporting another 312,686 AF in the first five months of the year. Depletions (i.e., water deliveries) between Bend Bridge and Wilkins Slough in June and July of this year totaled another 500,771 AF.

CSPA et al. and others pleaded with the SWRCB to reduce these water deliveries in order to protect cold water storage. The NMFS summed up the situation in their 1 July 2015 concurrence letter regarding USBR's temperature management request in observing, "We note that these conditions could have been largely prevented through upgrades in monitoring and modeling, and reduced Keswick releases in April and May." Daily average June/July temperatures in the Sacramento River at the Clear Creek compliance point have been significantly higher this year than they were last year.

As we show below, a 56ºF daily average temperature criterion is not protective of Chinook salmon spawning, egg incubation and fry emergence. The U.S. Environmental Protection Agency (USEPA), the states of Washington, Oregon and Idaho, both North Coast and Central Valley Regional Boards, NMFS, California Department of Fish and Wildlife (CDFW), the Pacific Fishery Management Council and the majority of the scientific literature have either adopted or recommended more restrictive temperature criteria based upon a daily maximum and/or a seven-day mean of daily maximums.

In sum, the SWRCB essentially bases its implementation of temperature criteria for Sacramento River Chinook salmon on the amount of water USBR has left over after supplying its contractors. Notwithstanding the law and the fact that protection, restoration and enhancement of fish and wildlife is a coequal purpose of the Central Valley Project (CVP), water deliveries always come first regardless of water year type.

Should winter-run Chinook salmon, Delta and longfin smelt and potentially several other species that have evolved and thrived over millennia go extinct, it will not be because of drought. It will be because the SWRCB has refused to comply with its responsibilities under the Water Code, CWA, ESA, Public Trust Doctrine and California Constitution.

Sacramento River Salmon Fisheries are in a State of Collapse

The precipitous collapse of the Central Valley's pelagic and anadromous fish populations in recent decades has been extensively documented in our referenced documents and need not be repeated at length here. Numerous species dependent on the Sacramento River for all or part of their life cycle have been listed pursuant to state and federal endangered species acts.[1]

Since 1967-68, the U.S. Fish & Wildlife Service's (USFWS) Anadromous Fisheries Restoration Program (AFRP) documents that, since 1967, in-river natural production of Sacramento River

---

[1] Southern DPS green sturgeon (*Acipenser medirostris*), federal threatened, candidate for federal endangered; Delta smelt (*Hypomesus transpacificus*), state endangered, federal threatened, Longfin smelt (*Spirinchus thaleichthys*), state threatened; Central Valley steelhead (Oncorhynchus mykiss), federal threatened; Sacramento winter-run Chinook salmon (Oncorhynchus tshawytscha), state endangered, federal endangered; Central Valley spring-run Chinook salmon (Oncorhynchus tshawytscha), state threatened, federal threatened; Central Valley fall/late-fall-run Chinook salmon (*Oncorhynchus tshawytscha*), federal species of concern, state species of special concern; Sacramento splittail (*Pogonichthys macrolepedotus*), state species of special concern; Pacific lamprey (*Entosphenus tridentate*), federal species of concern and river lamprey (*Lampetra ayresi*), state species of special concern. The Project also has potential to adversely affect Killer whales or Orcas (Southern Resident DPS) (*Orcinus orca*), federal listed as endangered because they are dependent upon Chinook salmon for 70% of diet and reduced quantity and quality of diet is one of the major identified causes of their decline.

winter-run, spring-run and fall-run Chinook salmon have decline by 98.2, 99.3 and 91.2 percent, respectively, and are only at 5.5, 1.2 and 31.6 percent, respectively, of doubling levels mandated by the Central Valley Project Improvement Act, California Water Code and California Fish & Game Code.

The construction of Shasta Dam eliminated the ability of Sacramento River winter-run, spring-run and late-fall-run Chinook salmon to reach the cold spring-fed headwaters of the Upper Sacramento, Pit, McCloud and Fall Rivers to spawn.[2] Before the Dam was constructed, there were an estimated 34,634 spawning sites for winter-run salmon available in the Upper Sacramento, McCloud, and Pit River systems. With the exception of Battle Creek, 100% of the winter-run salmon spawned upriver from the present site of Shasta Dam.[3] Pre-Shasta populations of spring-run salmon once had at least 51,377 spawning sites dispersed throughout the Upper Sacramento, the McCloud, and Pit Rivers (PG&E’s Pit River dams eliminated an additional 7,444 upriver spawning sites without mitigation). Only about 15% of the fall-run salmon generally spawned above the present site of Shasta Dam. Most fall-run spawned within the lower river and its foothill reaches at elevations less than 500 feet. The construction of Shasta Dam eliminated approximately 201 miles of historically available habitat in the Pit, McCloud and Upper (little) Sacramento Rivers.[4]

Shasta/Keswick dams not only eliminated the vast majority of spawning habitat for winter-run, spring-run and late-fall-run Chinook salmon, they eliminated the quality of drought-proof habitat. The remaining habitat is subject to droughts and USBR’s failure to retain sufficient reservoir storage in sequential low water years to meet temperature requirements. Additionally, the remaining spawning habitat is crammed into the 59 miles between Keswick and Red Bluff Diversion Dam (far less in most years) and does not provide necessary spatial separation between overlapping stocks, which leads to superimposition of redds. Under these degraded conditions, it is imperative that every effort be extended to ensure that the quality of remaining spawning habitat is protected. This means complying with temperature objectives for sensitive life stages during critical drought years.

Following the construction of Shasta Dam, significant numbers of winter-run Chinook salmon spawned below Red Bluff. Between 1987 and 1992, 19% of winter-run salmon spawned in the Sacramento River below Red Bluff as far down as Hamilton City. After construction of Red Bluff Diversion Dam in 1964, it was noted that 60% of fall-run Chinook salmon spawned below the Dam.[5] A 1988 DWR report titled *Water Temperature Effects on Chinook Salmon (Oncorhynchus tshawytscha), With Emphasis on the Sacramento River, A Literature Review*

reported: “By 1976 spawning activity was nearly uniform in the reaches from Balls Ferry to Keswick, Red Bluff to Balls Ferry, and Hamilton City to Red Bluff. More recent data show that the reach from Hamilton City to Red Bluff receives more spawning activity than do both upper reaches combined.”[6]

SWRCB Order 90-05 limited temperature protection to Red Bluff, excluding 44 river miles and more than half of the then-extant Chinook spawning habitat from temperature protection. This had the effect of shifting spawning upriver. USBR’s failure to provide adequate temperature control on the Sacramento River has pushed spawning ever further upstream. Between 2001 and 2005, only about 1% of winter-run salmon spawned below Red Bluff.[7]

The CDFW annually surveys the Sacramento River to estimate numbers of Chinook salmon that return and spawn. The results are published in annual reports titled *Chinook Salmon Populations for the Upper Sacramento River Basin* and include the results of aerial surveys of spawning redds. CDFW staff recommends using aerial redd data only for comparisons of redd distributions by river sections or for specific needs such as use of a specific area as a spawning location. Aerial redd surveys do not provide complete counts of new redds, but it is assumed that the proportion of redds visible in the various sections during a single flight are identical.

These reports establish that significant Chinook salmon spawning occurs below Red Bluff and, consequently, the Basin Plan’s temperature criteria for the reach between Red Bluff and Hamilton City are both justified and necessary. They also illustrate the compression of salmon spawning that has occurred in the extreme upper reaches below Keswick because USBR has failed to provide adequate cold water flows to meet temperature criteria in the river.

- In 2005, 21.1% of fall-run, 15.2% of spring-run, 9.8% of late-fall-run redds were identified below Red Bluff Diversion Dam and 88.9% of winter-run, 30.3% of fall-run, 29.5% of spring-run, and 51.63% of late-fall-run redds were found above the Highway 44 Bridge in Redding.[8]
- In 2007, 17% of fall-run and 10% of late-fall-run redds were below Red Bluff and 83% of winter-run, 25% of fall-run, 43% of spring-run, and 60% of late-fall-run redds were compressed into the 5 miles above Highway Bridge 44 in Redding.[9]
- In 2008, 6% of fall-run and 10% of late-fall-run redds were found below Red Bluff and 92% of winter-run, 35% of spring-run 56% of late-fall-run and 7% of fall-run redds were compressed into the reach above the Highway 44 Bridge.[10]

[9] Killam D, Kreb B, Chinook Salmon Populations for the Upper Sacramento River Basin 2007, SRSSAP Technical Report No. 08-4, 2008: California Department of Fish and Game, Summary of Aerial Redd Survey Data 2008, Table 2, p. 8.

- In 2011, 11% of fall-run redds were below Red Bluff and 78% of winter-run and 88% of late-fall-run and 34% of fall-run redds were above the Highway 44 Bridge. There were no spring-run aerial flights.[11]
- In 2012, 21% of fall-run redds were observed below Red Bluff and 99% of winter-run and 83% of late-fall-run and 22% of fall-run redds were identified into the reach above the Highway 44 Bridge.[12]

Failure to provide adequate temperatures protective of sensitive life stages of Chinook salmon and the resultant compression of spawning habitat are major factors in the continued decline of the species and the threatened extinction winter-run and spring-run salmon.

Violations of the CWA, Basin Plan, WR Order 90-05 and CVPIA

The Regional Board's Basin Plan was adopted pursuant to the CWA and approved by the EPA. With respect to the Sacramento River, the Basin Plan explicitly states, "The temperature shall not be elevated above 56ºF in the reach from Keswick Dam to Hamilton City nor above 68ºF in the reach from Hamilton City to the I Street Bridge during periods when temperature increases will be detrimental to the fishery." Hamilton City is located at River Mile (RM) 199 on the Sacramento River. These temperature requirements protecting Chinook salmon extend up-river for 103 miles to Keswick Dam (RM 302).

As described above, the construction of Shasta and Keswick Dams eliminated virtually the entire historical spawning habitat for winter-run and spring-run Chinook salmon and forced these species to spawn in the river below Keswick. Historically, only 15% of fall-run Chinook salmon spawned in the Sacramento River upstream of Shasta Dan. The majority spawned in the lower river between Keswick and Hamilton City and until recently more than half spawned in the reach between Red Bluff Diversion Dam and Hamilton City.

The Basin Plan also states that temperature objectives are limited to "controllable factors" and "in determining compliance with the water quality objectives for temperature, appropriate averaging periods may be applied *provided that beneficial uses will be fully protected*." Emphasis added.

The Basin Plan's Controllable Factors Policy states:

> Controllable water quality factors are those actions, conditions, or circumstances resulting from human activities that may influence the quality of the waters of the State that are subject to the authority of the State Water Board or Regional Water Board, and that may be reasonably controlled.

In 1990, the SWRCB issued WR Order 90-05, which implemented the Basin Plan with respect to USBR's water rights and licenses for the CVP. It requires USBR to meet a daily average water temperature of 56ºF in the Sacramento River at Red Bluff Diversion Dam (RM 243) during periods when higher temperatures will be detrimental to the fishery. WR Order 90-05 states that when factors beyond the control of USBR prevent attainment of 56ºF temperatures at Red Bluff Diversion Dam, USBR may, after consultations with the fishery agencies and subject to approval of the SWRCB, designate an upstream location where it can meet the 56ºF requirement.

The SWRCB addressed controllable factors in maintaining cold-water pools for temperature control in WR Order 92-02 (Order Establishing Drought-Related Requirements for the Bay-Delta Estuary During 1992) when it referenced WR Order 90-05, at page 9:

> The State Water Board also has advised the USBR that decisions on water deliveries are subject to the availability of water, and that water should not be considered available for delivery if it is needed as carryover to maintain an adequate cold water pool for the fishery.

WR Order 90-05 ignored and failed to protect the 44 miles of river between Hamilton City and Red Bluff that comprises almost 43% of the spawning habitat protected by the Basin Plan. The Order also violated the Basin Plan when it established an average temperature of 56ºF, without regard to whether daily average temperatures that allow daily exceedances above 56ºF will *fully protect beneficial uses* during critical periods. As we demonstrate below, daily average temperature criteria are not protective of the fishery, as daily maximums can be lethal to fish.

The SWRCB also ignores and violates the Basin Plan's Controllable Factors Policy and its own advice to USBR as it approves the yearly Sacramento River Temperature Management Plans (TMPs) submitted by USBR to the SWRCB that shifts the compliance point upstream thereby further restricting the amount of spawning habitat available to salmon. As discussed more fully below, in recent years the SWRCB has approved TMPs that establish the compliance point at Clear Creek. This compresses spawning to a 10 mile reach below Keswick: a 90% reduction of Basin Plan and 83% reduction in BO protected spawning habitat. In 2015, SWRCB even violated its average daily 56ºF criterion, when the Executive Officer unilaterally approved an USBR request to raise the temperature standard to a target of 57ºF not to exceed 58ºF.

USBR has consistently operated to a pattern and practice of maximizing water deliveries without regard to reserving sufficient water storage to comply with water quality standards. It schedules water deliveries in the spring based on assumptions of future rainfall and not what was stored from the preceding wet season. The adverse consequences of this reckless policy are magnified during drought sequences. Delivering excessive quantities of water and draining reservoirs to the point of not being able to comply with water quality standards is not a defensible excuse for the failure to provide adequate cold water to protect fisheries. The pattern and practice of delivering near normal water supplies in the early years of drought, depleting carryover storage and then relying on the SWRCB to weaken water quality standards has been extensively discussed and documented in previous protests, objections and SWRCB TUCP workshops and is referenced and need not be repeated here.

The SWRCB has acquiesced and participated in this pattern and practice. It has disregarded Basin Plan and CWA requirements, relied upon average temperature criteria, approved temperature criteria that permit lethality, excluded significant reaches of identified spawning habitat from requirements to comply with temperature criteria, approved relocated compliance locations based upon USBR's willingness to reserve storage to meet water quality standards, and failed to enforce violations of temperature criteria.

Enactment of the Central Valley Project Improvement Act (CVPIA) in 1992 seems to have been forgotten. Co-equal with water supply, the protection, restoration and enhancement of fish and wildlife are now primary purposes of the CVP. Mitigation for previous dam construction, contributions to efforts to protect the Bay-Delta and the doubling of natural production of anadromous fisheries in Central Valley rivers are now CVP purposes.

Yet, USBR, with SWRCB approval, ignores the CVPIA requirement to achieve a reasonable balance between competing demands, and continues to operate the CVP primarily to deliver water to its customers and only secondarily to protect and enhance fisheries and public trust values. Deliveries to Settlement Contractors cannot take precedence over fish and wildlife requirements because the water rights of both USBR and the Settlement Contractors are subject to compliance with water quality criteria, the reasonable use doctrine and public trust balancing.

Both the SWRCB and USBR appear to regard NMFS' BO for the Long-Term Operational Criteria and Plan for Coordination of the CVP and SWP (OCAP) as having primacy over the CWA, Basin Plan, WR Order 90-05 and Public Trust Doctrine. Additionally, NMFS appears to believe that its BO protecting Chinook salmon spawning on the Sacramento River is subservient to USBR's desires to maximize water deliveries to its Settlement Contractors.

The NMFS OCAP BO's Reasonable and Prudent Action (RPA) 1.2.1 (page 592) establishes performance measures for temperature compliance points and End-of-September (EOS) carryover storage that must be attained.

Performance measures for EOS storage at Shasta Reservoir include:

- 87 percent of years: Minimum EOS storage of 2.2 MAF
- 82 percent of years: Minimum EOS storage of 2.2 MAF and end-of-April storage of 3.8 MAF in following year (to maintain potential to meet Ball's Ferry compliance point)
- 40 percent of years: Minimum EOS storage 3.2 MAF (to maintain potential to meet Jerry's Ferry compliance point in the following year)

Review of Shasta Reservoir storage records reveals that, over the last 10 years, USBR has failed to meet the performance requirements. They met the 2.2 MAF EOS storage requirement only 50% of the time, met the 2.2 MAF EOS and 3.8 MAF end-of-April requirement only 60% of the time and met the EOS storage of 3.2 MAF requirement only 30% of the time.

Reasonable and Prudent Action performance measures for temperature compliance points during the summer season, measured as a 10-year running average, include:

- Meet Clear Creek Compliance point 95% of the time
- Meet Balls Ferry Compliance point 85% of the time
- Meet Jelly's Ferry Compliance point 40% of the time
- Meet Bend Bridge Compliance point 15% of the time

Review of daily average temperature data for the Clear Creek compliance point (RM 292), Balls Ferry (RM 276), Jelly's Ferry (RM 266) and Bend Bridge (RM 258) compliance points reveals that, between 2007 and 2015, there were temperature exceedances at Bend Bridge and Jelly's Ferry in all years, exceedances at Ball's Ferry 66.6% of the years and exceedances at Clear Creek 55.5% of the years.

The NMFS OCAP BO's RPA 1.2.3.C (page 600) establishes drought exception procedures if the February forecast, based on 90% hydrology, shows that the Clear Creek temperature compliance point or 1.9 MAF Shasta Reservoir EOS storage is not achievable. Under these conditions, there is clear potential that minimal requirements for winter-run egg survival and spring-run spawning requirements will not be achieved due to depletion of the cold water pool, resulting in temperature-related mortality to both winter-run spring-run salmon. The BO's effects analysis concludes that these conditions could be catastrophic to the species.

Consequently, RPA 1.2.3.C requires preparation of a contingency plan, relaxation of Wilkins Slough criteria to at most 4,000 cfs and:

> *Notification to State Water Resources Control Board that meeting the biological needs of winter-run* and the needs of resident species in the Delta, *delivery of water to nondiscretionary Sacramento Contractors* and Delta outflow requirements per D-1641, *may be in conflict* in the coming season and *requesting the Board's assistance* in determining appropriate contingency measures, and *exercising their authorities* to put these measures in place. [Emphasis added.]

The BO makes clear that an appeal to the SWRCB was necessary because Sacramento Settlement Contractor withdrawal volumes of water from the river can be substantial and because the court had concluded that USBR did not have discretion to curtail deliveries to Sacramento Settlement Contractors to meet federal ESA requirements. Unfortunately, while the SWRCB has the authority to reduce water deliveries to Settlement Contractors, it has demonstrated in this and previous droughts that it lacks the political will to do so.

Review of Shasta storage levels and deliveries to Sacramento Valley Contractors reveals that in the second drought year of 2013, USBR delivered 1.6 MAF to Sacramento Settlement Contractors and 249 TAF to Tehama-Colusa Canal, thereby drawing down EOS storage to only 1.9 MAF. In the third drought year of 2014, with a February projection of Shasta EOS storage to be less than 1.9 MAF, USBR delivered 1.99 MAF of water to Sacramento Settlement Contractors and Tehama-Colusa Canal drawing down Shasta EOS storage to only 1.16 MAF. Failure to meet temperature criteria in 2014 devastated the winter-run, spring-run and fall-run year classes.

In the fourth drought year of 2015, USBR scheduled 75% of contracted water deliveries on 27 February despite a February projection of Shasta EOS storage of only 903 TAF. In April and May, USBR delivered 337,339 AF of water to the Settlement Contractors and 36,898 AF to the Tehama-Colusa Canal, forcing USBR to request that the SWRCB increase the 56ºF temperature criterion at Clear Creek compliance point to 58ºF. In April 2015, the NMFS said that the fishery agencies believed an increase in the temperature criterion to 58ºF would result in significant impacts and a likelihood of adverse impacts to incubating winter-run eggs and alevin in redds compared to a daily average of 56ºF. But, by 1 July 2015, NMFS had been ***persuaded*** that an increase to 58ºF was consistent with the BO because there was a ***reasonable possibility*** that there would be ***some juvenile winter-run survival*** this year.

USBR's continuing lack of compliance with temperature requirements is illustrated in a review of Sacramento River temperature control history in the NMFS' OCAP BO. Figure 6-18, on page 263, titled *Historical exceedances and temperature control point locations in the upper Sacramento River from 1992 through 2008* shows Shasta storage, the starting compliance point and changes in temperature compliance points and the reasons for the changes. It reveals that compliance points were frequently moved, often multiple times in a single year, in response to exceedances of water quality criteria. Compared with recent actions discussed below, not much has changed: the compliance point is a floating target that is frequently relocated because it is dependent upon how much water USBR is prepared to provide to comply with water quality criteria and protect fisheries.

The rationale and justification for meeting temperature criteria is described in the OCAP BO at Page 91, Section 4.2.1.2.3.3.4 titled *Water Temperatures for Successful Spawning, Egg Incubation, and Fry Development.* It states:

> Reclamation releases cold water from Shasta Reservoir to provide for adult winter-run migration, spawning, and egg incubation. *However, the extent winter-run habitat needs are met depends on Reclamation's other operational commitments, including those to settlement contractors, water service contractors, D-1641 requirements, and projected end of September storage volume. Based on these commitments, and Reclamation's modeled February and subsequent monthly forecasts, Reclamation determines how far downstream 56ºF can be maintained and sustained throughout the winter-run spawning, egg incubation, and fry development stages. Although WRO 90-05 and 91-1 require Reclamation to operate Keswick and Shasta dams, and the Spring Creek Powerplant, to meet a daily average water temperature of 56ºF at RBDD, they also provide the exception that the water temperature compliance point (TCP) may be modified when the objective cannot be met at RBDD. In every year since the SWRCB issued WRO 90-05 and 91-1, operations plans have included modifying the RBDD compliance point to make best use of the coldwater resources based on the location of spawning Chinook salmon* (CVP/SWP operations BA page 2-40). Once a TCP has been identified and established, it generally does not change, and therefore, water temperatures are typically adequate for successful, egg incubation, and fry development for those redds constructed upstream of the TCP. *However, the annual change in TCP has degraded the conservation value of spawning habitat (based on water temperature).* [Emphasis added.]

Regardless of the OCAP BO's description of how USBR views its obligations to deliver water or the process of by which temperature compliance points are selected, it is USBR's ultimate responsibility to comply with the legal water quality criteria in the Basin Plan that was developed pursuant to the federal CWA and approved by USEPA as a condition of operations. USBR is not entitled to operate its project in violation of legal requirements simply because it is the USBR.

The approval of fishery agencies cannot be legally employed as an excuse for USBR's not complying with water quality standards. Nor is the SWRCB's failure to incorporate the full water quality protections in the Basin Plan a defensible excuse. Delivering contracted water and drawing down reservoir levels and depleting cold water storage to the point of not being able to meet temperature requirements is a controllable factor. USBR's contracts for delivering water are predicated on compliance with water quality standards, and USBR's desire to maximize water deliveries and the SWRCB's lack of political will to reduce deliveries to Sacramento Settlement Contractors cannot be used to justify failure to comply with the law.

Yet, over the years, USBR, the fishery agencies and SWRCB have gathered together in secret rooms to determine temperature compliance points. The Sacramento River Temperature Task Group (SRTTG) advises USBR on the best course of action to take regarding temperature compliance, based on fish surveys, real-time data and temperature modeling all functioning within the limits of the quantity of water USBR is willing to provide. The SRTTG is comprised of the USFWS, NMFS, CDFW, SWRCB, Western Area Power Administration and the Hoopa Tribe. A TMP is prepared yearly and submitted to the SWRCB for approval.

In an interesting conflict of interest conundrum, the SWRCB participates in the SRTTG that devises and recommends a TMP and then the SWRCB, as a regulatory agency, evaluates and approves the recommendation that is always less protective than CWA/Basin Plan requirements.

In 2009, the SRTTG set the temperature compliance point at Airport Road (RM 284) in Anderson, thus eliminating 85 miles of spawning habitat protected by the Basin Plan, 41 miles protected by the WR Order 90-05 or 26 miles under the BO. In 2010, Shasta Reservoir received above normal inflow and filled. The SRTTG set the temperature compliance point at Jelly's Ferry (RM 267), eliminating 68 miles of spawning habitat protected by the Basin Plan, 24 miles protected by WR Order 90-05 and 9 miles under the BP.

The SRTTG Annual Report for 2011 revealed that temperature compliance was targeted at Balls Ferry (RM 276) until 1 June and Jelly's Ferry (RM 266) until 31 October. Shasta Reservoir had 3.99 MAF of water, as of 1 April 2011, and inflow was expected to be above average. Yet USBR claimed that 56ºF temperatures could not be met at Red Bluff during a wet year and, with the approval of the fishery agencies, eliminated 61% of spawning habitat from any temperature requirement until 1 June and subsequently eliminated 46% of spawning habitat in the critical spawning period for winter-run Chinook salmon.

The 2011 Independent Panel report, as quoted in the 2012 SRTTG Annual Report observed:

> The TCP at Bend Bridge, which is required to be met only 15% of the time (i.e., 1.5 yrs out of 10), has not been met in either this or the previous year. *If the TCP at this location*

> *was not met in WY2011 –one of the least challenging years in terms of available reservoir storage – it seems unlikely that it can be met in any year.* [Emphasis added.]

In 2012, the temperature compliance point began at Jelly's Ferry (RM 266) was moved up to Balls Ferry (RM 276) and ended the year at Jelly's Ferry. The 2012 SRTTG Annual Report also highlighted another problem: when high releases to meet delivery and temperature requirements are dramatically reduced following the close of the irrigation and temperature control seasons, there is considerable dewatering of fall-run and late-fall-run Chinook salmon redds.

In 2013, the SRTTG recommended and USBR operated to meet an initial temperature compliance point at Balls Ferry (RM 276), but in June it was moved upstream to Anderson (RM 284). The 2013 SRTTG Annual Report demonstrated how relocating temperature compliance points upstream compressed spawning. In 2012, 63.6% of fall-run and 95.9% of late-fall-run Chinook salmon spawned in the 26 miles between Keswick and Balls Ferry and, in 2013, 98.4% of winter-run Chinook salmon spawned in the 3 miles between Keswick and the ACID Dam, with another 22.5% above the Highway 44 bridge. It also reported that 35% of monitored fall-run redds were dewatered when flows were abruptly reduced from 7,000 to 4,000 cfs in WY2013 and that 8,011 fall-run and 650 winter-run salmon were observed stranded by CDFW crews between 7 February 7 and 4 April 2013.

In 2014, the SRTTG established a temperature compliance point at Clear Creek (RM 292), with the approval of the SWRCB Executive Director. This provided 10 miles of spawning habitat but eliminated 34 miles of spawning habitat under the BO, 49 miles of spawning habitat under WR Order 90-05 and 93 miles of spawning habitat protected under the Basin Plan. However, flawed modeling and reckless mismanagement prevented USBR from even protecting this upper 10 miles of spawning habitat. The cold water pool in Shasta Reservoir was depleted because USBR delivered 1.2 MAF of water to Sacramento Settlement Contractors and 119 TAF to the Tehama-Colusa Canal and exported 1.5 MAF via the Jones Pumping Plant in the Delta during 2014, the third year of the drought. Shasta Reservoir was drawn down to 1.05 MAF by January 2015.

With cold water depleted, the temperature objective was exceeded and 100% of the winter-run Chinook salmon redds were exposed to temperatures above 56ºF. It is estimated that 95% of winter-run, 98% of fall-run and virtually all of the spring-run Chinook salmon brood year was lost because of the USBR's failure to comply with temperature objectives.

On 6 April 2015, the SWRCB Executive Director directed USBR to prepare and implement a 2015 TMP for the Sacramento River for the protection of winter-run, Chinook salmon and other salmonids. USBR submitted a draft TMP in mid-April and an updated plan on 4 May 2015. The Executive Director provisionally approved the TMP on 14 May. USBR subsequently informed the SWRCB that it could not meet the 56ºF temperature requirement at Clear Creek, and the Executive Director suspended his approval of the TMP on 29 May. The SWRCB held a workshop on 24 June, where CSPA, NRDC and the Bay Institute provided highly critical comments on the proposed TMP. USBR submitted a revised TMP on 25 June, the NMFS provide a concurrence letter on 1 July and the Executive Director approved the TMP on 7 July 2015.

The approved TMP set a daily average temperature target of 57ºF at Clear Creek, not to exceed 58ºF. To preserve cold-water storage, the Order limited Keswick releases to 7,250 cfs in June, July and August, 6,500 cfs in September and 5,000 cfs in October, subject to change in accordance with real-time monitoring and decision-making.

So far in 2015, daily average temperatures at the Clear Creek compliance point averaged 57.3ºF in June and 57.1ºF in July. Daily maximum temperatures at Clear Creek averaged 59.6ºF in June and 59.2ºF in July. USBR violated the not-to-exceed 58ºF weakened daily average criterion on June 16 (58.038), 17 (58.42), 18 (58.19) and 24 (58.18). Based upon the scientific literature, significant instantaneous mortality to the 2015 winter-run Chinook salmon brood class has already occurred, and substantial delayed mortality can be expected to occur.

The fishery agencies initially opposed USBR's proposal to increase temperature limits from 56ºF to 58ºF because they believed it was not protective of early Chinook salmon life stages. NMFS' 15 April 2015 *Evaluation of Alternatives for Sacramento River Water Temperature Compliance for Winter-fun Chinook Salmon* is posted on the SWRCB's website. The Evaluation points out, on page one:

> A requirement in NOAA's National Marine Fisheries Service's reasonable and prudent alternative is to provide water temperatures *no greater than a daily average of 56ºF in the upper Sacramento River to provide habitat needs for various life history stages of Sacramento River winter-run Chinook salmon.* [Emphasis added.]
>
> The fish agencies (NMFS, USFWS, and CDFW) have reviewed various alternatives to temperature compliance, including a targeted daily average water temperature Shasta Dam (e.g., 52ºF or 53ºF) and *increasing the temperature target from 56ºF to 58ºF* at the Sacramento River above Clear Creek CDEC monitoring station (CCR) compliance point after the eggs hatch. As a result of their assessment, the fish agencies *do not think that these alternatives would result in negligible impacts and/or little likelihood of adverse impacts to incubating winter-run eggs and alevin in redds compared to a daily average of 56ºF.* [Emphasis added.]
>
> For example, a heat wave in Redding (>105ºF) with these operation could lead to elevated *temperatures above 56ºF at CCR, leading to potentially significant winter-run egg mortality and sublethal effects.* [Emphasis added.]

Having acknowledged that NMFS, USFWS and CDFW believe that an increase of daily average temperatures from 56ºF to 58ºF would result in adverse impacts, the Evaluation observes, on page 5, that <u>violations occur nearly every year because of USBR commitments to water contractors</u>:

> Even though State Water Resources Control Board Orders 90-5 and 91-1 require Reclamation to operate Keswick and Shasta dams to meet a daily average temperature of 56ºF at Red Bluff Diversion Dam (RBDD) [or at a temperature compliance point (TCP) modified *when the objective cannot be met at RBDD based on Reclamation's other operational commitments including those to water contractors*, D-1641 regulations and

> criteria, and projected end of September storage volume], *nearly every year, Reclamation has exceeded the TCP at some point throughout the temperature control season.* Especially last year, 100% of winter-run brood year 2014 redds were exposed to temperatures above 56ºF degrees at the CCR TCP at some time period during the water year (see Figure 3). Emphasis added.

But USBR, with SWRCB acquiescence, did an end run around the fishery agencies and eliminated all possibility of using Shasta storage to meet a 56ºF temperature criterion, even at Clear Creek. In April and May of this year, USBR, despite pleas from CSPA, Bay Institute, NRDC and others to reduce deliveries in order to protect the cold water pool in Shasta Reservoir, delivered 366,794 AF to the Sacramento Settlement Contractors and Tehama-Colusa Canal and exported an additional 312,686 AF of water from the Delta. These deliveries eliminated any possibility that the water would be used to meet water quality standards and fishery needs.

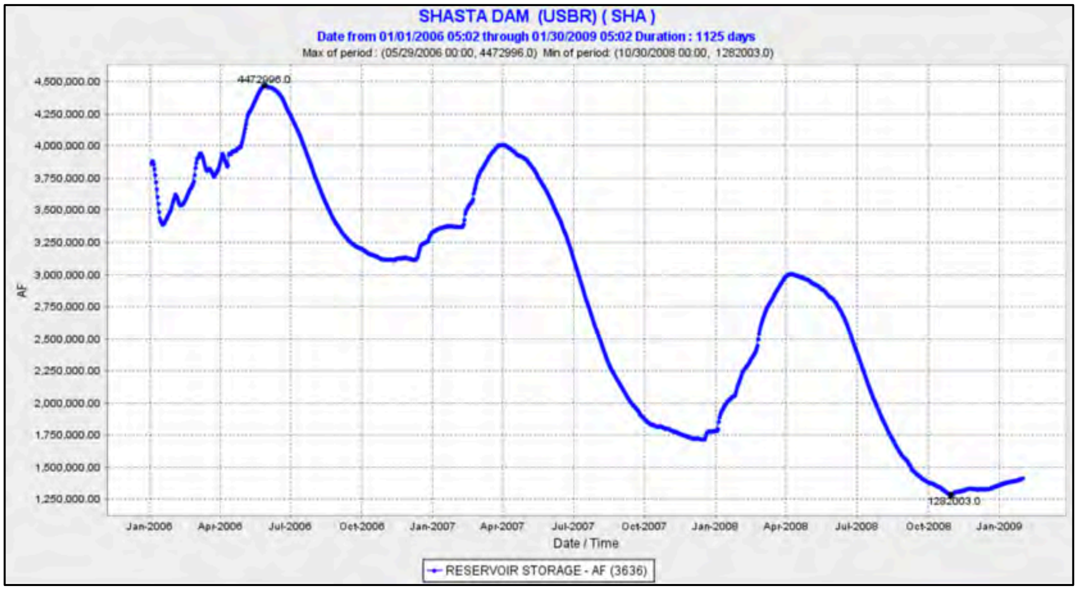
Faced with a *fait accompli* and unwilling to hold their partner accountable for violations of the CWA and ESA, the fishery agencies went along and issued consistency determinations that claimed the TMP was consistent with the BOs. The situation is described in the conclusion of NMFS's 1 July 2015 consistency determination for the TMP:

> NMFS acknowledges that storage in Shasta Reservoir at the beginning of the temperature management season in June, and the quantity and quality of the cold water pool, *will not provide for suitable winter-run habitat needs throughout their eggs and alevin incubation and fry rearing periods*. The base operations plan, including the Keswick release schedule, delayed use of full side gates, and real-time monitoring and decision-making based on winter-run timing, location of redds, air and surface water temperature modeling, and projected versus actual cold water storage conditions and downstream water temperatures, represents the best that can be done with a really bad set of conditions. *We note that these conditions could have been largely prevented through upgrades in monitoring and modeling, and reduced Keswick releases in April and May. Based on extensive analyses of alternative scenarios (6,000 to 8,000 cfs Keswick releases), the plan provides a reasonable possibility that there will be some juvenile winter-run survival this year.* [Emphasis added.]

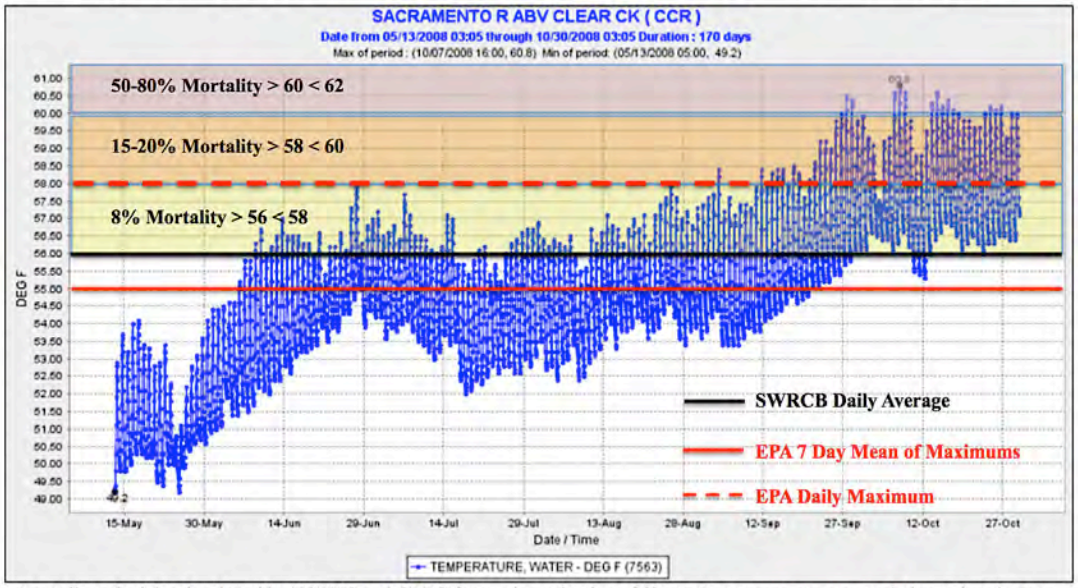
And that's the best that can be hoped for this year, "a reasonable possibility that there will be some juvenile winter-run survival this year." Had USBR and the SWRCB heeded the pleas to not deliver 2.8 MAF of water and draw down Shasta by 1.05 MAF of water last year in the third year of drought, had they heeded the pleas to not deliver 374,237 AF of water to Sacramento Settlement Contractors and the Tehama-Colusa Canal in April and May of this year, had they heeded pleas to not continue to further deplete cold water storage by delivering more than 500,000 AF in June and July to water agencies along the Sacramento River, there might be more than mere hope that some winter-run might survive this year.

But reserving water needed to meet water quality standards and public trust fishery needs has never been a part of USBRs operating protocols. The pattern and practice of draining reservoirs in the initial years of a drought sequence and then either violating water quality and fishery standards or turning to the SWRCB to bail them out of having to comply with water quality standards is deeply ingrained in USBR’s operations. The last two drought sequences illustrate the pattern.

During the drought of 2007-2009, USBR delivered 100% of the contracted water to water contractors along the Sacramento River. Deliveries to Sacramento Settlement Contractors and Tehama-Colusa Canal in 2006, 2007, 2008 and 2009 totaled 1.7, 1.9, 1.9 and 1.8 MAF, respectively. CVP Delta Exports in 2006, 2007, 2008 and 2009 were 2.6, 2.6, 1.8 and 1.9 MAF, respectively. Shasta Reservoir was drawn down from 4.47 MAF in April 2006 to 1.28 MAF in November 2008, leaving insufficient cold water remained to comply with temperature criteria.



Sacramento River Above Clear Creek Temperatures: 15 May – 30 November 2008



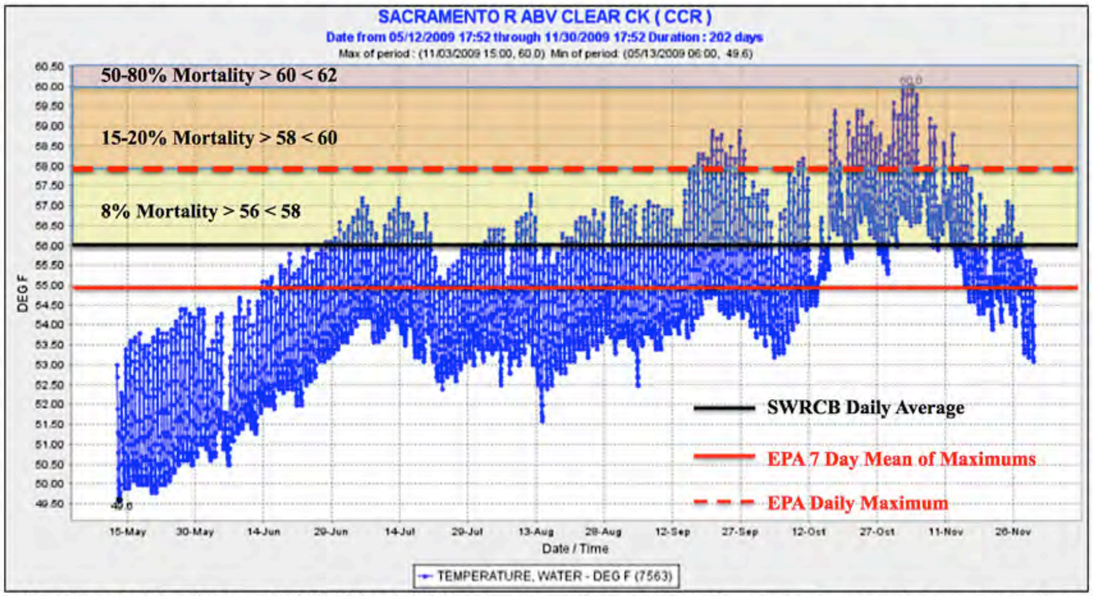
Mortality schedules developed by USFWS and CDFG for use in evaluation of Shasta Dam temperature control alternatives in June 1990 (Richardson et al. 1990).

Winter-run Chinook salmon spawning generally begins in late April and extends into early

August, eggs hatch between late June and middle-to-late September, and fry emerge between late July and late October. Spawning through incubation to emergence are critical life stages.

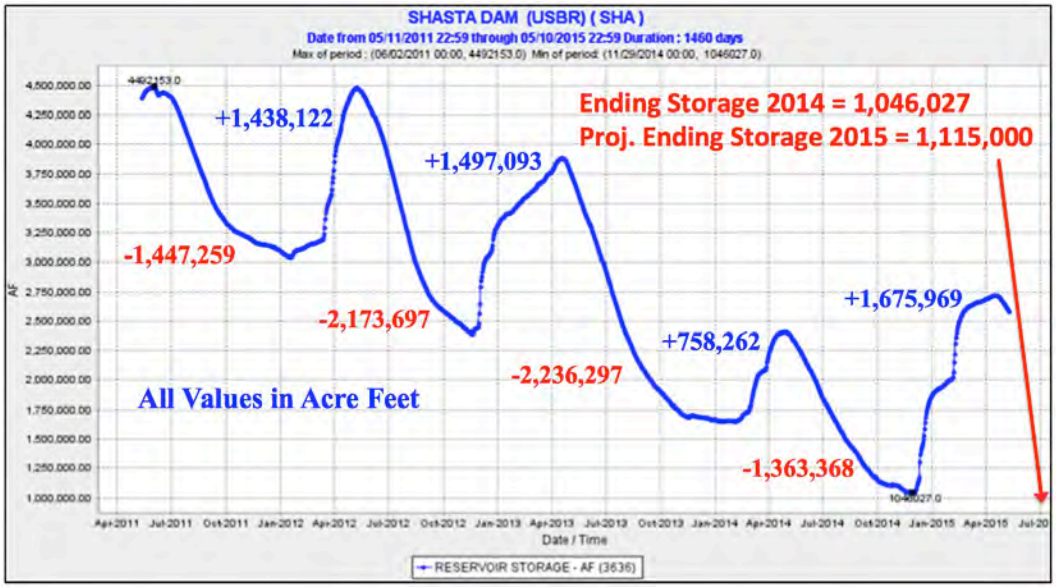
Temperatures at Clear Creek in 2008 ranged into lethal zones during spawning and egg incubation and exceeded even the SWRCB's inadequate daily averages during fry emergence. Temperatures in the 90% of identified spawning habitat below Clear Creek were much higher.

Sacramento River Above Clear Creek Temperatures: 15 May – 30 November 2009



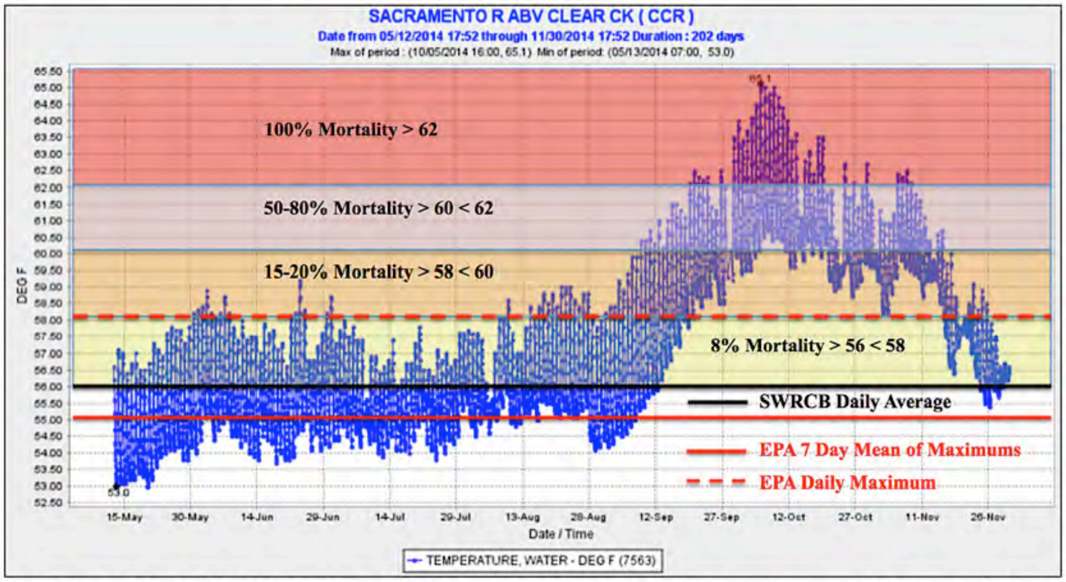
Mortality schedules developed by USFWS and CDFG for use in evaluation of Shasta Dam temperature control alternatives in June 1990 (Richardson et al. 1990).

