Abstract:

I previously estimated proportional losses of delta smelt to the water export facilities in the south Delta (Kimmerer 2008). This note is in response to Miller (2010), who disputes these estimated losses on several grounds. A re-analysis using a better analytical approach suggests a slight downward revision of the previous estimates for adult smelt. The distribution of smelt seems to have shifted northward in the last few years; if so, the delta smelt may now be less vulnerable to export losses than they previously were, although the reasons for such a shift are a concern. I argue, however, that it is legitimate to attempt such estimates in the absence of perfect information, and that mechanistic analyses are a valid way of estimating population-level impacts even in the absence of statistically significant correlations of estimated impact with subsequent population size.

Modeling Delta Smelt Losses at the South Delta Export Facilities

Wim J. Kimmerer[1]

ABSTRACT

I previously estimated proportional losses of delta smelt to the water export facilities in the south Delta (Kimmerer 2008). This note is in response to Miller (2010), who disputes these estimated losses on several grounds. A re-analysis using a better analytical approach suggests a slight downward revision of the previous estimates for adult smelt. The distribution of smelt seems to have shifted northward in the last few years; if so, the smelt may now be less vulnerable to export losses than they previously were, although the reasons for such a shift are a concern. I argue, however, that it is legitimate to attempt such estimates in the absence of perfect information, and that mechanistic analyses are a valid way of estimating population-level impacts even in the absence of statistically significant correlations of estimated impact with subsequent population size.

delta smelt, *Hypomesus transpacificus*, management, water diversions, population ecology

INTRODUCTION

I previously calculated proportional losses of delta smelt (*Hypomesus transpacificus*) to the water export facilities in the south Delta (Kimmerer 2008). Here I respond to Miller (2010), who presents analyses to show that my estimates of proportional losses were overstated. Miller raises some valid points but misinterprets some of my original analyses, and offers comments that cannot be addressed with available information. His critique also raises, albeit indirectly, two important general issues for quantitatively estimating the impacts of human activities: (1) how such estimates can and should be made in the absence of complete information; and (2) the nature of evidence useful in quantifying these impacts. I first discuss Miller's more specific comments, and then return to these broader issues.

Kimmerer (2008) calculated proportional losses during times when delta smelt are captured in substantial numbers at the fish salvage facilities, i.e., roughly January to March for adults and March to June for larvae and juveniles. The proportional losses for each life stage were estimated using a rather complex procedure to determine inputs to a survival model (modified from Equation 12 in Kimmerer 2008):

$$P_L = 1 - \prod_{d=1}^{D}\left(1-\frac{\Phi_d}{N_d}\right) \tag{1}$$

kimmerer@sfsu.edu

where P_L is the proportional loss during the season of vulnerability, that is, the decrement in the population by the end of the season attributable to export pumping. D is the number of days in that season, N_d is the population size on each day, and Φ_d is the daily loss to the fish facilities, including pre-screen mortality and assuming no successful salvage. Note that this formulation ignores mortality not attributable to export pumping, which was taken into account in the original analysis (see below).

To clarify Miller's arguments and my responses, I consider the following components of these calculations: (1) efficacy of the sampling programs used to estimate model inputs; (2) estimating the number of fish lost to entrainment per day Φ_d; (3) estimating the population size N_d; and (4) accumulating daily loss over the season of vulnerability.

EFFICACY OF SAMPLING

Sampling for fish involves numerous assumptions about their distribution and about the efficiency of the sampling gear used in relation to the particular species and size of fish collected (Rozas and Minello 1997). Generally, in any sampling process, the confidence limits around the estimate being made decrease as the number collected increases. Thus, very small catches do not invalidate a sampling effort, but the results are more uncertain than with large samples.

Three sets of sampling data were used in the original analysis. The Kodiak trawl survey of adults is considered to be an effective method that is roughly 100% efficient for fish in the channels. The 20–mm survey of larval and juvenile fish is most efficient for fish larger than 20mm, but less so for smaller fish. Kimmerer (2008, Equation 20) used a logistic model to correct catches for low gear efficiency for smaller fish. This model is based on the fact that surviving fish must grow through all size classes, and that therefore the abundance of the poorly sampled smaller sizes is constrained by the abundance of larger sizes. The principal assumption of the logistic model was that parameters of the model were constant *within* years but could vary *among* years. Statistical error in fitting the model contributed to rather large uncertainties in proportional losses, as much as a three-fold uncertainty in the relative abundance of the smallest (5 mm) size class. This error was propagated through subsequent analyses of proportional losses.

Miller argues that low catches of smaller fish in the 20–mm survey should not be scaled up using catch-efficiency curves. This is equivalent to saying that gear efficiency cannot be determined for small fish, and implies that the numbers in each size class must be determined independently of those in other size classes. However, he offers no argument why the logistic function cannot be used to estimate abundance of all size classes, how the larger fish might have arisen except by growth of the smaller ones, or what is wrong with providing estimates based on small catches if confidence limits are included. Furthermore, he labels as "unreliable" data from some 20–mm stations with zero catch, without an adequate explanation of why such data should be considered unreliable; 73% of the 20–mm tows from 1995 through 2005 had no delta smelt, but these contribute to the calculations of means and other population parameters.

The south Delta fish facilities sample far more volume and capture larger numbers of fish than the field surveys, but capture efficiency—the ratio of salvage to entrainment—is low and variable. Delta smelt are unlikely to be guided by the louvers, which were designed for and are most efficient for salmon (Bowen and others 2004). Mark–recapture studies with adult delta smelt gave an average 24% recovery of fish at the federal fish facility that had been released in front of the primary louvers. Castillo and others (2009) conducted a mark–recapture study of delta smelt in Clifton Court Forebay and concluded that pre-screen mortality presumably from predation was the largest source of mortality for fish entrained in the forebay, and likely much larger than for other studied fish such as salmon. These studies provide limited support, though not quantitative information, for the low capture efficiency of the salvage facilities.

Kimmerer (2008) found that catch per volume of water sampled differed between the two salvage facilities on a daily basis, but that the overall mean differences were very small. This was the basis for using the same salvage efficiencies for both facilities. The salvage values are useful for indicating the timing and relative magnitude of entrainment events, but underestimate entrainment and mortality of delta smelt many-fold as discussed above. Without calibration to field data, salvage is not a useful proxy for mortality.

Miller reports a lack of correlation between salvage of young delta smelt and estimated flux to the pumps, concluding from this lack of relationship that the calculated flux is biased upward. The reason for this putative bias is not really explained. Three factors interfere with such a correlation: (1) the low and variable efficiency of the salvage facilities, (2) the high variability and small number of samples per survey (six) used in calculating the flux (see below), and (3) the distance from the sampling stations to the export facilities. None of these should introduce bias. I previously showed that the south Delta catches and salvage during springs of 4 years matched reasonably well in timing and magnitude but with a lot of error, and a low but non-zero correlation (Figure 7 in Kimmerer 2008). Thus, there is evidence for substantial statistical error but not for bias.

ESTIMATES OF FISH FLUX

The flux or entrainment of fish toward the salvage facilities Φ_d comprises three factors: pre-screen mortality, losses through the louvers, and salvage. Because salvage is likely a small fraction of entrainment (see above), it gives a poor estimate of Φ_d, which must therefore be determined using other information, such as the density and rate of movement of fish in the waterways leading to the fish facilities.

The basis for such calculations (not spelled out by Kimmerer 2008) is a simple hydrodynamic flux calculation for a channel:

$$\Phi_C = A\left[(U + U_s)C - (K_h + K_s)\frac{dC}{dx}\right] \tag{2}$$

where Φ_C is the flux of a substance or particles with concentration C, A is cross-sectional area of a channel, U is water velocity, U_s is additional velocity of C (e.g., due to swimming in the positive x direction), K_h is a horizontal dispersion coefficient, K_s is an additional dispersion coefficient due to randomly directed swimming, and the last term is the longitudinal gradient in C. If the gradient is small and the particles are passive, the flux is simply $AU_C = Q_C$, where Q is the volume flow rate. Kimmerer (2008) used this to calculate the flux of young smelt with Q represented by the southward net flow in Old and Middle rivers and C by the catch per unit volume at six 20–mm stations in the south Delta. This calculation was not possible for adults because of low (often zero) catches, so the catches were used to calibrate salvage density (fish per unit volume of water) to catch per volume in the Kodiak trawl, and this calibration factor was applied to all salvage data to estimate flux.

Miller argues that since fish are not passive particles this calculation is invalid, but offers no alternative way to compute the fish flux. Larval fish have very limited swimming abilities and are essentially passive particles before they obtain a swim bladder, after which they can affect their position only through vertical migration. Tidal vertical migrations were found in pelagic fish larvae in the low-salinity zone but the sample size for delta smelt was small, and migration was not detected (Bennett and others 2002). Even the fish and copepods that demonstrably migrate tidally can overcome net seaward flow only in water that is stratified in salinity (Kimmerer and others 1998), which is not the case in the south Delta. The smelt that leave freshwater in early summer are post-larvae over 20mm long with developed swim bladders and initial distribution near the surface (also in the low-salinity zone, Bennett and others 2002). If this behavior applied in freshwater it would move most of the population westward to their brackish rearing habitat except those in the south Delta, which would move toward the pumps. Thus, during spring they can be treated as passive particles at the scale of the south Delta, and Equation 2 applies to these fish. Miller's argument implies that the fish are somehow escaping the southward flow of Old and Middle rivers, but there is no evidence that they are capable of doing that, nor do environmental cues exist that would persuade them to orient away from the export facilities.

Adult smelt move up-estuary during their spawning migration and are, therefore, demonstrably capable of moving against the net downstream flow in the Delta. However, high salvage numbers indicate the existence of a large southward flux of adults. I calculated an efficiency Θ (Equations 16 and 17 in Kimmerer 2008) relating salvage to the estimated fish flux based on the Kodiak trawl samples in the south Delta, and applied that to salvage to get the fish flux for all days of the season.

Miller argues on several grounds that Θ was overestimated. The most cogent argument is that there were too many zeros in the data to use a Poisson model to fit the data. I therefore re-fit the model in Equation 17 (Kimmerer 2008) with a zero-inflated Poisson model (Lambert 1992) which has two parameters; the Poisson mean and the proportion of excess zeros. This model was fit using a Bayesian approach in WinBUGS (Lunn and others 2004) using fitting and model checking procedures in Kimmerer and Gould (2010). The resulting estimate of Θ was 22 with a 95% credible interval of 13 to 33. This estimate is about 76% of the previous estimate but with better resolution. Estimates of mean adult loss in Kimmerer (2008) should, therefore, be reduced by 24%. Miller also argues that the data are contaminated by a single high catch of 17 fish. This might be true if the model were improperly cast as a linear regression, but for a properly formulated model it poses no problem. In any case, the analysis should be based on the data at hand.

Miller also argues that the adults are not passive particles, implying that they can overcome the effects of net flow in the south Delta. That is, the term U_S in Equation 2 may be negative, reducing the actual fish flux Φ_C. In that case salvage would be lower than expected if U_S were zero, and the effect of a negative U_S would be accounted for in the calculation of Θ.

According to Miller, Old and Middle river flows are unrelated to salvage of either adult or young delta smelt and therefore are insufficient for calculation of fish flux. The relationship between these flows and salvage is actually quite obvious, if nonlinear and noisy (Figure 4 in Kimmerer 2008): when these rivers flow southward, salvage is often high, and when they flow northward, salvage is either mostly zero (juveniles, adults in the state facility) or sometimes non-zero (adults for the federal facility only). The latter case is likely due to U_S in Equation 2 being positive for some fish, i.e., toward the export facilities. Thus, while the fish are not entirely behaving as passive particles, their behavior is not necessarily oriented to take them away from the facilities.

The calculations of proportional losses of young smelt were remarkably consonant with predictions made using the DSM2 particle tracking model (Figure 16 in Kimmerer 2008). This supports the use of Old and Middle River flows for the calculations, and the assumption of passive transport for this life stage. Furthermore, the estimate of Θ above is, if anything, low—considering the estimates to date of pre-screen losses and losses through the louvers.

Delta smelt are more abundant where the water is turbid (Feyrer and others 2007) and, therefore, salvage and salvage-related losses should be more predictable using information about turbidity than without this information. This issue arose after I had finished the final draft of the 2008 paper, but, in any case, turbidity data for the south Delta were not available for the time–period of this study. Ignoring it introduces error in the calculations but there is no reason to expect bias, since all the calculations were based either on salvage (adults) or fish collected in the south Delta (juveniles).

SIZE OF THE POPULATION

The denominator in Equation 1 is essentially the mean catch in all samples times the volume over which those samples were taken. An alternative is to calculate mean catch per trawl by region of the estuary, multiply by area or volume of each region, and sum the result to get an index of abundance. The assumptions underlying these two approaches are somewhat different, but there are no data to suggest one is superior to the other. The annual abundance indices in several monitoring programs are calculated by region, but simple mean catch per trawl over all stations is closely correlated to these indices (Kimmerer and Nobriga 2005). Thus Miller's calculations of population size using a region–by–region approach are unlikely to be much different from the simpler calculation in Kimmerer (2008).