The pattern repeated itself in 2009 as shown above.



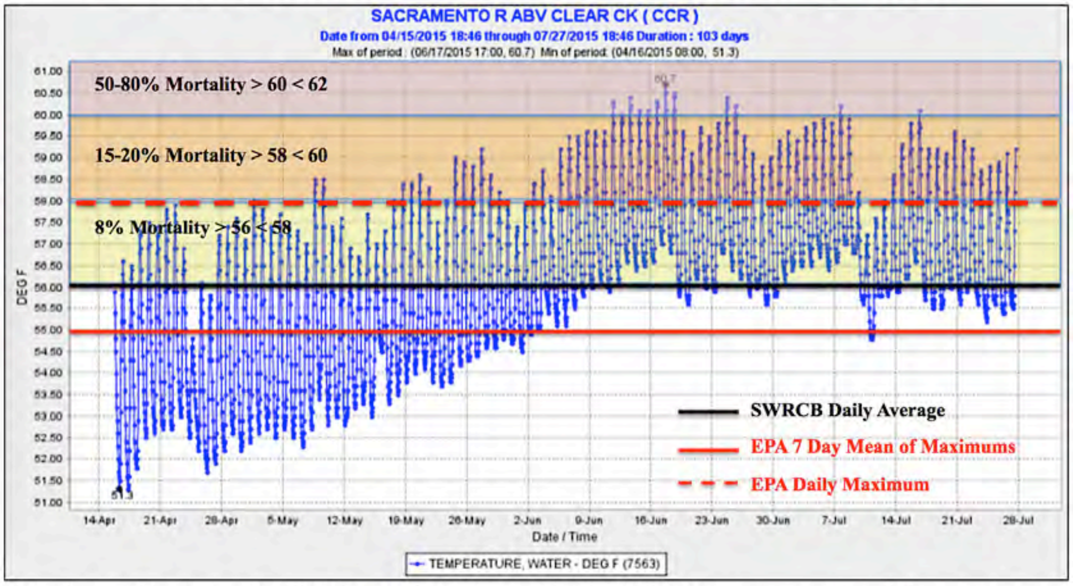
During the present drought, USBR scheduled deliveries of 100% of contracted water to Sacramento Contractors in 2012 and 2013 and 75% in 2014 and 2015. Deliveries to contractors along the Sacramento River in 2012, 2013 and 2014 totaled 1.8, 1.99 and 1.3 MAF, respectively. In 2012, 2013, 2014 and 2015 CVP Delta Exports were 2.1 MAF, 1.5 MAF, 874 TAF, and 334 TAF so far this year. Consequently, end-of-year storage in Shasta Reservoir plummeted.

Sacramento River Above Clear Creek Temperatures: 15 May – 31 October 2014



Mortality schedules developed by USFWS and CDFG for use in evaluation of Shasta Dam temperature control alternatives in June 1990 (Richardson et al. 1990).

Sacramento River Above Clear Creek Temperatures: 15 April – 27 July2015



Mortality schedules developed by USFWS and CDFG for use in evaluation of Shasta Dam temperature control alternatives in June 1990 (Richardson et al. 1990)

Excessive water deliveries in the initial drought years depleted cold water pools in Shasta. Water temperature intruded well into lethal zones during spawning and egg incubation and soared during late incubation are fry emergence. The entire brood years of winter-run, spring-run and fall-run Chinook salmon were devastated.

CSPA has been unable to find a single example of the SWRCB taking an enforcement action against USBR for violations that occur "nearly every year," including the 2014 violations that destroyed an estimated 95% of winter-run, 98% of fall-run and virtually all of the spring-run brood class. Perhaps the SWRCB's participation in the closed-door meetings that recommends TMPs that fail to comply with CWA/Basin Plan requirements precludes it from taking an enforcement action against a fellow SRTTG member for violations of the TMP. This exhibits all of the characteristics of classic "conflict of interest" and "regulatory capture."

Average Temperature Requirements are Not Protective of Chinook Salmon

Following a long extensively peer-reviewed court ordered proceeding, USEPA Region 10 issued *EPA Region 10 Guidance for Pacific Northwest State and Tribal Temperature Water Quality Standards* (Region 10 Guidance) in 2003. The Guidance establishes a recommended criterion of 13ºC (55ºF), as a 7 day average of the daily maximums (7DADM), for Chinook salmon, steelhead and trout spawning, egg incubation and fry emergence, 16ºC (61ºF) for salmon and steelhead "core" juvenile rearing and 18ºC (64ºF) for salmon and steelhead migration plus non-core juvenile rearing. The states of Washington, Idaho and Oregon have established temperature criteria for Chinook salmon spawning through fry emergence as 7DADM 13ºC (55.4ºF, 16ºC (60.8ºF) for salmonid core summer habitat and 17.5ºC (63.5ºF) for salmonid rearing and migration.

The 7DADM protects against not only the lethal effects of elevated temperatures but also the chronic and sublethal impacts that frequently occur in waters that meet weekly average temperatures. High daily maximum temperatures can lead to excessive mortality in waters that still meet weekly averages. Chronic and sublethal effects include reduce juvenile growth, increased incidence of disease, reduced viability of gametes in adults prior t spawning, increased susceptibility to predation and competitions and suppressed or reversed smoltification.

In 2011, USEPA Region 9, in disapproving the SWRCB's 2008-2010 306(d) list of impaired waterbodies, added the San Joaquin, Merced, Tuolumne and Stanislaus Rivers to the 303(d) list as impaired by temperature based partly on the Region 10 guidance and partly on recommendations by the California Department of Fish and Wildlife (CDFG) and the Regional Board, both of which used the Region 10 Guidance and other studies. The USEPA Region 9 letter stated,

> Additionally, EPA believes that EPA's Temperature Guidance values are appropriate for use in the Central Valley. The criteria have been used by California in their 303(d) list recommendation as well as selected as targets in Total Maximum Daily Loads (TMSLs) in the North Coast Regional of California (Carter 2008). They have also been used by National Marine Fisheries Service (NMFS") to analyze the effects of the long term operations of the Central Valley Project and State Water Project, and to develop the reasonable and prudent alternative actions to address temperature-related issues in the Stanislaus River (NMFS 2009a). Reviews of appropriate temperature criteria for use in

> the Stanislaus have yielded findings consistent with the EPA Temperature Guidance values (Deas (2004) and Marston (2003)).

The USEPA Region 9 letter also quoted a 2010 letter from Maria Rea, NMFS, to Alexis Straus (USEPA) that also supports the use of the Region 10 Guidance:

> The use of the US EPA 2003 criteria for listing water temperature impaired water bodies in the San Joaquin River basin is scientifically justified. It has been recognized that salmonid stocks do not tend to vary much in their life history thermal needs, regardless of their geographic location. There is not enough significant genetic variation among stocks or among species of salmonids to warrant geographically specific water temperature standards (US EPA 2001). Based upon reviewing a large volume of thermal tolerance literature, McCullough (1999) concluded that there appears to be little justification for assuming large genetic adaptation on a regional basis to temperature regimes.
>
> Although many of the published studies on the responses of Chinook salmon and steelhead to water temperature have been conducted on fish from stocks in Oregon, Washington, and British Columbia, a number of studies were reported for the Central Valley salmonids. Myrick and Cech (2001, 2004) performed a literature review on the temperature effects on Chinook salmon and steelhead, with a focus on Central Valley populations…
>
> It is evident that the difference in thermal response is minimal in terms of egg incubation, growth, and upper thermal limit. Healey (1979, as cited in Myrick and Cech 2004) concluded that Sacramento River fall-run Chinook salmon eggs did not appear to be any more tolerant of elevated water temperature than eggs from the more northern races. Myrick and Cech (2001) concluded that it appears unlikely that there is much variation among races with regard to egg thermal tolerance because data from studies on northern Chinook salmon races generally agree with those from California. They further concluded that fall-run Central Valley and northern Chinook salmon growth rates are similarly affected by water temperature.

In fact, the Myrick and Cech's 2004 study titled *Temperatures effects on juvenile anadromous salmonids in California's central valley: what don't we know?* noted that a recent study on Sacramento River Chinook salmon by the US Fish and Wildlife Service (1999) concurred that fall-run egg mortality increased at temperatures greater than 12ºC (53.6ºF), that winter-run egg mortality increased at temperatures over 13.3ºC (55.8ºF), and that temperatures between 6 and 12ºC appear best suited to Chinook salmon egg and larval development.

Chapter 6, page 2 of USBR's Biological Assessment (BA) for the 2008 Long-Term Operational Criteria and Plan for Coordination of the Central Valley Project and State Water Project (OCAP) contains Table 6-1 titled *Recommended water temperatures for all life stages of Chinook salmon in Central Valley streams as presented in Boles et al. (1988).* Recommended temperatures for Chinook salmon are migrating adult (<65ºF), holding adult (<60ºF), spawning (53-57.5ºF), egg incubation (<55ºF), juvenile rearing (53-57.5ºF) and smoltification (<64ºF). Table 6-2 (page 6-3) titled *Relationship between water temperature and mortality of Chinook salmon eggs and pre-*

emergent fry used in Reclamation egg mortality model shows that instantaneous daily salmon egg mortality begins at 57ºF and instantaneous daily pre-emergent fry mortality begins at 59ºF.

The NMFS 8 March 2012 Biological Opinion for DWR's proposed construction and operation of the South Delta Temporary Barriers Program acknowledges, at page 12, that the "upper preferred water temperature for spawning Chinook salmon is 55ºF to 57ºF (Chambers 1956, Smith 1973, Bjornn and Reiser 1991, and Snider 2001)" and the "optimal water temperature for egg incubation ranges from 41ºF to 56ºF (44ºF to 54ºF [Rich 1997], 46ºF to 56ºF [NMFS 1997 Winter-run Chinook salmon Recovery Plan], and 41ºF to 55.4ºF [Moyle 2002]). It noted a "significant reduction in egg viability occurs at water temperatures above 57.5ºF and total embryo mortality can occur at temperatures above 62ºF (NMFS 1997)."

The NMFS 4 June 2009, Chinook Salmon/Sturgeon Biological Opinion for OCAP establishes, on page 621, an RPA for specific temperature criteria to protect steelhead adult migration of (< 56ºF at Orange Blossom Bridge [OBB], 1 Oct – 31 Dec), smoltification (< 52ºF at Knights Ferry and < 57ºF at OBB, 1 Jan – 31 May), spawning and incubation (< 55ºF at OBB), 1 Jan - 31May) and juvenile rearing (< 65ºF, 1 June – 30 September). It states, "Temperature compliance shall be measured based on a seven-day average daily maximum temperature. While NMFS requires USBR to meet specific temperature criteria specified as a 7DADM on the Stanislaus River, it fails to require USBR to meet any specific temperature criteria on the Sacramento River; leaving it to the SRTTG to develop an annual flexible TMP based upon water available after USBR meets its contractor obligations.

The North Coast Regional Water Quality Control Board developed a Klamath River TMDL in 2010. As part of the process, staff conducted an extensive literature review to evaluate temperature needs of the various life stages of steelhead trout, coho salmon and Chinook salmon. The purpose of the review was to identify temperature thresholds that are protective of salmonids by life stage, as a basis for evaluating stream temperatures in California temperature TMDLs within the North Coast region. The results were reported in Appendix 4, Effects of Temperature, Dissolved Oxygen/Total Dissolved Gas, Ammonia, and pH on Salmonids of the Final Klamath River TMDL Staff Report. Table 13, on page 25 of Appendix 4 identifies life stage temperature thresholds for salmonid spawning, egg incubation and fry emergence as 13ºC (55.4ºF), expressed as a MWMT, which is the same as a 7DADM.

The Pacific Fishery Management Council, in a 29 May 2015 letter from its Executive Director Dr. D. O. McIsaac, to SWRCB Executive Director Tom Howard, recommended that the SWRCB insist that USBR actively manage to meet a 56ºF maximum temperature, rather than a 56ºF daily average.

The 2013 SRTTG annual report revealed that NMFS had broached the subject of switching to a 7DADM. It stated on page 12:

> NMFS expressed the idea of tracking the 7-day maximum (7DADM) water temperature in order to determine whether sub-lethal effects on salmonid life history stages (spawning, egg incubation and fry emergence) exist, despite the current temperature requirement metric of a daily average (Appendix B). *The*

> *7DADM metric is recommended by EPA as of 2003 and has been used in other Central Valley rivers (e.g., Stanislaus, Tuolumne, and Merced rivers).* NMFS looked at the 7DADM and what that might mean to the current daily average criterion (Figures 3-6). *7DADM can exceed daily average temperatures by as much as 4ºF at Balls Ferry and as much as 3ºF at Airport Road.* [Emphasis added.]

The report then observed that:

> *SRTTG indicated that a change in compliance metric would require considerable time and effort in negotiations among all of the agencies and the State Water Resources Control Board and a change to decision 90-5.* Emphasis added.

The SRTTG 2013 report then posed the question:

> *How does the Panel view using 7DADM as a measurement to consider potential sub-lethal effects on salmonid life history stages in lieu of daily average temperature?* Emphasis added.

CSPA poses two additional questions: has the SWRCB abdicated its regulatory and public trust responsibilities to the SRTTG and ceded its authority to those it is required to regulate and to the fishery agencies that have chaperoned the continued decline of Chinook salmon in the Sacramento River? Where in the CWA, ESA or the California Water Code is authority granted to USBR, NMFS, USFWS, CDFG, the Western Area Power Administration and the Hoopa Tribe to secretly decide what are the appropriate water quality criteria to protect beneficial uses?

The 2014 SRTTG annual report reiterated NMFS' recommendation but did not mention any discussion or decision related to pursuing a change to a 7DADM temperature standard from the present daily average. It stated on page 16:

> In 2013, NMFS expressed to the SRTTG the idea of tracking 7-day average of daily maximum water temperature in order to determine whether sub-lethal effects on salmonid life history stages (spawning, egg incubation, and fry emergency) exist, despite the current temperature requirement metric of daily average. As explained in Appendix B of the 2013 SRTTG Annual Report of Activities, daily average temperature does not consider the impacts of diurnal temperature changes and daily maximum temperature. The stressful impacts of higher water temperatures on salmonids are cumulative and positively correlated to the duration and severity of exposure. The longer the salmonid is exposed to thermal stress, the less chance it has for long-term survival. Sub-lethal effects from high water temperature can lead to delayed mortality due to reduced fry and smolt sizes from sub-optimal growth. These effects could result in reduced productivity of a stock and reduced population size. As the term suggests, 7-day average of daily maximum (7DADM) reflects an average of maximum temperatures that fish are exposed to in a week long period. Since this metric is oriented to daily maximum temperatures, it can be used to protect against acute and sub-lethal or chronic effects.

It then observed that:

> *7DADM was monitored for WY2014 and it was found that the reported 7DADM temperature was as much as 3ºF higher in the Sacramento above Clear Creek than was shown by the SWRCB's 56ºF average temperature criterion.* Emphasis added.

Violations of the Endangered Species Act

In enacting ESA, Congress stated that the purpose of the ESA is "to provide a means whereby the ecosystems upon which endangered species and threatened species depend may be conserved." 16 U.S.C. § 1531(b). As part of conserving endangered or threatened species, ESA prohibits the "taking" of any such listed species. 16 U.S.C. § 1538(a)(1)(B). A "take" is defined as "to harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, or collect, or to attempt to engage in any such conduct." 16 U.S.C. § 1532(9). To "harm" a listed species in the context of a "take" includes "[any] act which actually kills or injures wildlife. Such act may include significant habitat modification or degradation where it actually kills or injures wildlife by significantly impairing essential behavioral patterns, including breeding, feeding, or sheltering." 50 C.F.R. § 17.3 (1994). An indirect injury to a listed species through habitat modification also constitutes a "take." *Babbitt v. Sweet Home Chapter of Communities for A Great Oregon,* 515 U.S. 687 (1995). The 9th Circuit Court of Appeals ruled that "under Sweet Home, a habitat modification which significantly impairs the breeding and sheltering of a protected species amounts to 'harm' under the ESA." *Marbled Murrelet v Pacific Lumber Company,* 83 F.3d 1060 (9th Cir. 1996).

USBR has operated to a pattern and practice of delivering near normal water supplies in the early years of drought, depleting carryover storage and then relying on the SWRCB to weaken water quality standards. The SWRCB has operated to a pattern and practice of weakening water quality standards and thereby significantly degrading the habitat and impairing essential behavioral patterns, breeding, feeding, or sheltering of listed species. The SWRCB and USBR are in violation of the ESA.

As discussed at length above, USBR does not have discretion to curtail water deliveries to Sacramento Settlement Contractors to meet ESA requirements to comply with temperature requirements. The SWRCB has the authority but has refused to use it reduce water deliveries to Settlement Contractors in order to retain sufficient cold water storage necessary for temperature compliance. Both the SWRCB and USBR have failed to ensure compliance with the terms and conditions in the incidental take statement, i.e., that the reasonable and prudent measures in the RPAs and, consequently, are no longer in compliance with the ESA.

The BO does not address ESA section 7(a)(2) compliance for individual water supply contracts and, consequently, delivery of water that is "nondiscretionary" for the purposes of the ESA is not exempt from ESA section 9 take prohibitions. The SWRCB has sanctioned the illegal "take" of endangered species by the USBR and Sacramento Settlement Contractors.

Abundances of anadromous and pelagic species listed pursuant to the ESA have plummeted over the last few years to the point where they are facing the likelihood of imminent extinction. Over this period, the SWRCB has acceded to multiple requests by USBR to weaken basic minimum standards adopted to protect listed species and their habitats and the fishery agencies have acquiesced in issuing concurrence letters, frequently within hours or several days of receiving TUCPs and Reinitiation of Consultation requests. These serial actions have seriously modified and degraded the habitat and impaired the breeding and sheltering of listed species to the point of impending extinction.

For example, a year after violations of temperature criteria had decimated the year classes of Sacramento Chinook salmon, a month and a half after identifying Sacramento winter-run Chinook salmon as one of the eight species in the nation "most at risk of extinction in the near future" and after it had stated than an increase in the temperature compliance target would result in adverse impacts to incubating winter-run eggs and alevin in redds and that 58ºF was identified in the scientific literature as lethal to incubating salmon eggs and emerging fry, the NMFS issued a concurrence letter claiming that that increasing the temperature target was consistent with the BO because "the plan provides a ***reasonable possibility*** that there will be ***some juvenile winter-run survival*** this year." [Emphasis added.] A reasonable possibility that some winter-run might survive is not an acceptable ESA legal standard.

Notwithstanding the letters of concurrence from USFWS, NMFS and CDFW that claim these actions are consistent with existing Biological Opinions, nothing in the ESA legally allows or justifies the SWRCB and USBR to further degrade the habitats of species lingering on the precipice of extinction. Collectively, the excuses, justifications and serial weakening of water quality criteria emanating from the secret SRTTG meetings while the fishery agencies remain embraced in denial as fisheries plummet toward extinction, surely constitute one of the saddest and most wretched spectacles we've ever witnessed and could be easily construed as an illegal conspiracy to defraud the public of public trust resources to the benefit of special interests.

Violations of the Public Trust and Article X of the California Constitution

Article X, Section 2 of the California Constitution provides that:

> The right to water or to the use of the flow of water in or from any natural stream or water course in this state is and shall be limited to such water as shall be reasonably required for the beneficial use to be served, and such right does not and shall not extend to the waste or unreasonable use or unreasonable method of use or unreasonable method of diversion of water.

Because of this Constitutional requirement, the SWRCB must consider the reasonableness of a particular method of diversion of water when evaluating (or reevaluating) all permitted uses of water and the requirements controlling those uses. "The limitations of Art. X, Section 2 … apply to all water users of the state and serve as a limitation on every water right and method of diversion." See *Yuba River D-1644* at p. 29. USBR is a water user subject to Article X, Section 2 in the operation of its respective projects in the Central Valley. The SWRCB's responsibility under the reasonable use doctrine is illustrated in the recent summary of this doctrine by the First District Court of Appeal, in *Light v. SWRCB (2014) 226 Cal.App.4th 1463, 1479–80*:

> Water use by both riparian users and appropriators is constrained by the rule of reasonableness, which has been preserved in the state Constitution since 1928. (Cal. Const., art. X, § 2; hereafter Article X, Section 2.) ... As the Supreme Court recognized soon after Article X, Section 2 was added, the rule limiting water use to that reasonably necessary "appl[ies] to the use of all water, under whatever right the use may be enjoyed." (Peabody v. City of Vallejo (1935) 2 Cal.2d 351, 367–68 (Peabody).) The rule of reasonableness is now "the overriding principle governing the use of water in California." (People ex rel. State Water Resources Control Bd. v. Forni (1976) 54 Cal.App.3d 743, 750 (Forni).)
>
> California courts have never defined, nor as far as we have been able to determine, even attempted to define what constitutes an unreasonable use of water, perhaps because the reasonableness of any particular use depends largely on the circumstances. (Peabody, supra, 2 Cal.2d at p. 368.) "What may be a reasonable beneficial use, where water is present in excess of all needs, would not be a reasonable beneficial use in an area of great scarcity and great need. What is a beneficial use at one time may, because of changed conditions, become a waste of water at a later time." (Tulare Dist. v. Lindsay–Strathmore Dist. (1935) 3 Cal.2d 489, 567.) In this regard, the Joslin court commented, "Although, as we have said, what is a reasonable use of water depends on the circumstances of each case, such an inquiry cannot be resolved in vacuo isolated from statewide considerations of transcendent importance. Paramount among these, we see the ever increasing need for the conservation of water in this state, an inescapable reality of life quite apart from its express recognition in [Article X, Section 2]." ([Joslin v. Marin Municipal Water District (1967) 67 Cal.2d 132, 140 (Joslin)]; see similarly In re Waters of Long Valley Creek Stream System (1979) 25 Cal.3d 339, 354 ["it appears self-evident that the reasonableness of a riparian use cannot be determined without considering the effect of such use on all the needs of those in the stream system [citation], nor can it be made 'in vacuo isolated from statewide considerations of transcendent importance'"].) Few decisions have ruled on the reasonableness of a specific use of water, but in separate cases the Supreme Court has concluded, essentially as self-evident, that the use of water for the sole purpose of flooding the land to kill gophers and squirrels is unreasonable (Tulare Dist., at p. 568), as is the use of floodwaters solely to deposit sand and gravel on flooded land (Joslin, at p. 141.)

And the responsibility and authority of the SWRCB to prevent unreasonable use of water extends to all users, The Board's authority to prevent unreasonable or wasteful use of water extends to all users, regardless of the basis under which the users' water rights are held. ([*California Farm Bureau Federation vs. State Water Resources Control Board (2011) 51 Cal.4th 421, 429].)*

Considering the conditions of drought which are described in the "drought emergency" declared by Governor Brown - the curtailments of water rights, the serial waivers of D-1641 standards to protect fish and wildlife and water quality in the Delta watershed, and the continual weakening of temperature compliance requirements on the Sacramento River - it is time for the SWRCB to declare flood irrigation by agriculture during the drought emergency a waste and unreasonable use until the emergency is over.

If the SWRCB can require urban conservation, it can also require conservation in agriculture. As former SWRCB chief counsel and Delta Watermaster Craig Wilson put it “flood irrigating a field during drought can be considered unreasonable. Flood irrigation in the Sacramento Valley in particular is unreasonable when endangered salmon are facing extinction.

Alfalfa and irrigated pasture alone consumes 8.6 MAF of water in California and provides low net revenue and few jobs. The SWRCB can and must reduce the quantity of water allocated to irrigated pasture and low-value crops like alfalfa that use prodigious amounts of water and have very high “applied water” coefficients relative to other crops during the drought emergency. To continue this use is unreasonable and a waste of water, and must be stopped or reduced until the drought emergency is declared over.

The continued killing of threatened and endangered species by obsolete and non-protective export pumping facilities simply because the state and federal water contractors refuse to pay for new state-of-the-art fish screens is an unreasonable method of diversion. This is especially true when water diverted through those facilities deprives listed species of water and primary production necessary for survival. The SWRCB can and must curtail south Delta exports during the drought emergency until D-1641 water quality standards are met.

The SWRCB must also consider public trust issues in proceedings that concern water rights and water quality based on reserved jurisdiction or under the doctrine of reasonable use. The SWRCB may also modify permits of “the projects” that require the appropriator to reduce the quantity of exports. *United States v. SWRCB* (1986) 182 Cal.App. 3d 82, 124-131. The SWRCB has a complaint procedure that can exercise authority over both federal and state water projects by virtue of having state water rights permits issued by the Board.

The State’s management responsibilities include broad discretion to promote trust uses, such as the continued survival Chinook salmon in the Sacramento River, provided the discretion is exercised consistent with constitutional and statutory constraints. *People v. California Fish Co.* (1913) 166 Cal. 576, 597. While the State has discretion to promote trust issues, the SWRCB has “an affirmative duty” to protect trust resources. See *Illinois Central Railroad v. Illinois,* 146 U.S. 387; and *National Audubon Society v. Superior Court* (1983) 33 Cal.3d 419 (The state may not abdicate its supervisory role any more than the state may abdicate its police power); see also Stevens, The Public Trust: *A Sovereign’s Ancient Prerogative Becomes the People’s Environmental Right,* 14 U.C. Davis Law Review 195, 223.

Fish and wildlife are natural resources unequivocally protected by state sovereignty, whereby ownership of the resource is reserved to the states. *Geer v. Connecticut,* (1896) 161 U.S. 519. The court in *Audubon v. Superior Court,* (1983) 33 Cal.3d. 419 held that “no one may obtain a vested right to undertake an act that is harmful to the trust.” See also *SWRCB D-1644* (Yuba River) at page 29. The supremacy of the public trust over private individuals is reflected in a “judicial presumption against state or legislative alienation of trust resources.” *People v. California Fish*; see also *Illinois Central v. Illinois* (1892) 146 U.S. 387; *Montana v. U.S.*, (1981) 450 U.S.544. Historically, state sovereign ownership was limited to “the traditional triad of uses” – commerce, navigation, and fishing.

However, in 1971 the California Supreme Court expanded the protected uses to cover the environment generally. *Marks v. Whitney* (1971) 6 Cal 3d. 251, 259-260. State sovereign ownership imposes restraints on the state's discretion regarding the use of navigable waters. The use of trust resources must be consistent with the general trust purposes or it is invalid. *State of California v. Superior Court* (Lyon) (1981) 29 Cal 3d. 210, 220-230; *Marks v. Whitney*, supra; *City of Long Beach v. Mansell*, (1970) 3 Cal 3d. 462, 482-485. Preservation of a public trust resource such as the Sacramento River and San Francisco Bay/Delta estuary is a legitimate disposition of the public trust resource, and is consistent with general trust purposes. Thus, tidelands and water may be burdened with a negative easement against any active use or disposition of the trust reserve. Id; *National Audubon*, supra; *State of California v. Superior Court* (Fogerty), (1981) 29 Cal 3d. 240, 249-250.

Consequently, the SWRCB has both the authority and responsibility under its reserved jurisdiction in the permits and licenses of the USBR, and under its continuing authority and responsibilities pursuant to the public trust and reasonableness doctrine to protect fisheries, public trust resources and beneficial uses. To protect those resources and uses, it approved, among other things, the Basin Plan and issued WR Order 90-05 to protect the Sacramento River and issued the Bay-Delta Plan and D-1641 to protect the Sacramento-San Joaquin Delta Estuary.

Unfortunately, the SWRCB has ignored reasonable use and public trust considerations in its decision-making. It failed to analyze, discuss or justify its decision to significantly weaken protection for Sacramento River fisheries as opposed to maintaining near 75% deliveries to Settlement Contractors in its 7 July 2015 Order. The Order is devoid of any analysis and discussion weighing the costs and benefits of sending public trust species into extinction versus fallowing cropland that will be replanted when rains return. There is no economic study of Sacramento Valley agricultural beneficial uses to determine which crops provide important employment and economic benefits relative to crops that require large quantities of water but provide low net economic return and few jobs. Nor is there any analysis of "health and safety" needs and urban uses as opposed to agricultural or environmental.

USBR's pattern and practice of delivering near normal water supplies in the early years of drought, depleting carryover storage and then relying on the SWRCB to weaken water quality standards established to protect public trust resources as successive dry years occur has been amply documented in multiple documents and TUCP proceedings over the last several years. The SWRCB has failed to establish minimum reservoir storage levels that ensure compliance with water quality standards protective of public trust resources. When successive dry years occur, it then routinely weakens those standards, with little regard to its public trust and constitutional obligations.

In WR Order 92-02, the SWRCB previously made clear that water necessary to comply with water quality standards is not available for delivery for consumptive purposes. It must now explain or justify why it now chooses to reallocate that water to the Sacramento Settlement Contractors. Weakening water quality objectives and requirements simply because USBR recklessly delivered water that was otherwise necessary to maintain sufficient carryover storage to comply with water quality objectives and to protect public trust resources and agricultural beneficial uses in the Delta is a violation of Public Trust Doctrine. To send fisheries into extinction while continuing to supply water for low value crops like pasture and alfalfa is an unreasonable use of water and a violation of Public Trust Doctrine and the California Constitution.

It is not the SWRCB's responsibility or legal right to sacrifice public trust resources and the Sacramento River's beneficial uses in order to absolve USBR of the consequences of egregious mismanagement. If customers of water contractors are now suffering because USBR failed to exercise prudence and due diligence in water management and rashly delivered near normal water supplies in initial drought years with little thought that another dry year might occur, it is USBR and not the SWRCB that has the responsibility to alleviate the suffering it caused.

In Conclusion

We request that the SWRCB immediately use its public trust, constitutional and water rights authorities to reduce water deliveries to low valued crops that are further depleting already inadequate cold water reserves, to require USBR to modify operations to ensure that sufficient carryover reserves of cold water necessary to comply with CWA and Basin Plan temperature criteria remain in Shasta Reservoir, and to issue sanctions against USBR for its willful disregard for public trust resources and beneficial uses. We also request that the SWRCB accelerate the present review of Bay-Delta standards, including a comprehensive balancing of the public trust with competing uses, and provide us a response to our 13 August 2014 complaint regarding illegal diversion by DWR and USBR and petition to adjudicate Central Valley waters.

Thank you for your consideration. If you have questions or require clarification, please don't hesitate to contact us.

Sincerely,

Bill Jennings

Introduction

The Vernalis Adaptive Management Plan (VAMP) as part of the San Joaquin River Agreement has been measuring juvenile salmon survival through the Delta since 2000 (SJRGA 2013). Prior to 2000, similar south Delta coded-wire-tag (CWT) studies were funded by the Interagency Ecological Program and others (Brandes and McLain 2001). Since 2008, survival of juvenile Chinook Salmon through, or in, the Delta has been measured using acoustic tags. The main objective of the VAMP was to better understand the relationship between Chinook Salmon smolt survival through the Delta and San Joaquin River flows and combined CVP and SWP exports in the presence of the physical head of Old River barrier (HORB). The San Joaquin River Agreement and the VAMP study ended in 2011.

In 2012, the main objective of the Chinook Salmon survival study was to estimate survival through the Delta during the San Joaquin River Flow Modification Project (USBR 2012), during which the Merced River flows were augmented between April 15 and May 15, and compare it to survival, without the flow augmentation (after May 15), in the presence of the HORB. As part of the National Marine Fisheries Service and California Department of Water Resources Joint Stipulation Regarding South Delta Operations during April and May of 2012 (http://www.westcoast.fisheries.noaa.gov/central_valley/water_operations/ocapstip.html; accessed 8/27/15), the physical HORB was installed in 2012. The barrier had eight culverts in 2012, compared to between two and six culverts as in past years. Funding for this study was provided by the restoration fund of the Central Valley Project Improvement Act, the California Department of Water Resources (CDWR) and the U.S. Bureau of Reclamation (USBR).

These salmon studies also estimated route selection at some channel junctions in the south Delta along the main stem San Joaquin River and provided information on how route selection into some reaches influences overall survival through the Delta to Chipps Island. Recent advances in acoustic technology have allowed investigators to evaluate the influence of route selection and reach-specific survival of salmon to overall survival through the Sacramento-San Joaquin Delta (Perry et al. 2010). In this study, the hypothesis focused on the impact of changes in hydrology with the HORB, as the primary factor relative to juvenile salmon survival however we are aware that many other factors also influence survival through the Delta.

Goals and Objectives

The goal of this study was to determine if there were differences in survival resulting from changes in hydrology (i.e. increased flow) with the HORB installed.

Objectives:

1. Determine survival of emigrating salmon smolts from Mossdale to Chipps Island during two time periods (prior to May 15 and after May 15) in the presence of the HORB to determine if there was a benefit from the flow augmentation from the Merced River in the spring of 2012.
2. Assess whether the higher flows resulted in a reduction in travel time; a potential mechanism for why survival may be higher with higher flows.
3. Identify route selection at HOR and Turner Cut under the two periods with varied flows to determine its effect on survival to Chipps Island in 2012.
4. Assess the influence of flow on survival between Mossdale and Jersey Point with the HOR barrier installed in 2012 and compare it to past years to further evaluate if the increased flow from the Merced River flow augmentation likely resulted in higher smolt survival through the Delta.

Background

Survival during the smolt life-stage was assumed to be the link associated with two statistically significant relationships between San Joaquin basin escapement and 1) San Joaquin River flow at Vernalis and 2) the ratio of San Joaquin River flow to Central Valley Project and State Water Project exports, 2 ½ years earlier (Figures 5-20 and 5-21 in SJRGA 2007). It is these relationships between flow and flow/exports and escapement that are the basis for the hypothesis that increasing flow and decreasing exports during the smolt outmigration would increase adult escapement and production in the San Joaquin basin.

The early, pre-VAMP studies compared survival of CWT Feather River Hatchery (FRH) smolts released into upper Old River to those released on the main stem San Joaquin River at Dos Reis. Dos Reis is located on the San Joaquin River downstream of the head of Old River. These studies were conducted between 1985 and 1990 and suggested that survival was higher for salmon smolts released on the main stem San Joaquin River at Dos Reis than for fish released into Old River (Brandes and McLain 2001). The results of these studies were the basis for recommending a rock barrier at the head of Old River (HORB) to prevent juvenile salmon from migrating down Old River where survival appeared to be less.

CWT releases made at Dos Reis were also used to assess the survival of salmon smolts on the San Joaquin River downstream of Old River. Although it is assumed that fish released at Dos Reis migrated downstream via the main stem San Joaquin River, there is the potential for fish released at Dos Reis to have moved upstream into Old River on flood tides, especially during periods of low San Joaquin River flows and high exports or into the interior Delta via Turner or Columbia Cuts or other downstream connections to the interior Delta. Data from 1989 to 1999 indicated that as San Joaquin River flows increased downstream of Old River, survival increased from Dos Reis to Jersey Point (Figure 5-14 in SJRGA 2007). These data provided the basis for the hypothesis that increased flow in the San Joaquin

River would increase salmon smolt survival. However, with the addition of more recent data (2005 and 2006) from recoveries in the trawls (as there were no or limited recovery data from the ocean fishery due to fishery closures in 2008 and 2009), the strength of this relationship appeared to lessen (Figure 5-13 in SJRGA 2007).

With the HORB in place, the majority of the fish migrating downstream would stay on the main stem San Joaquin River at the junction between the San Joaquin River and the head of Old River. With the HORB, a statistically significant relationship between CWT survival in the reach between Mossdale or Durham Ferry and Jersey Point and San Joaquin River flow at Vernalis has been observed ($r^2 = 0.73$, $p<0.01$; Figure 5-11 in SJRGA 2007), further supporting our hypothesis that increased flow in the San Joaquin River would increase juvenile salmon survival in the Delta.

In 2010, as part of the VAMP peer review, a statistical model was used to model survival through the Delta as a function of flow and exports, based on the CWT releases in the south Delta (Appendix 1). The results of this modeling also suggested survival was generally higher on the San Joaquin River than in Old River and flow tended to improve survival in the San Joaquin River route, but there was a lot of environmental noise (low signal to noise ratio). This modeling also supported our hypothesis that a HORB would improve survival, because it would reduce the number of smolts migrating through Old River.

Conceptual Model

Our hypothesis in 2012 was that survival would increase with increased flow from the Merced River flow augmentation in the presence of the HORB. Flows were an average of 3,543 cfs during the flow augmentation period and 2,327 cfs afterwards. A potential mechanism for increased survival with increased flow is that increased flow results in shorter travel times (i.e. increased migration rates) through the riverine parts of the Delta, and thus reduces the period of exposure to mortality factors such as high water temperature, predation and toxics (Figure 1). Increased flow is also expected to reduce the effect of the mortality factors by 1) decreasing water temperatures to less stressful levels for juvenile salmon, 2) decreasing the impacts of predation due to lower metabolic rates of predators at lower water temperatures and 3) reducing toxicity concentrations through dilution (Figure 1). Survival through the entire Delta (i.e. to Chipps Island) was expected to increase with the higher flows in 2012 as a consequence of higher survival through the riverine portion of the Delta because of these hypothesized relationships.

The higher flows provided by the Merced flow augmentation in 2012 may also have resulted in the tidal prism moving further downstream, because most of the increased flow would have stayed in the San Joaquin River at the head of Old River (HOR) junction with the HORB, in contrast to when there is no HORB and a large majority of the flow moves into Old River at that junction. The shift in the tidal prism's position serves to increase the portion of the Delta that is riverine and the portion of the migration pathway that potentially responds to decreases in travel time in response to increased flow (Figure 1). It is unclear how far the tidal prism would be moved downstream from the increase in flow of approximately 1200 cubic feet per second (cfs) from the Merced flow augmentation in 2012. Additionally, the shifted position of the tidal prism further downstream, which is dependent on the magnitude of the increased flow, could also potentially reduce the proportion of flow and tagged fish that enter Turner Cut (Figure 1). In summary, survival through the entire Delta was expected to increase as the riverine component of the Delta increased and the proportion of water and fish that were diverted into Turner Cut was reduced from a positional shift of the tidal prism downstream from higher flows.

Once fish enter the interior Delta or into the strongly tidally influenced San Joaquin River, residence times are hypothesized to increase and survival is hypothesized to decrease compared to the river reaches. The increased residence times are anticipated to increase the exposure time of juvenile salmonids to predation or other mortality factors. The incremental increase in flow from the Merced River flow augmentation was not anticipated to decrease water temperatures or dilute toxics in the tidally dominant areas of the Delta as much as the riverine reaches because inflow is a much lower proportion of overall flow in these tidally dominated regions. Lastly, the change to the flow patterns at the HOR from the installation and operation of the HORB was expected to result in fewer tagged fish being salvaged or entrained at the CVP and SWP in 2012 because a low proportion of the San Joaquin flow (~ 5%) and tagged fish enter Old River when the HORB is in place.

Study Design and Methods

This study was conducted in conjunction with a separate, but coordinated study assessing the HORB in 2012 (CDWR, 2015). As part of this HORB assessment, other groups of juvenile salmon were tagged with Hydroacoustic Technology Incorporated (HTI) tags prior to, during, and after the salmon tagging as part of this study (with VEMCO V5 tags). While the methods and results of the HTI study will not be discussed in this report, we have listed when the HTI fish were released with our study fish (Table 1).

Sample Size Analyses

A unique sample size analyses was not conducted for the 2012 study, instead we used information derived from the 2011 VAMP sample size analyses to guide release numbers for the 2012 study (SJRGA 2013). For a single release at Durham Ferry it was determined that a sample size of 475 fish would allow estimation of parameters for low route specific survival (0.05), with high detection probability (90-97%) at Chipps Island. To estimate a relative effect of 100%, between two routes (San Joaquin and Old River), 790 fish would need to be tagged with low survival and 410 for medium survival (SJRGA 2013). To estimate a relative effect between the two routes of 50%, 3,510 would need to be released in years with low survival and 1,800 would need to be released in years with medium survival (SJRGA 2013). We did not have the resources to purchase enough tags to provide the power to estimate the relative effects between routes at either of these levels for the two groups released in 2012.

Study Fish

Study fish were obtained from the Merced River Hatchery (MRH) and transported to the Tracy Fish Collection Facility (TFCF) of the CVP on April 20 and May 7 for tagging. Fish were kept in chilled, ozonized, Delta water (14-15 ° C) until 3-4 days before tagging to minimize the progression of proliferative kidney disease (PKD). Low water temperatures inhibit the development of PKD (Ferguson 1981): PKD is progressive at temperatures greater than 15° C (Ferguson 1981). Thus 3-4 days before tagging, tanks holding the fish were slowly switched to ambient Delta water so that they could acclimate to Delta water temperatures prior to tagging and transport to the release site. Fish were sorted such that they were greater than 13 grams (~105 mm forklength [FL]) prior to tagging. Tagged study fish averaged 18.0 grams (SD = 3.7), and 112.8 mm FL (SD = 7.2). Fish were taken off feed 24 hours prior to moving them from MRH to the TFCF and 24 hours prior to surgery.

Tags

Juvenile salmon were tagged with VEMCO V5 180 kHz transmitters that weighed 0.66 grams (g) in air on average (SD = 0.012). Tags were 12.7 millimeters (mm) long, 4.3 mm in height, and 5.6 mm wide (http://vemco.com/products/v4-v5-180khz/; accessed 6/15/15). The percentage of tag weight to body weight averaged 3.8% (SD = 0.7%) for the 960 fish tagged, well below the recommended 5%. Only 3% (34 of the 960 fish) had a tag weight to body weight ratio slightly greater than 5%, with all less than 5.4%.

Tags were custom programmed with two separate codes; a traditional Pulse Position Modulation (PPM) style coding along with a new hybrid PPM/High Residence (HR) coding. The HR component of the coding allows for detection at high residence receivers. High residence receivers were placed where tag signal collisions (i.e. many tags emitting signals at the same time to the same receiver) were anticipated (CVP, CCF). The transmission of the PPM identification code was followed by a 25-35 second delay, followed by the PPM/HR code, followed by a 25-35 second delay, and then back to the PPM code, etc. The PPM code consisted of 8 pings approximately every 1.2 to 1.5 seconds. The PPM/HR code consisted of 1 PPM code and 8 HR codes (all the same for each individual fish) with 8 pings approximately every 1.2-1.5 seconds.

Tags were soaked in saline water for at least 24 hours prior to tag activation. Tags were activated using a VEMCO tag activator approximately 24 hours prior to tag implantation. For the first week of releases, time of activation was estimated to the nearest hour, whereas tag activation was identified to the nearest minute for the second group of releases.

Tagging training

Training those who conducted the tagging occurred between April 9 and April 13 at the TFCF using Chinook Salmon from MRH. Three hundred fish were used for training, and were brought to the TFCF on April 4. The training was conducted by staff from the U.S. Geological Survey (USGS)'s Columbia River Research Laboratory (CRRL). During training, the CRRL refined standard operating procedures, (SOP), and trained personnel to surgically implant acoustic tags (Liedtke 2012). Returning taggers received a refresher course on training during which they were required to tag a minimum of 35 fish. New taggers received a more thorough training on surgical techniques and were required to tag a minimum of 75 fish during training. Training included sessions on knot tying, tagging bananas, tagging dead fish and finally tagging live fish, holding them overnight and necropsying them to evaluate techniques and provide feed-back. Lastly, a mock tagging session was held on April 13 to practice logistic procedures and to identify potential problems and discuss solutions.