The fish fluxes Φ were calculated so that efficiency of the sampling gears was factored out of Equation 1. Therefore, the remaining issue for this part of the calculation is whether the samples in the south Delta represented the population there to the same degree that sampling throughout the Delta represented the overall population. Catchability is unlikely to differ between the south Delta and elsewhere (and we have no data either way on this), so the degree of representation boils down to whether the spatial coverage of sampling is adequate to represent the population.

Miller argues the contrary on the basis that high catches of adults in the Sacramento River Deep Water Ship Channel (sampled beginning in February 2005) indicate that most of the fish are in that region and are, therefore, under-sampled. Most of my analyses were for earlier years; furthermore, most of the salvage occurred between mid-December and the end of February (Figure 11 in Kimmerer 2008), when relatively few fish are yet in the north Delta (Figure 1). It does appear that more adults are in the north Delta during more recent years, mainly in the later surveys.

Miller makes a similar argument for young fish, although the argument is muddied by a claim that the 20–mm survey collects too few fish to provide a reliable index of total population size, based on projections of abundance of young fish from calculated abundance and assumed reproductive success of adults. If this were true it would call into question the results of all sampling programs. The stronger part of Miller's argument is the same as for adults: i.e., that a greater proportion of the population is in the north Delta and that it has been under-sampled. The data show an increasing proportion of the total catch in the north Delta stations (Figure 2) as the total catch has decreased. However, that proportion was never more than 8% during the period of this study.

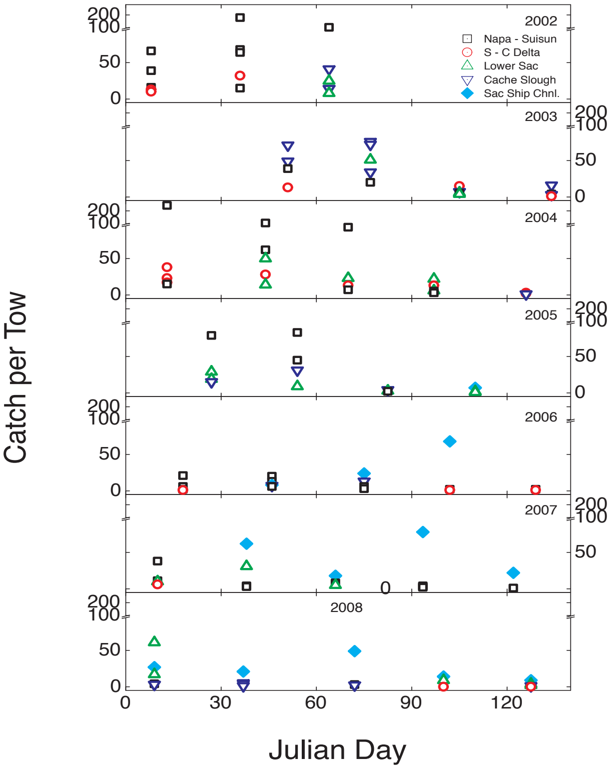

Figure 1 Delta smelt catch per tow in the Spring Kodiak trawl survey for the five stations with the highest catches during each month's sampling, by year. These stations made up at least 62% of the total catch of the respective surveys. Symbols indicate sampling regions, with stations included as follows: Napa–Suisun: stations <699 plus 801; South–Central Delta: 802 to 999; Lower Sacramento River: 704 to 707; Cache Slough area: 711 to 716; and Sacramento Ship Channel: 719, sampled beginning February 2005.

The apparent northward shift in distribution of adult and young smelt means that the exposure of the delta smelt population to export pumping is less in recent years than it was during the time period of my study. Although this might be considered a benefit, conceivable mechanisms for this shift are not promising for the long–term maintenance of the species. One possible such mechanism is that the south Delta is occupied less by delta smelt because of a degradation of the habitat (e.g., by increasing water clarity). The implications of that for proportional losses to exports would depend on the mechanism keeping abundance low in the south Delta, which are not yet known.

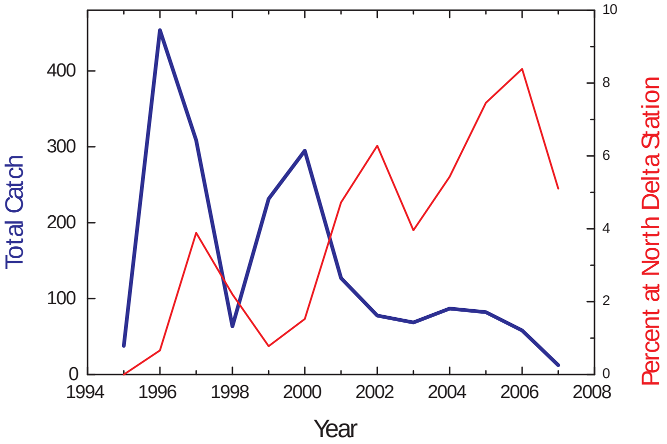

Figure 2 Delta smelt catch in the 20–mm survey. Heavy blue line, left axis: total catch in all samples; thin red line, right axis: percent of catch from Station 716 in Cache Slough in the north Delta. Note that catches at Station 719 in the Sacramento River Deep Water Ship Channel have been high since sampling at this station began in 2008, but there is no information on whether this is a sampling artifact or a result of smelt movement.

ACCUMULATING LOSSES OVER THE SEASON

Accumulating losses means calculating the proportional difference between the population that would have existed at the end of the exposure season with and without export losses. This requires that the relative size of the vulnerable population and other mortality be taken into account. For example, a high daily fractional loss early in spring when few young fish had hatched will have a smaller effect on ultimate population size than a high loss after all the fish had hatched.

Equation 1 could be parsed in a number of different ways, but the end result would not be very different using the same values of the fractional loss terms. The calculations are made a bit more difficult by the need to account for natural mortality of juveniles, as explained by Kimmerer (2008). Leaving mortality out of the calculations results in a modest increase in the calculated seasonal losses (Figure 15 in Kimmerer 2008). Although Miller argues that mortality is unlikely to be constant in space or time, the effects of such undeniable but unmeasured variability cannot, therefore, be very large. Since losses of larvae and juveniles were based on catches in the south Delta rather than salvage, an excess of mortality in the south Delta relative to the entire habitat would bias the loss estimates low, not high as Miller claims.

ALTERNATIVE APPROACHES TO ESTIMATING EXPORT EFFECTS

To date, nobody has reported a relationship between any measure of flow toward the export pumps or losses of delta smelt, and either subsequent population abundance indices or ratios of successive indices. Miller argues that this lack of statistical link to population estimates is evidence that losses calculated mechanistically are unimportant compared to other effects such as food limitation.

This is part of a broader issue: the nature of evidence to be used in estimating the magnitude of human impacts on a biological population. Fundamentally, such impacts can be estimated through correlative measures, or they can be determined mechanistically. I do not believe that Miller is arguing against the use of mechanistic approaches (as some have done), since far more of our current scientific understanding in most fields of science rests on mechanistic than on correlative analyses.

Mechanistic approaches are based on known or inferred processes that influence the population in some way. In the specific case of estimated mortality to a fish population, the key issue is whether subsequent density dependence compensates for that mortality. If not, it is tautological that mortality will proportionally reduce subsequent population size.

Density dependence is a controversial topic mainly because of statistical difficulties, although conceptual problems also contribute. Compensatory density dependence can arise through a wide variety of causes, most involving food supply or predation (Rose and others 2001). Density dependence in striped bass in the San Francisco Estuary apparently compensated for very high losses to the export facilities, at least during a period of relatively high abundance (Kimmerer and others 2000).

Density dependence in stock–recruit relationships for delta smelt were driven largely by high values in the 1970s, although some evidence for density dependence remained in the data after 1981 (Bennett 2005); however, these relationships and the influence of environmental factors on them have likely changed over the intervening decades. The key question for interpretation of export losses of delta smelt is whether density dependence is strong in the post-decline population. This seems unlikely: since 2002 abundance of delta smelt has been too low for most potential mechanisms for compensatory density dependence to exert much influence. If so, the delta smelt population does not compensate for reductions in abundance by, e.g., increased fecundity or reduced mortality. Therefore, losses at any life stage permanently and proportionally reduce the population from the trajectory it would have otherwise have followed.

Correlative measures can be useful to the extent that they offer statistical support for a relationship. However, they cannot establish cause. More importantly, there is a clear difference between a finding that a result does not meet statistical standards of significance, and concluding it is not important. Thus, in making such an argument it seems important to determine what level of impact could be detected by correlative methods.

I determined this level through simulations, assuming density-independent population processes by the arguments above. I used the observed ratio of the fall midwater trawl index to the previous year's index as a stock–recruit index that should be sensitive to losses in the spring. The percentage loss in a given year was set as:

$$P_L = P_{max} \left(\begin{array}{c} 0 \text{ if OMR} \geq 0 \\ \dfrac{\text{OMR}}{\text{OMR}_{min}} \text{ if OMR} < 0 \end{array} \right) \qquad (3)$$

where P_{max} is the maximum percentage loss in any year (a free parameter in this simulation), OMR is the mean flow in Old and Middle rivers in spring (negative is southward), and OMR_{min} is the minimum OMR flow (i.e., the maximum southward flow). OMR flows were determined for each spring as described in Kimmerer (2008). In this equation, P_L is zero for positive OMR, and scales linearly with negative OMR to a maximum at P_{max} when OMR = OMR_{min}. Alternative scaling would affect the quantitative results but not the qualitative conclusion.

For each year, the simulation ran using flow data from 1981 through 2006, with each year's fall population reduced by the simulated proportional loss during the previous spring. The choice of years to simulate was made to get a representative range of OMR flows, not to simulate an actual population trajectory, and the simulation was intended only to investigate the effects of export losses at low population size where density dependence would have a minimal effect. The flows were randomized among years to eliminate potential confounding factors from actual annual flow patterns. Then, for each integer value of P_{max} from 0 to 100% a regression was calculated between southward Old and Middle river flow (the quantity in parentheses in Equation 3) and the log of the stock–recruit index. The intent was to determine how large P_{max} had to be before losses become detectable in regression analyses.

The results (Figure 3) show that the losses were not generally detectable in the regression until P_{max} reached about 60% to 80%. The levels of loss reported by Kimmerer (2008) were obscured by interannual variability in nearly all simulations, and maximum losses less than 20% were undetectable. Yet a P_{max} of 20% (mean annual loss of ~10%) results in a 10-fold reduction in population size by the end of the 26-year simulation (Figure 3). Repeating the above simulation 10,000 times with P_{max} = 20%, the upper 95% and 90% confidence limits of the regression slope excluded zero (i.e., was statistically detectable) in 5% and 9% of the cases, respectively. Thus, a loss to export pumping on the order reported by Kimmerer (2008) can be simultaneously nearly undetectable in regression analysis, and devastating to the population. This also illustrates how inappropriate statistical significance is in deciding whether an effect is biologically relevant (Stephens and others 2007).

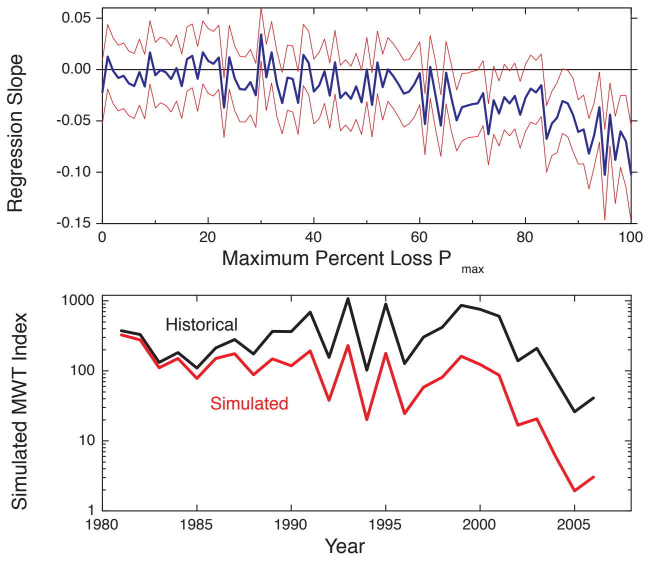

Figure 3 Results of simulation of ability to detect export loss through regression analysis. Upper panel: individual simulation results giving the slope (thick blue line) and 95% confidence limits (thin red lines) for regressions of the stock-recruit index on southward OMR flow. Lower panel: trajectory of the fall midwater trawl index (upper line) and the same index with a 20% P_{max} value imposed for the entire time series (mean P_L ~10%). This is for illustration only (see text), and does not imply anything about the cause of the decline in delta smelt.

CONCLUSIONS

Miller raises some valuable points about the data and methods used in calculating proportional losses. He also introduces new developments in understanding (e.g., turbidity effects) and in the delta smelt population (e.g, spatial distribution) that occurred recently. I do not believe these points cast doubt on the overall conclusion of my paper, which is that export–related losses to the delta smelt population during some of the years analyzed were substantial.

I previously reported that export effects had little effect on the striped bass population because of density dependence at levels of population abundance that existed up to 1995 (Kimmerer and others 2001). I also previously determined that export losses of mysids (*Neomysis mercedis*) were unlikely to be important to that population (reported by Orsi and Mecum 1996). During my work on the Environmental Water Account, I continually but unsuccessfully challenged my colleagues in the resource agencies to determine the effect of export pumping on fish populations, and therefore the magnitude of the benefit that the Account was having on fish (see Brown and others 2008). Therefore, my labors on export losses of delta smelt began with a strong skepticism about the importance of these losses, and ended with considerable surprise at their magnitude.

All of that said, neither my paper nor this exchange is the final word on this subject. More sophisticated statistical tools and models could and should be brought to bear on what controls delta smelt abundance, and these should be updated as new data become available. Information from new studies (e.g., Castillo and others 2009; Grimaldo and others 2009) and based on more recent distributional data should also be considered, both in refining understanding of influences on the smelt population and in assessing changes in the population itself.

ACKNOWLEDGMENTS

I thank William (Bill) Bennett for reviewing an earlier version of this paper, and William (B.J.) Miller for helpful comments and clarification.

Abstract. Four species of pelagic fish of particular management concern in the upper San Francisco Estuary, California, USA, have declined precipitously since ca. 2002: delta smelt (*Hypomesus transpacificus*), longfin smelt (*Spirinchus thaleichthys*), striped bass (*Morone saxatilis*), and threadfin shad (*Dorosoma petenense*). The estuary has been monitored since the late 1960s with extensive collection of data on the fishes, their pelagic prey, phytoplankton biomass, invasive species, and physical factors. We used multivariate autoregressive (MAR) modeling to discern the main factors responsible for the declines. An expert-elicited model was built to describe the system. Fifty-four relationships were built into the model, only one of which was of uncertain direction a priori. Twenty-eight of the proposed relationships were strongly supported by or consistent with the data, while 26 were close to zero (not supported by the data but not contrary to expectations). The position of the 2‰ isohaline (a measure of the physical response of the estuary to freshwater flow) and increased water clarity over the period of analyses were two factors affecting multiple declining taxa (including fishes and the fishes' main zooplankton prey). Our results were relatively robust with respect to the form of stock–recruitment model used and to inclusion of subsidiary covariates but may be enhanced by using detailed state–space models that describe more fully the life-history dynamics of the declining species.

Key words: Bayesian analysis; delta smelt; expert models; longfin smelt; Sacramento River, California, USA; San Joaquin River, California, USA; striped bass; threadfin shad; threatened species; water management.

Introduction

Estuaries, especially those associated with large rivers near major cities, are among the ecosystems most adversely affected by land use change (Nichols et al. 1986). Impacts of human actions in all upstream watersheds (catchments) are concentrated in the estuaries (Kennish 2002, Townend 2004). Diversion of water affects the location of boundaries between fresh, brackish, and saline water (Drinkwater and Frank 1994, Gillanders and Kingsford 2002, Gleick 2003). Large settlements often are located along shorelines, which convey contaminants and effects of boating and fishing to estuarine systems (Dauer et al. 2000). Shipping has led to introductions of many aquatic invasive species (Bollens et al. 2002, Williams and Grosholz 2008). Climate change will affect interactions between oceans and estuaries and will reduce catchment inflows in many regions (Scavia et al. 2002, Vicuna and Dracup 2007, Cai and Cowan 2008, Schindler et al. 2008).

The San Francisco Estuary is an archetype of a stressed estuarine system (Kimmerer et al. 2005*a*). The social, economic, and ecological effects of freshwater flows and diversions throughout the San Francisco Estuary have received much attention. Some 25 million Californians and 12 000 km^2 of agricultural land rely on water diversions from the delta created by the Sacramento and San Joaquin rivers. Annual agricultural

revenue from California's Central Valley, which accounts for about half of the production of fruits and vegetables in the United States, frequently approaches US$15 billion.

Populations of many aquatic species in the estuary have declined since extensive human activities began in the mid-1800s (Bennett and Moyle 1996, Brown and Moyle 2005). However, conflicts over water management recently have intensified because of the apparently precipitous decline in four species of pelagic fish (delta smelt [*Hypomesus transpacificus*], longfin smelt [*Spirinchus thaleichthys*], striped bass [*Morone saxatilis*], and threadfin shad [*Dorosoma petenense*]) since ca. 2002 (Thomson et al. 2010). Delta smelt was listed as threatened under the U.S. and California Endangered Species Acts in 1993. Recent litigation to protect the species resulted in court orders to halt water diversions temporarily (Wanger 2007*a*, *b*). Longfin smelt was listed as threatened under the California Endangered Species Act in 2009, although a petition for federal listing was declined. Striped bass was deliberately introduced to the Sacramento–San Joaquin Delta from the east coast of the United States in 1879 and supports a sport fishery (Moyle 2002). Threadfin shad was introduced into California reservoirs as a forage fish in 1954 and spread to the Delta (Moyle 2002, Feyrer et al. 2009).

To date, models and statistical analyses to identify mechanisms causing fish declines in the San Francisco Estuary generally have been on a species-by-species basis (Jassby et al. 1995, Kimmerer et al. 2001, Bennett 2005). These efforts suggest that several abiotic factors (e.g., water flows, salinity, turbidity), bottom-up biotic effects (e.g., zooplankton abundances, invasion of a filter-feeding, non-native clam [*Corbula amurensis*]), and top-down factors (e.g., incidental mortality associated with water diversions to pumping facilities) may play important roles. However, the relative importance of these factors remains unclear (Sommer et al. 2007). Identification of processes causing declines is critical because possible solutions include major investments in infrastructure, changes in water management, and rehabilitation of species' habitats, which would cost billions of dollars.

Although detailed analyses of the population dynamics of any one declining species are valid, it is plausible that more insight might be gained through multivariate analyses that consider community dynamics, including direct and indirect effects of interacting species and abiotic factors. These analyses might yield inferences on the biotic and abiotic factors that best explain patterns of abundance for multiple species in the community and on the relative influences of density dependence, among-species interactions, and abiotic factors on species abundances.

We used a multivariate statistical technique called multivariate autoregressive modeling (MAR) (Ives et al. 2003) with 40 years of data for pelagic fishes and their principal prey within the upper San Francisco Estuary. In a manner similar to path analysis (Shipley 1997), MAR uses time series data for multiple taxa to estimate the degree of association between the different taxa as well as between covariates and each taxon. Multivariate autoregressive modeling includes autoregressive terms for each species' abundance. Ives et al. (2003) provided a detailed introduction to the underlying theory and assumptions of MAR along with methods for estimating model parameters. Multivariate autoregressive modeling has been used in analyses of community dynamics in lakes in Wisconsin (Ives et al. 2003), Lake Washington (Hampton and Schindler 2006), and Lake Baikal (Hampton et al. 2008).

We developed a Bayesian implementation of MAR. Bayesian methods allow propagation of and account for multiple sources of uncertainty in complex models (Punt and Hilborn 1997) and allow great flexibility in model structure (Cressie et al. 2009). The Bayesian MAR modeling is a complementary approach to methods we used in a companion paper, which presented a Bayesian change point analysis (Thomson et al. 2010). The two methods were developed in tandem to evaluate whether the different strengths of the MAR and change point analyses provided similar inferences about factors potentially underlying causes of declines in the fish species. Multivariate autoregressive modeling is based on a food web structure, which allows both direct and indirect influences on the focal species (fish) to be represented. Moreover, MAR models the dynamics of all species (including prey) simultaneously. It is based on linear relationships (on a log-abundance scale), both within the food web and with covariates, over the entire time period.

Our implementation of MAR is underlain by an expert-elicited model, which draws on expert knowledge to specify whether particular trophic or covariate effects may be influential. The change point analysis is not embedded in a food web context, although availabilities of prey taxa can be used as covariates, but it does explicitly employ time dependence and nonlinearity in covariate relationships between log-abundances of the focal species and covariates. The change point method uses Bayesian variable selection (Green 1995) so that relationships do not need to be specified a priori. Both individual-species (species-specific model parameters) and multiple-species (common hyper-parameter distributions) versions of the change point analyses were implemented (Thomson et al. 2010), with the latter having some overlap, therefore, with the MAR analyses.

Here, we describe the upper San Francisco Estuary, the four species of fish on which we focused and their principal prey, and the set of covariates included in the MAR model. Multivariate autoregressive models are heavily parameterized because they describe many among-taxa interactions and relationships to covariates. Therefore, we developed an expert-elicited, circumscribed model that reduced the number of parameters to be estimated. We review the relative importance of

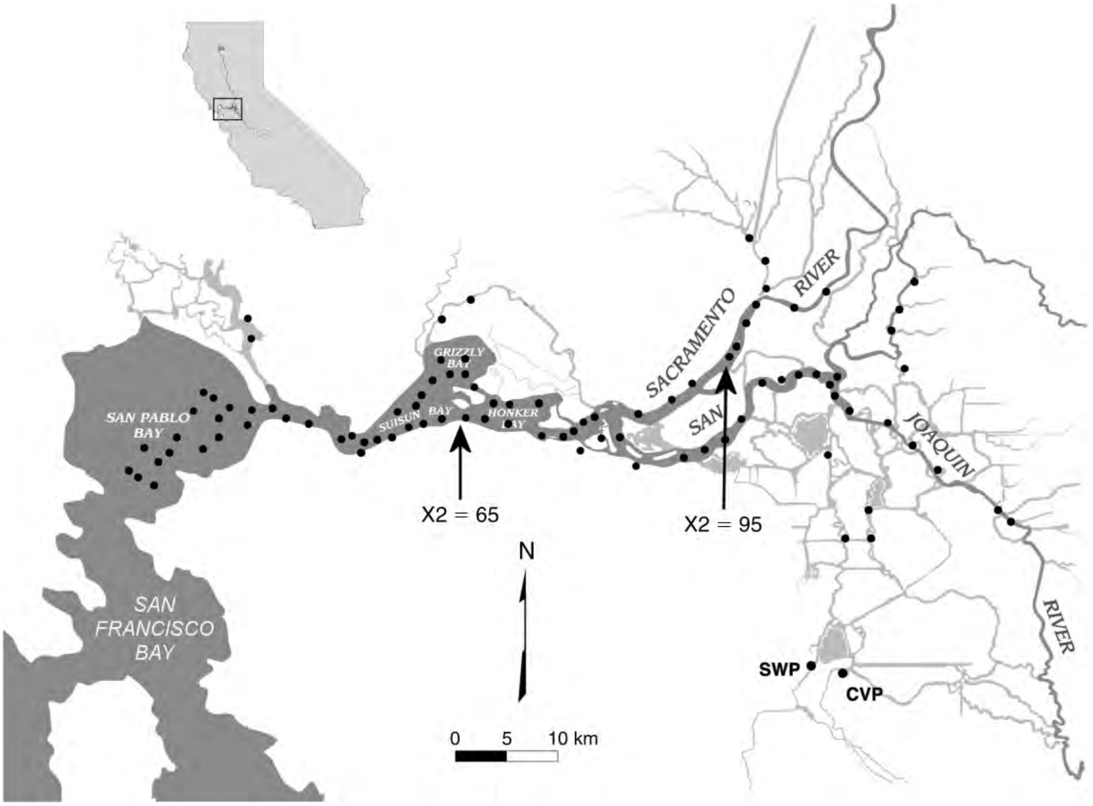

FIG. 1. Location and physiography of the upper San Francisco Estuary, California, USA. The solid circles denote sampling locations of the autumn midwater trawl surveys; arrows indicate two representative positions of the 2‰ isohaline (X2); SWP (State Water Project) and CVP (Central Valley Project) are locations of water exports from the estuary.

different factors in driving the temporal dynamics of our four declining fish species and comment on the usefulness and limitations of MAR models. Last, we comment on the agreement or otherwise between the MAR and change point approaches.

METHODS

The San Francisco Estuary

The San Francisco Estuary consists of three major regions: San Francisco Bay, the most seaward region; Suisun Bay, an intermediate brackish region; and the generally freshwater Sacramento–San Joaquin Delta (Fig. 1). The watershed has wet winters and dry summers. The Delta is the core of a massive system of dams and canals that store and divert water from the estuary for agricultural, industrial, and domestic use throughout California (Nichols et al. 1986). The water diversion facilities export ~30% of the annual freshwater flow into the Delta, although that percentage has exceeded 60% during many recent summers. Regulations, including standards for the position of the 2‰ isohaline (a measure of the physical response of the estuary to freshwater flow; Jassby et al. 1995), locally termed "X2," have become increasingly stringent.

Response variables: declining fish and their principal prey

Delta smelt is endemic to the San Francisco Estuary and reaches 60–70 mm standard length (SL) (Bennett 2005), feeding on zooplankton, mainly calanoid copepods, throughout life. The delta smelt is weakly anadromous, migrating between the brackish waters of Suisun Bay and the freshwaters of the Delta. Upstream migration begins in the late autumn or early winter and spawning occurs from March through May in freshwater. Most delta smelt spawn ~12 months after hatching, with a small percentage surviving for another year to spawn. Young delta smelt move downstream in early summer and remain in the low-salinity zone (0.5–10‰) until they migrate for spawning.