Tagging

In 2012, two groups of 480 Chinook Salmon were tagged with VEMCO V5 tags over two weekly periods: May 1-5 and May 16-20. Each group of salmon was tagged in 3 days, over a 6 day period; Chinook Salmon were tagged every other day, to facilitate survival comparisons between Chinook Salmon and steelhead (the comparison between salmon and steelhead will not be discussed in this report). Two sessions of tagging were conducted for salmon: one in the morning and one in the afternoon. Morning and afternoon tagging sessions were further divided into shifts with each shift incorporating groups of salmon tagged with either VEMCO or HTI tags. The salmon tagged as part of this study were tagged on May 1, May 3, May 5 and May 16, May 18 and May 20 (Table 1). Tagging was conducted at the TFCF as was done since 2009. Four surgeons were used to tag the fish and each surgeon had an assistant. Three additional individuals (runners) helped to move fish into and out of the tagging operation.

Tags were inserted into the fish body cavity after the fish had been anesthetized with between 6.0 and 6.5 millileters (ml) of tricane methanesulfonate (MS-222) buffered with sodium bicarbonate, until they lost equilibrium. Fish were weighed (to the nearest 0.1 g) and measured to the nearest mm (FL). Surgeries took between 1 minute 20 seconds and 6 minutes 57 seconds, but most were within 2 to 3 minutes. Tagging was done using standard operating procedures (SOP) developed by the CRRL and refined during the training week. The SOP (Appendix 2) directed all aspects of the tagging operation and was based on Adams et al. (1998) and Martinelli et al (1998) and modified as needed.

Transmitter Validation

After the surgical implantation of tags, one or two fish were placed into 19 liter (L) (5 gal) perforated buckets with high dissolved oxygen concentrations (110-130%) and allowed to recover from anesthesia for 10 minutes. During this time, tag codes were verified using a 180 khz hydrophone connected to a VR100.   Tags that would not verify using the VR100 were replaced with a new tag in a new fish. After validation, a pair of buckets containing either one or two fish was combined to create a bucket of 3 fish. The bucket was then moved into a holding flume of circulating water to await loading to the transport truck once the tagging session was completed.

Transport to Release Site

After tagging, the 19L perforated buckets, which usually contained three tagged Chinook Salmon each, were held in a flume at the TFCF until they were loaded into transport tanks at the end of each tagging session (morning or afternoon). Immediately prior to loading, all fish were visually inspected for mortality or signs of poor recovery from tagging (e.g. erratic swimming behavior). Fish that died or were not recovering from surgery were replaced with a new tagged fish.

In order to minimize the stress associated with moving fish and for tracking smaller groups of individually tagged fish, two specially designed transport tanks were used to move Chinook Salmon from the TFCF, where the tagging occurred, to the release site at Durham Ferry. The transport tanks for Chinook Salmon were designed to securely hold a series of 19 L perforated buckets filled with fish. Tanks had an internal frame that held 21 or 30 buckets in individual compartments to minimize contact between containers and to prevent tipping.   Buckets were covered in the transport tanks with stretched cargo nets to assure buckets did not tip over and lids did not come off. Both transport tanks were mounted on the bed of a 26 foot flatbed truck that was equipped with an oxygen tank and hosing to deliver oxygen to each of the tanks during transport. Two trips to the release site were made each tagging day, with the morning and afternoon sessions of tagged fish being transported separately (Table 1).

After loading buckets into the transport tank, de-chlorinated ice was usually added to the transport tanks to either 1) reduce water temperatures during transport such that they would be closer to the river temperature at the release site, or 2) to prevent water temperatures from increasing during transport. Water temperature and dissolved oxygen (DO) in the transport tanks were recorded after loading buckets and ice (if added) into transport tanks; before leaving the TFCF and at the release site after transport, prior to unloading buckets. The temperature and DO were also measured in the river at the holding/release site.

Transfer to Holding Containers

Once at the release site, the perforated buckets, which typically contained three Chinook Salmon each, were removed from the transport tanks and moved to the river. For all releases, perforated buckets were placed into "sleeves" in a pick-up truck and driven a short distance to the river's edge. A "sleeve" is a similar-sized, non-perforated bucket that allows more water to stay in the perforated bucket than would be the case without placing it in a "sleeve". Perforated buckets in sleeves were unloaded from the pick-up truck and carried to the river. Perforated buckets were then separated from the sleeves at the shoreline and submerged in-river to be transported to the holding containers which were anchored one to two meters from shore. Water temperature and dissolved oxygen levels were measured in the river prior to placing the salmon into the holding containers in the river.

Once at the river's edge, the tagged Chinook Salmon were transferred from the perforated buckets to the holding containers; 120 L (32 gal) perforated plastic garbage cans held in the river. These holding containers were perforated with hole sizes of 0.64 cm in diameter. Five buckets containing fish were emptied into each perforated garbage can. Only four of the five buckets emptied into the garbage cans contained VEMCO tagged fish while the fifth bucket of each group held 3 to 4 HTI fish. Each bucket and garbage can was labeled to track the specific tag codes and assure fish were transferred to the correct holding can for later release at the correct time. Tagged salmon were held in the perforated garbage cans for approximately 24 hours prior to release. Steelhead for the 6 Year Study were held at the same location and released either the day before or the day after the releases of Chinook Salmon; steelhead were released May 1-2, May 3-4, and May 5-6, and May 18-19, May 20-21, and May 22-23.

Fish Releases

The Chinook Salmon, held in perforated garbage cans, were transported downstream by boat to the release location which was in the middle of the channel downstream of the holding location. The fish were released downstream of the holding site to potentially reduce initial predation of tagged fish immediately after release, under the assumption that predators may congregate near the holding location. Releases were made every 4 hours after the 24 hour holding period, at approximately 1500, 1900, 2300 hours (the day after tagging), and 0300, 0700, and 1100 hours (2 days after tagging)(Table 1). Fish releases were made at these four-hour increments through-out the 24-hour period to spread the fish out and to better represent naturally spawned fish that may migrate downstream through-out the 24 hour period. The Chinook Salmon releases were made on May 2-3, May 4-5, May 6-7 and May 17-18, May 19-20, May 21-22 (Table 1).

Immediately prior to release, each holding container was checked for any dead or impaired fish. At the release time, the lid was removed and the holding container was rotated to look for mortalities. The container was then inverted to allow the fish to be released into the river. After the holding container was inverted, the time was recorded. As the holding containers were flipped back over, they were inspected to make sure that none of the released fish swam back into the container. Some exceptions to this procedure occurred as one group was released from shore due to high winds and waves, and three groups were released from shore due to a dead battery in the boat (Table 1).

Once the release was completed, the information on any dead fish was recorded and the tags removed. The tags were bagged and labeled and returned to the tagging location or office for tag code identification.

Dummy-tagged fish

In order to evaluate the effects of tagging and transport on the survival of the tagged fish, several groups of Chinook Salmon were implanted with inactive ("dummy") transmitters. Dummy tags in 2012 were systematically interspersed into the tagging order for each release group. For each day of tagging and transport, 15 fish were implanted with dummy transmitters and included in the tagging process (Table 1). Procedures for tagging these fish, transporting them to the release site, and holding them at the release site were the same as for fish with active transmitters. Dummy-tagged fish were evaluated for condition and mortality after being held at the release site for approximately 48 hours. After being held, dummy tagged fish were assessed qualitatively for percent scale loss, body color, fin hemorrhaging, eye quality, and gill coloration (Table 2). In addition, two additional groups of 15 dummy-tagged fish (tagged on the same day) were held for approximately 48 hours and assessed for pathogens and other diseases (discussed below).

Fish Health Assessment

As a part of the 2012 South Delta Chinook Salmon Survival Study, the U.S. Fish and Wildlife Service's CA-NV Fish Health Center (CNFHC) conducted a general pathogen screening and smolt physiological assessment on dummy-tagged fish held at the release site for 48 hours. The health and physiological condition of the study fish can help explain their performance and survival during the studies. Pathogen screenings during past VAMP studies using MRH Chinook Salmon have regularly found infection with the myxozoan parasite *Tetracapsuloides bryosalmonae*, the causative agent of Proliferative Kidney Disease (PKD). This parasite has been shown to cause mortality in Chinook Salmon with increased mortality and faster disease progression in fish at higher water temperatures (Ferguson 1981; Foott et al. 2007). The objectives of this element of the project were to evaluate the juvenile Chinook Salmon used for the studies for specific fish pathogens including *Tetracapsuloides bryosalmonae* and assess smolt development from gill Na^+ - K^+- ATPase activity to determine potential differences in health between groups. For a complete description of methods see Appendix 4.

Tag life tests

Two tag life tests were conducted in conjunction with this study. The first tag-life study began on May 16, with 43 tags. The second tag-life study began on May 24, with 40 tags. Tags were activated and then put into mesh bags and held in holding tanks at the TFCF containing ambient Delta water. A VEMCO VR2W was installed in each tank for recording detections of each individual tag. Files of detections were reviewed to identify the tag failure of each individual tag used in the tag life study. These results were then compared to observed tag travel times of the tags used in the study to estimate their tag life and make any necessary corrections to fish survival estimates.

Tag retention test

On May 25, 2012, each of the 4 surgeons tagged 9 to 10 fish with dummy tags to assess tag retention and longer-term mortality of tagged fish. Thirteen of these fish were held in each of 3 separate tanks for 30 days to determine if there was any longer-term mortality of the tagged fish and whether any tags were expelled. Fish were held in tanks at the TFCF for the duration of the 30 days.

Receiver deployment, retrieval, and receiver database

The 2012 Chinook Salmon Survival Study, in conjunction with the 6-Year Steelhead Study used receivers at 26 locations in the lower San Joaquin River and South Delta to Chipps Island (i.e. Mallard Slough) for detecting juvenile salmon and steelhead as they migrated through the Delta (Figure 2). These receivers were placed at key locations throughout the south Delta and similar to those used in VAMP in 2010 and 2011 (Figure 2). Although locations of receivers are similar, the VAMP study used an HTI receiver array, whereas the 2012 study used a VEMCO receiver array. The USBR funded the USGS to deploy, maintain and remove all of the receivers in the array, including receivers at both Jersey Point and Chipps Island in 2012. The detections of tagged salmon on these receivers allowed survival of juvenile salmon to be estimated from Durham Ferry to Chipps Island.

Data processing and survival model

This study used the tag detection data recorded on the receiver array to populate a release-recapture model similar to that used in the 2010 and 2011 VAMP studies (SJGRA 2011, 2013). The release-recapture model used the pattern of detections among all tags to estimate the probabilities of route selection, survival, and transition in various reaches and detection probability at receivers. Parameter estimates were then combined to calculate estimates of reach-specific survival, route-specific survival, and total survival through the Delta to Chipps Island. The release-recapture model (described in more detail below) is a multi-state model based on the models of Cormack (1964), Jolly (1965), and Seber (1965), in combination with the route-specific survival model of Skalski et al. (2002). Tags that appeared to be in predators were identified, and the model was fit first to the complete data set that included all detections, including those from predators, and then to the reduced data set that omitted detections that appeared to come from predators. This allowed comparison of estimates of survival and route selection probabilities with and without tags that appeared to come from predators in order to assess the potential bias associated with predator detections; this approach was similar to that used in the 2010 and 2011 VAMP studies (SJRGA 2011, 2013). More details on all statistical methods follow.

Statistical Methods

Data Processing for Survival Analysis

The University of Washington (UW) received the database of tagging and release data from the US Fish and Wildlife Service (USFWS). The tagging database included the date and time of tagging surgery for each tagged Chinook Salmon released in 2012, as well as the name of the surgeon (i.e., tagger), and the date and time of release of the tagged fish to the river. Fish size (length and weight), tag size, and any notes about fish condition were included, as well as the survival status of the fish at the time of release. Tag serial number and three unique tagging codes were provided for each tag, representing codes for various types of signal coding. Tagging data were summarized according to release group and tagger, and were cross-checked with Pat Brandes (USFWS) for quality control.

Acoustic tag detection data collected at individual monitoring sites (Table 3) were transferred to the USGS in Sacramento, California. A multiple-step process was used to identify and verify detections of fish in the data files, and produce summaries of detection data suitable for converting to tag detection histories. Detections were classified as valid if two or more pings were recorded within a 30 minute time frame on the hydrophones comprising a detection site from any of the three tag codes associated with the tag. The UW received the primary database of autoprocessed detection data from the USGS. These data included the date, time, location, and tag codes and serial number of each valid detection of the acoustic Chinook Salmon tags on the fixed site receivers. The tag serial number was linked to the acoustic tag ID, and was used to identify tag activation time, tag release time, and release group from the tagging database.

The autoprocessed database was cleaned to remove obviously invalid detections. The UW identified potentially invalid detections based on unreasonable travel times or unlikely transitions between detections, and queried the USGS processor about any discrepancies. All corrections were noted and made to the database. All subsequent analysis was based on this cleaned database.

The information for each tag in the database included the date and time of the beginning and end of each detection event when a tag was detected. Unique detection events were distinguished by detection on a separate hydrophone or by a time delay of 30 minutes between repeated hits on the same receiver. Separate events were also distinguished by unique tag encoding schemes (e.g., PPM vs. hybrid PPM/HR). The cleaned detection event data were converted to detections denoting the beginning and end of receiver “visits,” with consecutive visits to a receiver separated either by a gap of 12 hours or more between detections on the receiver, or by detection on a different receiver. Detections from receivers in dual or redundant arrays were pooled for this purpose, as were detections using different tag coding schemes.

Distinguishing between Detections of Salmon and Predators

The possibility of predatory fish eating tagged study fish and then moving past one or more fixed site receivers complicated analysis of the detection data. The Chinook Salmon survival model depended on the assumption that all detections of the acoustic tags represented live juvenile Chinook Salmon, rather than a mix of live salmon and predators that temporarily had a salmon tag in their gut. Without removing the detections that came from predators, the survival model would produce potentially biased survival estimates of actively migrating juvenile Chinook Salmon through the Delta. The size and type (positive or negative) of the bias would depend on the amount of predation by predatory fish and the spatial distribution of the predatory fish after eating the tagged salmon. In order to minimize bias, the detection data were filtered for predator detections, and detections assumed to come from predators were identified.

The predator filter used for analysis of the 2012 data was based on the predator filter designed and used in the analysis of the 2011 data (SJRGA 2013). That predator filter in turn was based on predator analyses presented by Vogel (2010, 2011), as well as conversations with fisheries biologists familiar with the San Joaquin River and Delta regions and the predator decision processes used in previous years (SJRGA 2010, 2011). The filter was applied to all detections of all tags. Two data sets were then constructed: the full data set including all detections, including those classified as coming from predators (i.e., "predator-type"), and the reduced data set, restricted to those detections classified as coming from live Chinook Salmon smolts (i.e., "smolt-type"). The survival model was fit to both data sets separately. The results from the analysis of the reduced "smolt-type" data set are presented as the final results of the 2012 Chinook Salmon tagging study. Results from analysis of the full data set including "predator-type" detections were used to indicate the degree of uncertainty in survival estimates arising from the predator decision process.

The predator filter was based on assumed behavioral differences between salmon smolts and predators such as striped bass and white catfish. All detections were considered when implementing the filter, including detections from acoustic receivers that were not otherwise used in the survival model. As part of the decision process, environmental data including river flow, river stage, and water velocity were examined from several points throughout the Delta (Table 4), as available. Hydrologic data were downloaded from the California Data Exchange Center website (http://cdec.water.ca.gov/selectQuery.html) and the California Water Data Library (www.water.ca.gov/waterdatalibrary/) on 27 September 2013. Environmental data were reviewed for quality, and obvious errors were omitted.

For each tag detection, several steps were performed to determine if it should be classified as predator or salmon. Initially, all detections were assumed to be of live smolts. A tag was classified as a predator upon the first exhibition of predator-type behavior, with the acknowledged uncertainty that the salmon smolt may actually have been eaten sometime before the first obvious predator-type detection. Once a detection was classified as coming from a predator, all subsequent detections of that tag were likewise classified as predator detections. The assignment of predator status to a detection was made conservatively, with doubtful detections classified as coming from live salmon. In general, the decision process was based on the assumptions that (1) salmon smolts were unlikely to move against the flow, and (2) salmon smolts were actively migrating and thus wanted to move downriver, although they may have temporarily moved upstream with reverse flow.

A tag could be given a predator classification at a detection site on either arrival or departure from the site. A tag classified as being in a predator because of long travel time or movement against the flow was typically given a predator classification upon arrival at the detection site. On the other hand, a tag classified as being in a predator because of long residence time was given a predator classification upon departure from the detection site. Because the survival analysis estimated survival within reaches between sites, rather than survival during detection at a site, the predator classifications on departure from a site did not result in removal of the detection at that site from the reduced data set. However, all subsequent detections were removed from the reduced data set.

The predator filter used various criteria on several spatial and temporal scales, as described in detail in previous reports (e.g., SJRGA 2013). Criteria fit under various categories, described in more detail in SJRGA (2013): fish speed, residence time, upstream transitions, other unexpected transitions, travel time since release, and movements against flow. The criteria used in the 2011 study were updated to reflect river conditions and observed tag detection patterns in 2012 (Table 5a and 5b). Differences between the 2011 filter and the filter used for the 2012 study (in addition to those identified in Table 5a and 5b) were:

1. Minimum migration rates on upstream-directed transitions were set to 0.1-0.2 km/hr for most upstream transitions. Upstream transitions in Old River from the Highway 4 area to the CVP trashracks and in the Sacramento or San Joaquin River from Threemile Slough to Chipps Island were limited to migration rates no less than 0.5 km/hr.
2. Maximum regional residence times allowed for smolts were set at 60 hours for the San Joaquin River upstream of the head of Old River, and 360 hours in all other regions. In most cases, the maximum regional residence time allowed for smolts making a downstream-directed transition was set at 3 – 5 times the maximum allowable near-field residence time.
3. A maximum of 3 upstream forays and 15 upstream river kilometers was imposed.
4. Maximum allowable travel time since release at Durham Ferry was set at 15 days (360 hours).

The predator scoring and classification method used for the 2011 study was used again for the 2012 study, resulting in tags being classified as in either a predator or a smolt upon arrival at and departure from a given receiver site and visit; for more details, see SJRGA (2013). All detections of a tag subsequent to its first predator designation were classified as coming from a predator, as well.

The criteria used in the predator filter were spatially explicit, with different limits defined for different receivers and transitions (Table 5a and 5b). General components of the approach to various regions are described below. Only regions with observed detections are described; regions that follow the general guidelines described in SJRGA (2013) are not highlighted here.

DFU, DFD = Durham Ferry Upstream (A0) and Durham Ferry Downstream (A2): ignore flow and velocity measures, allow long travel time to accommodate initial disorientation after release, and allow few if any repeat visits.

SJL = San Joaquin River near Lathrop (A5): upstream transitions from Stockton sites are not allowed.

ORE = Old River East (B1): repeat visits are not allowed.

SJG = San Joaquin River at Garwood Bridge (A6): transitions from upstream require arrival on flood tide

SJNB = San Joaquin River at Navy Bridge Drive (A7): allow longer residence time if arrive at slack tide; repeated visits require arriving with opposite flow and velocity conditions to departure conditions.

MAC, MFE/MFW = MacDonald Island (A8), Medford Island (A9): repeated visits require arriving with opposite flow and velocity conditions to departure conditions.

TCE/TCW = Turner Cut (F1): should not move against flow; repeated visits require arriving with opposite flow and velocity conditions to departure conditions.

ORS = Old River South (B2): repeated visits require arriving with opposite flow and velocity conditions to departure conditions.

CVP = Central Valley Project (E1): allow multiple visits; transitions from downstream Old River should not have departed Old River site against flow; no repeat visits or arrivals from downstream if not pumping.

JPE/JPW, FRE/FRW = Jersey Point (G1), False River (H1): no flow/velocity restrictions; allowed for transition from Threemile Slough (TMS/TMN)

Constructing Detection Histories

For each tag, the detection data summarized on the "visit" scale was converted to a detection history (i.e., capture history) that indicated the chronological sequence of detections on the fixed site receivers throughout the study area. In cases in which a tag was observed passing a particular receiver or river junction multiple times, the detection history represented the final route of the tagged fish past the receiver or river junction. Detections from the receivers comprising certain dual arrays were pooled, thereby converting the dual arrays to redundant arrays: the San Joaquin River near Mossdale Bridge (MOS, site A4), Lathrop (SJL, A5), and Garwood Bridge (SJG, A6); and Old River East near the head of Old River (ORE, B1). For some release groups, the receivers comprising the dual array just downstream of the initial release site (DFD, A2) were also pooled in order to achieve a better model fit; in other cases, very low detection probabilities at this site required omitting this site from analysis. Likewise, in some cases the dual arrays at either MacDonald Island (MAC, A8) or Old River South (B2) were pooled in order to improve model fit.

Survival Model

A two-part multi-state statistical release-recapture model was developed to estimate salmon smolt survival and migration route parameters throughout the study area. The full two-part model incorporates all receivers, with the exception of the San Joaquin River receiver just upstream of the head of Old River (HOR = B0), the northern-most receivers in Old and Middle rivers (OLD =B4 and MRE = C3) and the Threemile Slough receivers (TMS/TMN = T1) (Table 3, Figure 2). Because many acoustic receivers in the interior delta had no or few detections, a reduced model was developed by simplifying the full model and limiting it to receivers with sufficient detections for analysis. The full model is described in detail first, and then the reduced model is presented.

Full Model

The full release-recapture model is a slightly simplified version of the model used to analyze 2011 steelhead data (Buchanan 2013), and similar to the model developed by Perry et al. (2010) and the model developed for the 2009 – 2011 VAMP studies (SJRGA 2010, 2011, 2013). Figure 2 shows the layout of the receivers using both descriptive labels for site names and the code names used in the survival model (Table 3). The survival model represents movement and perceived survival throughout the study area to the primary exit point at Chipps Island (i.e., Mallard Island) (Figure 3, Figure 4). Individual receivers comprising dual arrays were identified separately, using “a” and “b” to represent the upstream and downstream receivers, respectively. Not all sites were used in the survival model, although all were used in the predator filter.

Fish moving through the Delta toward Chipps Island may have used any of several routes. The two primary routes modeled were the San Joaquin River route (Route A) and the Old River route (Route B). Route A followed the San Joaquin River past the distributary point with Old River near the town of Lathrop and past the city of Stockton. Downstream of Stockton, fish in the San Joaquin River route (Route A) may have remained in the San Joaquin River past its confluence with the Sacramento River and on to Chipps Island. Alternatively, fish in Route A may have exited the San Joaquin River for the interior Delta at any of several places downstream of Stockton, including Turner Cut, Columbia Cut (just upstream of Medford Island), and the confluence of the San Joaquin River with either Old River or Middle River, at Mandeville Island. Of these four exit points from the San Joaquin River between Stockton and Jersey Point, only Turner Cut was monitored and assigned a route name (F, a subroute of route A). Fish that entered the interior Delta from any of these exit points may have either moved north through the interior Delta and reached Chipps Island by returning to the San Joaquin River and passing Jersey Point and the junction with False River, or they may have moved south through the interior Delta to the state or federal water export facilities, where they may have been salvaged and trucked to release points on the San Joaquin or Sacramento rivers just upstream of Chipps Island. All of these possibilities were included in both subroute F and route A.

For fish that entered Old River at its distributary point on the San Joaquin River just upstream of Lathrop (route B), there were several pathways available to Chipps Island. These fish may have migrated to Chipps Island either by moving northward in either the Old or Middle rivers through the interior Delta, or they may have moved to the state or federal water export facilities to be salvaged and trucked. The Middle River route (subroute C) was monitored and contained within Route B. Passage through the State Water Project via Clifton Court Forebay was monitored at the entrance to the forebay and assigned a route (subroute D). Likewise, passage through the federal Central Valley Project was monitored at the entrance trashracks and in the facility holding tank and assigned a route (subroute E). Subroutes D and E were both contained in subroutes C (Middle River) and F (Turner Cut), as well as in primary routes A (San Joaquin River) and B (Old River). All routes and subroutes included multiple unmonitored pathways for passing through the Delta to Chipps Island.

Several exit points from the San Joaquin River were monitored and given route names for convenience, although they did not determine unique routes to Chipps Island. The first exit point encountered was False River, located off the San Joaquin River just upstream of Jersey Point. Fish entering False River from the San Joaquin River entered the interior Delta at that point, and would not be expected to reach Chipps Island without subsequent detection in another route. Thus, False River was considered an exit point of the study area, rather than a waypoint on the route to Chipps Island. It was given a route name (H) for convenience. Likewise, Jersey Point and Chipps Island were not included in unique routes. Jersey Point was included in many of the previously named routes (in particular, routes A and B, and subroutes C and F), whereas Chipps Island (the final exit point) was included in all previously named routes and subroutes except route H. Thus, Jersey Point and Chipps Island were given their own route name (G). Three additional sets of receivers located in Old River (Route B) and Middle River (Subroute C) north of Highway 4 and in Threemile Slough (Route T) were not used in the survival model. The routes, subroutes, and study area exit points are summarized as follows:

A = San Joaquin River: survival
B = Old River: survival
C = Middle River: survival
D = State Water Project: survival
E = Central Valley Project: survival
F = Turner Cut: survival
G = Jersey Point, Chipps Island: survival, exit point
H = False River: exit point
T = Threemile Slough: not used in survival model

The release-recapture model used parameters that denote the probability of detection (P_{hi}), route entrainment (ψ_{hl}), Chinook Salmon survival (S_{hi}), and transition probabilities equivalent to the joint probability of movement and survival ($\phi_{kj,hi}$) (Figure 3, Figure 4, Table A5-1). Unique detection probabilities were estimated for the individual receivers in a dual array: P_{hia} represented the detection probability of the upstream array at station i in route h, and P_{hib} represented the detection probability of the downstream array.

The model parameters are:

P_{hi} = detection probability: probability of detection at telemetry station i within route h, conditional on surviving to station i, where i = ia, ib for the upstream, downstream receivers in a dual array, respectively.

S_{hi} = perceived survival probability: joint probability of migration and survival from telemetry station i to station i+1 within route h, conditional on surviving to station i.

ψ_{hl} = route entrainment probability: probability of a fish entering route h at junction l (l =1, 2), conditional on fish surviving to junction l.

$\phi_{kj,hi}$ = transition probability: joint probability of route entrainment, and survival; the probability of migrating, surviving, and moving from station j in route k to station i in route h, conditional on survival to station j in route k.

A variation on the parameter naming convention was used for parameters representing the transition probability to the junction of False River with the San Joaquin River, just upstream of Jersey Point (Figure 2). This river junction marks the distinction between routes G and H, so transition probabilities to this junction are named $\phi_{kj,GH}$ for the joint probability of surviving and moving from station j in route k to the False River junction. Fish may arrive at the junction either from the San Joaquin River or from the interior Delta. The complex tidal forces present in this region prevent distinguishing between smolts using False River as an exit from the San Joaquin and smolts using False River as an entrance to the San Joaquin from Frank's Tract. Regardless of which approach the fish used to reach this junction, the $\phi_{kj,GH}$ parameter (e.g. $\phi_{A9,GH}$) is the transition probability from station j in route k to the junction of False River with the San Joaquin River via any route; ψ_{G1} is the probability of moving downstream toward Jersey Point from the junction; and $\psi_{H1} = 1 - \psi_{G1}$ is the probability of exiting (or re-exiting) the San Joaquin River to False River from the junction (Figure 3).

Because of the complexity of routing in the vicinity of MacDonald Island (referred to as "Channel Markers" in reports from previous years, e.g., SJRGA 2013) on the San Joaquin River, Turner Cut, and Medford Island, and the possibility of reaching the interior Delta via either route A or route B, the full survival model that represented all routes was decomposed into two submodels for analysis. Submodel I modeled the overall migration from release at Durham Ferry to arrival at Chipps Island without modeling the specific routing from the lower San Joaquin River (i.e., from the Turner Cut Junction) through the interior Delta to Chipps Island, although it included detailed subroutes in route B for fish that entered Old River at its upstream junction with the San Joaquin River (Figure 3). In Submodel I, transitions from MacDonald Island (A8) and Turner Cut (F1) to Chipps Island were interpreted as survival probabilities ($S_{A8,G2}$ and $S_{F1,G2}$) because they represented all possible pathways from these sites to Chipps Island. Submodel II, on the other hand, focused entirely on Route A, and used a virtual release of tagged fish detected at the San Joaquin River receiver array near Lathrop, (SJL) to model the detailed routing from the lower San Joaquin River near MacDonald Island and Turner Cut through or around the interior Delta to Jersey Point and Chipps Island (Figure 4). Submodel II included the Medford Island detection site (A9), which was omitted from Submodel I because of complex routing in that region.

Reduced Model

Detection data of tagged Chinook Salmon in the interior Delta in 2012 were very sparse. There were very few detections at the downstream Old and Middle river sites (OR4 [model code B3] and MR4

[C2]) and Central Valley Project (model codes E1 and E2) receivers, and no detections in Middle River at its head (C1) or radial gates (D1 and D2) receivers. There were also no detections at False River (H1) used in the survival analysis because all False River detections were followed by detections either at Jersey Point (G1) or Chipps Island (G2). With so few detections in the Old River route and the interior Delta portions of the San Joaquin River route, it was not possible to fit the full release-recapture model to the 2012 Chinook Salmon data set. Instead, it was necessary to omit all detection sites in the Old River route other than the first two sites in that route: ORE (B1) and ORS (B2). The simplified submodel I (Figure 5) includes the overall probability of surviving from the Old River receivers near the head of Middle River (ORS) to Chipps Island, $S_{B2,G2}$. This parameter includes all ways of getting from ORS (site B2) to Chipps Island (site G2), and is interpreted as the sum of products of the $\phi_{kj,hi}$ parameters from the full Submodel I:

$$S_{B2,G2} = \phi_{B2,D1}\phi_{D1,D2}\phi_{D2,G2} + \phi_{B2,E1}\phi_{E1,E2}\phi_{E2,G2} + \left(\phi_{B2,B3}\phi_{B3,GH} + \phi_{B2,C2}\phi_{C2,GH}\right)\psi_{G1}\phi_{G1,G2}.$$

The reduced Submodel I does not decompose $S_{B2,G2}$ into its route-specific components because of sparse data.

The reduced Submodel II focuses on transitions in and from the lower portions of the San Joaquin River, and omits transitions from this region to the interior Delta or water export facilities (Figure 6). While the full Submodel II included transitions from MacDonald Island, Medford Island, and Turner Cut to the interior Delta and water export facilities, insufficient observations of tags making these transitions made it necessary to omit these pathways from the reduced model. Thus, the reduced Submodel II models transitions only to the Jersey Point/False River junction from the MacDonald Island/Medford Island/Turner Cut region. In fact, because no tags were observed exiting the system at False River, it was not possible to separate the probability of getting to the Jersey Point/False River junction $\left(\phi_{hi,GH}\right)$ from the probability of turning toward Jersey Point $\left(\psi_{G1}\right)$; instead, only the product was estimable: $\phi_{hi,G1} = \phi_{hi,GH}\psi_{G1}$, for transitions from site i in route h. Thus, the reduced Submodel II used parameters $\phi_{A8,G1}$, $\phi_{A9,G1}$, and $\phi_{F1,G1}$, which jointly include all routes from the lower San Joaquin River receivers to Jersey Point, including those past the interior Delta receivers in northern Old and Middle rivers (B3 and C2). Likewise, without detections at the head of Middle River receiver (MRH, code C1), it was not possible to separately estimate the probability of surviving from the head of Old River to the head of Middle River $\left(S_{B1}\right)$ from the probability of remaining in Old River at the head of Middle River $\left(\psi_{B2}\right)$. Only the product was estimate: $\phi_{B1,B2} = S_{B1}\psi_{B2}$. Finally, there were insufficient detections at the receivers upstream of the Durham Ferry release site (DFU, code A0), so the A0 site was removed from the simplified submodel I (Figure 5).

The two simplified submodels I and II were fit concurrently using unique detection and transitions probabilities at shared receivers: SJG (A6), SJNB (A7), MAC (A8), TCE/TCW (F1), and MAE/MAW (G2). Parameters at these sites were estimated separately for the two submodels to avoid “double-counting” tags used in both submodels.

In addition to the model parameters, derived performance metrics measuring migration route probabilities and survival were estimated as functions of the model parameters. Both route entrainment and route-specific survival were estimated for the two primary routes determined by routing at the head of Old River (routes A and B). Route entrainment and route-specific survival were also estimated for the major subroutes of route A; subroutes were not distinguishable for route B. These subroutes were identified by a two-letter code, where the first letter indicates routing used at the head of Old River (i.e., A), and the second letter indicates routing used at the Turner Cut junction: A or F. Thus, the route entrainment probabilities for the route A subroutes were:

$\psi_{AA} = \psi_{A1}\psi_{A2}$: probability of remaining in the San Joaquin River past both the head of Old River and the Turner Cut Junction, and

$\psi_{AF} = \psi_{A1}\psi_{F2}$: probability of remaining in the San Joaquin River past the head of Old River, and exiting to the interior Delta at Turner Cut, where $\psi_{F2} = 1 - \psi_{A2}$.

Route entrainment probabilities were estimated on the large routing scale, as well, focusing on routing only at the head of Old River. The route entrainment parameters were defined as:

$\psi_A = \psi_{A1}$: probability of remaining in the San Joaquin River at the head of Old River

$\psi_B = \psi_{B1}$: probability of entering Old River at the head of Old River.

The probability of surviving from the entrance of the Delta near Mossdale Bridge (site A4, MOS) through an entire migration pathway to Chipps Island was estimated as the product of survival probabilities that trace that pathway:

$S_{AA} = S_{A4}S_{A5}S_{A6}S_{A7}S_{A8,G2}$: Delta survival for fish that remained in the San Joaquin River past the head of Old River and Turner Cut,

$S_{AF} = S_{A4}S_{A5}S_{A6}S_{A7}S_{F1,G2}$: Delta survival for fish that entered Turner Cut from the San Joaquin River, and

$S_B = S_{A4}\phi_{B1,B2}S_{B2,G2}$: Delta survival for fish that entered Old River at its head.

The overall probability of surviving through the Delta in the San Joaquin River route was defined using the subroute-specific survival probabilities and the probabilities of taking each subroute:

$S_A = \psi_{A2}S_{AA} + \psi_{F2}S_{AF}$: Delta survival (from Mossdale to Chipps Island) for fish that remained in the San Joaquin River at the head of Old River.

The parameters $S_{A8,G2}$ and $S_{F1,G2}$ used in S_{AA} and S_{AF} represent the probability of getting to Chipps Island (i.e., Mallard Island, site MAE/MAW) from A8 and F1, respectively. Both parameters represent multiple pathways around or through the Delta to Chipps Island (Figure 2). Fish that were detected at the A8 receivers (MacDonald Island) may have remained in the San Joaquin River all the way to Chipps Island, or they may have entered the interior Delta downstream of Turner Cut. Fish that entered the interior Delta either at Turner Cut or farther downstream may have migrated through the interior Delta to Chipps Island via Frank's Tract or Fisherman's Cut, False River, and Jersey Point; returned to the San Joaquin River via its downstream confluence with either Old or Middle River at Mandeville Island; or gone through salvage and trucking from the water export facilities. All such routes are represented in the $S_{A8,G2}$ and $S_{F1,G2}$ parameters, which were estimated directly using Submodel I.

The route-specific survival probability for the Old River route, S_B, includes a transition probability, $\phi_{B1,B2}$, as a factor. As indicated above, $\phi_{B1,B2}$ is the product of a survival probability and a route entrainment probability: $\phi_{B1,B2} = S_{B1}\psi_{B2}$. No tags were detected on the Middle River receivers near the head of Middle River (site C1). However, if some tags actually had entered Middle River at its head without detection, then $\psi_{B2} < 1$ and $\phi_{B1,B2} < S_{B1}$, resulting in S_B being a minimum estimate of true Delta survival in the Old River route.

Using the estimated migration route probabilities and route-specific survival for these two primary routes (A and B), survival of the population from A4 (Mossdale) to Chipps Island was estimated as:

$$S_{Total} = \psi_A S_A + \psi_B S_B .$$

Survival was also estimated from Mossdale to Jersey Point, although this was estimable only for fish in the San Joaquin River route. Survival through this region ("Mid-Delta" or MD) was defined as follows:

$S_{A(MD)} = \psi_{A2} S_{AA(MD)} + \psi_{F2} S_{AF(MD)}$: Mid-Delta survival for fish that remained in the San Joaquin River past the head of Old River,

where

$$S_{AA(MD)} = S_{A4} S_{A5} S_{A6} S_{A7} \left(\phi_{A8,G1} + \phi_{A8,A9} \phi_{A9,G1} \right), \text{ and}$$

$$S_{AF(MD)} = S_{A4} S_{A5} S_{A6} S_{A7} \phi_{F1,G1} .$$

Survival was also estimated through the southern portions of the Delta ("Southern Delta" or SD), although once again this was estimable only for fish in the San Joaquin River route:

$$S_{A(SD)} = S_{A4} S_{A5} S_{A6} S_{A7} .$$

The probability of reaching Mossdale from the release point at Durham Ferry, ϕ_{A1A4}, was defined as the product of the intervening reach survival probabilities:

$$\phi_{A1,A4} = \phi_{A1,A2} S_{A2} S_{A3} .$$

This measure reflects a combination of mortality and possible residualization upstream of Old River, although the Chinook Salmon in this study were assumed to be migrating (i.e., no residualization). In cases where the first detection site A2 (DFD) had to be removed from analysis, the alternative model parameter $\phi_{A1,A3} = \phi_{A1,A2} S_{A2}$ was used:

$$\phi_{A1,A4} = \phi_{A1,A3} S_{A3} .$$

Individual detection histories (i.e., capture histories) were constructed for each tag as described above. Each detection history consisted of one or more fields representing initial release (field 1) and the sites where the tag was detected, in chronological order. Detection on both receivers in a dual array was denoted by the code “ab”, detection on only the upstream receiver was denoted “a0”, and detection on only the downstream receiver was denoted “b0”. For example, the detection history DF A2a0 A5 A7 A8ab A9b0 G1a0 G2ab represented a tag that was released at Durham Ferry and detected at the first (but not the second) receiver just downstream of the release site (A2a0), at one or both of the receivers near Lathrop (A5), at the single receiver in the San Joaquin River near the Navy Drive Bridge (A7), both receivers at MacDonald Island (A8ab), the downstream receiver at Medford Island (A9b0), the upstream receiver at Jersey Point (G1a0), and both receivers at Chipps Island (G2ab). A tag with this detection history can be assumed to have passed by certain receivers without detection: A2b, A3, A4, A6, A9a, and G1b. In Submodel I, the detections at A9 and G1 were not modeled, yielding Submodel I parameterization:

$$\phi_{A1,A2} P_{A2a} \left(1 - P_{A2b}\right) S_{A2} \left(1 - P_{A3}\right) S_{A3} \left(1 - P_{A4}\right) S_{A4} \psi_{A1} P_{A5} S_{A5} \left(1 - P_{A6}\right) S_{A6} P_{A7} S_{A7} \psi_{A2} P_{A8a} P_{A8b} S_{A8,G2} P_{G2a} P_{G2b} .$$

In Submodel II, this detection history was parameterized starting at the virtual release at site A5 and included detections at A8, A9, and G1:

$$S_{A5} \left(1 - P_{A6}\right) S_{A6} P_{A7} S_{A7} \psi_{A2} P_{A8a} P_{A8b} \phi_{A8,A9} \left(1 - P_{A9a}\right) P_{A9b} \phi_{A9,G1} P_{G1a} \left(1 - P_{G1b}\right) \phi_{G1,G2} P_{G2a} P_{G2b} .$$

Another example is the detection history DF A2ab A4 A5 A6 A7 G2b0. A fish with this detection history was released at Durham Ferry, migrated downstream in the San Joaquin River past the head of Old River with detections at the receivers just downstream of the release site (A2ab), as well as at the Mossdale Bridge (A4), Lathrop (A5), Garwood Bridge (A6), and Navy Drive Bridge (A7) before being detected on the second Chipps Island receiver (G2b0). This fish passed the Turner Cut junction but we have no information on which route it took there, so both routes must be parameterized in both submodels. This fish presumably passed Jersey Point without being detected on either receiver there.

This detection history is modeled partially in Submodel I and partially in Submodel II. In Submodel I, the probability of this detection history is

$$\phi_{A1,A2}P_{A2a}P_{A2b}S_{A2}\left(1-P_{A3}\right)S_{A3}P_{A4}S_{A4}\psi_{A1}P_{A5}S_{A5}P_{A6}S_{A6}P_{A7}S_{A7}\theta P_{G2a}P_{G2b},$$

where $\theta=\psi_{A2}\left(1-P_{A8}\right)S_{A8,G2}+\psi_{F2}\left(1-P_{F1}\right)S_{F1,G2}$, $1-P_{A8}=\left(1-P_{A8a}\right)\left(1-P_{A8b}\right)$, and $1-P_{F1}=\left(1-P_{F1a}\right)\left(1-P_{F1b}\right)$.

In Submodel II, this detection history is parameterized

$$S_{A5}P_{A6}S_{A6}P_{A7}S_{A7}\left[\psi_{A2}\left(1-P_{A8}\right)\left(\phi_{A8,G1}+\phi_{A8,A9}\phi_{A9,G1}\right)+\psi_{F2}\left(1-P_{F1}\right)\phi_{F1,G1}\right]\left(1-P_{G1}\right)\phi_{G1,G2}\left(1-P_{G2a}\right)P_{G2b},$$

where $1-P_{G1}=\left(1-P_{G1a}\right)\left(1-P_{G1b}\right)$.

A final example is the detection history DF A3 A4 B1 B2a0. A fish with this detection history was released at Durham Ferry, passed the first receivers without detection, passed the receivers at Banta Carbona (A3) and Mossdale Bridge (A4) with detection, entered Old River through the barrier and was detected on at least one receiver at the first Old River site (B1) and on the upstream receiver at the Old River South site (B2a0). The fish was not detected again after passing the Old River South site. It may have died between that site and Chipps Island (the next site modeled), or it may have reached Chipps Island but evaded detection there. Both possibilities must be included in the model parameterization. This detection history is parameterized only in Submodel I:

$$\phi_{A1,A2}\left(1-P_{A2}\right)S_{A2}P_{A3}S_{A3}P_{A4}S_{A4}\left(1-\psi_{A1}\right)P_{B1}\phi_{B1,B2}P_{B2a}\left(1-P_{B2b}\right)\left[1-S_{B2,G2}P_{G2}\right],$$

where $1-P_{A2}=\left(1-P_{A2a}\right)\left(1-P_{A2b}\right)$ and $P_{G2}=1-\left(1-P_{G2a}\right)\left(1-P_{G2b}\right)$.

Under the assumptions of common survival, route entrainment, and detection probabilities and independent detections among the tagged fish in each release group, the likelihood function for the survival model for each release group is a multinomial likelihood with individual cells denoting each possible capture history.

Parameter Estimation

The multinomial likelihood model described above was fit numerically to the observed set of detection histories according to the principle of maximum likelihood using Program USER software, developed at the UW (Lady et al. 2009). Point estimates and standard errors were computed for each parameter. Standard errors of derived performance measures were estimated using the delta method (Seber 2002: 7-9). Sparse data prevented some parameters from being freely estimated for some release groups. Transition, survival, and detection probabilities were fixed to 1.0 or 0.0 in the USER model as appropriate, based on the observed detections. The model was fit separately for each release.

For each release, the complete data set that included possible detections from predatory fish was analyzed separately from the reduced data set restricted to detections classified as Chinook Salmon smolt detections. Population-level estimates of parameters and performance measures, representing both release groups, were estimated by fitting the model to the pooled detection data from both release groups. For each model fit, goodness-of-fit was assessed visually using Anscombe residuals (McCullagh and Nelder 1989). The sensitivity of parameter and performance metric estimates to inclusion of detection histories with large absolute values of Anscombe residuals was examined for each release group individually.

For each release group and for the pooled data set, the effect of primary route (San Joaquin River or Old River) on estimates of survival to Chipps Island was tested with a two-sided *Z*-test on the log scale:

$$Z = \frac{\ln\left(\hat{S}_A\right) - \ln\left(\hat{S}_B\right)}{\sqrt{\hat{V}}},$$

where

$$V = \frac{Var\left(\hat{S}_A\right)}{\hat{S}_A} + \frac{Var\left(\hat{S}_B\right)}{\hat{S}_B} - \frac{2Cov\left(\hat{S}_A, \hat{S}_B\right)}{\hat{S}_A \hat{S}_B}.$$

The parameter *V* was estimated using Program USER. Also tested was whether tagged Chinook Salmon smolts showed a preference for the San Joaquin River route using a one-sided *Z*-test with the test statistic:

$$Z = \frac{\hat{\psi}_A - 0.5}{SE\left(\hat{\psi}_A\right)}.$$

Statistical significance was tested at the 5% level (α=0.05).