Longfin smelt is native to the San Francisco Estuary. The species usually reaches 90–110 mm SL (Moyle 2002, Rosenfield and Baxter 2007) and is anadromous. It spawns at age 2 yr in freshwater in the Delta from December to April. Young longfin smelt occur from the low-salinity zone seaward throughout the estuary and into the coastal ocean. Longfin smelt feed on copepods as larvae and mysids and amphipods as young and adults.

Striped bass is a potentially large (>1 m), potentially long-lived (>10 yr) anadromous species. Females begin

TABLE 1. Definitions of variables used in the multivariate autoregressive modeling, years for which data were available, and ranges of values for variables.

Variable	Years (missing)	Range	Definition
Response variables			
Delta smelt (*Hypomesus transpacificus*)	1967–2007 (3)	0.06–4.02	autumn (Sep–Dec) midwater trawl, mean total catch per trawl
Longfin smelt (*Spirinchus thaleichthys*)	1967–2007 (3)	0.03–113.16	autumn (Sep–Dec) midwater trawl, mean total catch per trawl
Striped bass (*Morone saxatilis*)	1967–2007 (3)	0.12–59.38	autumn (Sep–Dec) midwater trawl, mean age-0 catch per trawl
Threadfin shad (*Dorosoma petenense*)	1967–2007 (3)	1.36–31.21	autumn (Sep–Dec) midwater trawl, mean total catch per trawl
Calanoid copepods, spring	1972–2007 (1)	0.98–43.87	mean biomass of calanoid copepodites and adults during spring (Mar–May) in low-salinity zone
Calanoid copepods, summer	1972–2007 (1)	2.93–27.62	mean biomass of calanoid copepodites and adults during summer (Jun–Sep) in low-salinity zone
Mysids	1972–2007 (0)	0.42–35.05	mean biomass of mysid shrimp during Jun–Sep in low-salinity zone
Covariates			
Northern anchovy (*Engraulis mordax*)	1980–2006 (1)	0.22–490.42	mean catch per trawl of northern anchovy in the Bay Study midwater trawl (Jun–Sep) in the low-salinity zone
"Other zooplankton" in spring	1972–2006 (0)	3.79–56.86	mean biomass of other zooplankton (not including crab and barnacle larvae, cumaceans) during spring (Mar–May) in the freshwater zone
Spring chlorophyll *a* (freshwater zone)	1972–2006 (0)	2.35–43.54	mean chl *a* (mg/m^3) during spring (Mar–May) in freshwater zone
Spring chlorophyll *a* (low-salinity zone)	1975–2006 (0)	1.12–21.32	mean chl *a* (mg/m^3) during spring (Mar–May) in low-salinity zone
Summer chlorophyll *a*	1975–2006 (0)	1.23–20.15	mean chl *a* (mg/m^3) during summer (Jun–Sep) in low-salinity zone
Cyclopoid copepod *Limnoithona tetraspina*	1972–2006 (0)	0–7.78	mean biomass of *Limnoithona* copepodites and adults during summer (Jun–Sep) in low-salinity zone
Inland silverside (*Menidia beryllina*)	1994–2006 (0)	19.88–116.54	mean catch per seine haul of inland silverside in the USFWS survey during Jul–Sep (for stations within the delta)
Largemouth bass (*Micropterus salmoides*)	1994–2006 (0)	0.02–8.00	mean catch per seine haul of largemouth bass in the USFWS survey during Jul–Sep (for stations within the delta)
Spring X2 (isohaline)	1967–2006 (0)	48.53–91.74	mean Mar–May position of the 2‰ isohaline (X2)
Autumn X2 (isohaline)	1967–2006 (0)	60.24–93.18	mean Sep–Dec position of the 2‰ isohaline (X2)
Water clarity	1967–2006 (0)	0.44–11.00	mean Secchi depth (m) for the autumn midwater trawl survey
Winter exports	1967–2006 (0)	0.13–12.00	total volume of water (km^3) exported by the California State Water Project and Central Valley Project during Dec–Feb
Spring exports	1967–2006 (0)	0.37–13.00	total volume of water (km^3) exported by the California State Water Project and Central Valley Project during Mar–May
Invasive clam *Corbula amurensis*	1967–2006 (0)	0–1	binary variable for presence (1987–2006, 1) or absence (1967–1986, 0)
Duration of spawning window for delta smelt	1975–2007 (0)	24–85	no. days for which mean temperature was between 15° and 20°C,† mean of five continuous monitoring stations throughout Suisun Bay and the Sacramento–San Joaquin Delta
Mean summer water temperature	1967–2006 (0)	20.45–23.65	mean water temperature (°C), mean of five continuous monitoring stations throughout Suisun Bay and the Sacramento–San Joaquin Delta during Jun–Sep

Notes: Mean catch per trawl was measured in terms of individuals. Biomass was measured as mg C/m^3. The freshwater zone was determined to be <0.5‰. The low-salinity zone was determined to be at 0.5–10‰. The X2 position was measured in km upstream from the Golden Gate Bridge.

† Range of water temperatures that best induce spawning by delta smelt (15°C) and limit larval survivorship (20°C).

to spawn at age 4 yr in the Sacramento River and, to a lesser extent, in the San Joaquin River, from April through June. Eggs drift with the current as they develop and hatch. Larvae drift into the low-salinity zone where they grow, later dispersing throughout the estuary. Adults occur primarily in saline waters of the estuary and the coastal ocean, except during spawning migrations. Age-0 striped bass feed mainly on copepods, later switching to macroinvertebrates and then to fish.

Threadfin shad typically is <100 mm total length and primarily inhabits freshwater. It switches between filter- and particle-feeding, consuming phytoplankton, zooplankton, and detritus. Most threadfin shad spawn in their second summer, although some may spawn at the end of their first year. Spawning occurs mainly in June and July. Threadfin shad is the most abundant pelagic fish in the upper San Francisco Estuary.

While other fish and plankton groups might be included in our model as response variables, we chose to limit our analysis to species of zooplankton that are especially important for delta smelt, longfin smelt, age-0 striped bass, and threadfin shad. Adult and juvenile (copepodites) calanoid copepods have different relationships with the fish in spring and summer, so we considered the two life stages as different "taxa" in our models. Mysid shrimps were regarded as most important to the fishes in the mid to late summer (Table 1).

Covariates

The covariates used in the MAR (Table 1) relate to factors thought to be important for one or more of the response variables (Table 2). Covariates included fish species that are potential competitors or predators of the four declining fish species (possibly at only certain life-history stages), food for the latter fishes or their crustacean prey (including phytoplankton), competitors (*Limnoithona*) or predators (*Corbula*) of the crustaceans, the primary surrogate of the fishes' habitat (X2) in spring and autumn, amounts of water extracted from the Delta in winter and spring, water clarity (measured using Secchi discs), and two water temperature variables (duration of the delta smelt spawning window, mean summer water temperature).

The expert model (Table 2) was based on extensive, long-term knowledge and experience of several of the authors (W. J. Kimmerer, F. Feyrer, W. A. Bennett, L. Brown, S. D. Culberson, G. Castillo), and justifications for expected relationships were drawn from the literature. Although Bayesian model selection (Green 1995) might have been incorporated into the MAR model, as was done for the complementary change point analyses (Thomson et al. 2010), we believe that there is didactic value in concentrating on the evidential support for the expert-elicited model.

STATISTICAL ESTIMATION

MAR: Gompertz dynamics

We used a variant of a MAR model (Ives et al. 2003) to represent dynamics of the response variables. We represented population dynamics with the Gompertz model (Dennis et al. 2006). We began with a deterministic version of the Gompertz model (Reddingius 1971):

$$n_{i,t} = n_{i,t-1}\exp(\gamma_i + \delta_i \ln n_{i,t-1}) \qquad (1)$$

in which $n_{i,t}$ is abundance of species i at time t, $n_{i,t-1}$ is abundance of species i at time $t-1$, γ_i is the intrinsic rate of population growth for species i, and δ_i, which has been interpreted as the degree of density dependence.

We extended Eq. 1 first by allowing propagation for longer lags (up to L years prior to the current year), that is, an Lth-order Gompertz model (Zeng et al. 1998):

$$n_{i,t} = n_{i,t-1}\exp\left(\gamma_i + \sum_{l=1}^{L}\delta_{il}\ln n_{i,t-l}\right). \qquad (2)$$

It is possible that the γ_i may vary, so we allowed linear time dependence: $\gamma_i(t) = \gamma_{i,0} + \gamma_{i,1}t$. We expected the $\gamma_{i,1}$ parameters to be <0 given the declines in the abundances of the fishes. Taking logarithms, setting $x_{i,t} = \ln n_{i,t}$, and allowing species-specific lags (L_i), we have

$$x_{i,t} = x_{i,t-1} + \gamma_i(t) + \sum_{l=1}^{L_i}\delta_{il}x_{i,t-l}. \qquad (3)$$

Interspecific interactions among the seven taxa included as response variables were incorporated by appending terms relating to the previous year $\beta_{ij}x_{j,t-1}$, excluding self-terms:

$$x_{i,t} = x_{i,t-1} + \gamma_i(t) + \sum_{l=1}^{L_i}\delta_{il}x_{i,t-l} + \sum_{j=1, j\neq i}^{J}\beta_{ij}x_{j,t-1}. \qquad (4)$$

We included effects of covariates u_k through α coefficients for the current year t:

$$x_{i,t} = x_{i,t-1} + \gamma_i(t) + \sum_{l=1}^{L_i}\delta_{il}x_{i,t-l} + \sum_{j=1, j\neq i}^{J}\beta_{ij}x_{j,t-1} + \sum_{k=1}^{K}\alpha_{ik}u_{k,t}. \qquad (5)$$

MAR implementation

We used a Bayesian framework for implementing the model. There are many advantages to so doing. First, propagation of measurement uncertainties is straightforward using hierarchical models. Second, missing data are easily accommodated and estimated within the same process by which the parameters estimated are made, rather than a clumsier two-stage imputation–estimation approach. Third, we believe that the prior expectations, which also are easily implemented in a Bayesian framework, are critical encapsulations of the state of knowledge before the modeling was undertaken and need to be made explicit, as we have done.

We implemented Eq. 5 using the following model in WinBUGS, version 1.4 (Spiegelhalter et al. 2003):

$$z_{i,t} \sim \mathcal{N}(x_{i,t}, \omega_{i,t}^2) \qquad x_{i,t} \sim \mathcal{N}(\mu_{i,t}, \sigma_i^2) \qquad c'_{k,t} \sim \mathcal{N}(u_{k,t}, \zeta_k^2)$$

$$\mu_{i,t} = x_{i,t-1} + \gamma_i(t) + \sum_{l=1}^{L_i}\delta_{il}x_{i,t-l} + \sum_{j=1, j\neq i}^{J}\beta_{ij}x_{j,t-1} + \sum_{k=1}^{K}\alpha_{ik}u_{k,t} \qquad (6)$$

($\mathcal{N}$ denotes the normal distribution). The model states

TABLE 2. Matrix of effects included in the model with explanations.

Response variable or covariate	Response variable							
	DS	LFS	SB	TFS	CA-SP	CA-SU	MYS	Explanation
Delta smelt (DS)					–	–		Calanoid copepods are consumed by delta smelt (Hobbs et al. 2006).
Longfin smelt (LFS)					–	–	–	Calanoid copepods and mysids are consumed by longfin smelt (Feyrer et al. 2003).
Striped bass (SB)					–	–	–	Calanoid copepods and mysids are eaten by young striped bass (Feyrer et al. 2003, Bryant and Arnold 2007).
Threadfin shad (TFS)								Threadfin shad consume phytoplankton and copepods but are most abundant in freshwater (Turner and Kelley 1966, Feyrer et al. 2007).
Calanoids, spring (CA-SP)	+	+	+					Key food for young fish in spring.
Calanoids, summer (CA-SU)	+	+	+				+	Key food for young fish in summer; mysids consume calanoids (Siegfried et al. 1979, Siegfried and Kopache 1980).
Mysids (MYS)		+	+			–		Key food for young longfin smelt and striped bass in summer.
Anchovy					–	–	–	Biomass dominant, consumes all plankton (Kimmerer 2006).
Other zooplankton				+				Threadfin shad consume zooplankton in freshwater (Turner and Kelley 1966).
Chlorophyll *a*, spring, freshwater					+			
Chlorophyll *a*, spring, low-salinity zone					+		+	Calanoids eat microplankton, including phytoplankton (Gifford et al. 2007) and respond positively to phytoplankton blooms (Kimmerer et al. 2005*b*).
Chlorophyll *a*, summer, low-salinity zone						+	+	Mysids eat phytoplankton and small zooplankton (Siegfried and Kopache 1908).
Limnoithona tetraspina						–		Indirect effect through depression of food resource (ciliates; not measured) (Bouley and Kimmerer 2006, Gifford et al. 2007).
Inland silverside	–				–	–		Silversides consume copepods and potentially delta smelt eggs and larvae (Bennett and Moyle 1996).
Largemouth bass	–		–	–				Potentially important predator on small fish in freshwater (Nobriga and Feyrer 2008).
X2, spring		–	–		+/–		–	Effects of spring X2 on subsequent abundance in the following autumn (Jassby et al. 1995, Kimmerer et al. 2009).
X2, autumn	–	–	–					X2 affects surface area available for fish through salinity distribution (Feyrer et al. 2007).
Water clarity	–	–	–	–				Turbidity favors all fish at various life-history stages by offering increased protection from predators (Feyrer et al. 2007, Nobriga and Feyrer 2008, Kimmerer et al. 2009).
Export flow, winter	–	–						Adult smelt are entrained by pumping facilities during winter (Baxter et al. 2008, Kimmerer 2008).
Export flow, spring	–	–	–	–				Juvenile and adult smelt and shad and juvenile striped bass are entrained by pumping facilities during spring (Baxter et al. 2008).
Corbula amurensis					–	–		Nauplius larvae of copepods are consumed by *Corbula* (Kimmerer et al. 1994).
Spawning window	+							Spawning window for delta smelt is constrained by temperature (Bennett 2005).
Mean summer water temperature	–							Delta smelt are negatively influenced by high water temperatures, reducing time spent in the freshwater Delta (Swanson et al. 2000).