Analysis of Tag Failure

The first of two tag-life studies began on May 16 with 43 tags; the last tag failure was recorded on July 6. The second tag-life study began on May 24 with 40 tags, and the last tag failure was recorded on July 12. Observed tag survival was modeled using the 4-parameter vitality curve (Li and Anderson 2009). Stratifying by tag-life study (mid-May or late May) versus pooling across studies was assessed using the Akaike Information Criterion (AIC; Burnham and Anderson 2002).

The fitted tag survival model was used to adjust estimated fish survival and transition probabilities for premature tag failure using methods adapted from Townsend et al. (2006). In Townsend et al. (2006), the probability of tag survival through a reach is estimated based on the average observed travel time of tagged fish through that reach. For this study, travel time and the probability of tag survival to Chipps Island were estimated separately for the different routes (e.g., San Joaquin route vs. Old River route). Standard errors of the tag-adjusted fish survival and transition probabilities were estimated using the inverse Hessian matrix of the fitted joint fish-tag survival model. The additional uncertainty introduced by variability in tag survival parameters was not estimated, with the result that standard errors may have been slightly low. In previous studies, however, variability in tag-survival parameters has been observed to contribute little to the uncertainty in the fish survival estimates when compared with other, modeled sources of variability (Townsend et al. 2006); thus, the resulting bias in the standard errors was expected to be small.

Analysis of Tagger Effects

Tagger effects were analyzed in several ways. The simplest method used contingency tests of independence on the number of tag detections at key detection sites throughout the study area. Specifically, a lack of independence (i.e., heterogeneity) between the detections distribution and tagger was tested using a chi-squared test (α=0.05; Sokal and Rohlf 1995). Detections from downstream sites were pooled for this test in order to achieve adequate cell counts, and the chi-squared test was performed via Monte Carlo simulations to accommodate remaining low cell counts.

Lack of independence may be caused by differences in survival, route entrainment, or detection probabilities. A second method visually compared estimates of cumulative survival throughout the study area among taggers. Sparse detection data in the Old River route for individual taggers prevented estimating reach survival within the Old River route by tagger, so only the overall survival to Chipps Island was estimated for route B for this analysis. A third method used Analysis of Variance to test for a tagger effect on individual reach survival estimates, and an F-test to test for a tagger effect on cumulative survival throughout each major route (routes A and B). Tagger effects on estimates of individual parameters were also assessed using an F-test. Finally, the nonparametric Kruskal-Wallis rank sum test (Sokal and Rohlf 1995, ch. 13) was used to test for whether one or more taggers performed consistently poorer than others, based on individual reach survival or transition probabilities through key reaches. In the event that survival was different for a particular tagger, the model was refit to the pooled release groups without tags from the tagger in question, and the difference in survival estimates due to the tagger was tested using a two-sided Z-test on the lognormal scale. The reduced data set (without predator-type detections), pooled over release groups, was used for these analyses.

Testing Effect of Release Group on Parameter Estimates

The effect of release group on the values of the model survival and transition probability parameters was examined by testing for a statistically significant decrease in parameter estimates for the second release group. For each model survival and transition probability parameter θ, where $\theta = \phi_{kj,hi}$ or $\theta = S_{hi}$, the difference in parameter values between the first and second release groups was defined as

$$\Delta_\theta = \theta_1 - \theta_2 \ ,$$

for model parameter θ_R for release group R ($R = 1, 2$). The difference was estimated by $\hat{\Delta}_\theta = \theta_1 - \theta_2$. The null hypothesis of no difference was tested against the alternative of a positive difference (i.e., higher parameter value for the first release group):

$$H_{0\theta} : \Delta_\theta = 0$$

vs

$$H_{A\theta} : \Delta_\theta > 0 .$$

A family-wise significance level of α=0.10 was selected, and the Bonferroni multiple comparison correction was used, resulting in a test-wise significance level of 0.0071 for 14 tests (Sokal and Rohlf 1995).

Analysis of Travel Time

Travel time was measured from release at Durham Ferry to each detection site. Travel time was also measured through each reach for tags detected at the beginning and end of the reach, and summarized across all tags with observations. Travel time between two sites was defined as the time delay between the last detection at the first site and the first detection at the second site. In cases where the tagged fish was observed to make multiple visits to a site, the final visit was used for travel time calculations. When possible, travel times were measured separately for different routes through the study area. The harmonic mean was used to summarize travel times.

To evaluate our hypotheses that reduced travel times increased survival, we compared average travel time and survival for the different reaches to see if they were different ($p<0.05$) for the two release groups. Given that the lengths of the reaches were different we also standardized the length of each reach and survival in the reach by the distance of each reach (in km) prior to comparing average travel time per km to survival per km (S^(1/km)) across reaches.

Route Entrainment Analysis

A physical barrier was installed at the head of Old River in 2012. The barrier was designed to keep fish from entering Old River, but included culverts that allowed limited fish passage. Only 11 of the 959 (1%) tags released in juvenile Chinook Salmon in 2012 were detected entering the Old River route in 2012, while 449 (47% of 959) were detected in the San Joaquin River route. Because of the barrier and the low number of tags detected in the Old River route, no effort was made to relate route entrainment at the head of Old River to hydrologic conditions in 2012. A route entrainment analysis was performed for the Turner Cut junction instead.

The effects of variability in hydrologic conditions on route entrainment at the junction of Turner Cut with the San Joaquin River were explored using statistical generalized linear models (GLMs) with a binomial error structure and logit link (McCullagh and Nelder 1989). The acoustic tags used in this analysis were restricted to those detected at either of the acoustic receiver dual arrays located just downstream of the Turner Cut junction: site MAC (model code A8) or site TCE/TCW (code F1). Tags were further restricted to those whose final pass of the Turner Cut junction came from either upstream sites or from the opposite leg of the junction; tags whose final pass of the junction came either from downstream sites (e.g., MFE/MFW) or from a previous visit to the same receivers (e.g., multiple visits to the MAC receivers) were excluded from this analysis. Tags were restricted in this way in order to limit the delay between initial arrival at the junction, when hydrologic covariates were measured, and the tagged fish's final route selection at the junction. No Chinook Salmon tags were observed moving from one junction leg to the other, so in fact only tags that came from upstream were used in this analysis. Predator-type detections were also excluded. Detections from a total of 89 tags were used in this analysis: 79 from release group 1, and 10 from release group 2.

Hydrologic conditions were represented in several ways, primarily total river flow (discharge), water velocity, and river stage. These measures were available at 15-minute intervals from the TRN gaging station in Turner Cut, maintained by the USGS (Table 4). The Turner Cut acoustic receivers (TCE and TCW) were located 0.15 – 0.30 km past the TRN station in Turner Cut. No gaging station was available in the San Joaquin River close to the MAC receivers. The closest stations were PRI (13 km downstream from the junction), and SJG (18 km upstream from the junction) (Table 4). These stations were considered too far distant from the MAC receivers to provide measures of flow, velocity, and river stage sufficiently accurate for describing localized conditions at the Turner Cut junction for the route entrainment analysis. Thus, while measures of hydrologic conditions were available in Turner Cut, measures of flow proportion into Turner Cut were not available.

Additionally, there was no measure of river conditions available just upstream of the junction that might inform about the environment as the fish approached the junction. Instead, gaging data from the SJG gaging station (18 km upstream of the junction) were used as a surrogate for conditions upstream of the junction. Because of the distance between the SJG station and the Turner Cut junction, and the fact that the San Joaquin River becomes considerably wider between the SJG station and the junction, conditions at SJG were used only as an index of average conditions during the time when the fish was in this reach. In particular, no measure of tidal stage or flow direction was used at SJG. Instead, the analysis used the average magnitude (measured as the root mean square, RMS) of flow and velocity at SJG during the tag transition from the time of tag departure from the SJG acoustic receiver (model code A6) to the time of estimated arrival at the Turner Cut junction.

Conditions at the TRN gaging station were measured at the estimated time of arrival at the Turner Cut junction. The location (named TCJ for Turner Cut Junction) used to indicate arrival at the junction was located in the San Joaquin River 1.23 km from the TCE receiver and 2.89 km upstream of the MACU receiver. Time of arrival at TCJ $\left(t_i\right)$ was estimated for tag i by a linear interpolation from the observed travel time from the SJNB or SJG acoustic receivers upstream to detection on either the MAC or TCE/TCW receivers just downstream of the junction. Linear interpolation is based on the first-order assumption of constant movement during the transition from the previous site. In a tidal area, it is likely that movement was not actually constant during the transition, but in the absence of more precise spatiotemporal tag detection data, the linear interpolation may nevertheless provide the best estimate of arrival time.

The TRN gaging station typically recorded flow, velocity, and river stage measurements every 15 minutes. Linear interpolation was used to estimate the flow, velocity, and river stage conditions at the estimated time of tag arrival at TCJ:

$$x_i = w_i x_{t_{1(i)}} + (1 - w_i) x_{t_{2(i)}}$$

where $x_{t_{1(i)}}$ and $x_{t_{2(i)}}$ are the two observations of metric x (x = Q [flow], V [velocity], or C [stage]) at the TRN gaging station nearest in time to the time t_i of tag i arrival such that $t_{1(i)} \le t_i \le t_{2(i)}$. The weights w_i were defined as

$$w_i = \frac{t_{2(i)} - t_i}{t_{2(i)} - t_{1(i)}},$$

and resulted in weighting x_i toward the closest flow, velocity, or stage observation.

In cases with a short time delay between consecutive flow and velocity observations (i.e., $t_{2(i)} - t_{1(i)} \le 60$ minutes), the change in conditions between the two time points was used to represent the tidal stage (Perry 2010):

$$\Delta x_i = x_{t_{2(i)}} - x_{t_{1(i)}}$$

for $x = Q, V, \text{ or } C$, and tag i.

Negative flow measured at the TRN gaging station was interpreted as river flow being directed into the interior Delta, away from the San Joaquin River (Cavallo et al. 2013). Flow reversal (i.e., negative flow at TRN) was represented by the indicator variable U (Perry 2010):

$$U_i = \begin{cases} 1, & for\ Q_i < 0 \\ 0, & for\ Q_i \ge 0 \end{cases}$$

Prevailing flow and velocity conditions in the reach from the SJG acoustic receiver to arrival at the Turner Cut junction were represented by the root mean square (RMS) of the time series of observed conditions measured at the SJG gaging station during the estimated duration of the transition:

$$x_{RMS(i)} = \sqrt{\frac{1}{n_i} \sum_{j=T_{1(i)}}^{T_{2(i)}} x_j^2}$$

where x_j = observed covariate x at time j at the SJG gaging station $(x = Q \text{ or } V)$, $T_{1(i)}$ = closest observation time of covariate x to the final detection of tag i on the SJG acoustic receivers, and $T_{2(i)}$ =

closest observation time of covariate x to the estimated time of arrival of tag i at TCJ. If the time delay between either $T_{1(i)}$ and final detection of tag i on the SJG acoustic receivers, or $T_{2(i)}$ and estimated time of arrival of tag i at TCJ, was greater than 1 hour, then no measure of covariate x from the SJG gaging station was used for tag i.

Daily export rate for day of arrival of tag i at TCJ was measured at the Central Valley Project $\left(E_{iCVP}\right)$ and State Water Project $\left(E_{iSWP}\right)$ (data downloaded from DayFlow on November 5, 2013). Fork length at tagging L_i and release group RG_i were also considered. Finally, arrival time (day vs. night) at the Turner Cut Junction site (TCJ) was measured based on whether the tagged Chinook Salmon first arrived at TCJ between sunrise and sunset $\left(day_i\right)$.

All continuous covariates were standardized, i.e.,

$$\tilde{x}_{ij} = \frac{x_{ij} - \overline{x}_j}{s(x_j)}$$

for the observation x of covariate j from tag i. The indicator variables U, RG, and day were not standardized.

The form of the generalized linear model was

$$\ln\left(\frac{\psi_{iA}}{\psi_{iF}}\right) = \beta_0 + \beta_1\left(\tilde{x}_{i1}\right) + \beta_2\left(\tilde{x}_{i2}\right) + \cdots + \beta_p\left(\tilde{x}_{ip}\right)$$

where $\tilde{x}_{i1}, \tilde{x}_{i2}, \ldots, \tilde{x}_{ip}$ are the observed values of standardized covariates for tag i (covariates 1, 2, …, p, see below), ψ_{iA} is the predicted probability that the fish with tag i selected route A (San Joaquin River route), and $\psi_{iF} = 1 - \psi_{iA}$ (F = Turner Cut route). Route choice for tag i was determined based on detection of tag i at either site A8 (route A) or site F1 (route F). Estimated detection probabilities for the two release groups were 0.97 – 1.00 for site A8 and 1.00 for site F1 (Appendix 5, Table 5A-2), so no groups were omitted because of low detection probability.

Single-variate regression was performed first, and covariates were ranked by P-values from the appropriate F-test (if the model was overdispersed) or x^2 test (McCullagh and Nelder 1989). Covariates found to be significant alone (α=0.05) were then analyzed together in a series of multivariate regression models. Because of high correlation between flow and velocity measured from the same site, and to a lesser extent, correlation between flow or velocity and river stage, the covariates flow, velocity, and river stage were analyzed in separate models. The exception was that the flow index in the reach from SJG to TCJ $\left(Q_{SJG}\right)$ was included in the river stage model. Exports at CVP and SWP had low correlation over the time period in question, so CVP and SWP exports were considered in the same models. The general forms of the three multivariate models were:

Flow model: $Q_{TRN} + Q_{SJG} + \Delta Q_{TRN} + U + day + E_{CVP} + E_{SWP} + L + RG$

Velocity model: $V_{TRN} + V_{SJG} + \Delta V_{TRN} + U + day + E_{CVP} + E_{SWP} + L + RG$

Stage model: $C_{TRN} + Q_{SJG} + \Delta C_{TRN} + U + day + E_{CVP} + E_{SWP} + L + RG.$

In general, only terms that were significant in the single-variate models were included as candidates in the flow, velocity, and stage models. However, the flow, velocity, and stage metrics from the TRN gaging station were included as candidates in their respective models, regardless of their significance in the single-variate models. Backwards selection with F-tests was used to find the most parsimonious model in each category (flow, velocity, and stage) that explained the most variation in the data (McCullagh and Nelder 1989). Main effects and two-way interaction effects were considered. The model that resulted from the backwards selection process in each category (flow, velocity, or stage) was compared using an F-test to the full model from that category to ensure that all significant main effects were included. AIC was used to select among the flow, velocity, and stage models. Model fit was assessed by grouping data into discrete classes according to the independent covariate, and comparing predicted and observed frequencies of route entrainment into the San Joaquin using the Pearson chi-squared test (Sokal and Rohlf 1995).

Comparison of survival between Mossdale and Jersey Point in 2012 compared to past years.

A multiple regression was run on the combined data set of survival estimates from Mossdale to Jersey Point with the HORB using CWT's in 1994, 1997, 2000-2004 (SJRGA 2013) and using acoustic tags for the two releases in 2012 to determine if tag type (acoustic tag or coded wire tag) was a significant factor in addition to flow for predicting survival. We also compared the results observed in 2012 to those predicted from the CWT relationship with flow at the same flow levels as those experienced by tagged fish in the two 2012 releases. The data were also plotted and the two regression lines were compared; CWT data only and the CWT data combined with the 2012 acoustic tag data.

Results

Transport to Release Site

No mortalities were observed after transport to the release site. Water temperatures ranged from 16.8°C to 20.3° C after loading, prior to transport. Water temperatures ranged from 16.5°C to 20.5°C after transport and before unloading at the release site. Water temperature in the river at the release site ranged from 17.5°C to 20.7°C, with the average during the first week being lower (18.3°C) than for the second week (19.7°C) (Table 6). By adding ice, water temperatures did not change substantially during transport (Table 6 and Appendix 3) and water temperatures in the transport tanks when arriving at the release site were usually within a degree C of the water temperature in the river (Table 6). During transport water temperatures did not rise or lower more than 0.5°C, and transport tank temperatures were similar between tanks within about 0.5 °C (Appendix 3). Dissolved oxygen levels ranged between 8.73 and 11.89 mg/l for all measurements in the transport tanks or in the river (Table 6).

Fish Releases

No mortalities occurred after holding and prior to release in the 2012 Chinook Salmon study (Table 6).

Dummy Tagged fish

None of the 60 dummy-tagged Chinook Salmon were found dead when evaluated after being held for 48 hours (Table 7). Three fish from the May 20 group had abnormal gill coloration. All remaining fish were found swimming vigorously, had normal gill coloration, normal eye quality, normal body coloration and no fin hemorrhaging. Mean scale loss for all fish assessed ranged from 2.3 to 5.5%. Eight of the 60 examined fish were found to have stitched organs. Mean FL of the four groups of dummy tagged fish ranged from 108.2 to 112.0 mm. These data indicate that the fish used for the Chinook Salmon study in 2012 appeared to be in generally good condition (Table 7).

Fish Health

Pathogen testing conducted on dummy-tag cohorts of acoustic tagged MRH juvenile Chinook Salmon used in studies corresponding to May 7 and May 23 releases showed no virus or *Renibacterium salmoninarum* infection detected in the fish. The May 23 group had 37% prevalence of both suture abnormalities and A*eromonas – Pseudomonas* sp. infection however there was little correlation between the two findings. As in the past, *Tetracapsuloides bryosalmonae* infection was highly prevalent ($\geq$ 97%) and the associated Proliferative Kidney Disease became more pronounced in the May 23 sample. No mortality occurred to these fish prior to assessment after they had been held for 48 hours for either sample date. Gill Na-K-ATPase data was not reported due to a problem with a key assay reagent. The combination of kidney impairment and poor suture condition of the May 23 salmon indicates that health of the two release groups was not equivalent. See Appendix 4 for more detail on the results of the fish health evaluations.

Tag retention test

Of the 39 dummy tagged fish held for 30 days, 3 died within the first 5 days after tagging. No other mortality was observed during the 30 day period. This suggests that the tagging process alone may have caused some (less than 10%) of the mortality observed during the study. None expelled their tag.

Detections of Acoustic-Tagged Fish

There were 960 acoustic tags released in juvenile Chinook Salmon at Durham Ferry in 2012, but one was removed from the analyses due to the tag “looking odd” resulting in data from only 959 being analyzed. Of these, 713 (74%) were detected on one or more receivers either upstream or downstream of the release site (Table 8), including any predator detections. A total of 707 tags (74%) were detected at least once downstream of the release site, and 482 (50%) were detected in the study area from

Mossdale to Chipps Island (Table 8). Although more tags from the second release group were detected between the release site and the upstream boundary of the study area (Mossdale), considerably more tags from the first release group were detected in the study area than from the second release group (301 vs. 181) (Table 8).

The large majority of the tags detected in the study area were detected in the San Joaquin River route (449 of 482), while only 11 tags were detected in the Old River route (Table 8). Additionally, some tags were detected in the study area near Mossdale Bridge but not downstream of the head of Old River. In general, tag detection counts in the San Joaquin River route decreased as distance from the release point increased. Of the 449 tags observed in the San Joaquin River route, 449 were detected on the receivers near Lathrop; 310 were detected on one or both of the receivers near Stockton (SJG or SJNB); 111 were detected on the receivers in the San Joaquin River near MacDonald Island or in Turner Cut; and 47 were detected at Medford Island (Table 9).

Some of the 449 tags detected in the San Joaquin River downstream of the head of Old River were not assigned to that route for survival analysis because they were subsequently observed upstream of Old River and had no later downstream detections (Table 8). Overall, 446 of the 449 tags observed in the San Joaquin River downstream of Old River were assigned to that route for survival analysis. Of these, 13 tags were observed exiting the San Joaquin River at Turner Cut, three were observed at the Old or Middle River receivers near of Empire Cut, one was observed at the Old and Middle River receivers near Highway 4, one was observed at the CVP trashrack, and none were observed at the radial gates at the entrance to the Clifton Court Forebay (Table 9). A total of 28 San Joaquin River route tags were detected at the Jersey Point/False River receivers, including seven detections on the False River receivers (Table 9). However, all of the tags detected at False River were later detected either at Jersey Point or at Chipps Island, and so no San Joaquin River route tags were used in the survival model at False River (Table10). A total of 14 San Joaquin River route tags were eventually detected at Chipps Island, including predator-type detections (Table 9).

Only 11 tags were detected in the Old River route, and all but one, were assigned to that route for survival analysis (Table 8). Nine (9) tags were detected both at the Old River East receivers near the head of Old River (ORE) and the Old River receivers near the head of Middle River (ORS). Four tags were detected at the CVP trashracks, and none at the radial gates at the entrance to the Clifton Court Forebay (Table 9). One tag from the Old River route was detected at both the Old River sites near Highway 4 and near Empire Cut; it was last detected at Empire Cut. No tags from the Old River route were detected at any of the Middle River sites (Table 9). One of the 11 tags in the Old River route was observed at Chipps Island, and it passed through the holding tank at the Central Valley Project (Tables 9 and 10).

In addition to the Old and Middle receivers located near Empire Cut, the Threemile Slough receivers recorded detections of tags but were purposely omitted from the full survival model. Six tags were detected on the Threemile Slough receivers: four came directly from the San Joaquin River receivers at Medford Island and MacDonald Island, and two were last detected at Jersey Point before being detected at Threemile Slough (Table 9). Those that had come from Medford Island and MacDonald Island continued on to either Jersey Point or Chipps Island, while those that came upriver to Threemile Slough from Jersey Point had no subsequent detections.

The predator filter used to distinguish between detections of juvenile Chinook Salmon and detections of predatory fish that had eaten tagged smolts classified 130 of the 959 tags released (14%) as being detected in a predator at some point during the study (Table 11). Of the 482 tags detected in the study area (i.e., at Mossdale or points downstream), 95 tags (20% of 482) were classified as being in a predator, and the majority (94 of 95) were first classified as being in a predator within the study area. The remaining tag was classified as a predator at Banta Carbona (upstream of the study area) but was later detected in the San Joaquin River at the Lathrop receiver (SJL). Approximately 7% (36 of 535) of the tags detected upstream of Mossdale were classified as being in a predator in that region (Table 11). Two of the tags that were first classified as predators in the study area were subsequently detected upstream of Mossdale. Two of the nine tags detected at upstream Old River sites (ORE and ORS) were classified as in a predator (Table 11).

Within the study area, the detection sites with the largest number of first-time predator-type detections were Lathrop (14 of 449, 3%), Garwood Bridge (18 of 310, 6%), Navy Drive Bridge (23 of 241, 10%), and MacDonald Island (18 of 100, 18%) (Tables 9 and 11). The majority of predator classifications at these four sites were assigned on tag departure from the detection site in question because of long residence times and movements against the flow. Because those detections that are assigned the predator classification only on departure are not removed from analysis in the survival model, only a few detections were actually removed from these sites.

When the predator-type detections were removed, slightly fewer detections were available for the survival analysis (Tables 12-14). With the predator-type detections removed, 697 of the 959 (73%) tags released were detected downstream of the release site, and 480 (50% of those released) were detected in the study area from Mossdale to Chipps Island (Table 12). A similar percentage of the tags from each release group were detected anywhere as a smolt (73% and 72% for the two release groups). Considerably more tags from the first release group were detected in the study area than from the second release group (63% vs. 37%) (Table 12).

Removing predator-type detections did not appreciably change the spatial patterns in the detection counts. The large majority of the tags detected in the study area were detected in the San Joaquin River route (444 of 480, 93%) and assigned to that route for the survival analysis. Only 11 tags were observed in the Old River route (Table 12). Another 25 tags were detected at the Mossdale receivers, but not downstream of the head of Old River (Table 12). Most of the changes to detection counts introduced by removing predator-type detections occurred at receivers in the San Joaquin River, both upstream and downstream of the head of Old River (Tables 9 and 13). There was no change in tag counts at Jersey Point, False River, and Chipps Island. There were very few detections at receivers throughout the western and northern regions of the interior Delta (Table 13), and somewhat fewer once detections were formatted for survival analysis (Table 14). Whether predator-type detections were included or not, detections from those sites had to be omitted from the survival model (Tables 10 and 14) (See *Statistical Methods: Survival Model – Reduced Model*).

Tag-Survival Model and Tag-Life Adjustments

The Akaike Information Criterion (AIC) indicated that pooling data from both tag-life studies (AIC = 18.1) was preferable to stratifying by study month (AIC = 33.4). Thus, a single tag survival model was fitted and used to adjust fish survival estimates for premature tag failure. The estimated mean time to failure from the pooled data was 41.7 days ($SE = 7.5$ days) (Figure 7).

The complete set of detection data, including predator-type detections, contained some detections that occurred after the tags began dying (Figures 8 and 9). The sites with the latest detections were Banta Carbona and the San Joaquin River receivers near the Lathrop, Garwood Bridge, Navy Bridge and MacDonald Island. Some of these late-arriving detections may have come from predators. Tag-life corrections were made to survival estimates to account for the premature tag failure observed in the tag-life studies. All estimates of reach survival for the acoustic tags were greater than 0.99 (out of a possible range of 0 – 1). Thus, there was very little effect of either premature tag failure or corrections for tag failure on the estimates of salmon reach survival in 2012.

Tagger Effects

Fish in the release groups were evenly distributed across tagger (Table 15). For each tagger, the number tagged was distributed evenly across the two release groups. A chi-squared test found no evidence of lack of independence of tagger across the release groups (χ^2 =0.0279, df=3, P=0.9988). The distribution of tags detected at various key detection sites or regions of the study area was well-distributed across taggers, showing no evidence of a tagger effect on survival, route entrainment, or detection probabilities at these sites (χ^2 =16.8759, simulated P-value = 0.5372; Table 16).

Estimates of cumulative survival throughout the San Joaquin River route to Chipps Island showed generally small, non-significant effects of tagger through the system (Figure10). Tagger C had consistently higher point estimates of cumulative survival through the receiver at Navy Drive Bridge, after which cumulative survival from this tagger were no greater than from the other taggers. Despite the higher point estimates of survival observed for Tagger C, the differences were not statistically significant (ANOVA, P = 0.1944). Furthermore, rank tests found no evidence of consistent differences in reach survival across fish from different taggers either upstream of the head of Old River (P=0.9217) or in the San Joaquin River route (P=0.9704). Fish tagged by Tagger B had significantly lower survival estimates through the San Joaquin River reach from the Navy Bridge to the Turner Cut junction (i.e., MacDonald Island and Turner Cut) (F-test: P = 0.0078); however, fish from Tagger B showed no difference in survival estimates in other reaches or to Chipps Island overall compared to the other taggers (Figure 10).

In particular, there was no difference in overall survival to Chipps Island among taggers through the San Joaquin River route (P=0.4655). Only one fish was observed to arrive at Chipps Island via the Old River route, so no tagger effects could be explored for that route. The survival model was fit to the data pooled from all taggers without Tagger B, and estimates of four key performance measures were compared to results found with Tagger B: S_{Total}, S_A, S_B, and $\phi_{A1,A4}$. Statistical Z-tests on the log-scale found no significant difference between estimates of these parameters with and without data from fish tagged by Tagger B (P≥ 0.5835).

Survival and Route Entrainment Probabilities

As described above, detections from the receivers at the entrances to the water export facilities and in the holding tank at the Central Valley Project were removed from the survival model because of sparse data, as were detections from the Old and Middle River receivers near Highway 4. In some cases, there were too few detections at the dual array just downstream of Durham Ferry (DFD, site A2) to include this site in the model. In these cases, the model used the composite parameter $\phi_{A1,A3} = \phi_{A1,A2} S_{A2}$ in place of $\phi_{A1,A2}$ and S_{A2}. Also, in several cases analysis of model residuals showed that incorporating the full dual receiver array at some detection sites reduced the quality of the model fit to the data. In such cases when it was possible to simplify the data structure and still attain useful and valid parameter estimates, detections from the dual array in question were pooled to create a redundant array for better model fit. This occurred at the downstream Durham Ferry site (A2), MacDonald Island (A8), Old River South (near the head of Middle River, B2), and Jersey Point (G1).

No tags from the second release group (released in mid-May) were detected at Chipps Island in 2012, yielding a total Delta survival estimate of 0 ($SE = 0$) for that group whether or not predator-type detections were included. The first release group (released in early May) had positive survival ($S_{total} =$ 0.05; $SE = 0.01$), yielding a population estimate for all fish in the tagging study of 0.03 ($SE = 0.01$) (Table 17). Using only those detections classified as coming from juvenile Chinook Salmon and excluding the predator-type detections, the estimated probability of remaining in the San Joaquin River at the junction with Old River $\left(\psi_A = \psi_{A1}\right)$ was 0.98 ($SE = 0.01$) for both release groups (Table 17), and both release groups demonstrated a significant preference for the San Joaquin River route (P<0.0001 for each group). The estimated survival from Mossdale to Chipps Island via the San Joaquin River route $\left(S_A\right)$ was 0.05 ($SE = 0.01$) for the first release group, and 0 ($SE = 0$) for the second group; the overall population estimate was 0.03 ($SE = 0.01$)(Table 17). Very few fish took the Old River route (11 overall). Although the point estimate of survival to Chipps Island via this route ($S_B = 0.16$) was relatively high compared to the estimated survival via the San Joaquin River route ($S_A = 0.05$), the small number of fish observed taking the Old River route resulted in very high uncertainty in the Old River route survival estimate ($SE = 0.15$ for S_B); thus no significant difference in route-specific survival was detected for the first release group (P=0.1977). The estimated route-specific survival to Chipps Island via the Old River route was 0 for the second release group, yielding a population estimate of $S_B = 0.11$ ($SE = 0.10$); again, there was no significant difference in population survival estimates between the two routes (P=0.1999) (Table 17).

Survival in the Old River route used the parameter $\phi_{B1,B2}$ in place of S_{B1} because there were no detections at site C1 (MRH) (see *Statistical Methods*). The transition parameter $\phi_{B1,B2} = S_{B1}\psi_{B2}$, so if $\psi_{B2} < 1$, then S_B is underestimated using this formulation. For the first release group, $\phi_{B1,B2}$ = 1 ($SE =$

0), so both $S_{B1} = 1$ and $\psi_{B2} = 1$, and S_B is not underestimated (Table A5-2). For the second release group, $\phi_{B1,B2}$=0.67 ($SE = 0.27$), implying that either $S_{B1} < 1$ or $\psi_{B2} < 1$, or both (Table A5-2). However, there was only a single tag detected at site B1 (ORE) that was not later detected as a smolt at site B2 (ORS), and this tag was actually detected at B2 with a predator classification at that site. Thus, there is no evidence that $\psi_{B2} < 1$ for either release group, and so it reasonable to interpret estimates of S_B as unbiased rather than as minima. Furthermore, the lack of detections of tags from the second release group at Chipps Island would yield $S_B = 0$ for that release group in any event. Thus, there is no reason to assume that survival to Chipps Island via the Old River route is underestimated.

Survival was estimated to Jersey Point for fish that used the San Joaquin River route. This survival measure $\left(S_{A(MD)}\right)$ was estimated at 0. 09 (SE =0.02) for the first release group, 0.01 (SE =0.01) for the second release group, and 0.06 (SE =0.01) overall (Table 17). No estimates were available for the Old River route. Survival $\left(S_{A(SD)}\right)$ to the receivers just downstream of the Turner Cut junction on the San Joaquin River (i.e., MacDonald Island and Turner Cut receivers) was estimated at 0.33 ($SE = 0.03$) for the first release group, 0.07 ($SE = 0.02$) for the second release group, and 0.23 ($SE = 0.02$) overall (Table 17). Thus it is apparent that survival was low both to the Turner Cut junction and from that junction to Jersey Point, especially for fish from the second release group.

Survival was lower for the second release group than for the first group throughout the San Joaquin River. Estimated survival from the release site to Mossdale ($\phi_{A1,A4}$) was considerably lower (p<0.0001) for the second release group (0.37 for the second group vs. 0.63 for the first group), as was survival through the Southern Delta (0.07 vs. 0.33; p<0.0001), Middle Delta to Jersey Point (0.01 vs. 0.09; p<0.0001), and the entire Delta to Chipps Island (0 vs. 0.05; p<0.0001)(Table 17). Estimated survival was also lower through the modeled portions of the Old River route, i.e., from the head of Old River to the head of Middle River for the second release group. For the first release group, estimated survival through this reach was 1.0; for the second release group, it was 0.67 ($SE = 0.27$); however, the difference was not statistically significant (p= 0.1106) (Table A5-2). Although the estimate for this reach for the second release group had high uncertainty, the point estimate fits the pattern observed in the San Joaquin River of lower survival for the second release group relative to the first release group.

Including predator-type detections in the analysis produced very similar results on all spatial scales, including survival to Chipps Island, Jersey Point, and the Turner Cut junction (Table 18). The largest difference was in estimates of San Joaquin River survival through the Southern Delta to the Turner Cut junction $\left(S_{A(SD)}\right)$, which increased by 0.01 for both release groups and overall (overall estimate = 0.24, $SE = 0.02$) (Table 18). Including predator detections did not alter the comparisons between release groups; estimated survival was lower for the second release group throughout the various San Joaquin River regions (Table 18; P<0.0001).

Parameter estimates were significantly (family-wise α=0.10) higher for the first release group compared to the second release group for parameters S_{A2}, S_{A3}, S_{A4}, S_{A5}, S_{A7}, $\phi_{A8,G1}$, and $\phi_{G1,G2}$ (Table 19).

Travel Time

Average travel time through the system from release at Durham Ferry to Chipps Island was 5.75 days based on 11 detections ($SE = 0.41$ days) (Table 20a). Travel time to Chipps Island ranged from 4.1 days to 10.4 days, all from the first release group. The large majority of tags that reached Chipps Island came via the San Joaquin River route; the single tag that arrived at Chipps Island via the Old River route had a total travel time of 4.12 days, which was faster than any of the 14 tags that arrived via the San Joaquin River route. All tags observed at Jersey Point arrived via the San Joaquin River route in 3 – 9 days, with an average of approximately 6 days (Table 20a).

Travel time from release to the Mossdale Bridge receivers ranged from 0.3 to 3.9 days, and averaged 0.53 days (harmonic mean; $SE = 0.01$ days) (Table 20a). Fish with the longer travel times to Mossdale tended to come from the second release group, although both release groups included fish that arrived in under 8 hours. Travel time from release to the Turner Cut junction receivers (i.e., to Turner Cut or MacDonald Island) ranged from 1.5 days to 8.2 days, and averaged between 2 and 4 days (Table 20a). Fish with the longer travel times to Mossdale tended to come from the second release group, although both release groups included fish that arrived in under 8 hours. Travel time from release to the Turner Cut junction receivers (i.e., to Turner Cut or MacDonald Island) ranged from 1.5 days to 8.2 days, and averaged between 2 and 4 days (Table 20a).

Only 2 tags were detected at the Old River receivers near Highway 4 (OR4). One of these tags came via the Old River route and arrived 4.3 days after release, while the other tag arrived via Turner Cut from the San Joaquin River route 5.1 days after release. For the few tags that were detected at the entrance to the Central Valley Project, tags that came via the Old River route tended to have shorter travel times than tags that arrived via the San Joaquin River route (Table 20a). Sample sizes were too small to draw definitive conclusions, but these observations may have been expected because of the longer route to the interior and western receivers via the San Joaquin River route.

Including predator-type detections had only a small effect on average travel times through the system (Table 20b). Travel times to the San Joaquin River receivers at MacDonald Island and Turner Cut were generally slightly longer when predator-type detections were included. This was because travel times were measured to the beginning of the tag's final visit to each site, and many tags classified as being in predators at those sites were observed making multiple visits to those sites. The longer travel times observed for the data set that includes the predator-type detections reflect the assumption used in the predator filter that predators are more likely than smolts to exhibit long travel times.

Average travel time through reaches for tags classified as being in smolts ranged from 0.01 days (approximately 20 minutes) for the single tag observed moving from the Central Valley Project trashracks to the holding tank, to over 2 days for tags moving from MacDonald Island to Jersey Point, and over 3 days for tags moving from MacDonald Island and Medford Island to Chipps Island (Table 21a). While there were several tags that moved from MacDonald Island to Jersey Point in under 2 days, there were also several tags that took over 5 days to make the journey. Similar travel times were observed from the Medford Island receivers to the Jersey Point receivers, although the average travel time was somewhat lower from Medford Island (approximately 1.54 days over both release groups) (Table 21a). The reach from MacDonald Island to Jersey Point was one of the longer reaches in the study area (approximately 26 rkm), so it not surprising that it had some of the longer observed travel times. However, the reach from Jersey Point to Chipps Island was also approximately 26 rkm in length, and travel time through this reached tended to be shorter, ranging from 16 hours to 2.1 days and averaging 1.21 days ($SE = 0.14$ days) (Table 21a). The region between Jersey Point and Chipps Island is strongly affected by tides, which may delay migrating fish, but it is nevertheless channelized. The region between MacDonald Island and Jersey Point, on the other hand, includes Frank's Tract, and it is possible that migrating Chinook Salmon smolts are delayed there for a considerable time. In general, there were too few detections in the interior Delta to make comparisons of travel time through reaches in that region with travel time through reaches contained within the San Joaquin River route. Including predator-type detections did not greatly affect the pattern of observed travel times through the various reaches (Table 21b).

There was a significant negative relationship ($p<0.05$) between travel time per km and survival per km in river reaches upstream of the Lathrop/Old River junction for the second release group, suggesting as travel time per km increased, survival per km decreased (Figure 11, Table 22). Survival also decreased as travel time increased in reaches between Durham Ferry and Lathrop/Old River junction for the first release group, but the regression line was not significant at the $p<0.05$ level. Survival was higher for the first release group, than for the second release group in these three reaches of the river (Figure 11, Table 19). Also there appeared to be a slight increase in travel time (slower migration rate) between Mossdale and Lathrop/Old River junction and between Banta Carbona and Mossdale for the second release group relative to the first release group (Figure 11, Table 22).

In contrast, there did not appear to be a relationship between travel time per km and survival per km for reaches between the Lathrop/Old River junction and Jersey Point (tidal reaches) for either of the release groups in 2012 (Figure 12). While survival through the reach (or joint probability of moving to and surviving to the downstream location) was significantly higher (Table 19) for the first release group for three of these reaches in the San Joaquin River downstream of Lathrop (Lathrop to Garwood Bridge, S_{A5} ; Navy Drive Bridge to MacDonald Island or Turner Cut, S_{A7} ; and the reach between MacDonald Island to Jersey Point, $\phi_{A8,G1}$ [not shown on Figure 12]0, others were not significantly higher (e.g. Garwood Bridge to Navy Bridge Drive [S_{A6}], MacDonald Island to Medford Island [$\phi_{A8,A9}$], and Medford Island to Jersey Point [$\phi_{,A9,G1}$]) (Table 19). Travel times in these reaches were similar for the two release groups (Figure 12).

Route Entrainment Analysis

River flow (discharge) at the TRN gaging station in Turner Cut ranged from -4,402 cfs to 3,361 cfs (average = -1070 cfs) during the estimated arrival time of the tagged Chinook Salmon at the Turner Cut junction location (TCJ) in 2012. Water velocity in Turner Cut was highly correlated with river flow ($r=0.999$), and velocity values ranged from -0.8 ft/s to 0.6 ft/s (average = -0.1 ft/s). The flow in Turner

Cut was negative (i.e., directed to the interior Delta) upon arrival at TCJ of approximately 61% (54 of 89) tags in this analysis. River stage measured in Turner Cut was moderately correlated with both river flow and velocity (r=-0.70), and ranged from 6.7 ft to 10.9 ft (average = 9.1 ft). Changes in river stage in the 15-minute observation period containing the arrival of the tagged Chinook Salmon to the TCJ ranged from -0.2 ft to 0.2 ft (average = 0 ft). Changes in river stage were not correlated with stage (r=-0.13). The index of river flow in the reach from Stockton to Turner Cut was uncorrelated with flow and velocity in Turner Cut upon arrival at TCJ (r= 0.01), and only moderately correlated with river stage at Turner Cut (r= -0.29). The flow index in the Stockton-Turner Cut reach ranged from 2,324 cfs to 3,400 cfs (average = 2,785 cfs).

The daily export rate at CVP ranged from 821 cfs to 1,016 cfs (average = 960 cfs); exports at CVP were generally low in both early and late May, and was greatest in mid-May. The daily export rate at the State Water Project (SWP) ranged from 507 cfs to 3,698 cfs (average = 1,908 cfs). SWP exports were more variable than CVP exports but also peaked in the third week of May. Exports from CVP and SWP were uncorrelated (r= -0.01). Neither CVP nor SWP exports was correlated with either flow (r=0.09 for CVP, r=-0.03 for SWP) or river stage (r=0.00 for CVP, r=-0.14 for SWP) in Turner Cut. The majority of tags (66 of 89, 74%) arrived at the Turner Cut junction during daylight hours.

The single-variate analyses found no significant effects (α=0.05) of any of the covariates considered (P>0.40 for all covariates; Table 23). This negative result may reflect the true lack of a relationship between environmental variables and route selection at Turner Cut, or it may be an artifact of the low degrees of freedom available and the resulting low statistical power; because only 11 fish were observed entering Turner Cut (out of 89), there were only 11 degrees of freedom total. A study with a larger sample size and more fish observed using Turner Cut may provide evidence of a relationship between one or more of the covariates and route selection at this junction in future.

Comparison of Delta Survival to Past Years

In a multiple regression, tag type (acoustic or CWT) did not come out as an important variable affecting survival, whereas flow did (Table 24). Using the relationship developed from the CWT data (Figure 13), we calculated what survival from Mossdale to Jersey Point was expected to be at the two flow levels in 2012: predicted survival was 0.12 at flows of 3543 cfs and 0 at flows of 2327cfs, very close to what we observed (0.09, $SE = 0.02$, at the higher flow and 0.01, $SE = 0.01$, at the lower flow). The relationships between flow at Vernalis and survival from Mossdale to Jersey Point with the HORB, developed from the historical CWT data and from all of the data (historic CWT data and acoustic tag data added from 2012), were similar (Figure 13). The slopes of the two linear regression lines were the same (0.0001), and the intercepts were similar (-0.2345 for the CWT data only and -0.2295 for the combined data (Figure 13)) . Both relationships were statistically significant (p <0.01).

Discussion

The similarity between parameter estimates with and without predator-type detections raises questions about the predator filter. One possible explanation for the similar estimates is that the majority of the mortality was not directly caused by the predatory fish used to build the predator filter, or that many of the predatory fish feeding on the tagged salmon merely evaded detection. Chinook Salmon smolts may have been eaten by sedentary predators, birds, or mammals (e.g., otters), or by predatory fish that moved about the Delta but evaded the acoustic receivers. Alternatively, Chinook Salmon smolts may have died due to disease or habitat quality. In either case, the tags of the deceased salmon smolts may have settled on the river bottom away from the acoustic receivers; in these cases, the predator filter would correctly identify existing detections of these tags as in smolts rather than predators, and the survival model estimates would be unbiased.

Another possibility is that the filter missed detections of predators, and thus the resulting filtered data set (which supposedly has no detections from predators) is only artificially similar to the unfiltered data set (which includes detections from predators). If this is the case, then survival estimates for the (presumed) smolt-only data set would be biased because they would be based partially on predator detections. The type of bias depends on where the predator filter failed. For example, none of the tags detected at Chipps Island were classified as being in predators by the existing filter. A filter that recategorizes some of those detections as predator detections may yield survival estimates to Chipps Island that are lower than that estimated in this study (0.03). This would happen as long as the revised filter agreed with the original filter in upstream regions. On the other hand, if the predator filter was inefficient (i.e., wrong) upriver of Mossdale such that detections passed by the filter as smolts were actually detections of predators, then it is possible that true survival to Chipps Island was actually higher than estimated (0.03); this may happen if there were fewer actual smolts starting at Mossdale than appeared from the original filter. Of the 959 tags released at Durham Ferry, only 480 (50%) were detected at Mossdale, and 478 of them were classified as in smolts upon arrival at Mossdale (Tables 9 and 13). Only 15 of these tags were detected at Chipps Island. Adjusting the predator filter cannot add more detections at Chipps Island, but it may remove detections at Mossdale. A revised filter that used more stringent criteria upstream of Mossdale was constructed and implemented on the detection data. The revisions to the filter were:

- no upstream-directed transitions allowed upstream of Mossdale
- no repeat visits to sites upstream of Mossdale
- maximum residence time of 2 hours at any site upstream of Mossdale
- maximum regional residence time of 15 hours upstream of Mossdale
- minimum migration rate of 0.2 km/hr for all transitions upstream of Mossdale

This stricter filter resulted in 477 of the 480 detections at Mossdale being classified as in smolts, compared to 478 classified as in smolts using the original predator filter. The Delta survival estimate from the stricter predator filter was 0.03 for the population (i.e., both release groups pooled), unchanged from the estimate using the original filter. Thus, it is unlikely that errors in the predator filter resulted in the similar results with and without the predator-type detections.

Our first objective of the 2012 study was to determine survival of emigrating salmon smolts from Mossdale to Chipps Island during two time periods (prior to May 15 and after May 15) in the presence of the HORB to determine if there was a benefit from the flow augmentation from the Merced

River in 2012. Average river flow measured at the Vernalis gaging station when fish from the first release group were traveling through the Delta to Chipps Island (from release through approximately 10 days after the end of release period) was 3,543 cfs, while for the period of comparable length for the second release group was 2,327 cfs (Figure 14). Survival was higher ($p < 0.0001$) through the Delta (S_{Total}) for the first release group (0.05) relative to the second release group (0.00) (Table 17). Thus these findings appear to support our hypothesis that the increased flow from the Merced River flow augmentation increased survival through the Delta.

Our second objective was to assess whether the higher flows from the Merced River flow augmentation resulted in a reduction in travel time and higher survival, specifically in the riverine reaches of the Delta, and resulted in higher through-Delta survival. Shorter travel times would reduce the time tagged fish were exposed to mortality factors such as predation, high water temperatures, and toxics. Travel times in reaches of the Delta between Durham Ferry and a series of downstream locations (Mossdale, Lathrop, Garwood Bridge, Navy Drive Bridge, and MacDonald Island) were all significantly less (i.e. faster migration) for the first release group than the second release group (Table 20a; $p < 0.05$). The travel times in these reaches appeared to be strongly influenced by the travel time for the reach between Lathrop (SJL) and Garwood Bridge (SJG). Travel time between SJL and SJG was significantly less ($p < 0.05$) for the first release group (0.60; $SE =$ 0.02) which experienced the higher flows, than for the second release group (0.86; $SE =$ 0.05) which experienced the lower flows (Table 21a). Survival through this reach was also higher for the first release group (0.81; $SE =$0.02) relative to the second release group (0.48; $SE =$0.04)($p < 0.0001$) (S_{A5}; Table A5-2). Thus, the data in this specific, partly riverine, reach of the Delta are consistent with our hypothesis that an increase in flow would reduce travel time and be associated with higher survival.

To further evaluate the possible relationship between travel time and survival in the remaining reaches, travel time and survival were standardized to a per-km basis. With this standardization, we found that as travel time per km increased, survival decreased for both release groups in the three riverine reaches between Durham Ferry and the Lathrop/Old River junction (Figure 11). Travel time per km was greater for the second group relative to the first group for two of the three reaches; (Banta Carbona to Mossdale and Mossdale to Lathrop/Old River, but not Durham Ferry to Banta Carbona) whereas survival was always lower for the second release group (lower flows) relative to the first group (higher flows) for these three reaches (Figure 11, Table 22). Thus the difference in travel time per km for the first group relative to the second did not always support our hypotheses that the higher survival per km resulted from a decrease in travel time per km from the higher flows in these riverine reaches.

Travel time per km was somewhat less and survival greater for the first release group relative to the second release group in two reaches: 1) between Lathrop and Garwood Bridge (discussed above) and 2) between Garwood Bridge and Navy Bridge Drive (Figure 12, Table 22); the shorter travel time from the increased flow may partially explain the higher point estimate of survival for release 1 compared to release 2 between Garwood Bridge and Navy Bridge, although the increase in survival is not statistically significant at the 5% level (Table 19); however, it is not possible to determine causation from this study.

Once fish enter the interior Delta or into the strongly tidally influenced San Joaquin River, travel times were expected to increase and survival was expected to decrease. While we did generally see longer travel times per km in the tidal reaches (reaches downstream of Navy Bridge Drive), it was not always greater (Table 22; e.g. travel time per km was shorter from MacDonald Island to Medford Island than it was from Lathrop to Garwood Bridge). Travel time per km was also less for the second release group than for the first, even though survival was generally higher for the first group relative to the second in all reaches downstream of Navy Bridge Drive, except between MacDonald Island and Medford Island, when survival per km was higher for the second group (Table 22). Since the increased flow probably was not enough to change velocities significantly in the downstream tidal reaches, the increased survival of the first group relative to the second in most of these tidal reaches suggests there are other mechanisms either associated with flow or other factors that resulted in the increases in survival in these tidal reaches of the Delta.

Once fish move into the interior Delta, they are exposed to flows moving toward the export facilities, which may increase their travel time and reduce their survival to Jersey Point or Chipps Island. While many of the tagged fish may have been diverted from the San Joaquin River into the interior Delta downstream of Turner Cut, we were only able to identify those entering the interior Delta through Turner Cut. We had hypothesized that tagged fish moving into the interior Delta (e.g. Turner Cut) would have increased travel times over those not being diverted into Turner Cut. Since none of the tagged fish that entered Turner Cut survived to Chipps Island for either the first or second release group, we could not compare travel times between release groups or for the Turner Cut route relative to the other routes. One fish that entered Turner Cut from the first release group was observed in the CVP holding tank, but did not survive to reach Chipps Island. We were also not able to assess the impact on survival of tagged fish being routed to the SWP and CVP as detections from the receivers at the entrances to the water export facilities and in the holding tank at the Central Valley Project were removed from the survival model because of sparse data due to the presence of the HORB.

The results of comparing travel time to survival suggests that the increased flow during the first release did not always result in decreased travel times, although it did coincide with an increase in survival in more of the riverine reaches. It was the higher survival in the majority of the reaches (both riverine and tidal) during the first release that resulted in a higher overall survival through the Delta for the first release group relative to the second release group.

However, there are other possible hypotheses for the lower survival in the second release group compared to the first release group, including differences in fish condition, tagging and release procedures, and other environmental conditions. The same tagging and release procedures were used for both release groups, including the same taggers, presumably with the same skill set, so that does not appear to be responsible for the differences in survival we observed. Fish from the second release group were slightly larger on average than fish from the first release group (mean FL = 109.9 mm and 115.7 mm for the first and second release groups, respectively), so it was reasonable to expect higher survival for the second release group rather than lower survival, but we did not observe this. Although the two release groups were released only two weeks apart, they experienced different environmental conditions other than flow. During the same two time periods, combined exports at CVP and SWP varied from 1,513 cfs to 5,054 (mean = 3,200 cfs), with similar means in the two periods. However, exports tended to be high toward the end of the first period, when relatively few fish from the first release were still migrating, and also high near the beginning of the second period, when the majority of fish from the second release group were migrating (Figure 15).

It is also possible that the difference in flow conditions may have resulted in the different survival rates via a mechanism other than travel time, such as temperature, increased predation or toxicity. We had hypothesized that the higher inflow from the Merced flow augmentation would potentially reduce the effects of these mortality factors by reducing temperature stress, diluting toxics or reducing predator metabolic demands from the lower water temperatures. Water temperature measured at the San Joaquin River gage near Lathrop was almost 2 degrees higher on average for the second release group (67.5 °F [19.7°C]) than for the first group (65.6 °F [18.7°C]), which may have negatively affected the survival of the second release group, and been a consequence of the lower flows experienced by the second release group (Figure 16). We were unable to assess the hypothesis that increased metabolic demands from predators due to the warmer water temperatures was the cause for the increased mortality for the second release group relative to the first release group.

To assess the hypothesis that the increased flow from the Merced River flow augmentation may have diluted toxicity in the Delta, we observed that survival was significantly higher for the first group relative to the second group in the reach between SJL and SJG (Table 19). This reach from SJL to the SJG is one of the longer reaches of the Delta at 18 km (Table 22), and it includes a variety of habitats. It is not entirely riverine, but includes the transition to tidal habitat, depending on inflow. The reach is more riverine at higher inflows, and more tidal at lower inflows. The Stockton Wastewater treatment plant releases its effluent in the lower part of this reach which may have an effect on survival, especially during periods of low flow. During periods of low flow the movement of the tidal prism upstream may result in concentration of the effluent in this reach and dilution from flow would be less. There is also the possibility that increased temperatures exacerbate the toxicity effects of the effluent on juvenile salmon survival. Further evaluation of water quality in this reach may be warranted, building on studies conducted near there in 2008 (SJRGA 2009) after a significant die-off of acoustic tags near this location in 2007 – a low flow year (SJRGA 2008).

In addition, it is possible that the higher incidence of PKD infection for the second release group reduced their survival to Chipps Island relative to the first release group. Infection does not necessarily lead to death but would reduce fitness from anemia, kidney dysfunction, and immune suppression even if the fish survived the disease (Angelidis et al 1987, Hedrick and Aronstien 1987 as cited in Nichols et al 2012). The increase in water temperature may have contributed to the higher incidence of PKD infection for the second release group relative to the first as PKD is a progressive disease at water temperatures greater than 15°C (Okamura and Wood 2002 as cited in SJRGA 2013).

Unfortunately, PKD infection is not just a problem for the experimental fish we used in 2012, but was noted as a problem in monitoring on the Merced River. Smolts caught in the Hopeton rotary screw trap on the Merced River (presumably wild stock) also had high levels of PKD infection in 2012 (Nichols et al. 2012). This is also not new, as 90-100% of naturally produced fish in a 2001 survey of Merced outmigrant salmonid health were observed to be infected with PKD (Nichols and Foott 2002 as cited in Nichols et al. 2012). Even some of salmon transferred from MRH to the lab at the Fish Health Center soon after ponding in February of 2012, developed light infections of PKD (Nichols et al 2012).

However, the worst infections identified in the 2012 study were later in the season, with gross clinical signs of PKD (anemia and swollen kidney) observed for naturally produced fish on May 9 (2 out of 24), and high numbers of parasites observed for both naturally produced (May 9 and May 15) and hatchery fish (May 15) (Nichols et al. 2012).

PKD is caused by infection by the endoparasitic myxozoan, *Tetracapsuloides bryosalmonae*. Reducing byrozoan habitat directly upstream of the hatchery and in the Merced River could be a viable disease management strategy (Foott et al. 2007). Increasing flows, if they result in decreasing water temperatures, would serve to reduce the severity of PKD for both experimental and wild fish emigrating from the San Joaquin basin. Higher water temperatures in the river and at the hatchery may have increased the severity of the PKD infection for the second group of tagged fish in 2012, relative to the first group; this may account for some of the increased mortality observed in the second group. Higher water temperatures are affected by both flow and air temperature upstream of the Delta. Cold water releases from the upstream reservoir on the Merced River may have reduced the water temperatures for the first release group over what they would have been without the water release.

Our third objective of the 2012 study was to identify route selection at HOR and at Turner Cut under the two different periods with varying flows and exports. Since the physical HORB was in place in 2012, route selection into the San Joaquin River was high for both groups (0.98; $SE = 0.02$) and did not vary between release groups (Table 17) or when predator type detections were included (Table 18). Route selection at Turner Cut was 0.11 ($SE = 0.03$) for the first release group, and 0.16 ($SE = 0.11$) for the second release group (Table 17) when predator-type detections were removed and similar when predator-type detections were included (0.12; $SE = 0.03$ for the first release group and 0.14; $SE = 0.04$ for the second release group) (Table 18). Differences in the proportion diverted into Turner Cut at the TCJ between release groups were not statistically different: with 11 to 16% of the tagged fish diverted into Turner Cut, none of which survived to Chipps Island ($S_{F1,G2}$; Tables A5-2 and A5-3). Zero probability of survival to Chipps Island for the tagged fish that entered Turner Cut negatively affected total through-Delta survival for both release groups. A study with a larger sample size and more fish observed using Turner Cut may provide evidence of a relationship between one or more covariates (e.g. flow, and tides) and route selection at this junction in future.

It is possible that the lower flows, higher water temperatures, higher toxicity, higher incident of disease (PKD) and possibly higher export rates during the time of peak migration may have combined to negatively affect salmon survival from the second release. Diversion into Turner Cut decreased survival of both groups. With only two release groups and observational data, however, it is not possible to conclude more. Combining these results with those from additional years may shed light on possible causes of mortality in the Delta. The Interagency Ecological Program has funded a multi-year analysis of the data from 2010, 2011, 2012 and 2013 and results will be forthcoming.

Based on the results of this study in 2012, naturally spawned or hatchery juvenile salmonids from the San Joaquin tributaries likely experienced variable survival within the migration period through the Delta, with greater survival during the Merced River flow augmentation period and lower survival during the later remainder period of migration. Higher flows appeared to benefit survival through multiple intertwined mechanisms including shorter travel times, lower water temperatures, and reduced disease impacts.

The comparison of estimates of survival from Mossdale to Jersey Point for the two release groups in 2012, to estimates generated using CWT's with the HORB, suggests that survival observed in 2012 was within that expected based on the past CWT relationship, and that differences in flow between the two releases in 2012 likely increased survival over what it would have been without the flow pulse. However, without direct manipulation and further replication, cause and effect cannot be determined.   While this comparison supports our hypothesis that the increased flow from the flow augmentation in the Merced River during the first release group increased survival, it also shows that survival for both groups in 2012 was relatively low, compared to that measured in other years with the HORB (Figure 13). These data suggest a higher flows of approximately 6,000 cfs with the HORB, are needed to achieve survival through the Delta of approximately 0.40. Additional studies, especially during higher flow periods, with the HORB in place, are needed to confirm these results.

Funding for the project came from the restoration funds of the Central Valley Project Improvement Act, the U.S. Bureau of Reclamation, and the Department of Water Resources. Several individuals from a variety of agencies made this project possible. Those agencies and individuals who participated in the tagging and release components of the project were; USFWS: Amber Aguilera, Denise Barnard, Crystal Castle, Dustin Dinh, David Dominguez, Kyle Fronte, Garrett Giannetta, Jack Ingram, Carlie Jackson, Joseph Kirsch, David LaPlante, Jerrica Lewis, Mike Marshall, Louanne McMartin, Greg Nelson, Jacob Osborne, Lori Smith, Brent Trim, and Rob Wilson; California Department of Water Resources: Roxanne Kesler, Bryce Kozak , and Matt Silva; AECOM: Curtis Yip; and USBR: Raymond Bark and Josh Israel. USGS provided training for the surgeons (Theresa [Marty] Liedtke) and was responsible for the deployment, maintenance and retrieval of the receiver array (Jon Burau, Chris Vallee, Jim George and Norbert VandenBranden). Mike Simpson, retired from USGS, processed the data prior to giving it to Rebecca Buchanan of University of Washington for analyses.

[1] one tag not used in analyses; tag looked odd, [2] released from shore due to high winds or dead battery in boat.

Table 2. Characteristics assessed for Chinook Salmon smolt condition and short-term survival

Characteristic	Normal	Abnormal
Percent Scale Loss	Lower relative numbers based on 0-100%	Higher relative numbers based on 0-100%
Body Color	High contrast dark dorsal surfaces and light sides	Low contrast dorsal surfaces and coppery colored sides
Fin Hemorrhaging	No bleeding at base of fins	Blood present at base of fins
Eyes	Normally shaped	Bulging or with hemorrhaging
Gill Color	Dark beet red to cherry red colored gill filaments	Grey to light red colored gill filaments
Vigor	Active swimming (prior to anesthesia)	Lethargic or motionless (prior to anesthesia)

Table 3. Names and descriptions of receivers and hydrophones used in the 2012 Chinook Salmon tagging study, with receiver codes used in Figure 2, the survival model (Figures 2 – 5), and in data processing by the United States Geological Survey (USGS). The release site was located at Durham Ferry.

Individual Receiver Name and Description	Hydrophone Location		Receiver Code	Survival Model Code	Data Processing Code
	Latitude (°N)	Longitude (°W)			
San Joaquin River near Durham Ferry upstream of the release site, upstream node	37.685806	121.256500	DFU1	A0a	300856
San Joaquin River near Durham Ferry upstream of the release site, downstream node	37.686444	121.256806	DFU2	A0b	300857
San Joaquin River near Durham Ferry; release site (no acoustic hydrophone located here)	37.687011	121.263448	DF	A1	
San Joaquin River near Durham Ferry downstream of the release site, upstream node	37.688222	121.276139	DFD1	A2a	300858
San Joaquin River near Durham Ferry downstream of the release site, downstream node	37.688333	121.276139	DFD2	A2b	300859
San Joaquin River near Banta Carbona	37.727722	121.298917	BCA	A3	300860
San Joaquin River near Mossdale Bridge, upstream node	37.792194	121.307278	MOSU	A4a	300861
San Joaquin River near Mossdale Bridge, downstream node	37.792356	121.307369	MOSD	A4b	300862
San Joaquin River upstream of Head of Old River, upstream node (not used in survival model)	37.805528	121.320000	HORU	B0a	300863
San Joaquin River upstream of Head of Old River, downstream node (not used in survival model)	37.805000	121.321306	HORD	B0b	300864
San Joaquin River near Lathrop, upstream	37.810875[a]	121.322500[a]	SJLU	A5a	300869/300870
San Joaquin River near Lathrop, downstream	37.810807[a]	121.321269[a]	SJLD	A5b	300871/300872
San Joaquin River near Garwood Bridge, upstream	37.934972	121.329333	SJGU	A6a	300877
San Joaquin River near Garwood Bridge, downstream	37.935194	121.329833	SJGD	A6b	300878
San Joaquin River at Stockton Navy Drive Bridge	37.946806	121.339583	SJNB	A7	300879
San Joaquin River at MacDonald Island, upstream	38.018022[a]	121.462758[a]	MACU	A8a	300899/300901
San Joaquin River at MacDonald Island, downstream	38.023877[a]	121.465916[a]	MACD	A8b	300900/300902
San Joaquin River near Medford Island, east	38.053134[a]	121.510815[a]	MFE	A9a	300903/300904
San Joaquin River near Medford Island, west	38.053773[a]	121.513315[a]	MFW	A9b	300905/300906
Old River East, near junction with San Joaquin, upstream	37.811653[a]	121.335486[a]	OREU	B1a	300865/300866

a = Average latitude and longitude given for sites with multiple hydrophones or for sites with multiple locations throughout the study

Table 3. (Continued)

Individual Receiver Name and Description	Hydrophone Location		Receiver Code	Survival Model Code	Data Processing Code

Table 21b. Average travel time in days (harmonic mean) of acoustic-tagged juvenile Chinook Salmon through the San Joaquin River Delta river reaches during the 2012 tagging study, with predator-type detections (see Table 21a for travel time through reaches without predator-type detections). Standard errors are in parentheses. Reaches beginning at sites with no detections are not shown (i.e., reaches that start at MRH, MR4, RGU, RGD, and FRE/FRW).

Table 22: Distance in km, estimated survival and survival rate per km (S^(1/km)), travel time in days, and travel time in days per km (TT^(1/km)), for the first (1st) and second (2nd) release groups of Chinook Salmon in 2012. Survival and travel time data were obtained from tables Table A5-2, and Table 21a. Distance was estimated using the shortest distance between the two points calculated from Google Earth. Data were used to generate Figure 12.

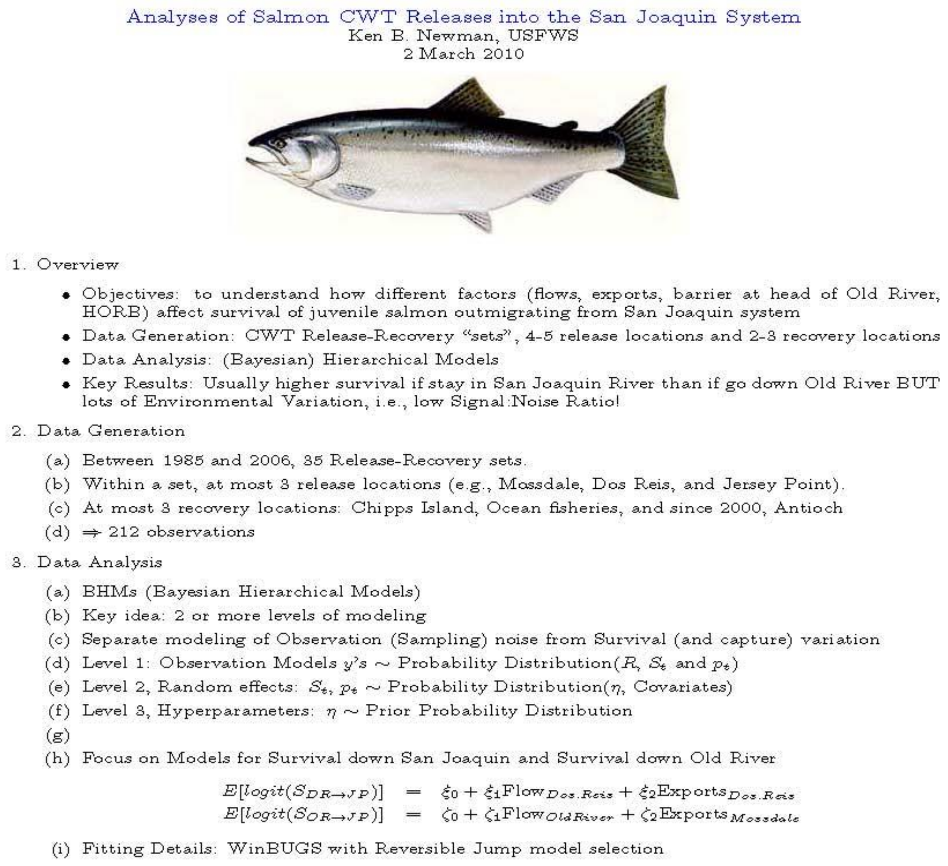
Appendices 1-5:

Appendix 1. Analyses of CWT salmon released in the south Delta by Ken Newman as part of the VAMP peer review in 2010.



Analyses of Salmon CWT Releases into the San Joaquin System

Ken B. Newman, USFWS
2 March 2010

1. Overview
    - Objectives: to understand how different factors (flows, exports, barrier at head of Old River, HORB) affect survival of juvenile salmon outmigrating from San Joaquin system
    - Data Generation: CWT Release-Recovery "sets", 4-5 release locations and 2-3 recovery locations
    - Data Analysis: (Bayesian) Hierarchical Models
    - Key Results: Usually higher survival if stay in San Joaquin River than if go down Old River BUT lots of Environmental Variation, i.e., low Signal:Noise Ratio!
2. Data Generation
    (a) Between 1985 and 2006, 35 Release-Recovery sets.
    (b) Within a set, at most 3 release locations (e.g., Mossdale, Dos Reis, and Jersey Point).
    (c) At most 3 recovery locations: Chipps Island, Ocean fisheries, and since 2000, Antioch
    (d) ⇒ 212 observations
3. Data Analysis
    (a) BHMs (Bayesian Hierarchical Models)
    (b) Key idea: 2 or more levels of modeling
    (c) Separate modeling of Observation (Sampling) noise from Survival (and capture) variation
    (d) Level 1: Observation Models y's $\sim$ Probability Distribution(R, S_t and p_t)
    (e) Level 2, Random effects: S_t, p_t $\sim$ Probability Distribution(η, Covariates)
    (f) Level 3, Hyperparameters: $\eta \sim$ Prior Probability Distribution
    (g)
    (h) Focus on Models for Survival down San Joaquin and Survival down Old River

$$\begin{aligned} E[logit(S_{DR\rightarrow JP})] &= \xi_0 + \xi_1 \text{Flow}_{Dos.Reis} + \xi_2 \text{Exports}_{Dos.Reis} \\ E[logit(S_{OR\rightarrow JP})] &= \zeta_0 + \zeta_1 \text{Flow}_{OldRiver} + \zeta_2 \text{Exports}_{Mossdale} \end{aligned}$$

    (i) Fitting Details: WinBUGS with Reversible Jump model selection

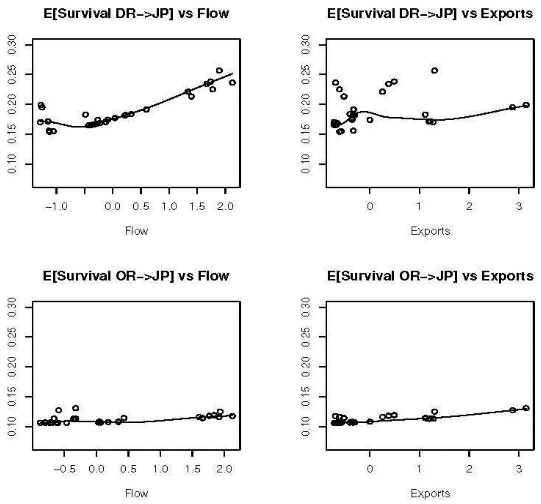
4. Results

   (a) Posterior Probabilities

Models	$S_{MD\rightarrow JP}$	$S_{OR\rightarrow JP}$
Constant	0.38	0.45
Flow	0.29	0.23
Exports	0.17	0.21
Both	0.16	0.11

   (b) Coefficients

Covariate	Average	SD	2.5%	median	97.5%
SJ-flow	0.16	0.25	-0.09	0.0	0.77
SJ-exports	0.07	0.19	-0.17	0.0	0.61
OR-flow	0.04	0.22	-0.42	0.0	0.62
OR-exports	0.04	0.20	-0.32	0.0	0.60



5. Caveats and Comments

   (a) Priors *do* matter, especially with Hierarchical Models
   (b) More to wring out of CWTs? Using time of capture? Add arrival time/travel time model?
   (c) Acoustic tags far preferable?
   (d) Value in probing extreme values for flows and exports

Appendix 2: Standard Operating Procedure

Acoustic Tagging for Salmon 2012 South Delta Studies 4/10/12 (file dated 4/23/12)

Equipment Set Up:

- Fill surgical instrument disinfection trays with chlorhexidine (brand name Nolvasan)
    - Autoclave instruments such that each tagging event begins with sterile instruments
- Activate transmitters and confirm operational status
    - Position the transmitter in an isolated compartment to enable tracking of the transmitter ID through the implantation process
- Disinfect transmitters in chlorhexidine
    - Ensure at least 20 minutes of contact time with chlorhexidine
    - Following disinfection, thoroughly rinse transmitters in distilled or de-ionized water prior to implantation
    - Following disinfection, transmitters should only be handled by gloved hands or clean surgical instruments such as forceps
- Fill rinse tray with de-ionized or distilled water
- Set up scale, measuring board, and surgical platform or foam
    - Apply stress coat to weigh boat, measuring board, and platform to reduce damage to fish skin or mucus layer
- Fill gravity feed carboys. Add 2 ml of the MS-222 stock solution and 2 ml of the sodium bicarbonate stock solution to the 10 L of water in the MS-222 carboy. Concentration may be increased upon group consensus and in consultation with coordinator.
- Fill anesthesia container to indicated volume line. Set the initial concentration in collaboration with the tagging coordinator. Suggested starting concentration is 70 mg/ L. Concentration may be adjusted upon group consensus and in consultation with coordinator. Concentration changes should be executed for all taggers simultaneously and recorded on the tagging datasheet.
- Prepare recovery containers by filling with water, adding stress coat, and supersaturating with oxygen
    - Immediately following surgery fish will be held in recovery containers that provide 130% to 150% DO for a minimum of 10 minutes
    - Holding time in recovery containers begins when the last fish is added to the container and will be monitored using a timer
- Prepare a reject container for fish that cannot be tagged by filling with water and equipping with a bubbler . These fish will be returned to a separate holding tank.
- Start tagging data sheets. Note the time the tagging session was started and complete all appropriate data fields. Start a Daily Fish Reject Tally datasheet to account for fish that are handled but not tagged.
- The tagger should wear medical-grade exam gloves during all fish handling and tagging procedures
- Prepare the transport truck to accept containers of tagged fish.
- Prepare transport containers and lids to receive tagged fish

Surgery

- Food should be withheld from fish for ~24 h prior to surgical implantation of the transmitter.
- Anesthetize fish
    - Net one fish from source tank/raceway and place directly into an anesthesia container. Immediately start a timer to monitor anesthesia exposure time and place a lid on the container.
    - Remove the lid after about 1 minute to observe the fish for loss of equilibrium. Keep the fish in the water for an additional 30-60 seconds after it has lost equilibrium. Time to sedation should normally be 2-4 minutes, with an average of about 3 minutes. If loss of equilibrium takes less than 1 minute or if a fish is exposed to anesthesia for more than 5 minutes, reject that fish. If after anesthetizing a few fish they are consistently losing equilibrium in more or less time than typical, the anesthesia concentration may need to

be adjusted. Anesthesia concentration should only be adjusted in coordination with all study taggers and the tagging coordinator.

        - Changes to anesthesia concentration should be done at 5 mg/L increments. For example, if the initial dosage was 70 mg/L, an adjusted dose should be 65 mg/L or 75 mg/L.
        - When an anesthesia change is agreed upon, all taggers should drain their anesthesia containers, refill with 10 L of water, and re-mix to the new anesthesia concentration
    - If a fish is unacceptable for tagging due to issues with anesthesia, place the fish in the “Reject” container and log it on the reject tally datasheet.
    - The anesthesia container should be emptied and remixed at regular intervals throughout the tagging operation to ensure the appropriate concentration and to avoid warming
    - The gravity feed containers should be monitored for volume and temperature and changed as needed to avoid inadequate volume to complete a surgery and significant warming

- Recording fish length, weight, and condition
    - Start a timer when a fish is removed from the anesthesia container to record the time the fish is out of water (recorded as “air time”).
    - Transfer the fish to the scale and record the weigh to the nearest 0.1g
        - Scales should be calibrated regularly to ensure accuracy
        - Fish must weigh at least 13 g to be selected for tagging so that tag burden does not exceed 5% of the weight of the fish. Transmitters used for this study are Vemco brand V5 models, weighing 0.65 g in air.
    - Transfer the fish to the measuring board and determine forklength to the nearest mm.
    - Check for any abnormalities and descaling. If the fish is abnormal or grossly descaled, note this on the datasheet and place the fish in the reject container.
        - Scale condition is noted as Normal (N), Partial (P), or Descaled (D) and is assessed on the most compromised side of each fish. The normal scale condition is defined as loss of less than 5% of scales on one side of the fish. Partial descaling is defined as loss of 6-19% of scales on one side of the fish. Fish are classified as descaled if they have lost 20% or more of the scales on one side of the fish, and should not be tagged due to compromised osmoregulatory ability.
    - Data must be vocally relayed to the recorder, and the recorder should repeat the information back to the tagger to avoid miscommunication.
    - Any fish dropped on the floor should be rejected.

- Transmitter Implantation
    - Anesthesia should be administered through the gravity feed irrigation system as soon as the fish is on the surgical platform. Use the flow control valves to adjust the flow rate as needed so that the opercular rate of the fish is steady.
        - Note that low-flow or inconsistent irrigation can mimic shallow anesthesia
    - Using a scalpel, make an incision approximately 3-5 mm in length beginning a few mm in front of the pelvic girdle. The incision should be about 3 mm away from and parallel to the mid-ventral line, and just deep enough to penetrate the peritoneum, avoiding the internal organs. The spleen is generally near the incision point so the depth and placement of the incision are critical.
        - There is no exact specification for the selection of a micro scalpel for steelhead. A general recommendation is to use a 5 mm blade for fish larger than about 50 g.
        - The incision should only be long enough to allow entry of the tag.
    - Forceps may be used to open the incision to check for potential organ damage. If you observe damage or note excessive bleeding, reject the fish.
    - Scalpel blades can be used on several fish, but if the scalpel is pulling roughly or making jagged incisions, it should be changed prior to tagging the next fish.

  - Gently insert the tag into the body cavity and position it so that it lies directly beneath the incision and the ceramic head is facing forward. This positioning will provide a barrier between the suture needle and internal organs.
  - Close the incision with two simple interrupted stitches.
    - Vicryl Plus sutures are recommended
    - 5-0 suture size is appropriate for juvenile Chinook Salmon or similar fish with weights less than~ 50 g
    - If the incision cannot effectively be closed with two stitches, a third stitch may be added. The presence of a third suture should be noted on the datasheet.
  - Ideally the gravity feed irrigation system should be switched to fresh water or a combination of sedation and freshwater during the final stages of surgery to begin recovery from anesthesia. Typically a good time to switch to freshwater is when the second suture is initiated.
  - Transfer the fish from the surgical platform to a recovery container and stop the timer recording air time
    - Avoid excessive handling of fish during transfer. Ideally the fish will be moved to the recovery container on the surgical platform to reduce handling.
  - Once a recovery container has been fully stocked, start a timer to monitor the 10 min of exposure to high DO concentrations for recovery.
  - Between surgeries the tagger should place surgical instruments and any partially consumed suture material into the chlorhexidine bath. Multiple sets of surgical instruments should be rotated to ensure 10 min of contact time with chlorhexidine. Once disinfected, instruments should be rinsed in distilled or de-ionized water. Organic debris in the disinfectant bath reduces effectiveness, so be sure to change the bath regularly.

Tag Validation

- Filled recovery containers will be moved to the tag validation station.
  - Recovery containers may be moved from the tagging location to the tag validation station during the 10 min recovery time, but they must not be established on flow-through water exchange. The flow-through exchange will immediately reduce the DO saturation.
- Use the appropriate receiving system to confirm the identity and function of the transmitters in the recovery container. Record validation on the datasheet.
- Following tag validation, recovery containers are held in a flow-through tank until the tagging session is complete, at which time they are loaded onto a truck for transport to the holding and release location.

Cleanup

- Both the tagger and assistant must review the full complement of tagging datasheets and initial each sheet to confirm that the set of transmitters they were assigned to implant have been implanted. Use the list of transmitters provided by the tag coordinator to ensure that all transmitters supplied to you were implanted and recorded. Both the tagger and the assistant must initial the header of each of the datasheets. This review step is completed for each tagging session (that is, for each transport truck that is loaded).
- Return tag tray and datasheets to coordinator at end of each tagging session.
- Complete the reject fish tally datasheet and return to the tag coordinator.
- Use a spray disinfectant to disinfect tagging surfaces and supplies, and position them to dry.
- Return any rejected fish to the appropriate raceway where they cannot be selected for future tagging efforts.
- At the completion of the tagging effort each day, package surgical instruments for the autoclave so they can be sterilized prior to the next tagging session.

Important things to remember:

- Water containers used for tagging should be filled just prior to tagging to avoid temperature changes and should be changed frequently.
- Fish cannot be transferred between water sources until the difference between the water temperatures of the two sources is less than two degrees Celsius.
- No water sources used in the tagging operation should be more than two degrees different in water temperature from the source water temperature.
- All containers holding fish should have lids in place.
- If a tag is dropped bring it to the tagging coordinator to confirm that it is still functioning before it is implanted. The transmitter may also require disinfection if it fell onto a dirty surface.
- Carefully handle all fish containers to minimize disturbances to fish.
- Containers used to transport fish to the release site cannot be used for tagging operations until they have been held in the freezer for 24 h.

Appendix 4:

U.S. Fish & Wildlife Service

FY2012 Technical Report:
Pathogen screening and gill Na-K-ATPase assessment of juvenile Chinook salmon used in south delta acoustic tag studies.

J. Scott Foott

September 2012

U.S. DEPARTMENT OF THE INTERIOR
MARCH 3, 1849

US Fish and Wildlife Service

California-Nevada Fish Health Center

24411 Coleman Fish Hatchery Rd

Anderson, CA 96007

SUMMARY:
Pathogen testing was conducted on dummy-tag cohorts of acoustic tagged Merced River Hatchery juvenile Chinook salmon used in studies corresponding to 7 May and 23 May releases. No virus or *Renibacterium salmoninarum* infection was detected in the fish. The 23 May group had 37% prevalence of both suture abnormalities and A*eromonas – Pseudomonas* sp. infection however there was little correlation between the 2 findings. As in the past, *Tetracapsuloides bryosalmonae* infection was highly prevalent (≥ 97%) and the associated Proliferative Kidney Disease became more pronounced in the 23 May sample. No mortality occurred in the live cage populations at either sample date. Gill Na-K-ATPase data is not reported due to a problem with a key assay reagent. The combination of kidney impairment and poor suture condition of the 23 May salmon indicates that health of the two release groups was not equivalent.

INTRODUCTION

As a component of the 2012 Chinook salmon survival studies on reach-specific survival and distribution of migrating Chinook salmon in the San Joaquin River and delta, the CA-NV Fish Health Center conducted a general pathogen screening and smolt physiological assessment. The health and physiological condition of the study fish can help explain their performance and survival during the studies. Pathogen screenings during past VAMP studies using Merced River Hatchery (MRH) Chinook have regularly found infection with the myxozoan parasite *Tetracapsuloides bryosalmonae*, the causative agent of Proliferative Kidney Disease (PKD). This parasite has been shown to cause mortality in Chinook salmon with increased mortality and faster disease progression in fish at higher water temperatures (Ferguson 1981; Foott et al. 2007). The objectives of this project were to survey the juvenile Chinook salmon used for the studies for specific fish pathogens including *Tetracapsuloides bryosalmonae* and assess smolt development from gill Na^+ - K^+- ATPase activity.

METHODS

Prior to the 7 May and 23 May sample, 30 juvenile salmon were held within live cages for approximately 48h in the San Joaquin River at Durham Ferry. These fish were surgically-implanted with a dummy tag similar in size to the acoustic tag of release cohorts. Fish were evaluated for gill and skin condition (including suture) and tissues collected for assays. A grading scale ranging 0-3 was used to score inflammation or ulceration of tissue at the suture location and openness of the surgical incision (based on training session by Cramer Fish Sciences attended by J. Day).

> 0: Clean, completely closed and healed incision with taut suture. No external indication of pulling of tissue or inflammation.
>
> 1: Mostly closed, but not healed incision. Minor petechial hemorrhage.
>
> 2: Incision more than half open, and not healed. Inflammation present over more than half the suture area.
>
> 3: Incision completely open. Severely inflamed tissue surrounding and/or pushing out from incision site. Severe hemorrhaging extending equal to or greater than the length of the incision site. Suture may be lost entirely or embedded within inflamed tissue. Necrotic tissue visible.

Gill lamellae were collected first into SEI buffer and frozen on dry ice. Gill Na^+/K^+-Adenosine Triphosphatase (ATPase) activity was assayed by the method of McCormick (1993). Kidney was collected aseptically and inoculated onto brain-heart infusion agar. Bacterial isolates were screened by standard microscopic and biochemical tests (USFWS and AFS-FHS 2010). *Renibacterium salmoninarum* (bacteria that causes bacterial kidney disease) was screened by fluorescent antibody test (FAT) of kidney imprints. Three fish pooled samples of kidney and spleen were inoculated onto EPC and CHSE-214 cell lines held at 15°C for 21 d (USFWS and AFS-FHS 2010). The gill, liver, intestine and posterior kidney were rapidly removed from the fish and immediately fixed in Davidson's fixative, processed for 5 µm paraffin sections and stained with hematoxylin and eosin (Humason 1979). Infections of the myxozoan parasite, *T. bryosalmonae,* were rated for intensity of parasite infection and associated tissue inflammation (Proliferative Kidney Disease). Intensity of infection was rated as none (zero), low (<10), moderate (11-30) or high (>30) based on number of *T. bryosalmonae* trophozoites observed in the kidney section. Severity of kidney inflammation (PKD) was rated as normal, focal, multifocal or diffuse.

RESULTS AND DISCUSSION

All salmon were alive at the time of sample collection for both dates. Suture condition of 23 May fish was judged to be poor (11 of 30 fish with #2 or 3 ratings). Several sutures were observed on the pelvic girdle. All sutures in the 7 May group were intact and showed no hemorrhage.

The prevalence of systemic bacterial infection (A*eromonas – Pseudomonas* sp. (aquatic bacteria clade) was also 37% in the 23 May group however there was little association with suture hemorrhage (only 4 of 11 fish with hemorrhaged sutures had bacterial infections). No virus or *Renibacterium salmoninarum* infection was detected in the fish (Table 1). *Tetracapsuloides bryosalmonae* was seen in $\geq$ 97% of the kidney sections from both sample groups (Table 1).

Table A4-1. Prevalence of infection (number positive / total sample) for systemic bacteria (AP= *Aeromonas* or *Pseudomonas sp.)*, *R. salmoninarum* by direct fluorescent antibody test (Rsal-DFAT), virus, and *T. bryosalmonae* observed in kidney sections.

Sample date	Bacteria	Rsal - DFAT	Virus	*T.byrosalmonae*
7 May	1 / 30 (3) AP	0 / 29	0 / 10 (3p)	29 / 30 (97)
23 May	11 / 30 (37) AP	0 / 30	0 / 10 (3p)	30 / 30 (100)

The *T. bryosalmonae* infection was judged to be at an early state in the 7 May sample fish. High numbers of the parasites were seen in both groups however kidney inflammation was markedly worse in the 23 May fish (Fig. 1 and 2). Swollen kidneys and spleens were also observed in the 23 May group. Overt anemia (pale gills) was not seen in any salmon on either collection date. The systemic nature of the infection was reflected in the occurrence of the parasite in multiple tissues (spleen, visceral adipose capillaries, liver sinuses, and kidney) including blood vessels within the gill (Fig. 3). One 7 May gill section contained two *Ichthyophthirius multifilii* trophozoites however there was little tissue response. Liver hepatocytes showed little glycogen or fat content in both sample groups possibly reflective of low feed rate. No gill Na-K-ATPase data is reported due to abnormal kinetic profiles. The ADP standard curve was normal which indicates that the majority of enzymes and co-factors were functional. The pH and magnesium conditions were also normal for the assay. We suspect that the recently purchased Sigma Chemical Adenosine TriPhosphate was faulty as this nucleotide is the substrate for the ouabain-sensitive gill Na-K-ATPase enzyme.

The advanced proliferative kidney disease, increased prevalence of systemic bacteria, and hemorrhaged sutures observed in the 23 May salmon suggests that the two release groups were not equivalent in health condition. The impact on immediate (1-3 days) post-release survival of these impairments on 23 May salmon is likely to be limited however longer term survival and swimming performance could be reduced. Past work on PKD effects on smolt performance have shown that severe kidney inflammation and anemia are associated with impaired swimming and saltwater adaptation (Foott et al. 2007 and 2008).

Figure A4-1. Prevalence of *T. byrosalmonae* intensity ratings for Chinook salmon sampled on 7 and 23 May. Intensity of *T. byrosalmonae* infection observed in kidney section rated as none (0), low (<10), moderate (11-30), and high (>30). Numbers over ratings are prevalence data. Majority of parasites observed in the 7 May kidneys were found in the sinuses indicating an early stage of infection.

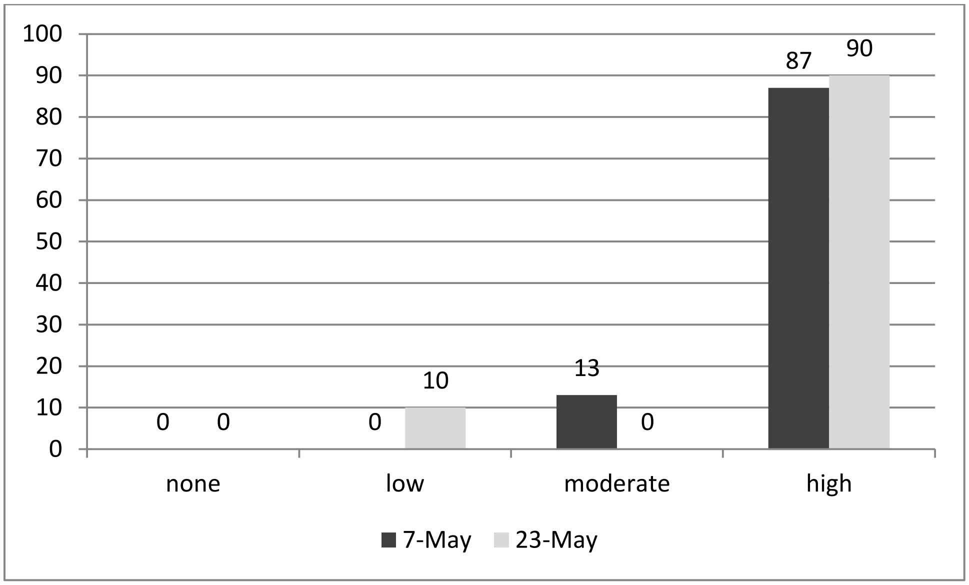

Figure A4-2. Prevalence of proliferative kidney disease ratings for Chinook salmon sampled on 7 and 23 May. Severity of kidney inflammation rated as normal, focal, multifocal, or diffuse. Numbers over ratings are prevalence data.