Notes: A "+" denotes that the covariate was expected to exert a positive influence on the response variable (e.g., food source). A "–" indicates that the covariate was expected to have a negative influence on the response variable (e.g., by consumption). All null entries were deemed likely to be unimportant by expert knowledge. The abbreviations "X2" refers to the position of the 2‰ isohaline (a measure of the physical response of the estuary to freshwater flow).

that the (ln-transformed) observed values ($z_{i,t}$) represent the true values ($x_{i,t}$). The former have observation errors, which are included by use of (ln-transformed) unobserved values ($x_{i,t}$) and observation errors, $\omega^2_{i,t}$. The observation errors were estimated from SEs of mean values for the response variables for each time period. Given that the $z_{i,t}$ were ln-transformed, we used a Taylor functional expansion to approximate the ln-transformed SEs [$\mathrm{SE}(\ln(\bar{n})) \approx \mathrm{SE}(\bar{n})/\bar{n}$] (Seber 1973, Stuart and Ord 1987). Process variances (σ^2_i) were allowed to be species-specific and were implemented with priors on σ_i of U(0.01, 10) (Gelman 2005) (U = Uniform). The true, unobserved values ($\mu_{i,t}$) are driven by the population dynamic parameters, trophic interactions, and covariates as described by the MAR model (Eq. 5).

Observed covariates $c_{k,t}$ were standardized for all available years of data (subtract mean $\bar{c}_k$, divide by standard deviations SD_k over all years, $c'_{k,t} = (c_{k,t} - \bar{c}_k)/\mathrm{SD}_k$). Standardizing is helpful for model convergence and for equalizing numerical ranges among different scales of measurement. Uncertainties in covariate measurements (within-year SEs) correspondingly were scaled by the interannual standard deviations (i.e., $\mathrm{SE}_{k,t}/\mathrm{SD}_k$). The model specifies that the true (standardized) covariate values ($u_{k,t}$) are related to the observed standardized values ($c'_{k,t}$) but include the covariate-specific uncertainties [$\zeta_k^2 = (\mathrm{SE}_{k,t}/\mathrm{SD}_k)^2$]. Uncertainties for most covariates were included in the models (a few variables, such as presence of *Corbula*, were regarded as fixed). There were sporadic missing data for some covariates, which we allowed to be interpolated within the Markov chain Monte Carlo (MCMC) modeling. These missing covariate values need to be segregated from the main estimation of effects by using the "cut()" function in WinBUGS. If the uncertainties are not so isolated, the model will "sacrifice" fitting precision for the parameters describing dynamics of the response variables to better "fit" missing covariate values, which is not intended (Carrigan et al. 2007).

Priors

Relatively uninformative priors were assigned for these model parameters:

$$\gamma_{i,0} \sim \mathcal{N}(0,1) \qquad \eta_\gamma \sim \mathcal{N}(0,10^3) \qquad \sigma_\gamma \sim \mathrm{U}(0.01,10)$$

$$\sigma_i \sim \mathrm{U}(0.01,10) \qquad \delta_{il} \sim \mathcal{N}(0,1). \tag{7}$$

Use of standard Normal priors for the γ_0 and δ parameters is consistent with the expected values being within approximately ±1 (i.e., constrained to reasonable values) given the ln-transforms for the response variables and the standardized covariates. From expert elicitation, species-specific lags were 2 (delta smelt), 3 (longfin smelt), 5 (striped bass), 2 (threadfin shad), and 1 (calanoids and mysids).

For the key α, β, and γ_1 parameters, we used a Weibull distribution to represent the prior beliefs of the expert-elicited model (Table 2). Use of the Weibull allows long tails in the expected direction if these are supported by the data. We used the construction $\psi_0\mathrm{Weibull}(2,\ 1) + \psi_1$, where $\psi_0 = 1$ for expected influences in a positive direction and is -1 for negative expected influences, while ψ_1 is -0.55 for expected influences in a positive direction and 0.55 for negative ones. These configurations invest ~3:1 prior probability mass in favor of the expected influence. Only one α parameter had a neutral expected influence (Table 2), so this was assigned a $\mathcal{N}(0,\ 10^3)$ prior (i.e., low precision). Many of the potential relationships were specifically excluded from the model (i.e., deemed unlikely to be important). For such relationships, coefficients were assigned $\mathcal{N}(0,\ 10^{-6})$ priors (i.e., 0 with high certainty).

Parameter inference

We inferred importance of model parameters from the probability distributions of the parameters. We computed the proportion of the posterior probability distribution for each parameter exceeding 0 (designated as PPM), which is computed in WinBUGS with the "step()" function. The posterior odds are PPM/(1 − PPM) for a positive parameter and (1 − PPM)/PPM for a negative parameter. The ratio of these posterior odds to the prior odds is termed the odds ratio (OR). Common decision criteria for ORs are 3.2–10 (substantial evidence) and 10–100 (strong evidence) (Jeffreys 1961). For an uninformative prior, in which the ratio of prior probabilities for the parameter is unity, the OR is PPM/(1 − PPM) (or (1 − PPM)/PPM for negative parameters). We used a decision criterion of $\geq$10 for such parameters.

For informative priors, the prior odds were 3 (positive or negative). If the OR $\geq$ 3.2, we concluded that there was substantial support in the data for the expected relationship. If $1 \leq \mathrm{OR} < 3.2$, the data did not invalidate the expectation but there was less support (Jeffreys 1961). If $1 \geq \mathrm{OR} > 1/3.2$, then the data weakly contradicted the expectation. If $\mathrm{OR} \leq 1/3.2$, then the prior ratio of 3:1 had been shifted to 1:1 (or more extreme), suggesting that the expected relationship was inconsistent with the data but likely to be null. We interpreted $\mathrm{OR} < 1/10$ (viz. from 3:1 prior expectation to 1:3.2 posterior odds) as clear refutation of the expected relationship.

Modeling details and model fit

Parameters were estimated from three MCMC chains of 20 000 iterations after 10 000 iterations of burn-in ("model settling"). We checked MCMC mixing and convergence using the "boa" package (Smith 2006) in *R* (R Development Core Team 2006).

We determined relative importance of the autoregressive (A), among-response variables (R), and covariate (C) factors of the best model. To do so, we calculated the r^2 for eight models: null (fitting constant-only averages for the seven response variables), A, R, C, A + R, A + C, R + C, A + R + C (full model). These models were effected by deleting terms from Eq. 6 as appropriate. The γ_i terms were retained for all models. The r^2 are the squared Pearson correlation coefficients between the z and μ values from the seven response variables and all years. To decompose variance we used hierarchical partitioning (Chevan and Sutherland 1991, Mac Nally 2000), which identifies independent contributions from individual terms (viz. A, R, and C) and joint variance explanation. We used the R package "hier.part" (Walsh and Mac Nally 2003) to perform the decomposition.

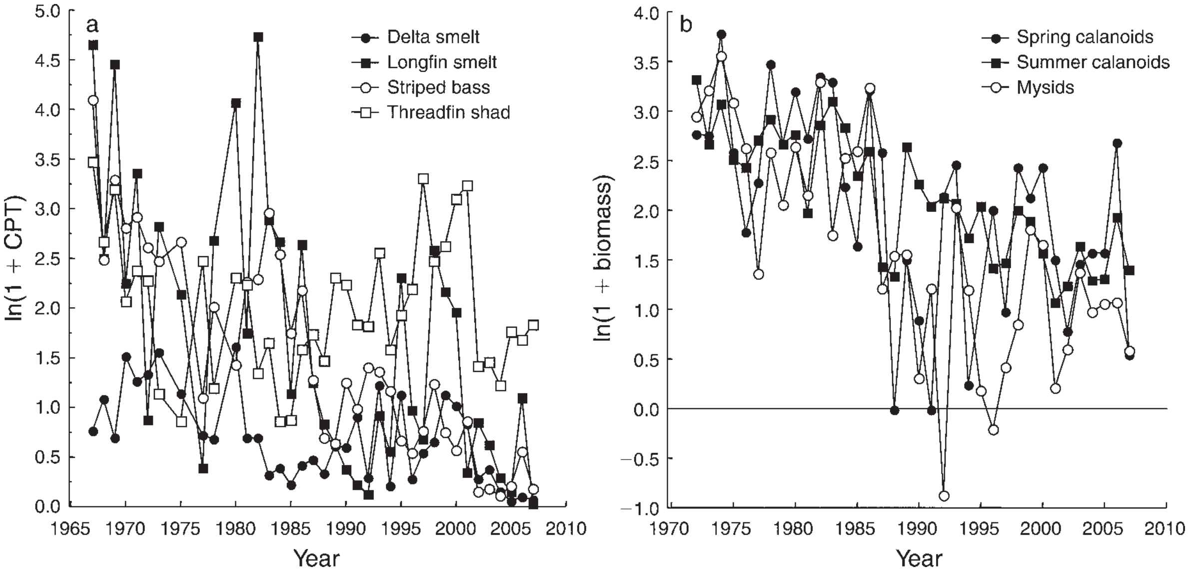

FIG. 2. Population trends (log-transformed) of (a) four fish species (mean catch per trawl [CPT]) and (b) zooplankton taxa (biomass, originally measured in mg C/m^3).

RESULTS

Abundance trajectories

Abundances of all four species of fish declined over the period of data collection, especially since about 2002 (Fig. 2a). Biomasses of the three crustacean groups have been declining consistently since the 1970s, with less evidence of a sudden decline in the 2000s (Fig. 2b).

Overall model characteristics

We used the r^2 (squared Pearson correlation coefficient) between the observed values and the posteriors of the fitted means as our measure of model fit. The full model (autoregressive components, among-response variables interactions, covariates) had an $r^2 = 0.69$. This explained variance was decomposed into independent explanatory amounts of (a) 0.13 for the autoregressive components (A), (b) 0.21 for among-response variable components (R), and (c) 0.35 for covariate relationships (C) (hence 1:1.62:2.69). Thus, the covariates were roughly 66% more important in explaining variation than the response variables, which in turn were ~62% more important than autoregressive elements.

Specific relationships

Parameter estimates and related details are provided in Appendix A. Some covariates appeared to affect more than one response variable (Fig. 3a, b). For expectations that seemed strongly supported by the data, the large values of spring X2 (upstream location) were negatively related to abundances of longfin smelt, biomass of calanoids in spring, and biomass of mysids (Fig. 3a). High water clarity was associated negatively with abundances of striped bass and threadfin shad, while high mean summer water temperatures had an inverse relationship with delta smelt abundance (Fig. 3a).

Several expectations were more weakly supported by the data, but were not refuted. Spring exports were negatively associated with abundances of delta smelt and threadfin shad (Fig. 3b). Many of the trophic interactions among response variables were supported to some extent, including negative relationships between the abundance of longfin smelt and delta smelt and biomass of calanoids in summer, negative correlations between abundance of striped bass and calanoid biomass in spring, and a positive relationship between concentration of chlorophyll *a* in spring and biomass of mysids and calanoids. Calanoid biomass in spring and summer was negatively associated with presence of the nonnative clam *Corbula amurensis*, while abundance of largemouth bass and volume of winter exports were negatively associated with abundance of delta smelt (Fig. 3b).

For all four declining fish species, the parameters indicating density dependence (δ) from the previous year were strongly negative, ranging from -0.79 ± 0.26 (mean ± SD) for threadfin shad to -1.03 ± 0.18 for longfin smelt (Appendix A). Current abundances were positively related to those for two years previous for longfin smelt (0.30 ± 0.16). Other lag effects were deemed unimportant, although a four-year lag (positive) for striped bass had OR = 9.2.