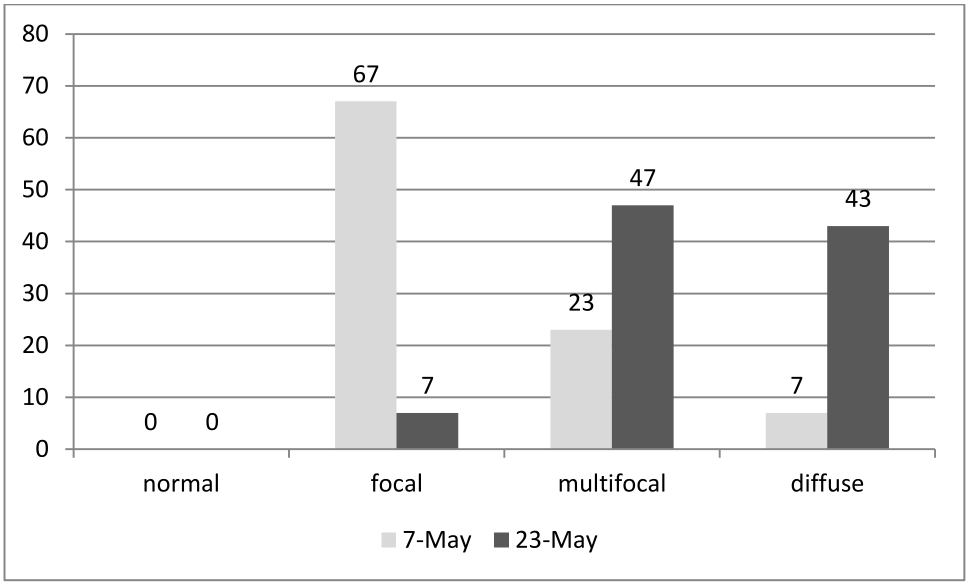

Figure A4-3. Micrograph of *T. byrosalmonae* (arrow) within gill blood vessel.

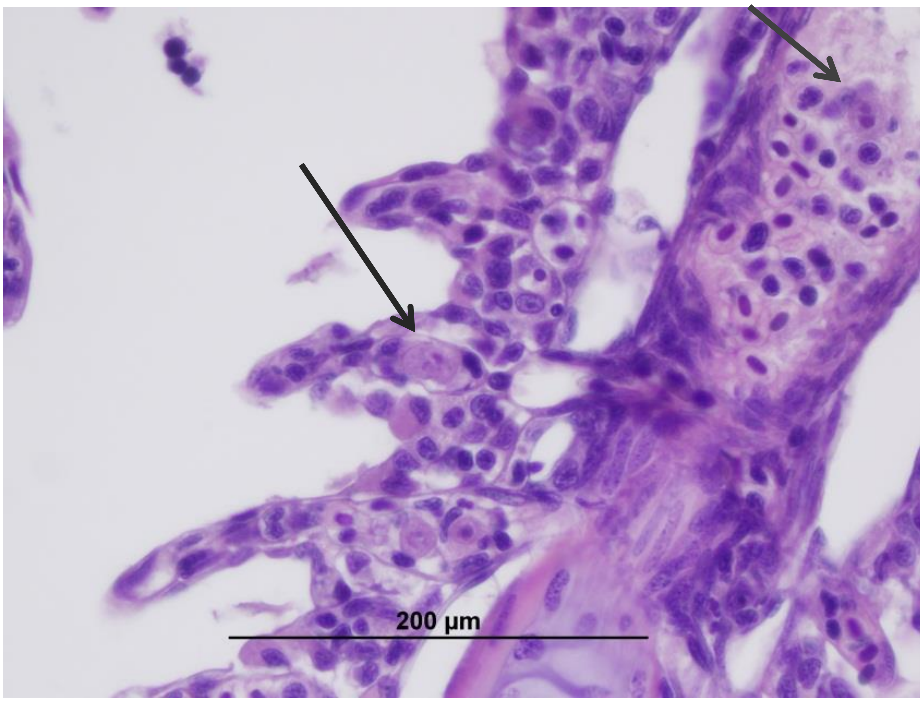

Figure A4-4. Suture condition rating 2 (exposed edge with hemorrhage) in 23 May salmon.

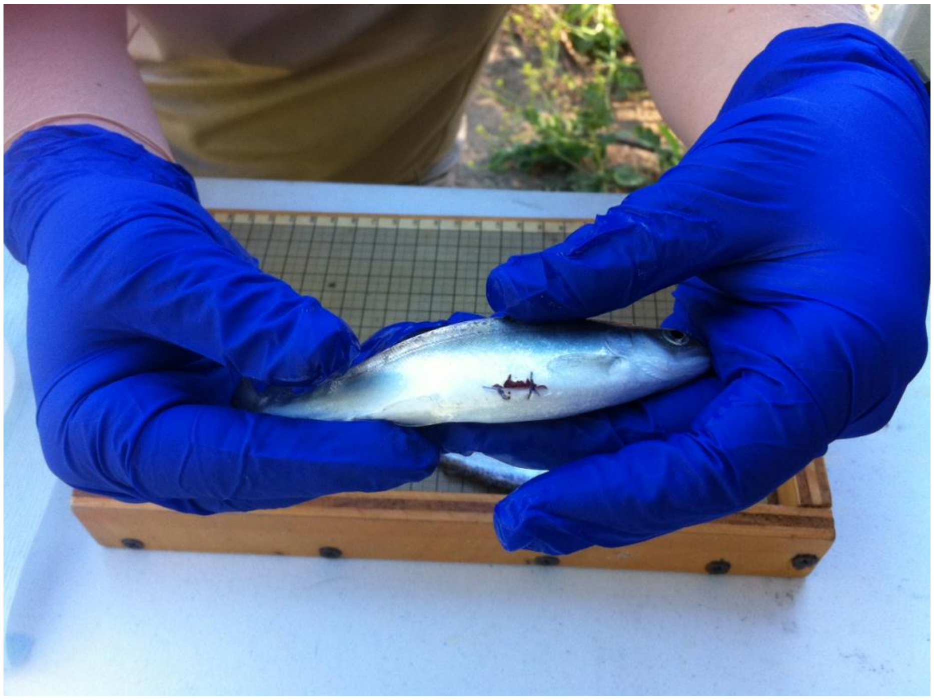

ACKNOWLEDGEMENTS
Ken Nichols, Anne Bolick, Kim True, and Julie Day with the FHC performed both field and laboratory work on this project and biologists with the USFWS Stockton FWO provided access to the live cages at Durham Ferry.

Appendix 5. Survival Model Parameters

Table A5-1. Definitions of parameters used in the release-recapture survival model; full or reduced model, or both, is specified. Parameters used only in particular submodels are noted.

Parameter	Model	Definition
S_{A2}	Both	Probability of survival from Durham Ferry Downstream (DFD) to Banta Carbona (BCA)
S_{A3}	Both	Probability of survival from Banta Carbona (BCA) to Mossdale (MOS)
S_{A4}	Both	Probability of survival from Mossdale (MOS) to Lathrop (SJL) or Old River East (ORE)
S_{A5}	Both	Probability of survival from Lathrop (SJL) to Garwood Bridge (SJG)
S_{A6}	Both	Probability of survival from Garwood Bridge (SJG) to Navy Drive Bridge (SJNB)
S_{A7}	Both	Probability of survival from Navy Drive Bridge (SJNB) to MacDonald Island (MAC) or Turner Cut (TCE/TCW)
$S_{A7,G2}$	Both	Overall survival from Navy Drive Bridge (SJNB) to Chipps Island (MAE/MAW) (derived from Submodel I)
$S_{A8,G2}$	Both	Overall survival from MacDonald Island (MAC) to Chipps Island (MAE/MAW) (Submodel I)
S_{B1}	Full	Probability of survival from Old River East (ORE) to Old River South (ORS)
$S_{B2,G2}$	Reduced	Overall survival from Old River South (ORS) to Chipps Island (MAE/MAW) (derived from Submodel I)
$S_{F1,G2}$	Both	Overall survival from Turner Cut (TCE/TCW) to Chipps Island (MAE/MAW) (Submodel I)
$\phi_{A1,A0}$	Full	Joint probability of moving from Durham Ferry release site upstream toward DFU, and surviving to DFU
$\phi_{A1,A2}$	Both	Joint probability of moving from Durham Ferry release site downstream toward DFD, and surviving to DFD
$\phi_{A1,A3}$	Both	Joint probability of moving from Durham Ferry release site downstream toward BCA, and surviving to BCA; = $\phi_{A1,A2}\ S_{A2}$
$\phi_{A8,A9}$	Both	Joint probability of moving from MAC toward MFE/MFW, and surviving from MAC to MFE/MFW (Submodel II)
$\phi_{A8,B3}$	Full	Joint probability of moving from MAC toward OR4, and surviving from MAC to OR4 (Submodel II)
$\phi_{A8,C2}$	Full	Joint probability of moving from MAC toward MR4, and surviving from MAC to MR4 (Submodel II)
$\phi_{A8,GH}$	Full	Joint probability of moving from MAC directly toward Jersey Point (JPE/JPW) or False River (FRE/FRW) without passing Highway 4 sites, and surviving JPE/JPW or FRE/FRW (Submodel II)
$\phi_{A8,G1}$	Reduced	Joint probability of moving from MAC toward Jersey Point (JPE/JPW) and surviving to JPE/JPW (Submodel II); = $\phi_{A8,GH}\psi_{G1(A)}$
$\phi_{A9,B3}$	Full	Joint probability of moving from MFE/MFW toward OR4, and surviving from MFE/MFW to OR4 (Submodel II)
$\phi_{A9,C2}$	Full	Joint probability of moving from MFE/MFW toward MR4, and surviving from MFE/MFW to MR4 (Submodel II)
$\phi_{A9,GH}$	Full	Joint probability of moving from MFE/MFW directly toward Jersey Point (JPE/JPW) or False River (FRE/FRW) without passing Highway 4 sites, and surviving to JPE/JPW or FRE/FRW (Submodel II)
$\phi_{A9,G1}$	Reduced	Joint probability of moving from MFE/MFW toward Jersey Point (JPE/JPW) and surviving to JPE/JPW (Submodel II); = $\phi_{A9,GH}\psi_{G1(A)}$
$\phi_{B1,B2}$	Reduced	Joint probability of moving from ORE toward ORS, and surviving from ORE to ORS; = $S_{B1}\psi_{B2}$
$\phi_{B2,B3}$	Full	Joint probability of moving from ORS toward OR4, and surviving from ORS to OR4
$\phi_{B2,C2}$	Full	Joint probability of moving from ORS toward MR4, and surviving from ORS to MR4
$\phi_{B2,D1}$	Full	Joint probability of moving from ORS toward RGU, and surviving from ORS to RGU
$\phi_{B2,E1}$	Full	Joint probability of moving from ORS toward CVP, and surviving from ORS to CVP
$\phi_{B3,D1}$	Full	Joint probability of moving from OR4 toward RGU and surviving from OR4 to RGU conditional on coming from lower San Joaquin River (Submodel II)

Table A5-1. (Continued)

Parameter	Model	Definition
$\phi_{B3,E1}$	Full	Joint probability of moving from OR4 toward CVP, and surviving from OR4 to CVP, conditional on coming from lower San Joaquin River (Submodel II)
$\phi_{B3,GH(A)}$	Full	Joint probability of moving from OR4 toward Jersey Point (JPE/JPW) or False River (FRE/FRW), and surviving from OR4 to JPE/JPW or FRE/FRW (Submodel II [route A])
$\phi_{B3,GH(B)}$	Full	Joint probability of moving from OR4 toward Jersey Point (JPE/JPW) or False River (FRE/FRW), and surviving from OR4 to JPE/JPW or FRE/FRW (Submodel I [route B])
$\phi_{C1,B3}$	Full	Joint probability of moving from MRH toward OR4, and surviving from MRH to OR4
$\phi_{C1,C2}$	Full	Joint probability of moving from MRH toward MR4, and surviving from MRH to MR4
$\phi_{C1,D1}$	Full	Joint probability of moving from MRH toward RGU, and surviving from MRH to RGU
$\phi_{C1,E1}$	Full	Joint probability of moving from MRH toward CVP, and surviving from MRH to CVP
$\phi_{C2,D1}$	Full	Joint probability of moving from MR4 toward RGU and surviving from MR4 to RGU conditional on coming from lower San Joaquin River (Submodel II)
$\phi_{C2,E1}$	Full	Joint probability of moving from MR4 toward CVP, and surviving from MR4 to CVP, conditional on coming from lower San Joaquin River (Submodel II)
$\phi_{C2,GH(A)}$	Full	Joint probability of moving from MR4 toward Jersey Point (JPE/JPW) or False River (FRE/FRW), and surviving from MR4 to JPE/JPW or FRE/FRW (Submodel II [route A])
$\phi_{C2,GH(B)}$	Full	Joint probability of moving from MR4 toward Jersey Point (JPE/JPW) or False River (FRE/FRW), and surviving from MR4 to JPE/JPW or FRE/FRW (Submodel I [route B])
$\phi_{D1,D2}$	Full	Joint probability of moving from RGU toward RGD, and surviving from RGU to RGD (equated between submodels I and II)
$\phi_{D2,G2}$	Full	Joint probability of moving from RGD toward Chipps Island (MAE/MAW) and surviving from RGU to MAE/MAW (equated between submodels I and II)
$\phi_{E1,E2}$	Full	Joint probability of moving from CVP toward CVPtank, and surviving from CVP to CVPtank (equated between submodels I and II)
$\phi_{E2,G2}$	Full	Joint probability of moving from CVPtank toward Chipps Island (MAE/MAW) and surviving from CVPtank to MAE/MAW (equated between submodels I and II)
$\phi_{F1,B3}$	Full	Joint probability of moving from TCE/TCW toward OR4, and surviving from TCE/TCW to OR4 (Submodel II)
$\phi_{F1,C2}$	Full	Joint probability of moving from TCE/TCW toward MR4, and surviving from TCE/TCW to MR4 (Submodel II)
$\phi_{F1,GH}$	Full	Joint probability of moving from TCE/TCW directly toward Jersey Point (JPE/JPW) or False River (FRE/FRW) without passing Highway 4 sites, and surviving to JPE/JPW or FRE/FRW (Submodel II)

NOTE TO READERS

Recovery of Coded-Wire Tags from Chinook Salmon in California's Central Valley Escapement and Ocean Harvest in 2010 presents important data for the improvement of Central Valley salmon management. Until 2007, only experimental releases of fall-run Chinook salmon from Central Valley hatcheries were marked and coded-wire tagged (low, inconsistent numbers), resulting in a lack of data for harvest management, evaluation of hatchery rearing and release practices, hatchery impacts to natural-origin fish, and the success of habitat improvement programs.

The Central Valley Constant Fractional Marking Program (CFM) was initiated in 2007 to estimate in a statistically valid manner the relative contribution of hatchery production and to evaluate the various release strategies being employed in the Central Valley. Beginning with Brood Year 2006 fall-run Chinook, the program has marked and coded-wire tagged a minimum of 25 percent of releases from the Central Valley hatcheries each year (Buttars 2007, 2008, 2009, 2010). The program is a cooperative effort of the California Department of Fish and Game (DFG), the California Department of Water Resources (DWR), the U.S. Bureau of Reclamation, the U.S. Fish and Wildlife Service (FWS), the East Bay Municipal Utilities District (EBMUD), and the Pacific States Marine Fisheries Commission (PSMFC).

In 2010, almost 27,000 Code Wire Tags were recovered from ad-clipped Chinook sampled in Central Valley natural area spawning surveys, at Central Valley hatcheries, Central Valley river creel surveys, and California commercial and recreational ocean fisheries. Almost all of the fall run Chinook Code Wire Tags recovered in the Central Valley were tagged as part of the CFM program, since most Central Valley fish return at ages two, three, or four, and age five Chinook made up a very small fraction (0.01%) of the total Central Valley fall escapement in 2010.

This report evaluates the 2010 Central Valley fall, spring, and late fall runs Chinook Code Wire Tags recovery data in accordance with program objectives. In particular, this report attempts to answer the following questions with this first full year of recovery data from the CFM program:

- What are the proportions of hatchery and natural-origin fish in spawning returns to Central Valley hatcheries and natural areas, and in ocean harvest?
- What are the relative recovery and stray rates for hatchery fish released in-basin versus salmon trucked to and released into the waters of the Carquinez Straits?
- What are the relative recovery rates for fish acclimated in net pens and released in the bay compared to salmon released directly into the waters of the Carquinez Straits?
- What are the relative contribution rates of hatchery fish, by run and release type, to the ocean harvest?

As with all of its products, Fisheries Branch is interested in comments on the utility of this document, particularly regarding its application to monitoring and management decision processes. Therefore, we encourage you to provide us with your comments. Comments should be directed to Ms. Alice Low, Fisheries Branch, 830 S Street, Sacramento, CA 95814, (916) 323-9583, alow@dfg.ca.gov.

Stafford Lehr
Chief, Fisheries Branch

Introduction

Each year, approximately 32 million fall-run Chinook salmon are produced at five hatcheries in California's Central Valley (CV): Coleman National Fish Hatchery (CNFH), Feather River Hatchery (FRH), Nimbus Fish Hatchery (NFH), Mokelumne River Hatchery (MOK), and Merced River Fish Facility (MER). Production from these hatcheries contributes to major sport and commercial fisheries in ocean and inland areas. Prior to 2007, only small experimental releases (generally <100,000 fish) of CV fall-run Chinook were consistently released with microscopic (≤ 1 mm) coded-wire tags (CWT) inserted in their snouts. Each CWT contains a binary or alpha-numeric code that identifies a specific release group of salmon (e.g., agency, species, run, brood year, hatchery or wild stock, release size, release date(s), release location(s), number tagged and untagged). Any CV salmon containing a CWT is also externally marked with a clipped adipose fin (ad-clipped) to allow for visual identification. Although FRH did mark and tag a portion of their fall-run Chinook during 2000 through 2006, tagging rates were not consistent or representative of the 6-8 million fish produced annually by FRH. Almost all of the fall-run Chinook production releases at the other CV hatcheries were untagged during this time.

In 2004, the CALFED Ecosystem Restoration Program (ERP) funded a study to design a constant fractional marking and coded-wire tagging program for CV fall-run Chinook production at all CV hatcheries. The primary goal of this program was to estimate in a statistically valid manner the relative contribution of hatchery production and to evaluate the various release strategies being employed throughout the CV. The study recommended the implementation of a system-wide marking and tagging program for production releases. Planning studies indicated an optimum marking and tagging rate of 25% for all CV fall-run Chinook production releases (Hicks et al. 2005).

Beginning with brood year 2006, at least 25% of fall-run Chinook production releases at CNFH (12-13 million), FRH (9-10 million), NFH (5-6 million), and MOK (4-5 million) have been marked and tagged each spring-run (Buttars 2007, 2008, 2009, 2010). This Constant Fractional Marking (CFM) program is a cooperative effort of the California Department of Fish and Game (DFG), the California Department of Water Resources (DWR), the U.S. Bureau of Reclamation, the U.S. Fish and Wildlife Service (FWS), the East Bay Municipal Utilities District (EBMUD), and the Pacific States Marine Fisheries Commission (PSMFC).

In addition, 100% of the fall-run Chinook produced at the MER (approximately 50,000-300,000 annually) are marked and coded-wire tagged. Almost 100% of the spring-run Chinook reared at FRH and the late fall-run Chinook reared at CNFH have also been marked and coded-wire tagged. It should be noted that due to their extremely low production numbers, MOK marked and tagged 100% of their fall-run Chinook releases for brood years 2008 and 2009.

During 2010, almost 27,000 CWTs were recovered from ad-clipped Chinook sampled in CV natural area spawning surveys, at CV hatcheries, in CV river creel surveys, and in California ocean commercial and recreational fisheries. Almost all of the fall-run Chinook CWTs recovered in the CV were tagged as part of the CFM program since most CV fish return at ages two, three, or four. Age five Chinook made up a very small fraction (0.01%) of the total CV fall-run escapement in 2010. This report evaluates the 2010 CV fall, spring, and late fall runs Chinook CWT recovery data in accordance with program objectives. In particular, this report attempts to answer the following questions with this first essentially complete year of recovery data:

- What are the proportions of hatchery and natural-origin fish in spawning returns to CV hatcheries and natural areas, and in ocean harvest? Of the hatchery proportions, what proportions originated from in-basin versus out-of-basin CWT recoveries?

- What are the relative recovery and stray rates for hatchery fish released in-basin versus salmon trucked to and released into the waters of the Carquinez Straits? The latter includes salmon acclimated in net pens that are pulled for several hours into San Pablo Bay before fish are released.

- What are the relative recovery rates for fish acclimated in net pens and released in the bay versus salmon released directly into the waters of the Carquinez Straits?

- What are the relative contribution rates of hatchery fish, by run and release type, to the ocean harvest?

Data and Methods

Inland Escapement Monitoring

During 2010, monitoring of Chinook escapement occurred at all five salmon hatcheries and on major rivers and tributaries throughout the CV. In addition, creel surveys were conducted on river fisheries in the Feather, American, and Sacramento River basins. Returning salmon were counted and 100% sampled at CV hatcheries while sample rates and methods (e.g., carcass surveys, weir counts, redd counts) varied among natural spawner surveys (Table 1).

Approximately 26,500 ad-clipped salmon were observed and 25,700 heads collected by various CV projects. Monitoring agencies include DFG, DWR, EBMUD, FWS, and PSMFC. Most heads were processed by DFG at the Santa Rosa CWT lab (15,839 heads) and by FWS staff at CNFH (9,531 heads). Remaining heads were processed by individual projects and their data submitted to the Santa Rosa CWT Lab. Almost 97% (24,838) of these heads contained valid CWTs, 2% of heads had shed their CWTs prior to processing, and 1% contained CWTs that either were lost during processing or too damaged to read.

Total escapement estimates and the number of salmon sampled for ad-clips in this report were provided by individual CV projects or hatcheries. These data, along with their respective CWT recovery data, were uploaded to the Regional Mark Processing Center (RMPC) and are readily accessible at www.rmpc.org.

Ocean Harvest Monitoring

Since 1962, the DFG's Ocean Salmon Project (OSP) has monitored California's ocean salmon fisheries at approximately 20 ports between Point Conception and the California-Oregon border. The goal of OSP is to sample at least 20% of all Chinook landed and to collect the heads from all ad-clipped salmon observed during monitoring. In 2010, the seasons for California sport and commercial ocean salmon fisheries were relatively constrained (Table 2) to protect both

Sacramento River fall-run Chinook and Klamath River fall-run Chinook. Field staff sampled 13,344 salmon and collected 2,211 heads that were processed by the Santa Rosa CWT lab. About 90% (1,987) of these heads contained valid CWTs, 10% were missing CWTs and <1% contained CWTs that were too damaged to read. Although it is generally agreed that CWTs missing from inland head recoveries is the result of salmon "shedding" these tags prior to release, this can not be assumed for heads recovered from mixed-stock ocean fisheries. Oregon and Washington hatcheries have recently begun to "mass-mark" (i.e., ad-clipped salmon that do not contain a CWT) Chinook to support small mark-selective fisheries in the northwest. During the last several years, OSP has noticed a gradual increase in the number of ocean heads collected that do not contain CWTs, especially in California's northern ports, and assume that this is due to the increased production of mass-marked salmon in Oregon and Washington.

CWT Data Analysis

A "Master" release database of CWT codes was created to determine species, brood year, run, stock origin (hatchery or natural), release site, release date(s), number of salmon CWT tagged, total number of salmon released and any other pertinent release information (e.g., trucked, net pen acclimation, disease) for all 2010 CWT recoveries. All west coast CWT release data for broods 2006 through 2009 were downloaded from the RMPC. Approximately 105 million CV Chinook were released for these five brood years, of which, 37 million fish were marked and tagged utilizing 500 unique CWT codes. Although a few natural origin salmon are trapped, marked, and tagged each year, salmon produced by hatcheries make up more than 95% of all releases. In 2010, there were 319 individual CWT codes recovered in the CV, primarily from age two-, three-, and four-year old Chinook. The CWT master file was updated with any additional information obtained for these CV Chinook releases (e.g., number of untagged salmon associated with 2008 fall-run CNFH production CWT releases) and the production factor calculated for each CWT code. The production factor, $F_{prod,}$ is the total number of fish released (tagged and untagged) represented by each CWT recovery. $F_{prod,}$ was calculated for each CWT code and is defined as,

$$F_{prod} = (Ad.CWT + Ad.noCWT + noAd.CWT + noAd.noCWT) / Ad.CWT ,$$

where Ad.CWT is the number of fish released with ad-clips and CWTs, Ad.noCWT is the number of fish released with ad-clips but without CWTs (i.e., shed tags), noAd.CWT is the number of fish released without ad-clips but with CWTs, and noAd.noCWT is the number of fish released without ad-clips and without CWTs. F_{prod} allows expansion to total hatchery production from observed recoveries of CV CWTs.

For this analysis, each CV CWT release was further classified into "release types" based on the following criteria: run, stock, hatchery or natural, production or experimental, release location, and holding strategy. All CV CWT codes were assigned by brood year into one of 16 fall-run Chinook release types, 4 spring-run Chinook release types, or 2 late fall-run Chinook release types:

Sacramento River Basin Fall-run Chinook Release Types

CFHFe	Coleman National Fish Hatchery fall-run experimental releases
CFHFh	Coleman National Fish Hatchery fall-run in-basin (at hatchery) releases
CFHFn	Coleman National Fish Hatchery fall-run net pen releases

FRHFe	Feather River Hatchery fall-run experimental releases
FRHFn	Feather River Hatchery fall-run net pen releases
FRHFt	Feather River Hatchery fall-run trucked releases (no net pen acclimation)
FRHFtn	Feather River Hatchery fall-run Tiburon net pen releases (held 3-4 months; released in fall)
FeaFw	Feather River fall-run wild
YubFw	Yuba River fall-run wild
NIMF	In-basin releases
NIMFn	Nimbus Fish Hatchery fall-run net pen releases
NIMFtib	Nimbus Fish Hatchery fall-run Tiburon net pen releases (held 3-4 months; released in fall)

San Joaquin River Basin Fall-run Chinook Release Types

MOKF	Mokelumne River Hatchery fall-run in-basin releases
MOKFn	Mokelumne River Hatchery fall-run net pen releases
MOKFt	Mokelumne River Hatchery fall-run trucked releases (no net pen acclimation)
MokFw	Mokelumne River fall-run wild
MERF	Merced River Fish Facility fall-run releases (primarily in-basin)

Central Valley Spring-run Chinook Release Types

FRHS	Feather River Hatchery spring-run in-basin releases
FRHSn	Feather River Hatchery spring-run net pen releases
FRHSt	Feather River Hatchery spring-run trucked releases (no net pen acclimation)
YubSw	Yuba River spring-run wild

Central Valley Late fall-run Chinook Release Types

CFHLe	Coleman National Fish Hatchery late fall-run experimental releases
CFHLh	Coleman National Fish Hatchery late fall-run in-basin (at hatchery) releases

It should be noted that not all release types occurred every brood year and release sites sometimes varied within a given release type (Table 3). There were also several problem CWT releases where stock origin did not match hatchery origin (e.g., American River fall-run Chinook salmon raised at MOK), stocks or runs were mixed prior to CWT tagging and released utilizing various strategies (e.g., American and Mokelumne fall-run Chinook accidentally mixed and tagged together at MOK, FRH fall-run and spring-run Chinook spawned together and released as experimental "hybrid" salmon for Delta studies), or a percentage of the salmon trucked for net pen acclimation were actually released directly into the waters of the Carquinez Strait.

To estimate the total escapement (or harvest) associated with each CWT recovery, each tag recovery was expanded by its respective F_{prod} and sample expansion factor, F_{samp}, which is defined as,

$$F_{samp} = 1 / (f_e \times f_a \times f_d),$$

where f_e is the fraction of the total salmon escapement sampled and examined for ad-clipped fish, f_a is the fraction of heads from ad-clipped salmon collected and processed, and f_d is the fraction of observed CWTs that were successfully decoded (Tables 4 and 5). A few heads were collected opportunistically during redd counts and snorkel surveys but are not included in this analysis since they are not representative of the escapement.

To help delineate between raw CWT recoveries, CWT recoveries expanded for production, CWTs expanded for sampling, and CWTs expanded for production and sampling, the following nomenclature will be used:

CWT = Raw count CWT recoveries
CWT_{prod} = CWT recoveries expanded only by their respective production factor, F_{prod}
CWT_{samp} = CWT recoveries expanded only by their respective sample expansion factor, F_{samp}
CWT_{total} = CWT recoveries expanded by both F_{prod} and F_{samp}

Determining hatchery and natural-origin proportions in CV escapement

To determine the contribution of hatchery and natural-origin Chinook for each natural-area escapement survey or hatchery, all hatchery CWT_{total} were summed to produce the total number of hatchery fish. The contribution of natural-origin fish was then determined by subtracting the total number of hatchery fish from the total escapement estimate, as follows:

$$\text{Estimate of natural-origin Chinook} = \text{Total Escapement Estimate} - \sum_{i=1}^{m} CWT_{total,i} \ ,$$

where m = total number of CWT release groups identified in an escapement survey or hatchery.

Determining recovery rates of various release types in CV escapement and ocean harvest

To determine the relative CV recovery rate, R_{cwt}, of each unique CWT release group (i.e., code), all recoveries were expanded by their location-specific F_{samp}, summed over all recovery locations, and then divided by the total number of fish tagged and released with this CWT. Since expanded recoveries for several individual CWT groups were less than 0.001% of the numbers released, recovery rates are reported in recoveries per 100,000 CWT salmon released, as follows:

$$R_{cwt} = \sum_{j=1}^{l} CWT_{samp,j} \text{ recoveries } / \text{ (CWT release group size / 100,000)},$$

where *j (=1,2,3,,,l)* denotes recovery location.

Data from all CWT release groups belonging to the same brood year and release type were combined and an overall release type-specific CV recovery rate, R_{type}, was calculated as:

$$R_{type} = \sum_{j=1}^{l} \sum_{k=1}^{n} CWT_{samp,j,k} \ / \ (\sum_{k=1}^{n} \text{release group size of CWT } k \ / \ 100{,}000),$$

where: *k* (= 1,2,3,,,n) denotes release group and *j (=1,2,3,,,l)* denotes recovery location.

Determining stray proportions of various release groups in CV escapement

Basin of origin is defined here as the drainage of any major river as it pertains to the geographic region of the CV where a hatchery is located. For this report the CV was segregated into five primary hatchery basins: Battle Creek (including the mainstem of the upper Sacramento River), Feather River (including the Yuba River), American River, Mokelumne River, and the Merced River. Hatchery-origin Chinook returning to streams not included in these five primary basins were considered to be strays. Through discussion with regional biologists it was determined that CNFH stocks are often considered to be analogous to Chinook that originate from the mainstem of the upper Sacramento River and thus are not considered to be strays. Alternatively, FRH stocks are often considered to be strays when they return to the Yuba River, a major tributary in the basin. As a result of differing opinions of what constitutes a stray throughout the CV any CWTs recovered outside of these defined basins of origin based on their reported stock or hatchery were considered strays. Further evaluation of these definitions is warranted as future CFM recovery data become available.

To determine the CV stray proportion, S_{cwt}, for each CWT code, the sum of all CWT_{samp} recoveries collected out of the basin of origin was divided by total CV CWT_{samp} recoveries for that release group, as follows:

$$S_{cwt} = \sum_{p=1}^{o} CWT_{samp,p} \text{ (out-of-basin locations) } / \sum_{p=1}^{q} CWT_{samp,p} \text{ (all CV locations)},$$

where p denotes recovery location, o denotes the number of out-of-basin recovery locations, and q denotes the total number of recovery locations.

Data from all CWT releases belonging to the same brood year and release group were then combined and release type-specific CV stray proportion, $S_{type,}$ was calculated as:

$$S_{type} = \sum_{p=1}^{o}\sum_{k=1}^{n} CWT_{samp,p,k} \text{ (out-of-basin) } / \sum_{p=1}^{o}\sum_{k=1}^{n} CWT_{samp,p,k} \text{ (all CV locations)}$$

Results

General Overview of 2010 CV inland recoveries and California ocean harvest

All but two of the 24,838 valid CWTs recovered in the CV during 2010 were CV Chinook releases; most CWTs originated from brood year 2006 through 2008 releases (Table 6). More than 84% of all expanded CWT recoveries were fall-run Chinook, followed by spring-run (10%) and late fall-run (6%) releases. No Sacramento River winter-run Chinook CWTs were recovered. The majority of fall-run CWTs were age-3 (67%) and age-2 (31%) fish. It should be noted that a few age-1 fall-run CWTs were also sampled which is relatively rare in the CV. Age-3 (92%) fish dominated the spring-run return while age-4 (59%), age-3 (20%), and age-5 (16%) made up most of the late fall-run return. A few age-6 late fall-run fish were also recovered.

All but 141 of the 1,987 valid CWT recoveries from the California ocean harvest in 2010 were CV Chinook releases; most CWTs were brood year 2006 through 2008 releases (Table 7). Approximately 62% of all expanded CWTs in the ocean harvest were fall-run Chinook, followed by late fall-run (30%), spring-run (3%), and winter-run (<1%). The majority of fall-run Chinook CWTs were age-3 (86%) and age-2 (12%) fish. Age-3 (93%) fish dominated the spring-run Chinook harvest while age-4 (62%), age-3 (21%), and age-5 (17%) made up most of the late-fall Chinook catch. A few age-6 late fall-run Chinook were also caught. The remaining 5% of ocean CWT recoveries originated from non-CV rivers, including the Klamath, Trinity, Smith, Chetco and Columbia rivers; most were age-3 (51%) and age-4 (49%) fish.

1. Proportion of hatchery- and natural-origin fish in CV escapement

The proportion of hatchery-origin fish on the natural area spawning grounds varied throughout the CV and by run. The lowest hatchery proportion (1%) was observed in the Butte Creek spring-run

Chinook mark-recapture survey while the highest proportion (78%) was observed in the Feather River fall/spring-run Chinook mark-recapture survey (Figure 1).

The hatchery proportion of fall-run Chinook returning to CV hatcheries ranged from 79% to 95% (Figure 2). The spring-run Chinook return to FRH was 82% hatchery-origin fish whereas the late fall-run return to CNFH was almost 100% hatchery-origin fish.

Overall, there were 23 individual CWT release types contributing to CV escapement in 2010. To facilitate the breakout of the hatchery proportion by stock and release strategy, all release types from the same hatchery/basin were given the same color scheme (Figure 3) in Figures 4 through 9. All net pen releases contain black dots while most trucked, experimental, or Tiburon net pen releases are designated by black stripes when possible (i.e., release types did not overlap for a particular basin).

Upper Sacramento River Basin

Ten escapement surveys were conducted in the Upper Sacramento River Basin: fall and late fall runs Chinook counts at CNFH, fall and late fall runs Chinook mark-recapture surveys in the mainstem Sacramento River, a fall-run Chinook mark-recapture survey in Clear Creek, and spring-run and fall-run Chinook mark-recapture surveys in Butte Creek. Spring and fall runs Chinook redd count surveys were conducted in Mill Creek and a spring-run Chinook snorkel survey (maximum count) was conducted in Deer Creek. Representative sampling for ad-clipped salmon did not occur in Mill and Deer Creek. Returns to CNFH were predominantly hatchery-origin fish released from this facility while escapement into natural areas was primarily natural-origin fish (Figures 4 and 5):

- Fall-run returns at CNFH were 89% hatchery-origin fish (96% CFHFh)
- Fall-run spawners in the mainstem Sacramento River were 20% hatchery-origin fish (48% FRHFn, 19% CFHFh, 17% FRHSn)
- Fall-run spawners in Clear Creek were 4% hatchery-origin fish (45% FRHFn, 32% CFHFh)
- Late fall-run returns at CNFH were almost 100% hatchery-origin fish (99% CFHLh)
- Late fall-run spawners in the mainstem Sacramento River were 6% hatchery-origin fish (73% CFHLh)
- Spring-run spawners in Butte Creek were 1% hatchery-origin fish (63% FRHSn)
- Fall-run spawners in Butte Creek were 11% hatchery-origin fish (89% FRHFn)

Feather River Basin

Four escapement surveys were conducted in the Feather River Basin: spring and fall runs Chinook counts at FRH, a combined fall/spring run Chinook mark-recapture survey in the Feather River, and a combined fall/spring run Chinook mark-recapture survey in the Yuba River. Spring and fall runs Chinook returns to FRH and in the natural areas were predominantly of hatchery-origin (Figure 6):

- Spring-run returns at FRH were 82% hatchery-origin (50% FRHS, 39% FRHSn)
- Fall-run returns at FRH were 95% hatchery-origin (87% FRHFn)
- Fall/spring-run spawners in the Feather River were 78% hatchery-origin (88% FRHFn)
- Fall/spring-run spawners in the Yuba River were 71% hatchery-origin (48% FRHFn, 22% FRHS, 21% FRHSn)

American River Basin

Three escapement surveys were conducted in the American River Basin: fall-run Chinook counts at NFH, a fall-run Chinook mark-recapture survey on the American River and a single late fall-run Chinook carcass count on the American River. In addition, dead salmon were recovered from the NFH weir, which is located just upstream from the hatchery and was installed on September 15th to force returning salmon into NFH. Salmon that migrated upstream beyond the hatchery prior to installation of the weir were trapped in the upstream area. Many of those salmon washed back onto the weir upon death. There is minimal spawning habitat above the weir. Spawner returns to natural areas and those from the NFH weir fish were predominantly of natural-origin while returns to NFH were predominantly of hatchery-origin (Figure 7):

- Fall-run returns to NFH were 79% hatchery-origin (81% NIMFn)
- Fall-run spawners in the American River were 32% hatchery-origin (48% NIMFn, 24% FRHFn, 19% CFHFn)
- Late fall-run spawners in the American River were 24% hatchery-origin (97% CFHLe)
- Salmon recovered on the NFH Weir were 38% hatchery-origin (40% NIMFn, 36% FRHFn)

Mokelumne River Basin

Three escapement surveys were conducted in the Mokelumne River Basin: fall-run Chinook counts at MOK, a video weir count at Woodbridge Dam of all fall-run Chinook escapement into Mokelumne River, and a daily collection of salmon carcasses from the MOK weir, which is installed to prevent salmon from bypassing the MOK fish ladder. This barrier was originally installed on October 8th but removed on October 15th to allow for increased water releases from Camanche Reservoir designed to produce attraction flows for upstream migrating Chinook. The weir was then reinstalled on October 19th when flows returned to a rate that would not damage the weir. Any salmon above the weir when it was installed were trapped and many washed back onto the weir after their death.

All adult Chinook salmon migrating upstream into the Mokelumne River to spawn were counted by the video fish counting device operated by EBMUD at Woodbridge Dam. These counts also included the number of ad-clipped salmon entering the system. By subtracting the 5,520 Chinook that returned to MOK and that were collected on the MOK weir from the total video count of 7,196 Chinook, it was assumed that the remaining 1,676 Chinook remained in the Mokelumne River. Utilizing the same logic, it was also assumed that there were 820 ad-clipped Chinook remaining in the river since only 2,866 of the 3,686 ad-clipped Chinook counted in the video monitoring were recovered at MOK and on the weir. After reviewing the CWT codes recovered from 59 heads collected during sporadic surveys on the Mokelumne River, we found that the proportions of the 12 individual CWT codes collected were very similar to the proportion of these codes recovered at MOK and on the weir; however there were 45 additional CWT codes recovered at the hatchery and weir. Because 100% of Chinook salmon observed at MOK and the weir were sampled, we felt that the MOK recoveries best represented the entire run and thus expanded the estimated 820 ad-clips in the Mokelumne River based on their proportions, including heads that lacked a CWT (approx 1.5%). This approach is based on the methodology used by the Klamath River Technical Team (KRTT) to determine the hatchery composition of fall-run Chinook above Willow Creek Weir on the Trinity River (e.g.,KRTT 2011).

Spawner returns to the Mokelumne River Basin were dominated by hatchery-origin fish (Figure 8):

- Fall-run returns at MOK were 90% hatchery-origin (34% MOKFt, 18% MOKFn, 32% NIMFn)
- Salmon carcasses recovered on the MOK weir were 74% hatchery-origin (50% MOKFt, 18% MOKFn, 27% NIMFn)
- Fall-run spawners in the Mokelumne River were 73% hatchery-origin (50% MOKFt, 18% MOKFn, 31% NIMFn)

San Joaquin River Basin Tributaries
Four additional escapement surveys were conducted in tributaries of the San Joaquin River: fall-run Chinook counts at MER, as well as fall-run Chinook mark-recapture surveys conducted on the Stanislaus, Tuolumne, and Merced rivers. Fall-run Chinook returns to the Merced River were dominated by hatchery-origin fish while the Stanislaus and Tuolumne rivers were almost equally split between hatchery- and natural-origin spawners (Figure 9):

- Fall-run returns at MER were 79% hatchery-origin (37% MOKFt, 18% NIMFn, 12% NIMFtib, 11% CFHFn, 10% MERF)
- Fall-run spawners in the Merced River were 78% hatchery-origin (31% NIMFn, 20% FRHFn, 16% MOKFn, 14% MOKFt)
- Fall-run spawners in the Stanislaus River were 50% hatchery-origin (31% NIMFn, 26% MOKFn, 23% MOKFt)
- Fall-run spawners in the Tuolumne River were 49% hatchery-origin (29% CFHFn, 23% MERF, 19% FRHFn)

2. Relative recovery and stray proportions for hatchery-origin Chinook released in-basin versus hatchery-origin Chinook trucked and released into the waters of the Carquinez Strait (includes Chinook salmon acclimated in net pens and released into San Pablo Bay).

Release strategies vary widely among hatcheries from year to year. This variability has often been in response to fluctuating abundances of certain stocks or differing policies among mitigating agencies with respect to “best” release practices. Lack of consistency and “problem releases” among CV hatcheries has limited the number of release groups available for direct comparison of differing release strategies. For these reasons, there are only six release groups recovered in 2010 that allows in-basin releases to be compared directly to trucked/net pen releases.

Table 8 summarizes the recovery rates R_{type} (in-basin, stray, and ocean) for all release groups with representative recoveries from the CV in 2010. Figures 10 and 11 provide a graphical representation of R_{type} for the Sacramento River fall-run Chinook and other CV stocks, respectively. In general, Chinook that were trucked and released directly into the waters of Carquinez Strait or acclimated in bay area net pens had higher relative recovery rates than their respective in-basin releases. These releases also had higher stray proportions than their paired in-basin counterparts.

Coleman National Fish Hatchery Releases - Fall-run Chinook Broods 2007 and 2008
For brood 2008 CNFH fall-run Chinook releases, the CV age-2 recovery rate for net pen CNFHn releases (161.5) was 2.3 times greater than in-basin CFHFh releases (70.9). However, while

CNFHh releases were only recovered in-basin, the proportion of CFHFn recoveries out-of-basin was very high at 89%.

There were three different CNFH release types for brood 2007 fall-run Chinook. The CV age-3 recovery rate for experimental CFHFe releases (164.0) was more than 3.0 times greater than in-basin CFHFh (54.6) and net pen CFHFn (41.2) releases. Less than 1% of CFHFh were recovered out-of-basin compared to straying proportions of 98% and 25% for CFHFn and CFHFe, respectively.

Feather River Hatchery Releases – Spring-run Chinook Broods 2006, 2007, and 2008
For brood 2008 FRH spring-run releases, the CV age-2 recovery rate for net pen FRHSn releases (32.2) was slightly higher than in-basin FRHS (28.0) releases. Approximately 10% of FRHSn were recovered out-of-basin while all FRHS CWTs were recovered in-basin.

For brood 2007 FRH spring-run releases, the CV age-3 recovery rate for net pen FRHSn releases (440.4) was 1.3 times higher than in-basin FRHS (348.4) releases. Approximately 15% of age-3 FRHSn were recovered out-of-basin while all FRHS CWTs were recovered in-basin.

For brood 2006 FRH spring-run releases, the CV age-4 recovery rate for net pen FRHSt releases (19.4) was 3.0 times higher than in-basin FRHS (6.4) releases. Approximately 18% of both FRHSt and FRHS CWTs were recovered out-of-basin.

Nimbus Fish Hatchery Release – Fall-run Chinook Brood 2008
For brood 2008 NFH fall-run releases, the CV age-2 recovery rate for net pen NIMFn releases (86.9) was 2.6 times greater than in-basin NIMF releases (33.5). However, while NIMF releases were only recovered in-basin, the proportion of NIMFn recoveries out-of-basin was very low at 6%.

Feather River Hatchery Releases – Fall-run Chinook Brood 2008
Although FRH did not have any in-basin releases for broods 2006, 2007 or 2008, they did have experimental FRHFe, net pen FRHFn and trucked FRHFt releases that can be compared.

For brood 2008 FRH fall-run releases, the CV age-2 recovery rate for experimental FRHFe releases (135.6) was slightly higher than net pen FRHFn (117.6) releases. The FRHFe releases were actually “hybrid” fish (FRH fall-run x FRH spring-run Chinook). Approximately 5% of both FRHFe and FRHFn were recovered out-of-basin.

For brood 2006 FRH fall-run releases, the CV age-4 recovery rate for net pen FRHFn releases (17.2) was 3.1 times higher than experimental FRHFe (5.6) releases. Recoveries of trucked FRHFt (0.7) releases were too low for comparison purposes. Approximately 10% of FRHFn and 9% of FRFHe releases were recovered out-of-basin. It should be noted that many of the FRHFn releases had some fish released directly into the bay so it is impossible to separate true net pen releases from trucked/direct bay ones.

3. Relative CV recovery and stray rates of bay releases acclimated in net pens and released directly without acclimatization

The same issues related to release practices that limited the available recovery comparisons in the previous section also limited the comparison of net pen releases and direct releases in the Carquinez Strait area. As a result there is only one release type comparison possible.

Feather River Hatchery Release – Fall-run Chinook Brood 2007

For brood 2007 FRH fall-run releases, the CV age-3 recovery rate for net pen FRHFn releases (478.4) was 3.9 times higher than trucked/direct bay FRHFt (122.9) releases. Approximately 19% of FRHFt fish were recovered out-of-basin compared to 8% of FRHFn releases.

4. Relative recovery rate and contribution of CV release groups to ocean harvest

The relative recovery rate of CV hatchery releases in the 2010 ocean salmon fisheries (sport and commercial combined) varied by age and release group (Figure 12). Of the 4,755 CV CWT_{samp} collected in the fisheries, most were age-3 (84%), followed by age-2 (12%), age-4 (4%) and age-5 (<1%) fish.

The majority of age-2 CV Chinook harvested were in the sport fishery due to its lower size limit (20”-24” total length) compared to the commercial fishery (27” total length). For all age-2 CV releases, trucked MOKFt (42.7) had the highest recovery rate per 100,000 fish released, followed by net pen CFHFn (23.6), San Joaquin basin MERF (11.3), and net pen FRHFn (7.9) releases (Table 8).

Net pen releases had the highest recovery rates for age-3 CV fall and spring runs Chinook. The recovery rate for net pen FRHFn (81.2) was more than twice that of NIMFn (37.7) CFHFn, (32.1), FRHSn (29.4) and MOKFn (22.8). There were only in-basin releases of CV late fall-run CFHLh (24.4) for age-3 fish.

Relatively few age-4 or age-5 CWT recoveries were made compared to age-2 and age-3 CV fish. In-basin CV late fall-run Chinook CFHLh had the highest recovery rate for age-4 (16.0) and age-5 (0.6) CV releases.

Contribution of CV release groups to sport ocean harvest

In 2010, anglers harvested an estimated 14,697 Chinook in the California sport ocean salmon fishery. Based on the expanded CWT_{total} collected in the fishery, including non-CV Chinook release types, hatchery-origin fish contributed 31%-63% of the total harvest, depending on major port area (Figure 13). Of the hatchery-origin fish, fall-run net pen FRHFn releases dominated the sport catch in all port areas: Monterey (43%), San Francisco (38%), Fort Bragg (22%), and Eureka/Crescent City (27%). Other CV releases contributing to all sport fisheries were net pen NIMFn (4-8%), in-basin CFHFh (5-10%) and net pen CFHFn (3-5%); however there were no recoveries of CFHFh and CFHFn in the Eureka/Crescent City port area. Non-CV stocks also made up a higher proportion (3%) in this northern area.

Contribution of CV release groups to commercial ocean harvest

Commercial trollers landed an estimated 15,098 Chinook in the California commercial ocean salmon fishery; most salmon (83%) were caught in the Fort Bragg port area. Based on the expanded CWT_{total} collected in the fishery, hatchery-origin fish contributed 22%-74% of the total harvest, depending on major port area (Figure 14). Of the hatchery release types, fall-run net pen FRHFn dominated the commercial catch in all port areas: Monterey (50%), San Francisco (14%), and Fort Bragg (22%). The Eureka / Crescent City port area was completely closed to commercial fishing in 2010. Other CV releases contributing to the California commercial fishery were net pen NIMFn (3%-10%) and in-basin CFHFh (3%-8%). In addition, non-CV stocks contributed at a higher overall proportion in the commercial fishery (6%) than in the sport fishery (1%), especially in Fort Bragg (7%) where most of the commercial season occurred in 2010.

Discussion

Estimates of hatchery contributions that are presented in this report should be viewed simply as a "single year (2010) snapshot" of CV Chinook escapement and the California ocean harvest. This was the first year that the majority of all CWT recoveries from CV releases were representatively marked and tagged at a minimum 25% level. Although there were definite differences observed in recovery rates and straying proportions among runs, brood years, and CV release groups, this is just the first step in many needed to statistically analyze the contribution of hatchery and natural-origin salmon to natural areas throughout the CV, evaluate hatchery release strategies, improve California ocean and river salmon fisheries management, and determine if other goals of the CFM program are being met. It is also important to note that most of the CV CWT release groups in this study were produced, released and/or recovered during a time when Sacramento River fall-run Chinook were at historically low levels. Thus these salmon were not susceptible to "normal" ocean or river salmon fisheries since these fisheries were either completely closed or very constrained during the last three years.

The effect of interannual variation in survival and year-class strength of both hatchery-origin and natural-origin stocks should be considered when evaluating the status of CV Chinook stocks. At this time neither year class strength or age structure of CV natural-original Chinook are known. Scale-aging work done on 2006, 2007, and 2008 CV Chinook escapement by OSP has indicated that there may be different maturation rates for hatchery and natural-origin fish by stock and basin. It is premature to compare hatchery and natural-origin proportions without having complete brood- and/or stock-specific population estimates. While it may appear that total escapement by hatchery fish in the CV may exceed that of natural-origin fish in any given year, comparing age-specific total escapement (hatchery and natural) once broods complete their life cycle may indicate differences in hatchery and natural ratios for specific age groups and stocks. Such analyses may provide the basis for changing hatchery practices to better mimic wild population parameters. They may also further clarify the effects of specific environmental stressors unique to natural-origin fish and/or specific hatchery CWT release groups.

Strategies for CV fall-run production releases in any given year are often a result of two conflicting objectives. Increasing survival rates to allow for greater harvest and escapement often favors release strategies that bypass the Sacramento-San Joaquin Delta. Alternatively, in-basin release practices are aimed at maximizing homing rates back to the hatchery of origin to reduce impacts on natural stocks. It is impossible to make a thorough comparison of hatchery release practices at this time due to the large variability that existed among CWT release types within the same CV hatchery broods examined in this study. Most release types included individual CWT codes that were released at numerous locations at different times and under various conditions (e.g., river water flows and temperatures, bay tidal flows for trucked and net pen releases). While some individual CWT codes were recovered at a relatively high rate, others within the same release type were not recovered at all. The recovery rate R_{cwt} for individual CWT codes should be examined on a release type basis and the release strategies (in-basin, trucked, net-pen acclimation) that produce the greatest resource value (i.e., highest recovery rate, lowest straying proportion) adopted for future release strategy evaluation. Coordinated and paired hatchery release types will allow for direct comparisons to be made between them and will enrich the available data set used for subsequent evaluation of the hatchery program in the future. The CDFG Fisheries Branch has performed some very preliminary statistical testing to evaluate the significance of differences noted between the performance of individual pairs of release types (Ferreira 2011).

Prior to the CFM program, the primary purpose of CV Chinook escapement monitoring was to provide basic status information (e.g., grilse and adult escapement counts) by individual stocks and basins for California hatchery and ocean harvest management needs. The marking, tagging, or collection of CV CWT fish was not a high priority. CV escapement monitoring has expanded to provide data for a broad range of management applications related to recovery planning for listed stocks. These applications include assessing recovery efforts, including habitat restoration work, improving ocean and river fisheries management, and evaluating CV salmon hatchery programs to ensure both mitigation and conservation goals are being met. To meet the needs of these various assessment efforts, a review of current methodologies being employed among CV inland escapement monitoring programs was undertaken by DFG in 2008. The goal of this review was to identify needed changes and/or additions to survey protocols that will ensure both statistically valid estimates of escapement and the collection of biological data, including CWTs and scales, needed for assessment efforts. In 2012, DFG completed the Central Valley Chinook Salmon Escapement Monitoring Plan that recommends methods for estimating escapement and collecting biological data necessary for improved stock assessment in the CV (Bergman et al. 2012). Survey modifications included changes in the current mark-recapture models being utilized, changes in sampling protocols to ensure representative sampling and proper accounting, and the use of counting devices in place of some mark-recapture programs. This monitoring plan is now being implemented among CV surveys to provide the basis for sound CV Chinook assessment and subsequent management. The OSP and DFG Fisheries Branch CWT laboratories in Santa Rosa and Sacramento respectively, have both been expanded and additional staff hired to process the 40,000-60,000 tagged Chinook expected to be recovered annually during CV escapement and California ocean salmon fisheries monitoring. The OSP lab has also expanded its scale-aging capability utilizing state-of-the-art digital imaging. If these data are going to be used in a timely manner to manage CV salmon production and ocean/river fisheries, all CWT data and stock-specific age composition of CV escapement will be needed by February each year.

The CV CFM program has been successful in marking and tagging the target numbers of salmon each year at each of the CV hatcheries, and has just begun recovering CWTs in a statistically valid manner throughout the CV. The results from this program, in conjunction with future aging work will provide the best opportunity to manage CV Chinook salmon based on scientifically defensible data. The CFM program should be continued with the current design for several years to provide comparable, consistent data needed for harvest and hatchery management. Current funding for both CFM CWT recovery/processing and scale-aging programs expires in July 2013. Identifying future funding for these programs is essential for the continued enhancement of Chinook management in California's Central Valley.

Acknowledgements

Thanks to the following individuals for their assistance in compiling, reviewing and editing data for this report: Jennifer Simon, Barry Miller, and Julie Coombes. Thanks to Rob Titus and Russ Bellmer of DFG Fisheries Branch and David Hankin of Humboldt State University for providing text review and edits for this report. Special kudos are extended to Roxanne Jordan and Barry Dreher of the OSP Santa Rosa CWT lab for processing and reading the thousands of CWTs used in this analysis. We thank the following agencies for providing 2010 CV escapement estimates and their salmon heads/CWT recoveries: DWR Feather River Program, FWS, PSFMC, EBMUD, and YARMT. Additional thanks are extended to staff at the following hatcheries for their cooperation in this monitoring effort: Coleman National Fish Hatchery, Feather River Hatchery, Nimbus Fish Hatchery, Mokelumne River Fish Hatchery, and the Merced River Fish Facility. Last but not least, we want to acknowledge Stan Allen (PSMFC) for his efforts in facilitating the funding, staffing, tagging, and coordination needs of the CFM program. Funding was provided by DFG, DWR, EBMUD, BOR, and the CALFED Ecosystem Restoration Program.

List of Acronyms and Abbreviations

Ad-clipped	clipped adipose fin
BOR	U.S. Bureau of Reclamation

Table 1. Estimation and sampling methods used for the 2010 Central valley Chinook run assessment. (page 1 of 3)

Sampling Location	Estimation and Sampling Methods	Agency
Hatchery Spawners		
Coleman National Fish Hatchery (CNFH) Fall and Late Fall	Direct count. All fish examined for fin-clips, tags, marks. Hatchery takes a one month break in between the fall and late fall run spawning periods. Fish that arrive during this 'break' are counted and excised. Those fish that contain a fall cwt code or have their adipose fin present are later counted as a part of the fall run. Fish containing a late fall CWT code are later counted as late fall. Systematic random bio-sample[a/] of all fish with adipose fin absent. Grilse cutoff: 760 mm.	FWS
Feather River Hatchery (FRH) Spring and Fall	Direct count. All fish examined for fin-clips, tags, marks. All fish arriving at the hatchery April-June tagged with two uniquely-numbered floytags. All fish marked with floytags returning to FRH during August and September are spawned as spring run. All other fish are spawned as fall run. All spring Chinook are bio-sampled. Systematic random bio-sample ~10% of aggregate fall run fish with adipose fin present and absent. All fall run fish with adipose fin absent are bio-sampled. All spawned fall run fish are bio-sampled. Grilse cutoff: 650 mm.	CDFG
Nimbus Fish Hatchery (NFH) Fall	Direct count. All fish examined for fin-clips, tags, marks. Systematic random bio-sample ~10% of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 610 mm.	CDFG
Nimbus Weir Fall	Direct count. All fish examined for fin-clips, tags, marks. All fish with adipose fin absent are bio-sampled.	CDFG
Mokelumne River Hatchery (MOK) Fall	Direct count. All fish examined for fin-clips, tags, marks. Systematic random bio-sample ~10% of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 680 mm females, 710 males.	CDFG
Mokelumne Weir Fall	Direct count. All fish examined for fin-clips, tags, marks. All fish with adipose fin absent are bio-sampled.	CDFG
Merced River Fish Facility (MER) Fall	Direct count. All fish examined for fin-clips, tags, marks. All fish with adipose fin absent are bio-sampled.	CDFG

Table 1. Estimation and sampling methods used for the 2010 Central valley Chinook run assessment. (page 2 of 3)

Sampling Location	Estimation and Sampling Methods	Agency
Natural Spawners		
Upper Sacramento River Mainstem Fall and Late Fall	Superpopulation modification of the Jolly-Seber mark-recapture estimate applied using large females with adipose fin present within survey area (Keswick Dam to Balls Ferry). Chinook removed during the survey for CWT recovery are added to the J-S estimate. Total escapement estimate (Keswick Dam to Princeton) is derived using expansions for: Fish spawning outside of the survey area (Balls Ferry to Princeton) through aerial redd surveys, large male Chinook based on the sex ratio at CNFH, and grilse based on the rate encountered during the mark recapture survey. All fish examined for fin-clips, tags, marks. Bio-data collected from all fresh fish with adipose fin present and absent. Systematic random bio-sample of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 610 mm.	CDFG, FWS
Clear Creek Fall	Modified Schaefer mark-recapture estimate. All fish examined for fin-clips, tags, marks. Bio-data collected from all fresh fish with adipose fin present and absent. Systematic random bio-sample of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 610 mm.	CDFG, FWS
Butte Creek Spring and Fall	Modified Schaefer mark-recapture estimate for spring run. Peterson mark-recapture estimate for fall run. All fish examined for fin-clips, tags, marks. Systematic random bio-sample of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 610 mm.	CDFG
Feather River Fall	Modified Schaefer mark recapture-estimate. All fish examined for fin-clips, tags, marks. Systematic random bio-sample of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Spring run Chinook are included. Grilse cutoff: 650 mm.	DWR
Yuba River Fall	Modified Schaefer mark-recapture estimate. All fish examined for fin-clips, tags, marks. Systematic random bio-sample of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Spring Chinook are included in estimate. Grilse cutoff: 650	CDFG, YARMT
American River Fall	Modified Schaefer mark-recapture estimate. All fish examined for fin-clips, tags, marks. Systematic random bio-sample of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 680 mm.	CDFG
Mokelumne River Fall	Video count at Woodbridge Irragation District Dam. Additionally, in river survey conducted to collect bio-samples from all fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 680 mm females, 710 males.	EBMUD
Stanislaus River Fall	Pooled-Petersen mark-recapture estimate. All fish examined for fin-clips, tags, marks. All fish with adipose fin absent are bio-sampled.	CDFG
Tuolumne River Fall	Pooled-Petersen mark-recapture estimate. All fish examined for fin-clips, tags, marks. All fish with adipose fin absent are bio-sampled.	CDFG
Merced River Fall	Pooled-Petersen mark-recapture estimate. All fish examined for fin-clips, tags, marks. All fish with adipose fin absent are bio-sampled.	CDFG

Table 1. Estimation and sampling methods used for the 2010 Central valley Chinook run assessment. (page 3 of 3)

Sampling Location	Estimation and Sampling Methods	Agency
Recreational Harvest		
Upper Sacramento River Fall	Open October 9th to October 31st from Highway 113 Bridge to Deschutes Road Bridge. Stratified-random sampling design (one weekday and one weekend sample per week per section during the open season per management zone) that included both roving and access interview components, and the collection of coded-wire tags from adipose fin-clipped salmon for stock identification. Bio-data collected during angler interviews.	CDFG
Feather River Fall	Open July 31st to August 29th below the Thermolito Afterbay Outlet. Stratified-random sampling design (one weekday and one weekend sample per week per section during the open season per management zone) that included both roving and access interview components, and the collection of coded-wire tags from adipose fin-clipped salmon for stock identification. Bio-data collected during angler interviews.	CDFG
American River Fall	Open October 30th to November 28th from the mouth to the SMUD power line crossing at Ancil Hoffman Park. Stratified-random sampling design (one weekday and one weekend sample per week per section during the open season per management zone) that included both roving and access interview components, and the collection of coded-wire tags from adipose fin-clipped salmon for stock identification. Bio-data collected during angler interviews.	CDFG
Lower Sacramento River Fall	Open September 4th to October 3rd from the Carquinez Bridge to the Highway 113 Bridge. Stratified-random sampling design (one weekday and one weekend sample per week per section during the open season per management zone) that included both roving and access interview components, and the collection of coded-wire tags from adipose fin-clipped salmon for stock identification. Bio-data collected during angler interviews.	CDFG
Upper Sacramento River Late Fall	Open November 1st to December 12th from Highway 113 Bridge to Deschutes Road Bridge. Stratified-random sampling design (one weekday and one weekend sample per week per section during the open season per management zone) that included both roving and access interview components, and the collection of coded-wire tags from adipose fin-clipped salmon for stock identification. Bio-data collected during angler interviews.	CDFG

a/ Biological samples ("bio-samples" or "bio-data") of live fish or carcasses generally include: sex, fork length, scales, tags or marks, and CWT recovery from ad-clipped fish.

Table 2. 2010 California ocean sport and commerial salmon fishery seasons by major port area.

	Sport		Commercial

NOTE TO READERS

Recovery of Coded-Wire Tags from Chinook Salmon in California's Central Valley Escapement and Ocean Harvest in 2011 presents important data for the improvement of Central Valley salmon management. Until 2007, only experimental releases of fall-run Chinook salmon from Central Valley hatcheries were marked and coded-wire tagged (low, inconsistent numbers), resulting in a lack of data for harvest management, evaluation of hatchery rearing and release practices, hatchery impacts to natural-origin fish, and the success of habitat improvement programs.

The Central Valley Constant Fractional Marking Program (CFM) was initiated in 2007 to estimate in a statistically valid manner the relative contribution of hatchery production and to evaluate the various release strategies being employed in the Central Valley. Beginning with Brood Year 2006 fall-run Chinook, the program has marked and coded-wire tagged a minimum of 25 percent of releases from the Central Valley hatcheries each year (Buttars 2007, 2008, 2009, and 2010). The program is a cooperative effort of the California Department of Fish and Game (DFG), the California Department of Water Resources (DWR), the U.S. Bureau of Reclamation, the U.S. Fish and Wildlife Service (FWS), the East Bay Municipal Utilities District (EBMUD), and the Pacific States Marine Fisheries Commission (PSMFC).

In 2011, more than 55,300 Code Wire Tags were recovered from ad-clipped Chinook sampled in Central Valley natural area spawning surveys, at Central Valley hatcheries, Central Valley river creel surveys, and California commercial and recreational ocean fisheries. All of the fall run Chinook Code Wire Tags recovered in the Central Valley were tagged as part of the CFM program.

This report evaluates the 2011 Central Valley fall, spring, and late fall runs Chinook Code Wire Tags recovery data in accordance with program objectives. In particular, this report attempts to answer the following questions with this second complete year of recovery data:

- What are the proportions of hatchery- and natural-origin fish in spawning returns to CV hatcheries and natural areas, in inland harvest, and in ocean harvest? Of the hatchery proportions, what proportions originated from in-basin versus out-of-basin CWT recoveries?

- What are the relative recovery and stray rates for hatchery fish released in-basin versus salmon trucked to and released into the waters of the Carquinez Strait? The latter includes salmon acclimated in net pens that are pulled for several hours into San Pablo Bay before fish are released. In addition, salmon trucked to and held for several days in coastal net pens before release are also evaluated.

- What are the relative recovery rates for fish acclimated in net pens and released in the bay versus salmon released directly into the waters of the Carquinez Strait?

- What are the relative contribution rates of hatchery fish, by run and release type, to the ocean harvest?

As with all of its products, Fisheries Branch is interested in comments on the utility of this document, particularly regarding its application to monitoring and management decision processes. Therefore, we encourage you to provide us with your comments. Comments should be directed to Dr. Russell J. Bellmer, Fisheries Branch, 830 S Street, Sacramento, CA 95814, (916) 327-8840, Russ.Bellmcr@ wildlife.ca.gov.

Stafford Lehr
Chief, Fisheries Branch

INTRODUCTION

Each year, approximately 32 million fall-run Chinook salmon (salmon) are produced at five hatcheries in California's Central Valley (CV): Coleman National Fish Hatchery (CNFH), Feather River Hatchery (FRH), Nimbus Fish Hatchery (NFH), Mokelumne River Hatchery (MOK), and Merced River Hatchery (MER). Production from these hatcheries contributes to major sport and commercial fisheries in ocean and inland areas. Prior to 2007, only small experimental releases (generally <100,000 fish) of CV fall-run salmon were consistently released with microscopic (≤ 1 mm) coded-wire tags (CWT) inserted in their snouts. Each CWT contains a binary or alpha-numeric code that identifies a specific release group of salmon (e.g., agency, species, run, brood year, hatchery or wild stock, release size, release date(s), release location(s), number tagged and untagged). Any CV salmon containing a CWT is also externally marked with a clipped adipose fin (ad-clipped) to allow for visual identification. Almost all of the fall-run salmon production releases from CV hatcheries were either untagged or tagged at inconsistent and relatively low rates prior to the Constant Fractional Marking (CFM) program.

In 2004, the CALFED Ecosystem Restoration Program (ERP), under the direction of the Central Valley Salmon Project Work Team (CVSPWT), funded a study to design a constant fractional marking and coded-wire tagging program for CV fall-run salmon production at all CV hatcheries. The primary goal of this program was to estimate in a statistically valid manner the relative contribution of hatchery production and to evaluate the various release strategies being employed throughout the CV. The study recommended the implementation of a system-wide marking and tagging program for production releases. Planning studies indicated an optimum marking and tagging rate of 33% for all CV fall-run salmon production releases (Hicks et al. 2005). Following subsequent review of the planning study recommendations, and communication with managers in the Northwest, the CVSPWT recommended a marking and tagging rate of 25% of fall-run production releases. The CVSPWT is an interagency group tasked with coordinating salmon and steelhead monitoring activities in the CV and they helped develop the CFM program. CVSPWT members included staff from the California Department of Fish and Wildlife (CDFW), California Department of Water Resources (DWR), East Bay Municipal Utility District (EBMUD), Metropolitan Water District, Central Valley Project Water Association, National Marine Fisheries Service (NMFS), Pacific States Marine Fisheries Commission (PSMFC), U.S. Bureau of Reclamation (BOR), and the U.S. Fish and Wildlife Service (FWS).

Beginning with brood year 2006, at least 25% of fall-run salmon production releases at CNFH (12-13 million), FRH (9-10 million), NFH (5-6 million), and MOK (4-5 million) have been marked and tagged each spring (Buttars 2007, 2008, 2009, 2010, 2011). This CFM program is a cooperative effort of the CDFW, DWR, BOR, FWS, EBMUD, and PSMFC. It should be noted that due to extremely low production numbers, MOK marked and tagged 100% of their fall-run salmon releases for brood years 2008 and 2009. In addition, almost all of the fall-run salmon production at MER (50,000-300,000 fish), spring-run salmon production at FRH (2 million fish), late-fall-run salmon production at CNFH (1 million fish), and winter-run salmon production reared at Livingston Stone National Fish Hatchery (100,000-200,000 fish) have been marked and coded-wire tagged each year.

During 2011, more than 55,300 CWTs were recovered from ad-clipped salmon sampled in CV fall-, spring-, and late-fall-run natural area spawning surveys, at CV hatcheries, in CV river creel surveys, and in California ocean commercial and recreational fisheries. All of the fall-run salmon CWTs recovered in 2011 were tagged as part of the CFM program. This report evaluates the 2011 CV fall-, spring-, and late-fall-run salmon CWT recovery data in accordance with program objectives. In particular, this report attempts to answer the following questions with this second complete year of recovery data:

- What are the proportions of hatchery- and natural-origin fish in spawning returns to CV hatcheries and natural areas, in inland harvest, and in ocean harvest? Of the hatchery proportions, what proportions originated from in-basin versus out-of-basin CWT recoveries?

- What are the relative recovery and stray rates for hatchery fish released in-basin versus salmon trucked to and released into the waters of the Carquinez Strait? The latter includes salmon acclimated in net pens that are pulled for several hours into San Pablo Bay before fish are released. In addition, salmon trucked to and held for several days in coastal net pens before release are also evaluated.

- What are the relative recovery rates for fish acclimated in net pens and released in the bay versus salmon released directly into the waters of the Carquinez Strait?

- What are the relative contribution rates of hatchery fish, by run and release type, to the ocean harvest?

DATA AND METHODS

Inland Escapement Monitoring

During 2011, monitoring of salmon escapement occurred at all five salmon hatcheries and on major rivers and tributaries throughout the CV. In addition, creel surveys were conducted on sport fisheries in the Feather, American, and Sacramento River basins. Returning salmon were counted and 100% of the ad-clipped salmon sampled at all CV hatcheries except CNFH, which sampled every other ad-clipped salmon (i.e., 50% sample rate) for fall-run escapement and 100% of ad-clipped salmon for the late-fall-run escapement. Similar to 2010, sample rates and methods (e.g., carcass surveys, weir counts, redd counts) varied among natural spawner surveys throughout the CV (Table 1).

Approximately 52,900 ad-clipped salmon were observed and 48,138 heads collected by various CV projects. Monitoring agencies include CDFW, DWR, EBMUD, FWS, and PSMFC. Most heads were processed by CDFW at their Santa Rosa and Sacramento CWT labs with the exception of approximately 9,500 heads collected from Clear Creek and CNFH that were processed by FWS staff at the Red Bluff FWS office. Additionally a few hundred heads were processed by individual projects, most notably at the Red Bluff and La Grange CDFW offices. Their respective data were submitted to the Santa Rosa CWT Lab for inclusion in the 2011 CV CWT recovery database. Almost 97% (46,596) of these heads contained valid CWTs, 2% of heads had shed their CWTs prior to processing, and less than 1% contained CWTs that were either too damaged to read or lost during processing.

Total escapement estimates and the number of salmon sampled for ad-clips in this report were provided by individual CV projects or hatcheries. These data, along with their respective CWT recovery data, were uploaded to the Regional Mark Processing Center (RMPC) and are readily accessible at www.rmpc.org.

Ocean Harvest Monitoring

Since 1962, the CDFW's Ocean Salmon Project (OSP) has monitored California's ocean salmon fisheries at approximately 20 ports between Point Conception and the California-Oregon border. The goal of OSP is to sample at least 20% of all salmon landed and to collect the heads from all ad-clipped salmon observed during monitoring. In 2011, the seasons for California sport and commercial ocean salmon fisheries were less constrained (Table 2) than in recent years due to an increase in the ocean abundance of both Sacramento River and Klamath River fall-run salmon. Field staff sampled more than 47,600 salmon and collected 9,768 heads that were processed by the Santa Rosa CWT lab. About 90% (8,717) of these heads contained valid CWTs, 10% were missing CWTs and <1% contained CWTs that were too damaged to read or lost during processing. Although it is generally agreed that CWTs missing from inland head recoveries is the result of salmon "shedding" these tags prior to release, this cannot be assumed for heads recovered from mixed-stock ocean fisheries. Oregon and Washington hatcheries have been "mass-marking" salmon (i.e., ad-clip only without a CWT) to support small mark-selective fisheries in the northwest. During the last several years, OSP has noticed a gradual increase in the number of ocean heads collected that do not contain CWTs, especially in California's northern ports, and assume that this is due to the increased production of mass-marked salmon in Oregon and Washington.

CWT Data Analysis

A "master" release database of CWT codes was created to determine species, brood year, run, stock origin (hatchery or natural), release site, release date(s), number of salmon CWT tagged, total number of salmon released and any other pertinent release information (e.g., trucked, net pen acclimation, disease) for all 2011 CWT recoveries. All west coast CWT release data for broods 2007 through 2010 were downloaded from the RMPC. Approximately 100.6 million CV salmon were released for these four brood years (BY), of which, 38.5 million fish were marked and tagged utilizing 444 unique CWT codes. Although a few natural-origin salmon are trapped, marked, and tagged each year, salmon produced by hatcheries make up more than 98% of all CWT releases. In 2011, there were 310 individual CWT codes recovered in the CV, primarily from age-2, age-3 and age-4 salmon. The CWT master file was updated with any additional information obtained for these CV salmon releases (e.g., number of untagged salmon associated with BY 2008 fall-run CNFH production CWT releases) and the production factor calculated for each CWT code. The production factor, $F_{prod,}$ is the total number of fish released (tagged and untagged) represented by each CWT recovery. F_{prod} was calculated for each CWT code and is defined as,

$$F_{prod} = (\text{Ad.CWT} + \text{Ad.noCWT} + \text{noAd.CWT} + \text{noAd.noCWT}) \ / \ \text{Ad.CWT}\ ,$$

where Ad.CWT is the number of fish released with ad-clips and CWTs, Ad.noCWT is the number of fish released with ad-clips but without CWTs (i.e., shed tags prior to release or CWT not correctly inserted), noAd.CWT is the number of fish released without ad-clips but with CWTs, and noAd.noCWT is the number of fish released without ad-clips and without CWTs. F_{prod} allows expansion to total hatchery production from observed recoveries of CV CWTs.

For this analysis, each CV CWT release was further classified into "release types" based on the following criteria: run, stock, hatchery or natural, production or experimental, release location, and holding strategy. All CV CWT codes were assigned by brood year into one of 17 fall-run release types, 3 spring-run release types, or 2 late-fall-run release types:

Sacramento River Basin fall-run Chinook salmon release types

CFHFe	Coleman National Fish Hatchery fall-run experimental releases
CFHFh	Coleman National Fish Hatchery fall-run in-basin (at hatchery) releases
CFHFn	Coleman National Fish Hatchery fall-run net pen releases
FRHFe	Feather River Hatchery fall-run experimental releases (includes fall x spring hybrid salmon)
FRHFn	Feather River Hatchery fall-run net pen releases
FRHFnc	Feather River Hatchery fall-run net pen coastal releases (Santa Cruz)
FRHFt	Feather River Hatchery fall-run trucked releases (no net pen acclimation)
FRHFtib	Feather River Hatchery fall-run Tiburon net pen releases (held 2-6 months)
FeaFw	Feather River fall-run wild
NIMF	Nimbus Fish Hatchery fall-run in-basin releases
NIMFn	Nimbus Fish Hatchery fall-run net pen releases
NIMFtib	Nimbus Fish Hatchery fall-run Tiburon net pen releases (held 3-4 months)

San Joaquin River Basin fall-run Chinook salmon release types

MOKF	Mokelumne River Hatchery fall-run in-basin releases
MOKFn	Mokelumne River Hatchery fall-run net pen releases
MOKFt	Mokelumne River Hatchery fall-run trucked releases (no net pen acclimation)
MokFw	Mokelumne River fall-run wild
MERF	Merced River Fish Facility fall-run releases (primarily in-basin)

Central Valley spring-run Chinook salmon release types

FRHS	Feather River Hatchery spring-run in-basin releases
FRHSn	Feather River Hatchery spring-run net pen releases
ButSw	Butte Creek spring-run wild

Central Valley Late-Fall-run Chinook salmon release types

CFHLe	Coleman National Fish Hatchery late-fall-run experimental releases
CFHLh	Coleman National Fish Hatchery late-fall-run in-basin (at hatchery) releases

It should be noted that not all release types occurred every brood year and release sites sometimes varied within a given release type (Table 3). There were also several problem CWT releases where stock origin did not match hatchery origin (e.g., BY 2007 American River fall-run salmon raised at MOK), stocks or runs were mixed prior to CWT tagging and released utilizing various strategies (e.g., known pairs of FRH fall- and spring-run salmon spawned and identified by CWT subsequently released as experimental "hybrid" salmon for Delta studies), or a high percentage of the salmon trucked for net pen acclimation actually died prior to release (e.g., 75% mortality reported in truckload of CNFH fall-run salmon being transported to San Pablo Bay net pens).

To estimate the total escapement (or harvest) associated with each CWT recovery, each tag recovery was expanded by its respective F_{prod} and sample expansion factor, F_{samp}, which is defined as,

$$F_{samp} = 1 / (f_e \times f_a \times f_d),$$

where f_e is the fraction of the total salmon escapement sampled and examined for ad-clipped fish, f_a is the fraction of heads from ad-clipped salmon collected and processed, and f_d is the fraction of observed CWTs that were successfully decoded (Tables 4 and 5). A few heads were collected opportunistically during redd counts or snorkel surveys; these CWTs were given an F_{samp} of 1.00 (i.e., no expansion) since they were not representative of the total escapement.

After the release of the 2010 report (Kormos et al. 2012), Mohr and Satterthwaite (in press) demonstrated how the potential misidentification of ad-clipped salmon in carcass surveys can significantly bias estimations of the total hatchery contribution since they frequently encounter both fresh and non-fresh (decayed) carcasses.

Salmon sampled in some CV carcass surveys are generally recorded as ‘fresh’ or ‘decayed’ based on criteria such as condition of the eyes (clear vs. opaque) or gills (pink vs. grey). Often the ad-clipped (marked) status of a decayed salmon can be uncertain due to the deteriorating condition of the carcass. Mohr and Satterthwaite (in press) identified four possible outcomes: 1) certain (all ad-clipped and non-marked salmon are correctly identified), 2) false negatives (ad-clipped salmon identified as not marked), 3) false positives (non-marked salmon identified as ad-clipped) or 4) false negatives/positives (ad-clipped salmon identified as non-marked and non-marked salmon identified as ad-clipped).

While condition criteria are somewhat ambiguous and classification may be inconsistent among surveys, differences in the ad-clip rate between fresh and decayed fish have been observed. During the 2010 upper Sacramento River fall-run salmon carcass survey, 21% of the fresh fish sampled were classified as ad-clipped compared to only 6% of decayed fish (i.e., false negative). The fresh carcass heads also contained a CWT more frequently than the heads collected from decayed carcasses (i.e., false positive). Furthermore, the sample sizes for these categories were also significantly different, with the number of decayed fish sampled (n=1,124) nearly four times greater than the fresh fish (n=291). The latter appears to be fairly common among CV carcass surveys currently collecting fish condition data.

Mohr and Satterthwaite (in press) demonstrated how the differences noted above negatively biased the hatchery contribution estimations for the 2010 upper Sacramento River fall-run salmon carcass survey as reported in Kormos et al. (2012). This was also shown to be true for the 2010 upper Sacramento late-fall-run survey. Furthermore, they cautioned that using only fresh CWT data may eliminate the occurrence of rare CWT codes in analyses due to the small sample sizes common with fresh carcasses in these surveys. Since both of these surveys contained false negatives and false positives, and sample sizes for decayed carcasses were much larger than those of fresh carcasses, we have adopted the following equation developed by Mohr and Satterthwaite (in press) to calculate F_{samp} for carcass surveys collecting fish condition data, thus reducing the potential bias associated with these surveys:

$$F_{samp} = (\,N \times p\_adc|fresh \times p\_cwt|fresh,adc) \,/\, n_{valid\ cwt}\ ,$$

where N = estimated total escapement, p_adc|fresh = proportion of fresh fish sampled that were ad-clipped, p_cwt|fresh,adc = proportion of ad-clipped fresh fish that contained a CWT, and $n_{valid\ cwt}$ = total number of valid CWTs collected from both fresh and decayed fish.

Table 6 shows the original and revised F_{samp} for the 2010 upper Sacramento River fall-run and late-fall-run carcass surveys. This new equation was also used to determine F_{samp} for the five CV salmon carcass surveys that collected fish condition sample data in 2011: upper Sacramento River fall-run, upper Sacramento late-fall-run, Clear Creek fall-run, Cottonwood Creek fall-run, and American River fall-run. We are hopeful that other CV carcass surveys will begin to collect fish condition information to reduce the known bias in CWT sample rate calculations and hatchery contribution estimations as demonstrated by Mohr and Satterthwaite (in press). We realize that the calculated hatchery contribution rates of the other carcass surveys in this report are most likely negatively biased.

To help delineate between raw CWT recoveries, CWT recoveries expanded for production, CWTs expanded for sampling, and CWTs expanded for production and sampling, the following nomenclature will be used:

CWT = Raw count CWT recoveries
CWT_{prod} = CWT recoveries expanded only by their respective production factor, F_{prod}
CWT_{samp} = CWT recoveries expanded only by their respective sample expansion factor, F_{samp}
CWT_{total} = CWT recoveries expanded by both F_{prod} and F_{samp}

Determining hatchery- and natural-origin proportions in CV escapement and harvest

To determine the contribution of hatchery- and natural-origin salmon, all CWT_{total} were summed to estimate the total number of hatchery fish in each survey. The contribution of natural-origin fish for each survey was then determined by subtracting the total number of hatchery fish from the total escapement estimate, as follows:

$$\text{Estimate of natural-origin salmon} = \text{Total escapement estimate} - \sum_{i=1}^{m} CWT_{total,i}\ ,$$

where m = total number of hatchery-origin CWT release groups identified in an escapement survey or hatchery.

Determining recovery rates of various release types in CV escapement and ocean harvest

To determine the relative CV recovery rate, R_{cwt}, of each unique CWT release group (i.e., code), all recoveries were expanded by their location-specific F_{samp}, summed over all recovery locations, and then divided by the total number of fish tagged and released with this CWT. Since expanded recoveries for several individual CWT groups were less than 0.001% of the total number released, recovery rates are reported in recoveries per 100,000 CWT salmon released, as follows:

$$R_{cwt} = \sum_{j=1}^{l} CWT_{samp,j} \text{ recoveries } / \text{ CWT release group size } / \text{ } 100{,}000,$$

where *j (=1,2,3,,,l)* denotes recovery location.

Data from all CWT release groups belonging to the same brood year and release type were combined and an overall release type-specific CV recovery rate, R_{type}, was calculated as:

$$R_{type} = \sum_{j=1}^{l} \sum_{k=1}^{n} CWT_{samp,k} \ / \sum_{k=1}^{n} \text{ release group size of CWT }_{k} / \text{ } 100{,}000,$$

where *k* (= 1,2,3,,,n) denotes release group.

Determining stray proportions of various release groups in CV escapement
To be consistent with Kormos et al. (2012), basin of origin is defined here as the drainage of any major river as it pertains to the geographic region of the CV where a hatchery is located. The CV was again segregated into five primary hatchery basins: upper Sacramento River (including Battle Creek), Feather River (including the Yuba River), American River, Mokelumne River, and the Merced River. Hatchery-origin salmon returning to streams not included in these five primary basins were considered to be strays. Any CWTs recovered outside of these defined basins of origin based on their reported stock or hatchery were considered strays.

Further evaluation of these definitions is warranted as future CFM recovery data become available and the definition of straying as it pertains to sub-basins of the CV is determined through hatchery program evaluation. To help facilitate this discussion, Appendix 1 presents alternative recovery and stray rates for CNFH and FRH CWT releases based on the assumption that recoveries in the upper Sacramento River and Yuba River, respectively, are strays.

To determine the CV stray proportion, S_{cwt}, for each CWT code, the sum of all CWT_{samp} recoveries collected out of the basin of origin was divided by total CV CWT_{samp} recoveries for that release group, as follows:

$$S_{cwt} = \sum_{p=1}^{o} CWT_{samp,p} \text{ (out-of-basin locations) } / \sum_{p=1}^{q} CWT_{samp,p} \text{ (all CV locations)},$$

where *p* denotes recovery location, *o* denotes the number of out-of-basin recovery locations, and *q* denotes the total number of recovery locations.

Data from all CWT releases belonging to the same brood year and release type were then combined and release type-specific CV stray proportion, $S_{type,}$ was calculated as:

$$S_{type} = \sum_{p}^{o} \sum_{k}^{n} CWT_{samp,p,\,k} \text{ (out-of-basin) } / \sum_{p}^{o} \sum_{k}^{n} CWT_{samp,p,k} \text{ (all CV locations)}$$

RESULTS

General Overview of 2011 CV inland recoveries and California ocean harvest

All but three of the 46,596 valid CWTs recovered in the CV during 2011 were CV salmon releases; most CWTs originated from brood year 2007 through 2009 releases (Table 7). More than 93% of all expanded salmon CWT recoveries were fall-run, followed by spring-run (3%) and late-fall-run (3%) releases. Data from the 2011 escapement survey of Sacramento River winter-run (SacW) salmon is not included in this report (USFWS report); however there were two SacW CWTs recovered at CNFH during fall-run spawning operations.

The majority of fall-run CWTs were age-2 (57%) and age-3 (36%) fish. Three age-1 fall-run CWTs were also sampled. The spring-run CWTs consisted primarily of age-3 (56%), age-2 (24%), and age-4 (20%) fish. Age-4 (51%), age-3 (30%), and age-5 (14%) made up most of the late-fall-run return. Only four age-6 fish were recovered in the CV; all were BY 2006 late-fall-run. It should be noted that there were also eight coho CWTs recovered from BY 2009 Lake Oroville releases; six were recovered during fall-run spawning at FRH while the other two were recovered in the Yuba River carcass survey above the Daguerre Point Dam (DPD) dam. Non-Chinook salmon CWTs were not included in any analyses.

Almost 90% of the 8,717 valid CWT recoveries from the California ocean harvest in 2011 were CV salmon releases; most CWTs were brood year 2007 through 2009 releases (Table 8). Approximately 86% of all expanded CWTs in the ocean harvest were fall-run, followed by late-fall-run (2%), spring-run (1%), and winter-run (<0.4%) salmon. The majority of fall-run salmon CWTs were age-3 (60%) and age-2 (35%) fish. Age-3 (85%) and age-4 (14%) made up most of the late-fall-run salmon catch while age-3 (72%) and age-2 (25%) fish dominated the spring-run salmon harvest. Almost all (99%) of the winter-run salmon were age-3. A few age-6 late-fall-run salmon were also caught. The remaining 10% of ocean CWT recoveries originated from non-CV hatcheries or waters, including the Klamath, Trinity, and Smith rivers in northern California as well as the Rogue, Chetco, Umpqua, Columbia, Snake and other Pacific Northwest rivers; most were age-3 (64%) and age-4 (34%) fish.