For the γ parameters, only one result seemed unexpected. The anticipated negative slope for threadfin shad was positive, with high certainty (OR < 1/57.8; Appendix A). This suggested, counterintuitively, that the intrinsic population growth parameter had increased over the duration of study.

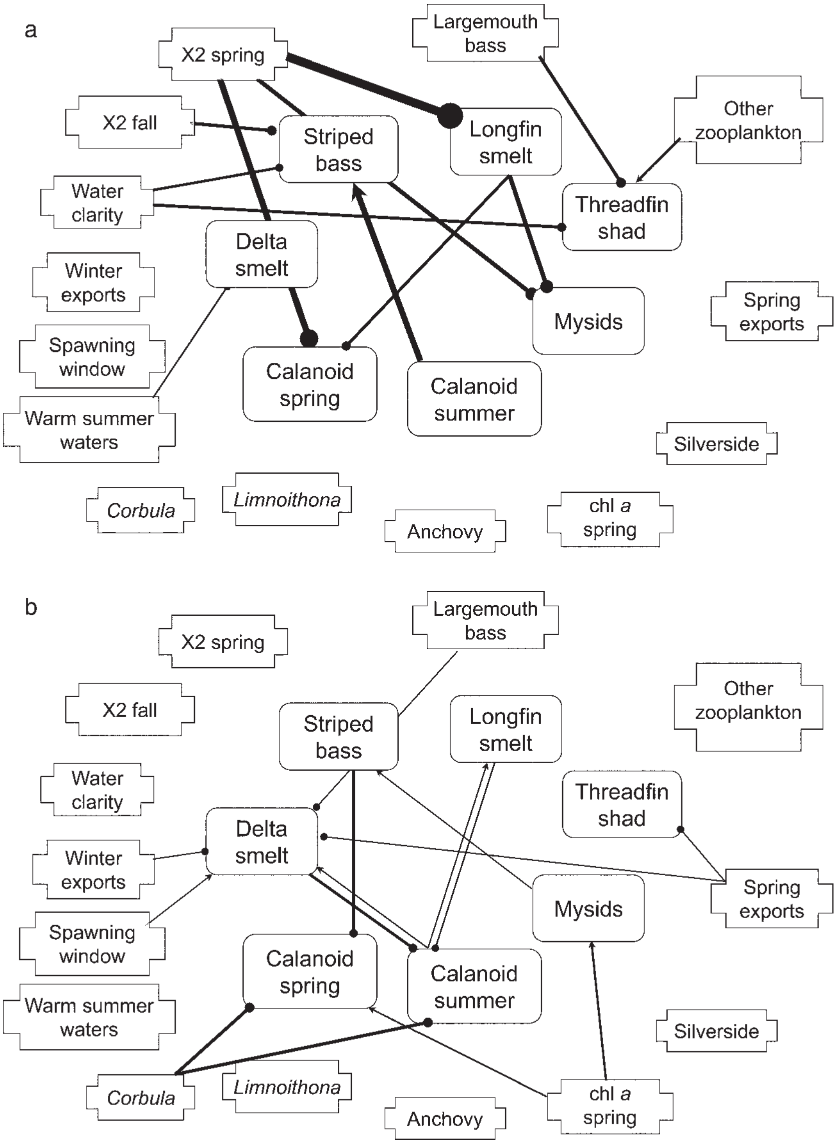

FIG. 3. Relationships supported by the Bayesian multivariate autoregressive analysis of the expert-elicited model, with width of lines proportional to the regression coefficient divided by its standard error. Response variables (focal taxa) are enclosed in rounded boxes while covariates are in boxes with side tabs. Arrows toward a focal taxon indicate a positive effect related to the focal taxon or covariate of line origin, while solid circles indicate negative relationships. (a) Relationships for which the odds ratio ≥ 3.2. (b) Relationships for which the odds ratio falls between 1 and 3.2. The abbreviation "X2" refers to the 2‰ isohaline.

DISCUSSION

Overview of the MAR results

The importance of covariates (51% of explained variation) suggests that some aspects of the environment that can be managed are associated with the declining fish species (e.g., X2 and exports). However, other potential remedial actions would be difficult or impossible to enact (e.g., total removal of *Corbula amurensis*). The relatively large proportion of variance explained by interactions among the declining fishes and their prey suggests that trophic interactions also are important, but it is less clear how management actions could modify such relationships.

The MAR analysis largely supported the expert model, suggesting that existing knowledge is sufficient to identify important interactions and processes, although not all relationships were supported. The expert model included 54 relationships, all but one of which was assigned an expected direction (Table 2). The latter was an "uninformed" expectation that calanoids in spring would be affected by spring X2. The direction was found to be strongly negative (Fig. 3a), suggesting that spring calanoid abundance is greater when X2 is more seaward. Of the 53 relationships with expected directions, 13 were strongly supported on the basis of odds ratios (OR) of ≥ 3.2 (Fig. 3a) and 15 were not inconsistent with the expected direction ($3.2 > \text{OR} \geq 1$) (Fig. 3b). The other 25 coefficients had posterior means close to zero, indicating that the data did not support the expected directions.

One advantage of using the MAR approach is that results can be represented easily in a form with which most ecologists are familiar, a (partial) food web (Fig. 3). The predator–prey relationships involving the calanoids and mysids support existing reports of direct and indirect effects on the four declining fish species. For example, abundance of striped bass was positively related to availability of calanoid copepods in summer (Fig. 3a). This was negatively associated with the occurrence of the introduced clam *Corbula amurensis* (Fig. 3b), which has induced an ongoing decrease of ~60% in chlorophyll *a* concentration in the low-salinity zone (Alpine and Cloern 1992). Other indirect food limitation relationships may be the chlorophyll *a* (spring) → mysids → striped bass and chlorophyll *a* (spring) → calanoids (spring) → striped bass pathways (Fig. 3b). Longfin smelt abundances had strong negative correlations with calanoids in spring and summer and mysids in spring (Fig. 3a, b). Abundance of delta smelt was related to calanoid biomass in summer (Fig. 3b). These results and relationships of copepods and mysids to chlorophyll *a* concentrations (Fig. 3b) suggest that food web dynamics are important for both smelt species. The isohaline position (X2) in spring had strong negative relationships with spring calanoids and mysids, which also would propagate back through those food pathways (Fig. 3a).

Few covariate relationships were expressed clearly for more than one of the four declining fish species (Fig. 3a, b). Increased water clarity appeared to be related negatively to both striped bass and to threadfin shad (Fig. 3a). Increased water clarity has been attributed to reduction of sediment supply in the rivers (Wright and Schoellhamer 2004) and to sediment capture by submerged aquatic vegetation. Water clarity affects fish feeding (Hecht and Vanderlingen 1992) and vulnerability to predation (Gregory and Levings 1998). Abundance of largemouth bass, a potential predator of the declining fish species (Nobriga and Feyrer 2008), was negatively related to abundance of threadfin shad and, more weakly, to abundance of delta smelt (Fig. 3). Abundance of largemouth bass has increased in the Delta concurrently with expansion of submerged aquatic vegetation (Brown and Michniuk 2007), which provides high-quality habitat for the species. Greater cover of submerged aquatic vegetation also reduces turbidity. Reduced water clarity has been identified as a key component of habitat for delta smelt, at least in autumn (Feyrer et al. 2007). The absence of a discernible relationship between water clarity and abundance of delta smelt may be due to an indirect expression through trophic relationships. Young delta smelt require suspended particles in the water column to feed properly (Baskerville-Bridges et al. 2002, Mager et al. 2002), so reduced prey availability (e.g., summer calanoids) may mask the direct water clarity effect. The multiple effects of temperature, feeding, exports, and introduced species are more consistent with understanding of delta smelt biology (Bennett 2005, Baxter et al. 2008) than are effects of individual covariates per se.

There were clear relationships between warmer summer waters (negative) and duration of water temperatures suitable for spawning (positive) (Fig. 3) and delta smelt, which were consistent with known effects of high temperatures on delta smelt survival (Swanson et al. 2000) and spawning requirements (Bennett 2005).

Increases in water exports in both winter and spring were negatively associated with abundance of delta smelt and increases in spring exports with abundance of threadfin shad. Losses of delta smelt previously have been related to exports through entrainment and mortality at pumping facilities and may be important to population dynamics under some circumstances, particularly during dry years (Kimmerer 2008). Effects of spring exports on threadfin shad have not been measured but possibly are important given that this is the only species of the four to occupy freshwater throughout its life cycle and whose main distribution is near the export facilities (Feyrer et al. 2009).

Modeling formulation: data and limitations

Using MAR, we identified plausible results, notwithstanding a number of important caveats within the model framework, which relate to the nature of the underlying data and to the structure of the analytical model.

Data limitations.—Three major forms of data limitation inherent in MAR are relevant to our study: (1) characterization of all variables and covariates by using a single value per year; (2) lack of spatially and temporally explicit data; and (3) selection of covariates and their measurement. For the declining fish species, we used an estimate of abundance based on average catch per sampling trawl over ~100 sampling stations over each of the four autumn months (September to December). Fish have been collected by other sampling methods (e.g., beach seine nets), but either not consistently over the duration of the data collection or only recently. We included observation error as the standard error from the ~400 trawls per year, but whether this is the most appropriate measure is arguable (Newman 2008).

Apart from allowing γ_i to be time-dependent (albeit linearly), the MAR model assumed process stationarity over the entire duration, which means that the structure of the model and distributions of model parameters are regarded as being the same over the 40+ years. It is possible that population dynamics of the declining taxa changed greatly as a function of population size. It is plausible that per capita reproductive rates, age structures, social (e.g., schooling) behaviors, Allee effects (Stephens and Sutherland 1999), and vulnerability to predation may differ when there are many individuals compared to when there are few. This is a common tenet in conservation biology (Caughley 1994).

Given the high certainty that all four species declined in concert in 2002 (Thomson et al. 2010), we modified Eq. 6 to allow all parameters to have a two-phase structure. The first phase was the 1967–2001 period and the second phase was 2002–2007. Each parameter was represented by a term of the form $\varpi + \delta\varpi$, where $\delta\varpi$ was the deviation in the second phase from values in the first phase. There were no parameters in which $\delta\varpi$ differed substantially from zero using our OR criteria. This suggests that the stationarity assumption of the MAR model is reasonable, although the small number of years in phase two may make changes difficult to detect.

Stakeholders have commissioned extensive correlative analyses (D. Fullerton, W. J. Miller, and B. F. J. Manly, *unpublished data*), which suggest a wide range of possibilities for potential covariates that might have sparked the precipitous declines. We included eight commonly mentioned covariates in additional runs of the MAR model (Appendix B). Our inferences were little changed, which suggests that our expert model was resilient to inclusion of additional variables and that the latter were largely uninformative.

Model form and structure.—The MAR model is underlain by the Gompertz population dynamic model (Eq. 1). Inference on stock recruitment is contingent on the form of the model (Maunder 2003). We explored whether our inferences were highly dependent on the use of the Gompertz by replacing it with another widely used formulation, the Ricker model (Appendix C; Zeng et al. 1998). The Ricker model emphasized more strongly several relationships: for example, the negative relationships between striped bass and X2 (autumn) and between spring calanoids and X2 (spring) (Appendix C). The Ricker and Gompertz versions of the MAR model generally provided similar inferences but the Gompertz appeared to resolve with greater precision a larger number of relationships given our criteria for their identification (i.e., using ORs).

The values for the δ_{i1} coefficients for the four declining fish species suggested strong negative density dependence (values between −0.79 and −1.03 for one-year lag; Appendix A). Such results seem difficult to reconcile biologically given that the fish sampled each year are young-of-the-year and it is difficult to conceive of a mechanism producing such density dependence. It is possible that this apparent contradiction may be a statistical artifact of the parameterization of the usual Gompertz model. Estimates of γ and δ can be highly correlated and identifiability depends upon length of time series (J. Ponciano, *personal communication*). Even if there were estimation problems for γ and δ, these probably do not affect our estimates of trophic interactions and covariate relationships. From simulations of a Gompertz model with one covariate, we found that the estimate for the covariate coefficient was unbiased even though the estimates of γ and δ were biased (results not shown).

The MAR formulation assumed linear relationships (on the log-abundance scale) and no interactions among covariates, although many interactions are plausible. Interactions would add substantially to the complexity and difficulty of interpretation of an already highly parameterized model. Inclusion of nonlinear functions and interactions among covariates may reduce capacity to resolve drivers of responses if used injudiciously.

A comparison of major outcomes of the MAR analysis with those of the change point analyses, which did allow nonlinear functions of covariates, showed some commonalities, but also several differences. Relationships with water clarity were important in the change point analyses for delta smelt, striped bass, and longfin smelt, although the relationship for the latter was rather stronger in a multispecies model (Thomson et al. 2010). A correlation of water clarity with abundances of threadfin shad, but not with delta smelt, was identified in MAR. A pervasive relationship of spring X2 with abundances of longfin smelt was clear in both analyses. A correlation of winter exports with delta smelt was evident in the change point, but was weaker in the MAR (Fig. 3b). The MAR analysis, but not the change point analysis, identified a correlation between autumn X2 and striped bass. Spring exports appeared to be related to abundances of threadfin shad in both analyses, although the magnitude of the correlation was less in the MAR. Unlike the change-point analysis, the MAR analysis did not identify a relationship between winter exports and threadfin shad. However, in the change-point analysis the magnitude of the average regression coefficient for winter exports and threadfin shad was substantially less than that for spring exports (Thomson et al. 2010). The trophic interactions evident in the MAR, of which many were pronounced (Fig. 3), were less evident in the model selection procedures used in the change point analysis.

A broader life-history model with a more general state–space approach to modeling the pelagic species decline should be more informative (M. N. Maunder and K. B. Newman, *personal communication*). Such a model would incorporate multiple sources of survey data, including data pertinent to egg, larval, juvenile, and adult phases and covariates appropriate for each stage (Maunder 2004).

Estuarine management

Our application of the MAR model provides evidence from a multivariate analysis of how abiotic habitat factors directly relate to declining fish abundance in the upper San Francisco Estuary and indirectly to these fish populations through the food web. Synthesis of previous univariate analyses have come to similar conclusions, albeit indirectly (Bennett 2005, Baxter et al. 2008). Before the fish species declined precipitously, the abiotic component of their habitat in the estuary was represented mainly as X2 because position of the salinity field was correlated with the abundances of many organisms (Jassby et al. 1995). Recent results have highlighted the importance of other abiotic variables, including water clarity and water temperatures, in the estuary (Feyrer et al. 2007, Nobriga and Feyrer 2008). Our results, which identify trophic relationships, suggest the need to better understand the processes underlying the influence of abiotic conditions on the food web of the estuary. The upper San Francisco Estuary is an exemplar, perhaps an extreme one, of severe, adverse ecological response to many of the stressors to which such systems increasingly are exposed (Fig. 3). Some of the key issues relate to how the isohaline position (X2), which seems to have a profound effect on the declining fish and on their prey, might be managed. While evidence that water exports directly affect striped bass or longfin smelt in a consistent linear manner is weak, there is evidence of potential effects of water exports on delta smelt and threadfin shad. Successfully managing the estuary, at least for the declining fish species, requires a more complete understanding of how the direct effects of water exports interact with the indirect effect of controlling abiotic conditions and the food web.

Acknowledgments

This work was supported by cooperative agreement number 113325G004 between the University of California–Santa Barbara and the U.S. Fish and Wildlife Service and conducted as part of a working group convened at the National Center for Ecological Analysis and Synthesis. Other members of the working group, including Howard Townsend, Dennis D. Murphy, Mark Maunder, John M. Melack, and Marissa Bauer, contributed to the work through discussions. S. Slater and D. Contreras of the California Department of Field and Game kindly assisted in data compilation. W. J. Kimmerer was supported by funds from the Interagency Ecological Program. This is contribution 190 from the Australian Centre for Biodiversity at Monash University.

Abstract:

Adult salmon that stray when they escape into non-natal streams to spawn is a natural phenomenon that promotes population growth and genetic diversity, but excessive stray rates impede adult abundance restoration efforts. Adult San Joaquin River (SJR) Basin fall-run Chinook salmon (*Oncorhynchus tshawytscha*) that return to freshwater to spawn migrate through the San Francisco Bay and Sacramento–San Joaquin River Delta (Delta). The Delta has been heavily affected by land development and water diversion. During the fall time-period for the years 1979 to 2007 Delta pumping facilities diverted on average 340% of the total inflow volume that entered the Delta from the SJR. The hypothesis tested in this paper is that river flow and Delta exports are not significantly correlated with SJR salmon stray rates. Adult coded-wire-tagged salmon recoveries from Central Valley rivers were used to estimate the percentage of SJR Basin salmon that strayed to the Sacramento River Basin. SJR salmon stray rates were negatively correlated ($P = 0.05$) with the average magnitude of pulse flows (e.g., 10 d) in mid- to late-October and positively correlated ($P = 0.10$) with mean Delta export rates. It was not possible to differentiate between the effects of pulse flows in October and mean flows in October and November on stray rates because of the co-linearity between these two variables. Whether SJR-reduced pulse flow or elevated exports causes increased stray rates is unclear. Statistically speaking the results indicate that flow is the primary factor. However empirical data indicates that little if any pulse flow leaves the Delta when south Delta exports are elevated, so exports in combination with pulse flows may explain the elevated stray rates. For management purposes, we developed two statistical models that predict SJR salmon stray rate: (1) flow and export as co-independent variables; and (2) south Delta Export (E) and SJR inflow (I) in the form of an E:I ratio.

ABSTRACT

Adult salmon that stray when they escape into non-natal streams to spawn is a natural phenomenon that promotes population growth and genetic diversity, but excessive stray rates impede adult abundance restoration efforts. Adult San Joaquin River (SJR) Basin fall-run Chinook salmon (*Oncorhynchus tshawytscha*) that return to freshwater to spawn migrate through the San Francisco Bay and Sacramento–San Joaquin River Delta (Delta). The Delta has been heavily affected by land development and water diversion. During the fall time-period for the years 1979 to 2007 Delta pumping facilities diverted on average 340% of the total inflow volume that entered the Delta from the SJR. The hypothesis tested in this paper is that river flow and Delta exports are not significantly correlated with SJR salmon stray rates. Adult coded-wire-tagged salmon recoveries from Central Valley rivers were used to estimate the percentage of SJR Basin salmon that strayed to the Sacramento River Basin. SJR salmon stray rates were negatively correlated ($P = 0.05$) with the average magnitude of pulse flows (e.g., 10 d) in mid- to late-October and positively correlated ($P = 0.10$) with mean Delta export rates. It was not possible to differentiate between the effects of pulse flows in October and mean flows in October and November on stray rates because of the co-linearity between these two variables. Whether SJR-reduced pulse flow or elevated exports causes increased stray rates is unclear. Statistically speaking the results indicate that flow is the primary factor. However empirical data indicates that little if any pulse flow leaves the Delta when south Delta exports are elevated, so exports in combination with pulse flows may explain the elevated stray rates. For management purposes, we developed two statistical models that predict SJR salmon stray rate: (1) flow and export as co-independent variables; and (2) south Delta Export (E) and SJR inflow (I) in the form of an E:I ratio.

tion actions is to ensure that mature fall-run salmon (salmon) return to the SJR basin to spawn. Results from previous studies indicate that Sacramento–San Joaquin River Delta (Delta) flow conditions when salmon escape the ocean (salmon escapement) may influence returning SJR origin salmon stray rates (Mesick 2001). Straying by SJR salmon hinders population goals and necessitates evaluating relationships between Delta flow conditions and SJR salmon straying into the Sacramento Basin. The specific hypothesis tested in this paper is that no statistically significant relationship between fall south Delta inflow and/or export flow conditions, and SJR origin salmon stray rates exists.

It is well established that some proportion of adult salmon, both wild and hatchery origin, stray from one river basin to another upon return to their natal home from the sea (Quinn 1993). Identifying what, if any, Sacramento–San Joaquin River Delta environmental factors increase the likelihood of SJR fall-run to stray into the Sacramento River Basin will help scientists, water project managers, and state and federal government regulators better manage Delta flow conditions (Hallock and others 1970; Mesick 2001) to accomplish their ultimate goal of restoring the SJR Basin fall-run salmon population. Published results of stray rate studies conducted within California rivers are few in number and are essentially limited to Snyder's (1931) work on the Klamath River, Hallock and others' (1970) work on the San Joaquin River, Sholes and Hallock's (1979) work on the Feather River, and Mesick's (2001) work on the San Joaquin River. Where necessary and applicable, stray rate information was gleaned from published stray rate research conducted in river basins in Oregon, Washington, Alaska, and Canada. Since Mesick's (2001) work directly relates to San Joaquin River salmon stray rates, his work is extensively cited.

Adult SJR Basin fall-run Chinook salmon that return to freshwater to spawn must pass through the San Francisco Bay (Bay) and Delta (Figure 1). The Delta has been heavily affected in the last century by land development and water diversion and comprises a labyrinth of man-made and natural channels that convey Delta inflow, direct water for diversion, and/or allow ocean-going ships to dock at Stockton for commerce (Figure 2). The Delta today is effectively managed to store water upstream of the Delta and release it at times, and volumes, when pumping facilities in the south Delta can capture and convey it for agriculture and municipal use. The primary water diversions located in the south Delta are California's State Water Project (SWP) and the federal Central Valley Project (CVP) export pumping facilities located near Byron and Tracy, respectively (Figure 2). The CVP began operations in 1955, and the SWP in 1967. Smaller Delta diversions are made by the Contra Costa Canal Water District (CCC) at Rock Slough and Old River (Figure 2) and by the Solano County Water Agency from the North Bay Aqueduct (NBA) located on Barker Slough.

Historically the CVP, SWP, and CCC pumping facilities operate year-round and collectively have a combined pumping capacity of approximately 394.4 $m^3\ s^{-1}$ (14,000 $ft^3\ s^{-1}$). In the 1990s, because of concern over excessive entrainment of springtime emigrating juvenile Sacramento River and SJR salmon (various races), springtime diversions at the CVP and SWP were greatly curtailed with much of the displaced pumping moved to the fall when the adult fall-run migrate. Between 1979 and 2007, average October–November exports ranged from a low of 18% of SJR Basin flow to a maximum of more than 740%, averaging nearly 340% of the volume of water inflowing from the SJR. Water movements through the historic Old and Middle SJR channels (Figure 1) are affected by Delta pumping because these channels directly feed the CVP and SWP pumps. Most times, the river in these channels downstream of the pumps is pulled back upstream by the pumps. Rock barriers also have been placed in several locations in the south Delta to improve agricultural water quality and quantity by increasing surface water elevation. These barriers are collectively called the south Delta barriers and include the Head of Old River Barrier, Grant Line Canal Barrier, Old River at Tracy Barrier, and the Middle River Barrier (Figure 2). Some of the barriers are impassable for fish. Further, the Stockton Deep Water Ship Channel (SDWSC, Figure 2) can be a migration barrier for returning salmon during the fall because of low dissolved oxygen levels (e.g., <5 mg L^{-1}) when flows are low (Hallock and others