1. Proportion of hatchery- and natural-origin fish in CV escapement

In 2011, there were 22 individual CWT release types contributing to CV escapement and ocean fisheries. To facilitate the breakout of the hatchery proportion by stock and release strategy, all release types from the same hatchery/basin were given the same color scheme (Figure 1) in all pie chart figures. All net pen releases, except salmon released from net pens in Santa Cruz and Tiburon, contain black dots. Coastal and Tiburon net pen releases are designated with a crisscross pattern. Trucked and experimental releases are designated by black stripes. The revised hatchery and natural components of the 2010 upper Sacramento River fall-run and late-fall-run carcass surveys from Kormos et al. (2012) are shown in Figure 2.

The proportion of hatchery-origin fish on the natural area spawning grounds in 2011 varied throughout the CV and by run. The lowest hatchery proportion occurred in the Butte Creek spring-run salmon mark-recapture survey where no ad-clipped salmon were encountered (0%)

while the highest proportion (90%) was observed in the Feather River fall/spring-run salmon carcass mark-recapture survey (Figure 3).

It should be noted that since there has not been a carcass survey or CWT recovery program in Battle Creek since 2005, it is not possible to directly determine the hatchery contribution, recovery rate, or stray rate into the natural escapement of this tributary. Total natural escapement is estimated by subtracting the number of salmon returning to CNFH from the total video weir count into Battle Creek. The hatchery contribution to the natural area escapement in Battle Creek is considered equivalent to the hatchery return at CNFH (Robert Null, FWS, pers comm).

The hatchery proportion of fall-run salmon returning to CV hatcheries ranged from 77% to 98% (Figure 4). The spring-run salmon return to FRH was 94% hatchery-origin fish whereas the late-fall-run return to CNFH was almost 100% hatchery-origin fish. The percentage of hatchery and natural-origin contribution to the total escapement for all surveys by release type is shown in Table 9.

Upper Sacramento River Basin

Eight escapement surveys were conducted in the Upper Sacramento River Basin that allow for expansion of CWTs: fall-run and late-fall-run salmon counts at CNFH, fall-run and late-fall-run salmon mark-recapture carcass surveys in the mainstem Sacramento River, a fall-run salmon mark-recapture survey in Clear Creek, a video count and associated carcass survey in Cottonwood Creek, and spring- and fall-run salmon mark-recapture carcass surveys in Butte Creek. Four additional escapement surveys were conducted: video counts of fall-run salmon escapement with associated carcass surveys to opportunistically collect CWTs and other bio-data were conducted in Mill and Deer Creeks while redd surveys were conducted in Mill and Deer Creeks to estimate spring-run salmon escapement. Since representative sampling for ad-clipped salmon did not occur in any of these surveys, any CWT recovery in these creeks represents only itself (i.e., $F_{samp} = 1.00$) and the reported hatchery percentages represent their minimal hatchery contribution. Returns to CNFH were predominantly hatchery-origin fish released from this facility while escapement into natural areas was primarily natural-origin fish (Table 9, Figures 5 and 6):

- Fall-run returns at CNFH were 89% hatchery-origin fish
- Late-fall-run returns at CNFH were 100% hatchery-origin fish
- Fall-run spawners in the upper Sacramento River were 27% hatchery-origin fish
- Late-fall-run spawners in the upper Sacramento River were 44% hatchery-origin fish
- Fall-run spawners in Clear Creek were 8% hatchery-origin fish
- Fall-run spawners in Cottonwood Creek were 58% hatchery-origin fish
- Fall-run spawners in Butte Creek were 7% hatchery-origin fish
- Spring-run spawners in Butte Creek were 0% hatchery-origin fish

Feather River Basin

Five escapement surveys were conducted in the Feather River Basin: spring-run and fall-run salmon counts at FRH, a combined fall/spring-run salmon mark-recapture survey in the Feather River, a combined fall/spring-run salmon mark-recapture survey in the Yuba River below DPD, and a combined fall/spring-run salmon Vaki Riverwatcher count above DPD (with associated bio-sample). The Vaki Riverwatcher count also included the number of ad-clipped salmon entering the system. The 107 heads recovered in the bio-survey above DPD were expanded to the total 1,733 ad-clipped salmon counted at DPD. Hatchery contribution by release type was based on the proportion of valid CWT codes recovered. Spring-run and fall-run salmon returns to FRH and in the natural areas were predominantly of hatchery-origin (Table 9, Figures 7 and 8):

- Spring-run returns at FRH were 94% hatchery-origin
- Fall-run returns at FRH were 96% hatchery-origin
- Fall/spring-run spawners in the Feather River were 90% hatchery-origin
- Fall/spring-run spawners in the Yuba River below DPD were 34% hatchery-origin
- Fall/spring-run spawners in the Yuba River above DPD were 65% hatchery-origin

American River Basin

Two escapement surveys were conducted in the American River Basin: fall-run salmon counts at NFH and a fall-run salmon mark-recapture survey on the American River. In addition, dead salmon were recovered from the NFH weir, which is located just upstream from the hatchery and was installed on September 10th to force returning salmon into NFH. Salmon that migrated upstream beyond the hatchery prior to installation of the weir were trapped in the upstream area. Many of those salmon washed back onto the weir upon death. There is minimal spawning habitat above the weir. Spawner returns to natural areas and those from the NFH were predominantly of hatchery-origin while returns above the NFH weir were predominantly of natural-origin (Table 9, Figure 6):

- Fall-run returns to NFH were 77% hatchery-origin
- Fall-run spawners in the American River were 66% hatchery-origin
- Salmon recovered on the NFH Weir were 26% hatchery-origin

Mokelumne River Basin

Two escapement surveys were conducted in the Mokelumne River Basin: fall-run salmon counts at MOK and a video weir count at Woodbridge Dam of all fall-run salmon escapement into the Mokelumne River.

All adult salmon migrating upstream into the Mokelumne River to spawn were counted by the video fish counting device operated by EBMUD at Woodbridge Dam. These counts also included the total number of ad-clipped salmon above the Dam. By subtracting the 15,922 salmon that returned to MOK from the total video count of 18,589 Chinook, it was assumed that the remaining 2,667 salmon remained in the Mokelumne River. Utilizing the same logic, it was also assumed that there were 2,227 ad-clipped salmon remaining in the river since only 14,724 of the 16,951 ad-clipped salmon counted in the video monitoring were recovered at MOK. After reviewing the CWTs recovered from heads collected during sporadic surveys on the Mokelumne River, it was found that the proportions of the CWT codes collected were very similar to the proportion of the same codes recovered at MOK. Because 100% of Chinook salmon observed at MOK were sampled, including seven ad-clipped salmon recovered from the hatchery weir, we felt that the MOK CWT recoveries best represented the entire run and thus expanded the estimated 2,227 ad-clips in the Mokelumne River based on the proportion of valid CWTs recovered. This approach is based on the methodology used by the Klamath River Technical

Team (KRTT) to determine the hatchery composition of fall-run salmon above Willow Creek Weir on the Trinity River (KRTT 2012).

Spawner returns to the Mokelumne River Basin were dominated by hatchery-origin fish (Table 9, Figure 10):

- Fall-run returns at MOK were 98% hatchery-origin
- Fall-run spawners in the Mokelumne River were 88% hatchery-origin

San Joaquin River Basin Tributaries

Four escapement surveys were conducted in tributaries of the San Joaquin River that allow for expansion of CWTs: fall-run salmon counts at MER, as well as fall-run salmon mark-recapture surveys conducted on the Stanislaus, Tuolumne, and Merced rivers. One additional redd survey was conducted on the Calaveras River with an associated carcass survey to opportunistically collect CWTs and other bio-data. Fall-run salmon returns to the Merced, Stanislaus, and Tuolumne Rivers were dominated by hatchery-origin spawners (Table 9, Figure 11):

- Fall-run returns at MER were 88% hatchery-origin
- Fall-run spawners in the Merced River were 89% hatchery-origin
- Fall-run spawners in the Stanislaus River were 83% hatchery-origin
- Fall-run spawners in the Tuolumne River were 73% hatchery-origin

Inland Creel Survey

Five separate creel surveys were conducted in the Sacramento River and its tributaries: upper and lower Sacramento River fall, American River fall, Feather River fall, and a late-fall-run survey on the Sacramento River. The results of these surveys were not shown in 2010 due to extremely high sample expansions that caused hatchery contribution estimates to exceed estimated harvest totals in some cases. Although this over-estimation did not occur in 2011, sample expansions remained high for some of these surveys and thus estimates of hatchery contribution may also be biased high. All inland harvest was dominated by hatchery-origin salmon (Table 9, Figures 12 and 13):

- Upper Sacramento River fall-run harvest was 75% hatchery-origin
- Lower Sacramento River fall-run harvest was 81% hatchery-origin
- Feather River fall-run harvest was 83% hatchery-origin
- American River fall-run harvest was 95% hatchery-origin
- Sacramento River late-fall-run harvest was 68% hatchery-origin

2. Relative recovery and stray rates for hatchery-origin salmon released in-basin versus hatchery-origin salmon trucked and released into the waters of the Carquinez Strait (includes salmon acclimated in net pens and released in San Pablo Bay or Santa Cruz Harbor).

Release strategies vary among hatcheries from year to year. This variability has often been in response to fluctuating abundances of certain stocks or differing policies among mitigating agencies with respect to "best" release practices. Lack of consistency and "problem releases" among CV hatcheries has limited the number of release groups available for direct comparison of differing release strategies. In 2011, there were 11 release groups consisting of 22 individual brood specific release types recovered that allow in-basin releases to be compared directly to trucked/net pen releases.

Table 10 summarizes the recovery rates R_{type} (in-basin, stray, and ocean) for all release groups with representative recoveries from the CV and ocean in 2011. Recovery rates displayed there, in the following figures, and discussed below are scaled for comparison at total recoveries per 100,000 salmon released. Figures 14 and 15 provide a graphical representation of R_{type} for the Sacramento River fall-run salmon and other CV stocks, respectively, and include the total number of salmon released with CWTs for each release type. In general, salmon that were trucked and released directly into the waters of Carquinez Strait or acclimated in net pens had higher relative recovery rates than their respective in-basin releases. These releases also had higher stray proportions than their paired in-basin counterparts.

Coleman National Fish Hatchery releases - Fall-run salmon broods 2007, 2008, and 2009

For brood 2009 CNFH fall-run salmon releases, the overall age-2 inland and ocean recovery rate for net pen CNFHn releases (729) was 1.9 times greater than in-basin CFHFh releases (385). While the total CV recovery rate was equivalent (216) between these two release types, the CNFHn ocean recovery rate (513) was 3.0 times higher than that of CNFHh (170). However, the proportion of CNFHh out-of-basin recoveries was only 1%, while the proportion of CFHFn out-of-basin recoveries was very high at 95%.

For brood 2008 CNFH fall-run salmon releases, the overall age-3 inland and ocean recovery rate for net pen CNFHn releases (1,387) was 3.5 times greater than in-basin CFHFh releases (399). The total CV recovery rate for CNFHn releases (296) was also more than double that of CNFHh (120) and the CNFHn ocean recovery rate (1,091) was 3.9 times higher than that of CNFHh (279). However, again the proportion of CNFHh out-of-basin recoveries was only 1%, while the proportion of CFHFn out-of-basin recoveries was very high at 95%.

For brood 2007 CNFH fall-run salmon releases, the overall age-4 inland and ocean recovery rate for net pen CNFHn releases (97) was 3.7 times greater than in-basin CFHFh releases (26). The total CV recovery rate for CNFHn releases (27) was also double that of CNFHh (13) and the CNFHn ocean recovery rate (70) was 5.4 times higher than that of CNFHh (13). However, zero CNFHh recoveries came from out-of-basin, while the proportion of CFHFn out-of-basin recoveries was very high at 98%.

Feather River Hatchery releases – Spring-run salmon broods 2007, 2008, and 2009
For brood 2009 FRH spring-run releases, the overall age-2 inland and ocean recovery rate for net pen FRHSn releases (121) was 1.8 times higher than in-basin FRHS releases (66). The total CV recovery rate for FRHSn releases (110) was also higher than that of FRHS (58) by 1.9 times, and the FRHSn ocean recovery rate (11) was fairly equivalent to that of FRHS (8). Approximately 2% of FRHSn were recovered out-of-basin while all FRHS CWTs were recovered in-basin.

For brood 2008 FRH spring-run salmon releases, the overall age-3 inland and ocean recovery rate for net pen FRHSn releases (238) was slightly lower than that of FRHS releases (249). The total CV recovery rate for FRHSn releases (207) was also slightly lower than that of FRHS (233), and the FRHSn ocean recovery rate (31) was fairly equivalent to that of FRHS (26). Approximately 2% of FRHSn were recovered out-of-basin while all FRHS CWTs were recovered in-basin.

For brood 2007 FRH spring-run salmon releases, the overall age-4 inland and ocean recovery rate for net pen FRHSn releases (67) was slightly higher than that of FRHS releases (50). The total CV recovery rate for FRHSn releases (66) was also slightly higher than that of FRHS (49), and the FRHSn ocean recovery rate (1) was identical to that of FRHS (1). Again, approximately 2% of FRHSn were recovered out-of-basin while all FRHS CWTs were recovered in-basin.

Feather River Hatchery releases – Fall-run salmon broods 2007, 2008, and 2009
Although FRH did not have any in-basin releases for broods 2007, 2008 or 2009, they did have experimental FRHFe, bay net pen FRHFn, coastal net pen FRHFnc, central bay net pen FRHFtib, and trucked direct bay FRHFt releases that can be evaluated.

For brood 2009 FRH fall-run salmon releases, the overall age-2 inland and ocean recovery rate for net pen FRHFn releases (578) was higher than that of central bay net pen FRHFtib releases (301), but lower than that of coastal net pen FRHFnc releases (644). The differences however, in recovery rates for CV and ocean areas are more revealing. The CV recovery rate for net pen FRHFn releases (349) was higher than that of central bay net pen FRHFtib releases (227), and much higher than that of the relatively few coastal net pen FRHFnc releases (60). The ocean recovery rate for net pen FRHFn releases (229) was much higher than that of central bay net pen FRHFtib releases (75), but much lower than that of coastal net pen FRHFnc releases (584). Approximately 4% and 5% of FRHFn and FRHFtib were recovered out-of-basin respectively, while 18% of FRHFnc CWTs were recovered out-of-basin.

For brood 2008 FRH fall-run salmon releases, the overall age-3 inland and ocean recovery rate for net pen FRHFn releases (754) was much higher than that of central bay net pen FRHFtib releases (433) and experimental FRHFe releases (401). The FRHFe releases were actually “hybrid” fish (FRH fall-run x FRH spring-run). The CV recovery rates for net pen FRHFn releases (358), central bay net pen FRHFtib releases (299), and experimental FRHFe releases (332) were fairly equivalent. The ocean recovery rate for net pen FRHFn releases (396) was much higher than that of central bay net pen FRHFtib releases (133) and experimental FRHFe releases (69). Approximately 4% of FRHFn and FRHFe were recovered out-of-basin, while 14% of FRHFtib CWTs were recovered out-of-basin.

For brood 2007 FRH fall-run salmon releases, the overall age-4 inland and ocean recovery rate for net pen FRHFn releases (165) was much higher that experimental FRHFe releases (8). Approximately 2% of FRHFe were recovered out-of-basin. A more in-depth comparison of the net pen FRHFn and trucked direct bay FRHFt releases from this brood are discussed in Section 3 below.

Nimbus Fish Hatchery releases – Fall-run salmon broods 2008 and 2009

For brood 2009 NFH fall-run salmon releases, the CV overall age-2 inland and ocean recovery rate for net pen NIMFn releases (315) was 1.8 times lower than that of NIMF releases (584). The total CV recovery rate for NIMFn releases (129) was 1.5 times lower than that of NIMF (196), and the NIMFn ocean recovery rate (185) was over 2 times lower than that of NIMF (388). Approximately 11% of NIMFn were recovered out-of-basin while only 2% of NIMF CWTs were recovered out-of-basin.

For brood 2008 NFH fall-run salmon releases, the CV overall age-3 inland and ocean recovery rate for net pen NIMFn releases (1,372) was 18.5 times higher than that of NIMF releases (74). The total CV recovery rate for NIMFn releases (247) was 7 times higher than that of NIMF (35), and the NIMFn ocean recovery rate (1,124) was nearly 29 times higher than that of NIMF (39). Approximately 4% of NIMFn were recovered out-of-basin while all NIMF CWTs were recovered in-basin.

Mokelumne Fish Hatchery releases – Fall-run salmon broods 2007 and 2009

For brood 2009 MOK fall-run salmon releases, the CV overall age-2 inland and ocean recovery rate for net pen MOKFn releases (947) was 4.2 times higher than that of MOKF releases (224). The total CV recovery rate for MOKFn releases (811) was 3.6 times higher than that of MOKF (224) The MOKFn ocean recovery rate was 135 while the MOKF ocean recovery rate was zero. Approximately 14% of MOKFn were recovered out-of-basin while only 1% of MOKF CWTs were recovered out-of-basin.

For brood 2007 MOK fall-run salmon releases, the CV overall age-4 inland and ocean recovery rate for net pen MOKFn releases (35) was much higher than that of MOKF releases (1). The total CV recovery rate for MOKFn releases (11) was also much higher than that of MOKF (1), The ocean recovery rate for MOKFn releases was 24 while there were no ocean recoveries for MOKF. Approximately 65% of MOKFn were recovered out-of-basin while the lone MOKF recovery was in-basin.

3. Relative CV recovery and stray rates of bay releases acclimated in net pens and released directly without acclimatization

The same issues related to release practices that limited the available recovery comparisons in the previous section also limited the comparison of net pen releases and direct releases in the Carquinez Strait area. As a result there is only one release type comparison possible.

Feather River Hatchery releases – Fall-run salmon brood 2007

For brood 2007 FRH fall-run salmon releases, the overall age-4 recovery rate inland and ocean for net pen FRHFn releases (165) was 3.5 times higher than that of trucked direct bay FRHFt releases (47). The CV recovery rate was 2.7 times higher for net pen FRHFn releases (97) compared to that of trucked direct bay FRHFt releases (36) and the ocean recovery rate for net pen FRHFn releases (68) was 6.8 times higher than that of trucked direct bay FRHFt releases (10). Approximately 11% of FRHFn were recovered out-of-basin while 66% of FRHFt CWTs were recovered out-of-basin.

4. Relative recovery rate and contribution of CV release groups to ocean harvest

The relative recovery rate of CV hatchery releases in the 2011 ocean salmon fisheries (sport and commercial combined) varied by age and release type (Figure 16). Of the 58,843 CV CWT_{samp} recovered in the fisheries, most were age-3 (60%), followed by age-2 (34%), age-4 (1%) and age-5 (<.01%) fish (Table 10). The majority of age-2 CV salmon were harvested in the sport fishery (Figure 16) due to its lower size limit (24" total length) compared to the commercial fishery (27" total length).

For all age-2 CV releases, coastal net pen FRHFnc (584) had the highest recovery rate, followed by net pen CFHFn (513), in-basin NIMF (388), and San Joaquin basin MERF (372) releases.

Net pen releases also had the highest recovery rates for age-3 CV salmon releases. The recovery rates for net pen NIMFn (1,124) and CFHFn (1,091) releases were similarly high, almost double that of trucked MOKFt releases (573), and nearly three times that of net pen FRHFn releases (396).

Relatively few age-4 or age-5 CWT recoveries were made compared to age-2 and age-3 CV fish. The central bay NIMFtib releases had the highest recovery rate for age-4 (144) and late-fall-run in-basin CFHLh had the highest recovery rate for age-5 (0.6).

Contribution of CV release groups to sport ocean harvest

In 2011, anglers harvested an estimated 49,822 salmon in the California sport ocean salmon fishery. The majority (65%) of the harvest occurred in San Francisco and Monterey port areas (Table 11). Based on the expanded CWT_{total} collected in the fishery, including non-CV salmon release types, hatchery-origin fish contributed 57%-77% of the total harvest, depending on major port area (Figure 17). Of all hatchery release types, fall-run net pen FRHFn contributed the most (18.2%) to the total sport harvest, followed by fall-run in-basin CFHFh (14.4%), net pen NIMFn (8.5%) and in-basin NIMF (7.2%). Non-CV releases contributed 3.2% to the total harvest.

Fall-run net pen FRHFn releases contributed the greatest to the sport harvest in Monterey (23%), San Francisco (20%), and Fort Bragg (16%). In Eureka-Crescent City, the fall-run in-basin CFHFh releases contributed the most (12%) to the hatchery sport catch. Other CV releases contributing to California sport fisheries were net pen NIMFn (6-14%), in-basin CFHFh (12-16%), in-basin NIMF (2-12%), and net pen CFHFn (4-9%). The contribution of non-CV stocks was highest (11%) in the Eureka-Crescent City port area, most likely due to its proximity to rivers and salmon hatcheries in northern California, Oregon and Washington.

Contribution of CV release groups to commercial ocean harvest

Commercial trollers landed an estimated 70,028 salmon in the California commercial ocean salmon fishery; most salmon (56%) were landed in the Fort Bragg port area (Table 11). Based on the expanded CWT_{total} collected in the fishery, hatchery-origin fish contributed 26%-57% of the total harvest, depending on major port area (Figure 18). Of all hatchery-origin release types, fall-run net pen NIMFn contributed the most (11.2%) to the total commercial harvest, followed by fall-run in-basin CFHFh (8.9%), net pen FRHFn (8.8%) and non-CV releases (7.4%).

The Monterey port area catch was dominated by fall-run net pen FRHFn releases (20%), while San Francisco and Fort Bragg port areas were dominated by fall-run net pen NIMFn releases (16% and 10%, respectively). The Eureka-Crescent City port area was dominated by non-CV releases (10%). The other CV release type contributing a relatively high percentage to the California commercial fishery was in-basin CFHFh (4%-13%). The contribution of non-CV stocks was highest (11.1%) in the Fort Bragg area, followed by Eureka-Crescent City (10.3%). Again this is most likely due to the proximity of these port areas to rivers and salmon hatcheries in northern California, Oregon and Washington.

DISCUSSION

Estimates of 2011 hatchery contributions and recovery rates by release type that are presented in this report should be viewed as the second “single year snapshot” of salmon escapement and harvest in the CV and California ocean fisheries. All CWT recoveries in 2011 were from CV releases that were representatively marked and tagged at the CFM minimum 25% level. Although there were definite differences observed in recovery rates and straying proportions among runs, brood years, and CV release groups, this effort continues the initial phase of the work needed to statistically analyze the contribution of hatchery- and natural-origin salmon to hatchery and natural areas throughout the CV, evaluate hatchery release strategies, improve California ocean and river salmon fisheries management, and determine if other goals of the CFM program are being met. Most of the CV CWT release groups in this study were produced, released and recovered during a time when Sacramento River fall-run salmon were at historically low levels or still in the stages of recovery. Although the 2011 ocean and river salmon fisheries were much less constrained than those in 2009-2010, salmon were still not susceptible to the historical levels of effort observed in ocean or river salmon fisheries prior to 2008.

Another critical factor to consider is that 2011 had the highest age-2 escapement of CV fall-run salmon on record. Thus the age-2 recoveries presented in this report are part of a very strong brood, compared to the weaker broods that preceded it. This apparent disparity in year class strength is important to note when comparing the relative recovery rates and hatchery contribution of various release types to harvest and escapement.

Again, the effects of interannual variation on survival and year-class strength for both hatchery- and natural-origin stocks should be considered when evaluating the status of CV salmon stocks. At this time, neither year class strength or age structure of CV natural-original salmon is known.

As noted in Kormos et al. (2012), scale-aging work done on 2006, 2007, and 2008 CV salmon escapement has indicated there may be different maturation rates between hatchery- and natural-origin fish by stock and basin. It remains premature to compare hatchery and natural-origin proportions without having complete brood- and/or stock-specific population estimates. While it may appear that total escapement of hatchery fish in the CV may exceed that of natural-origin fish in any given year, comparing age-specific total escapement (hatchery and natural) after broods complete their life cycle may identify differences in hatchery and natural ratios on a basin- and stock-specific basis. Such analyses may provide the basis for changing hatchery practices to better mimic wild population parameters. They may also further clarify the effects of specific environmental stressors unique to natural-origin fish or specific hatchery CWT release groups.

Strategies for CV fall-run production releases in any given year are often a result of two conflicting objectives. Increasing survival rates to allow for improved escapement and harvest often favors release strategies that bypass the Sacramento-San Joaquin Delta and acclimate salmon prior to release to reduce mortality from predators or other environmental factors. Alternatively, in-basin release practices are aimed at maximizing homing rates back to the hatchery of origin to reduce impacts on natural stocks. It is impossible to make a thorough comparison of hatchery release practices at this time due to the large variability that existed among CWT release types within the same CV hatchery broods examined in this study. Many release types included individual CWT codes that were released at numerous locations at different times and under various conditions (e.g., river water flows and temperatures, different net pen locations, incoming vs. outgoing bay tidal flows). While some individual CWT codes were recovered at a relatively high rate, others within the same release type were recovered at minimal levels if at all. The recovery rate R_{cwt} for individual CWT codes should be examined on a release type basis and the release strategies (e.g., in-basin, net pen acclimation) that produce the greatest resource value (i.e., high recovery rate with low straying) adopted for future release strategy evaluation. Coordinated and paired hatchery release types will allow for direct comparisons to be made between them and will enrich the available data set used for subsequent evaluation of the hatchery program in the future. Only FRH spring-run salmon in-basin and net pen releases have consistently allowed a true comparison during the last several broods.

There has been much debate among salmon biologists and managers on the definition of straying. Although it seems straight-forward to simply define any salmon not returning to the river of its hatchery location as a stray, decades of sharing broodstock and juvenile production among hatcheries, including different run-types, and releasing juvenile salmon at various sites and times throughout the CV have complicated this issue.

Years of sharing broodstock or progeny can confound the straying definitions in any system, especially when salmon return en masse to rivers where the shared broodstock or progeny originated. In addition, juvenile salmon production raised at other rearing facilities or released near the confluences of other rivers or within the delta system appear to exacerbate the problem of salmon straying to other systems. Although many of these practices have been recently terminated, it may take years before the long-term effects of these actions diminish and stray rates can be accurately determined and compared. In addition, preliminary analysis of individual

CWT codes within the same release type indicate that the timing of water releases within the CV during juvenile outmigration and adult escapement may also affect recovery and stray rates.

Another critical issue is the definition of straying when a mitigation hatchery is not located on the river being impacted. In 1942, CNFH was built specifically to mitigate for the loss of salmon spawning habitat in the upper Sacramento River basin caused by the construction of Shasta Dam. Because CNFH was built on Battle Creek, approximately 6 miles upstream of its confluence with the Sacramento River, the Keswick Fish Trap was constructed concurrently in the upper Sacramento River specifically to collect salmon broodstock for the hatchery (Black 1999). Historically, salmon taken at the Keswick Fish Trap contributed as much as 50 to 75 percent of the annual fall-run broodstock used at CNFH from the 1940s through the late 1970s (USFWS 2011) and this facility was utilized for fall-run broodstock collection until the late 1980s. Although the collection of fall-run broodstock at Keswick Fish Trap ceased completely in 1987, the introgression of CNFH hatchery- and natural-origin fall-run salmon continues naturally in the upper Sacramento River. Late-fall-run salmon are still collected at the trap for CNFH propagation purposes so that a genetically integrated hatchery stock can be maintained and the effects of domestication can be reduced (USFWS 2011). It is for these reasons that some salmon biologists continue to consider CNFH stocks to be analogous to salmon that originate from the mainstem of the upper Sacramento River.

Hatchery objectives for CNFH fall-run salmon unambiguously state that CNFH stocks are intended to escape to Battle Creek alone, and all other recoveries outside of that stream are strays. Tributaries of a larger river basin with an existing mitigation hatchery are also not intended to receive hatchery escapement, as is the case with the Yuba River. Hatchery objectives for FRH state that hatchery salmon originating there are intended to escape to only the Feather River. This is true despite many factors beyond the control of managers that affect salmon migration patterns such as dam operations, water temperatures and water diversions. Hatchery release location alone is the tool available to managers to mitigate the straying of hatchery stocks, and it often comes at a cost to the survival of hatchery production. In both the upper Sacramento River and Feather River basins, the rate of historical and present introgression of natural-origin stocks among their respective tributaries is unknown.

Given the issues identified above and to be consistent with Kormos et al. (2012), the same primary CV basins were used to define stray rates in this report; however to allow further evaluation and discussion of these issues, all CNFH and FRH CWT releases that were recovered in the upper Sacramento River and Yuba River, respectively, during 2011 are treated as strays in Appendix 1. It should be noted that differences in stray rates for FRH and CNFH under this alternative stray definition are relatively small as compared to the previous definition. A primary goal of this report is to provide information that will be useful in California salmon management, including the upcoming hatchery review process.

The advent of Santa Cruz coastal bay net pen release recoveries in the CV and ocean fisheries during 2011 also warrants some attention. These “enhancement” releases are intended to provide additional harvest to local ocean fisheries in the Monterey Bay area but they may also pose a potential risk to coastal salmon and steelhead stocks that may suffer from introgression or competition with hatchery stocks. As noted above, this release type should be evaluated after several broods have completed their respective life cycle so that their relative age-specific contribution to ocean fisheries and inland escapement can be determined. However, work is currently underway to monitor central California coastal streams to determine if this release type is straying into these areas. All coastal net pen releases are ad-clipped and contain a unique CWT code so identifying these fish should be relatively simple. If it appears that coastal net pen releases are competing or hybridizing via introgression with ESA-listed coastal salmon or steelhead stocks, then these programs should be seriously evaluated in the near term.

Prior to the creation of the CFM program, the primary purpose of CV salmon escapement monitoring was to provide basic status information (e.g., grilse and adult escapement counts) by individual stocks and major tributaries for California hatchery and ocean harvest management needs. The marking, tagging, or collection of CV CWT fish was not a high priority. CV escapement monitoring has since expanded to provide data for a broad range of management applications, including the recovery planning for ESA-listed salmonid stocks. These applications include assessing recovery efforts, including habitat restoration work, improving ocean and river fisheries management, and evaluating CV salmon hatchery programs to ensure both mitigation and conservation goals are being met. To meet the needs of these various assessment efforts, a review of current methodologies being employed among CV inland escapement monitoring programs was undertaken by CDFW in 2008. The goal of this review was to identify needed changes and/or additions to survey protocols that will ensure both statistically valid estimates of escapement and the collection of biological data, including CWTs and scales, needed for assessment efforts. In 2012, CDFW completed the "Central Valley Chinook Salmon Escapement In-River Monitoring Plan" that recommends methods for estimating escapement and collecting biological data necessary for improved stock assessment in the CV (Bergman et al. 2012). Survey modifications included changes in the current mark-recapture models being utilized, changes in sampling protocols to ensure representative sampling and proper accounting, and the use of counting devices in place of some mark-recapture programs. This monitoring plan is now being implemented among CV surveys to provide the basis for sound CV salmon assessment and subsequent management.

One critical item that was omitted from the recommended CV sampling protocol modifications was the need to account for the fresh versus decayed condition of fish sampled in CV carcass surveys. As identified by Mohr and Satterthwaite (in press) and discussed in this report, this information is needed to minimize the bias in determining the hatchery contribution by release type in natural areas. We know it is incorrect to assume that all sampled carcasses have the same ad-clip detection probability when a large disparity between fresh and decayed fish has been shown. Sample sizes related to these two conditions are also a factor when attempting to recover relatively small CWT releases (e.g., less than 200,000 ESA-listed Sacramento River winter-run salmon CWTs are released annually) or release types with typically low rates of contribution.

Overall, the CV CFM program has been successful in marking and tagging its targeted numbers of salmon each year at the five CV hatcheries. In addition, CWTs are now being recovered throughout the CV in a statistically valid manner. The CDFW CWT laboratories in Santa Rosa and Sacramento have both been expanded and are able to process the 50,000-70,000 heads recovered annually from ad-clipped salmon observed during CV escapement and California ocean and river fisheries monitoring.

The CFM program should be continued with the current design for several years to provide comparable, consistent data needed for harvest and hatchery management. Efforts continue to secure future funding for this program. The results from this program, in conjunction with the creation and funding of a permanent scale-aging program, should provide the best opportunity to manage CV salmon based on scientifically defensible data. Secure adequate funding will allow both CWT and scale-aging data to be available by February each year in order to manage CV salmon stocks, hatchery production, and California ocean and river fisheries in a real-time manner, similar to Klamath River fall-run salmon management. This work is essential for the continued enhancement of salmon management in California's Central Valley.

ACKNOWLEDGEMENTS

Thanks to the following individuals for their assistance in compiling, reviewing and editing data for this report: Vanessa Gusman, Jennifer Simon, Alex Letvin and Barry Miller. Thanks to Michael Lacy, Alive Low, Rob Titus, Kevin Shaffer and Doug Killam of CDFW for providing internal text review and edits for this report. Our sincere appreciation is extended to Michael Mohr and Will Satterthwaite of the NMFS Southwest Fisheries Science Center in Santa Cruz for reviewing this document and developing a new methodology to reduce bias associated with expansions of carcass survey recovery data. Additional thanks go to FWS Red Bluff and CNFH staff Scott Hamelberg, Kevin Niemela, and Robert Null for their thoughtful review and comments.

Credit and admiration must be offered to the myriad of staff among the many agencies that work tirelessly in the field to gather the necessary data and CWT recoveries that provide the basis for this report. They are too numerous to name, however without them, this valuable analysis would not be available for evaluation. We thank the following agencies for providing 2011 CV escapement estimates and their salmon heads/CWT recoveries: Department of Water Resources, United States Fish and Wildlife Service, Pacific States Marine Fisheries Commission, East Bay Municipal Utilities District, and the Yuba Accord River Management Team. Additional thanks are extended to staff at the following hatcheries for their cooperation in this monitoring effort: Coleman National Fish Hatchery, Feather River Hatchery, Nimbus Fish Hatchery, Mokelumne River Fish Hatchery, and the Merced River Hatchery.

Special kudos are extended to both the OSP Santa Rosa and Fisheries Branch Sacramento CWT labs for processing, reading, and validating the thousands of CWTs used in this analysis. Further thanks must be given to the CDFW staff in the Red Bluff and La Grange offices, as well as FWS staff in Red Bluff for their efforts in processing, reading, and validating CWTs collected from their regional surveys and hatcheries.

Last but not least, we want to acknowledge Stan Allen (PSMFC) and Alice Low for their efforts in facilitating the funding, staffing, tagging, and coordination needs of the CFM program. Funding was provided by CDFW, DWR, EBMUD, BOR, and the CALFED Ecosystem Restoration Program.

Table 1. Estimation and sampling methods used for the 2011 CV Chinook run assessment. (page 1 of 3)

Sampling Location	Estimation and Sampling Methods	Agency
Hatchery Spawners		
Coleman National Fish Hatchery (CNFH) Fall and Late-Fall	Direct count. All fish examined for fin-clips, tags, marks. Hatchery takes a one month break in between the fall and late-fall run spawning periods. Fish that arrive during this 'break' are counted and excised. Those fish that contain a fall CWT code or have their adipose fin present are later counted as a part of the fall run. Fish containing a late-fall CWT code are later counted as late-fall. Systematic random bio-sample[a/] of all fish with adipose fin absent. Grilse cutoff: 700 mm.	FWS
Feather River Hatchery (FRH) Spring and Fall	Direct count. All fish examined for fin-clips, tags, marks. All fish arriving at the hatchery April-June tagged with two uniquely-numbered floytags. All fish marked with floytags returning to FRH during August and September are spawned as spring run. All other fish are spawned as fall run. All spring Chinook are bio-sampled. Systematic random bio-sample ~10% of aggregate fall run fish with adipose fin present and absent. All fall run fish with adipose fin absent are bio-sampled. All spawned fall run fish are bio-sampled. Grilse cutoff: 650 mm.	CDFW
Nimbus Fish Hatchery (NFH) Fall	Direct count. All fish examined for fin-clips, tags, marks. Systematic random bio-sample ~10% of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 685 mm.	CDFW
Nimbus Weir Fall	Direct count. All fish examined for fin-clips, tags, marks. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 685 mm.	CDFW
Mokelumne River Hatchery (MOK) Fall	Direct count. All fish examined for fin-clips, tags, marks. Systematic random bio-sample ~10% of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 680 mm females, 710 mm males.	CDFW
Mokelumne Weir Fall	Direct count. All fish examined for fin-clips, tags, marks. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 680 mm females, 710 mm males.	CDFW
Merced River Fish Facility (MER) Fall	Direct count. All fish examined for fin-clips, tags, marks. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 635 mm.	CDFW
Natural Spawners		
Upper Sacramento River Mainstem Fall and Late-Fall	Superpopulation modification of the Cormack-Jolly-Seber mark-recapture estimate applied using all females within survey area (Keswick Dam to Balls Ferry). Total female escapement estimate (Keswick Dam to Princeton) is derived using expansions for females spawning outside of the survey area (Balls Ferry to Princeton) through aerial redd surveys. Male Chinook expanded based on the sex ratio at CNFH. Total estimate from Keswick to Princeton is then males and females. All fish examined for fin-clips, tags, marks. Bio-data collected from all fresh fish with adipose fin present and absent. Systematic random bio-sample of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 675 mm females, 755 mm males.	CDFW, FWS

Table 1. Estimation and sampling methods used for the 2011 CV Chinook run assessment. (page 2 of 3)

Sampling Location	Estimation and Sampling Methods	Agency
Clear Creek Fall	Superpopulation modification of the Cormack-Jolly-Seber mark-recapture estimate. All fish examined for fin-clips, tags, marks. Bio-data collected from all fresh fish with adipose fin present and absent. Systematic random bio-sample of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 675 mm females, 755 mm males.	CDFW, FWS
Cottonwood Creek Fall	Video weir count at mouth of creek to determine total escapement. Systematic carcass survey conducted to collect bio-samples from all fish with adipose fin present and absent. Grilse cutoff: 750 mm.	FWS, CDFW
Butte Creek Spring and Fall	Superpopulation modification of the Cormack-Jolly-Seber mark-recapture estimate for spring run. Peterson mark-recapture estimate for fall run. All fish examined for fin-clips, tags, marks. Systematic random bio-sample of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 610 mm.	CDFW
Feather River Fall	Superpopulation modification of the Cormack-Jolly-Seber mark recapture-estimate. All fish examined for fin-clips, tags, marks. Systematic random bio-sample of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Spring run Chinook are included. Grilse cutoff: 650 mm.	DWR
Yuba River Fall	Above Daguerre Point Dam: Vaki Riverwatcher direct count. Additionally, systematic random bio-sample of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Below Daguerre Point Dam: Superpopulation modification of the Cormack-Jolly-Seber mark-recapture estimate. All fish examined for fin-clips, tags, marks. Systematic random bio-sample of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Spring Chinook are included in estimate. Grilse cutoff: 650 mm.	CDFW, YARMT
American River Fall	Superpopulation modification of the Cormack-Jolly-Seber mark-recapture estimate. All fish examined for fin-clips, tags, marks. Systematic random bio-sample of aggregate fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 680 mm.	CDFW
Mokelumne River Fall	Video count at Woodbridge Irrigation District Dam. Additionally, in river survey conducted to collect bio-samples from all fish with adipose fin present and absent. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 680 mm females, 710 mm males.	EBMUD
Stanislaus River Fall	Superpopulation modification of the Cormack-Jolly-Seber mark-recapture estimate. All fish examined for fin-clips, tags, marks. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 680 mm females, 760 mm males.	CDFW
Tuolumne River Fall	Superpopulation modification of the Cormack-Jolly-Seber mark-recapture estimate. All fish examined for fin-clips, tags, marks. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 680 mm females, 760 mm males.	CDFW
Merced River Fall	Superpopulation modification of the Cormack-Jolly-Seber mark-recapture estimate. All fish examined for fin-clips, tags, marks. All fish with adipose fin absent are bio-sampled. Grilse cutoff: 680 mm females, 760 mm males.	CDFW

Sampling Location	Estimation and Sampling Methods	Agency
Recreational Harvest		
Upper Sacramento River Fall	Open July 16th to December 18th from Highway 113 Bridge to the Lower Red Bluff Boat Ramp. An additional river reach from the Red Bluff Diversion Dam to the Deschutes Road Bridge was open August 1st through December 18th.Stratified-random sampling design (one weekday and one weekend sample per week per section during the open season per management zone) that included both roving and access interview components, and the collection of coded-wire tags from adipose fin-clipped salmon for stock identification. Bio-data collected during angler interviews.	CDFW
Feather River Fall	Open July 16th to December 11th from the mouth to 1,000 ft below the Thermolito Afterbay Outfall. Stratified-random sampling design (one weekday and one weekend sample per week per section during the open season per management zone) that included both roving and access interview components, and the collection of coded-wire tags from adipose fin-clipped salmon for stock identification. Bio-data collected during angler interviews.	CDFW
American River Fall	Open July 16th to December 31st from the Jiboom Street Bridge to the base of Nimbus Dam with the following reach specific exceptions. The reach from the mouth to the Jiboom Street Bridge was open from July 16th to December 11th. The reach from the SMUD power line crossing to the USGS cable crossing was open from July 16th to October 31st, and the reach from the USGS cable crossing to the Hazel Avenue Bridge was open from July 16th to September 14th. Stratified-random sampling design (one weekday and one weekend sample per week per section during the open season per management zone) that included both roving and access interview components, and the collection of coded-wire tags from adipose fin-clipped salmon for stock identification. Bio-data collected during angler interviews.	CDFW
Lower Sacramento River Fall	Open July 16th to December 11th from the Carquinez Bridge to the Highway 113 Bridge. Stratified-random sampling design (one weekday and one weekend sample per week per section during the open season per management zone) that included both roving and access interview components, and the collection of coded-wire tags from adipose fin-clipped salmon for stock identification. Bio-data collected during angler interviews.	CDFW
Upper Sacramento River Late Fall	Open November 1st to December 18th from Highway 113 Bridge to Deschutes Road Bridge. Stratified-random sampling design (one weekday and one weekend sample per week per section during the open season per management zone) that included both roving and access interview components, and the collection of coded-wire tags from adipose fin-clipped salmon for stock identification. Bio-data collected during angler interviews.	CDFW

a/ Biological samples ("bio-samples" or "bio-data") of live fish or carcasses generally include: sex, fork length, scales, tags or marks, and CWT recovery from ad-clipped fish.

Table 2. 2011 California ocean sport and commerial salmon fishery seasons by major port area.

Major Port Area	Sport		Commercial

Total		**302,326**	**128,774**	**52,912**	**48,138**	**46,596**				

a/ Number of salmon sampled and visually checked for an ad-clip.

b/ Late-fall hatchery and natural escapement occurred in late fall 2010; late-fall sport harvest occurred in late fall 2011.

c/ Sample expansion factor calculated based on the ad-clip rate and proportion of ad-clipped fish containing CWTs of fresh fish only and expanded to all CWTs (Mohr and Satterthwaite, in press).

d/ Battle creek fall Chinook natural escapement not sampled; escapement estimate based on total Battle Creek adult and jack video weir counts minus returns to Coleman National Fish Hatchery.

e/ Escapement estimates based on redd surveys or video counts; CWTs collected opportunistically and are not representative of total escapement.

Table 5. Catch estimates and sample data for 2011 Ocean Salmon Sport and Commercial Fisheries by major port area.

a/ Any values resulting in less than 0.05% are displayed here as "-". Note: These values represent a small number of recoveries and are not actual zeros.

b/ Natural-origin Feather River (FeaW) and Mokelumne River (Mokw) CWT releases are not included in this table due to minimal recoveries occurring only at the Feather River and Mokelumne hatcheries (contributed 0.02% and 0.01%, respectively).

c/ Surveys without representative sampling of CWTs; proportions shown are based only on CWTs collected opportunistically.

d/ No CWT recovery survey or ad-clip count available for Battle Creek natural escapement. CWT release group and total hatchery proportions assumed to be equivalent to Coleman National Fish Hatchery (FWS staff, per. comm).

e/ Total natural area fall run total only includes surveys with representative sampling of CWTs.