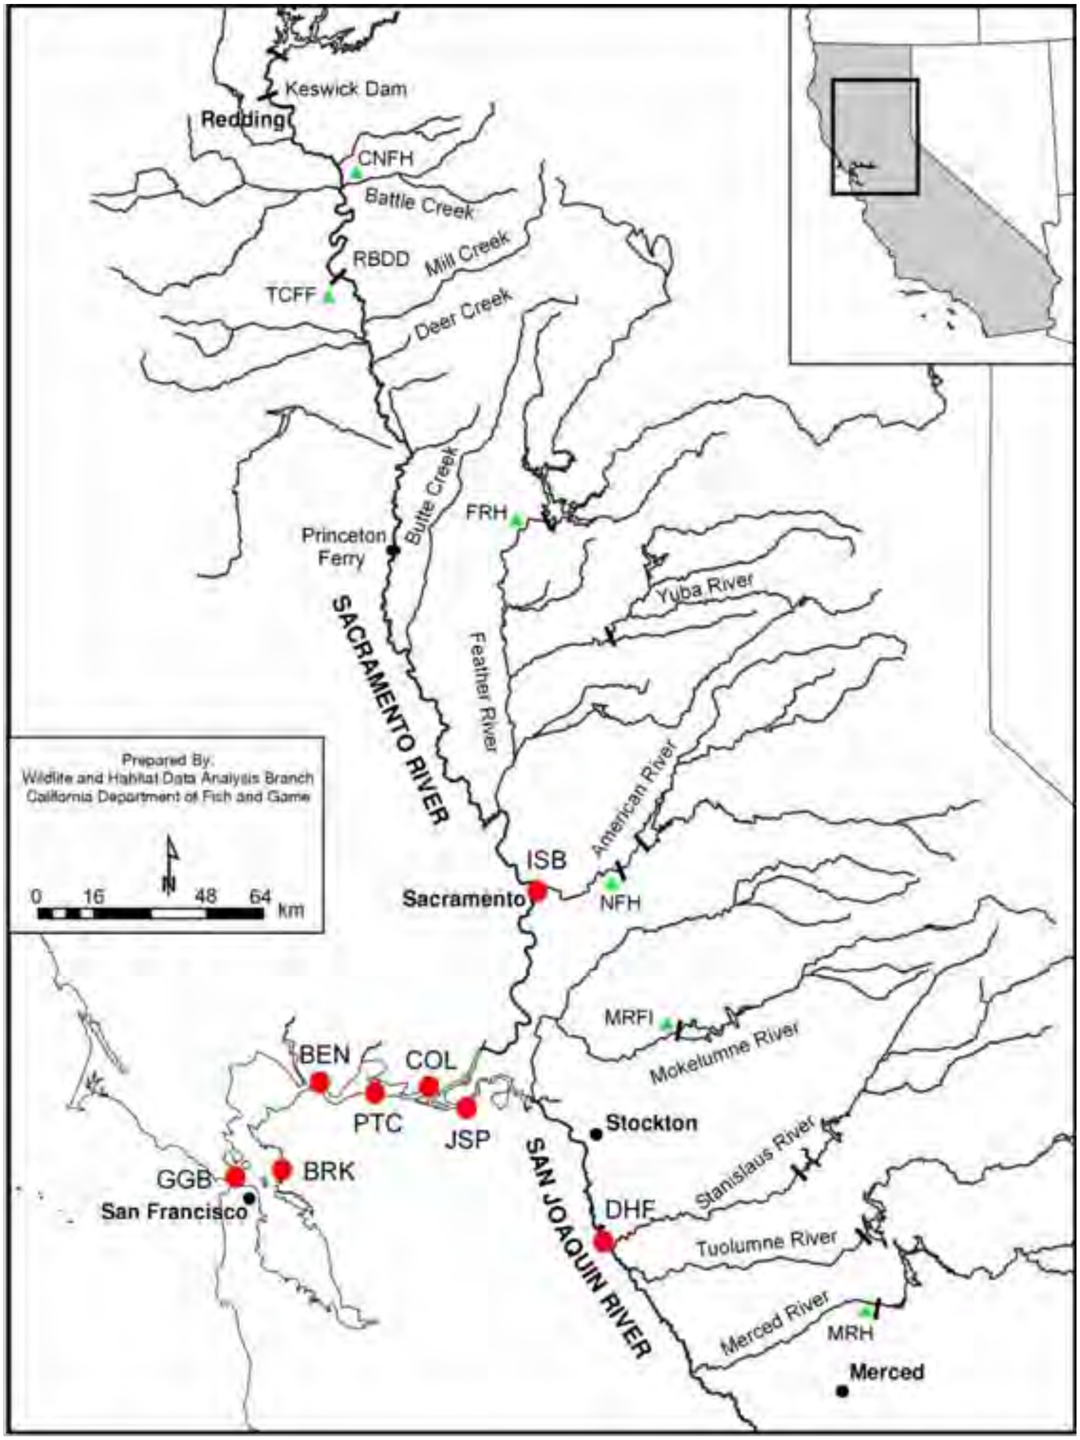

Figure 1 Map of the major Central Valley rivers, the Merced River Hatchery (MRH), Feather River Hatchery (FRH), Tehama Colusa Fish Facility (TCFF), Coleman National Fish Hatchery (CNFH), Mokelumne River Fish Installation (MRFI), and the Nimbus Fish Hatchery (NFH). Bay releases of tagged juveniles were made between Collinsville (COL) on the Sacramento River, Jersey Point (JSP) on the San Joaquin River, and the Golden Gate Bridge (GGB). Example release sites in the Bay include Berkeley (BRK), Benicia (BEN), and Port of Chicago (PTC). Delta releases were made upstream of COL and JSP to Durham Ferry (DHF) on the San Joaquin River and the I Street Bridge on the Sacramento River (ISB). Inland releases were made upstream of ISB and DHF.

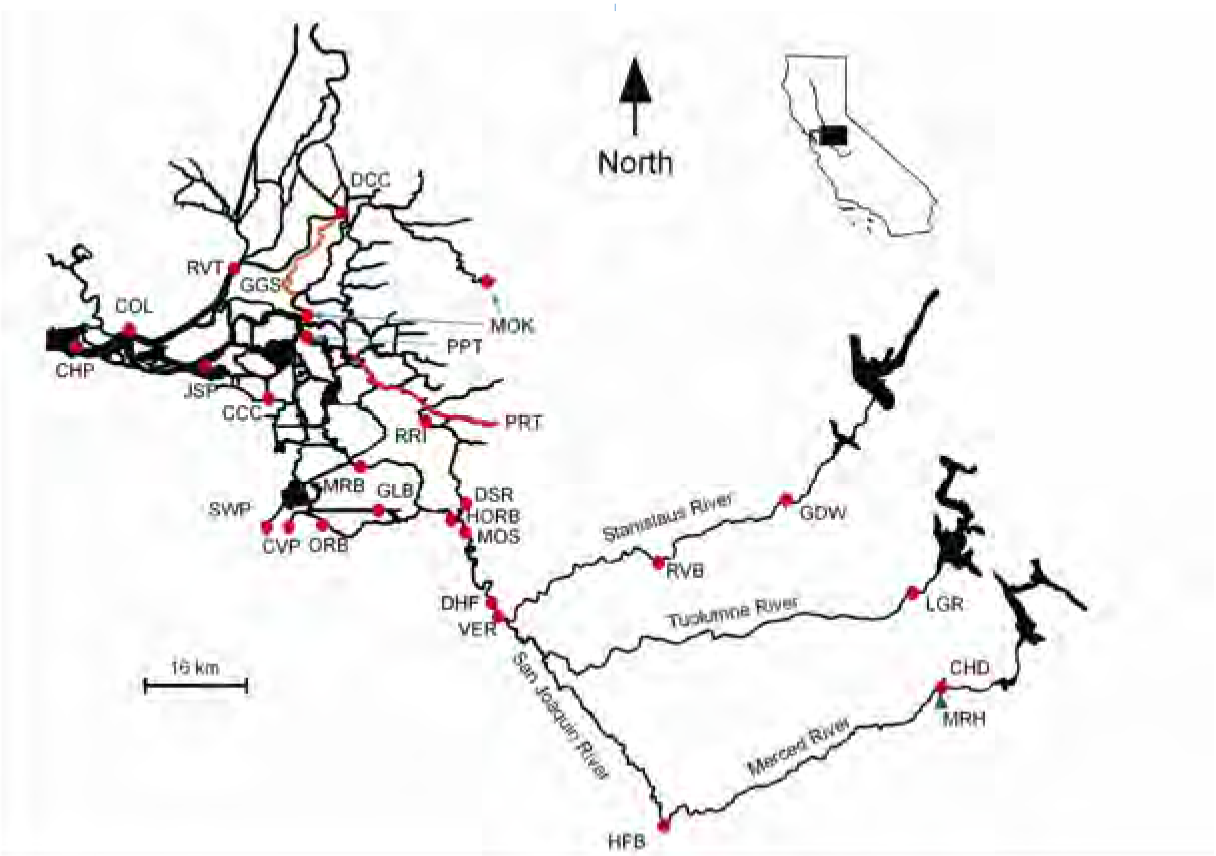

Figure 2 Map of the San Joaquin River and Delta showing the lowermost dams that block upstream passage for fall-run Chinook salmon including Goodwin Dam (GDW) on the Stanislaus River, La Grange Dam (LGR) on the Tuolumne River, Crocker-Huffman Dam (CHD) on the Merced River, and the Hills Ferry Barrier (HFB) on the mainstem San Joaquin River. The Merced River Hatchery (MRH) is shown as a green triangle. The lower Mokelumne River (MOK) is shown to its confluence with the SJR. Other study locations (red dots) include Riverbank (RVB), the State (SWP), Federal (CVP), and Contra Costa Canal (CCC) pumping facilities, stream gage at Vernalis (VER), Prisoner's Point (PPT), Durham Ferry (DHF), Mossdale (MOS), Dos Reis Road (DSR), Port of Stockton (PRT), Rough and Ready Island (RRI), Rio Vista (RVT), Delta Cross Channel (DCC), and Georgiana Slough (GGS, highlighted orange). The temporary rock barriers at the Head of the Old River (HORB), Grant Line Canal (GLB), Old River Barrier (ORB), and Middle River Barrier (MRB) are shown. The San Joaquin River mainstem downstream of the Port of Stockton (highlighted red) is dredged for ocean-going vessels. As defined here, releases of juvenile salmon in the Delta were made upstream of Jersey Point (JSP) to DHF on the San Joaquin River and upstream of Collinsville (COL) to the I Street Bridge (in the City of Sacramento, which is not shown) on the Sacramento River.

1970) or when water temperatures are high (Hallock and others 1970; Rich 2007). The SDWSC dissolved oxygen barrier can occur when SJR at Vernalis flows are less than approximately 42.5 m^3 s^{-1} (1,500 ft^3 s^{-1}). Water temperatures in the SJR can reach lethal levels and also block migration (Rich 2007) when temperatures exceed 21 °C to 22 °C (USEPA 2003). Reverse flows, physical barriers or chemical barriers that delay adult salmon migration may increase the likelihood of straying.

Chinook salmon rely primarily on olfactory cues to successfully migrate through the Delta's maze of waterways to home back to their natal river (Groves and others 1968; Mesick 2001). Juvenile salmon imprint by acquiring a series of chemical waypoints at every major confluence that enables them to relocate their river of origin (Quinn 1997; Williams 2006). Juvenile hatchery-reared salmon released downstream gather fewer chemical waypoints and are more likely to stray (CDFG and NOAA Fisheries 2001; Newman 2008). Adult SJR basin Chinook pass through the Delta from late September through November, with peak immigration usually in October (Mesick 2001).

Since olfaction plays such a strong role in a salmon's ability to return (home) to its natal river of origin (Groves and others 1968; Quinn 1997; Williams 2006), providing sufficient water to enable salmon to home in on their natal river is paramount. The Sacramento River basin is approximately 2.5 times larger than the San Joaquin River basin, has a hydrograph dominated by fall and winter rainfall compared to the spring-time snow-melt hydrograph on the SJR, and can provide ten times greater fall Delta inflows than the SJR. Comparatively, the SJR is the most heavily diverted of the two rivers. The mainstem SJR is discontinuous (dry over 90% of the time in one or more reaches) upstream of its confluence with the Merced River (Figure 2) and provides flow to the Delta only in wet years (Rose 2000). Only the major east-side SJR tributaries flow year-round. The SJR is managed to provide fall pulse inflows to the south Delta, typically for 7 to 10 days in late October. The goal is to compensate for the extreme Delta inflow differential between the Sacramento River and SJR basins, to remove the SDWSC dissolved oxygen barrier, and to decrease water temperatures. A secondary purpose of the fall pulse flows is to reduce SJR salmon from straying into the Sacramento River basin by enabling salmon to successfully locate and immigrate into the SJR basin.

The term "straying" has four spatially implied definitions: (1) adult salmon returning to a non-natal river basin; (2) adult salmon returning to a non-natal sub-basin; (3) adult salmon returning to a non-natal tributary; and (4) adult salmon returning to a hatchery in their natal river if naturally spawned. For this reason, stray rates between studies cannot be directly compared without considering which straying definition was used. For the purpose of this paper, the term "stray" means an adult salmon that strayed into the wrong sub-basin of the Central Valley (i.e. the Sacramento River basin rather than the SJR basin).

Mesick (2001) evaluated the effects of SJR flows and Delta export rates during October on adult San Joaquin Chinook salmon stray rates. Mesick reviewed the results of an earlier study (Hallock and others 1970) where adult San Joaquin salmon were tagged, then monitored (1964 to 1967), as they migrated through the Delta under varying environmental conditions (e.g. Delta inflow and export patterns, dissolved oxygen, and water temperature). Mesick also evaluated recovery data of coded-wire-tagged (CWT) adult salmon, released in years 1983 to 1996, that were reared at the California Department of Fish and Game's (CDFG's) Merced River Hatchery.

Mesick (2001) made two important observations from the Hallock and others (1970) data that describe adult migratory behavior through the Delta. First, adult San Joaquin salmon are migrating through the San Joaquin Delta near Prisoner's Point, which is about 5 km upstream from its confluence with the Mokelumne River (Figure 2), primarily during October, when they are likely to be susceptible to low SJR inflow and high Delta export conditions. Second, San Joaquin salmon migrate slowly through the Delta and do not enter the San Joaquin tributaries until approximately 4 weeks after they pass Prisoner's Point even if environmental conditions (dissolved oxygen, water temperature, and both south Delta inflow and exports levels) appear suitable for migration. These observations indicate that hydraulic conditions in the Delta are most likely to affect adult migrations during October rather than in November when they are observed on the spawning grounds in the tributaries.

Mesick (2001) found three primary flow factors that influence San Joaquin salmon stray rates. First, stray rates were directly correlated with the Delta export (E) to San Joaquin River Delta inflow (I) ratio (E:I). Second, the critical period to provide Delta flow protection (conditions conducive to SJR salmon migration) is between October 1st and 21st. Third, pulse flows from the SJR tributaries (the Merced, Tuolumne, and Stanislaus rivers) or, a reduction of Delta exports, that resulted in an E:I ratio of 3 (exports no greater than 300% of SJR inflow at Vernalis) for 8 to 12 days in mid-October were sufficient to keep stray rates at a minimum level (<3%). Mesick (2001) qualified his findings by saying that the accuracy of the estimated numbers of strays was questionable because of the uncertainties about the numbers of fish examined for CWTs within escapement surveys conducted in Central Valley rivers. As a result, he was unable to discern the specific effects of flow versus export rates on SJR Basin salmon stray rates or determine the precise period when flows and export rates had the greatest effect. He qualified his analysis of the Hallock and others (1970) data by stating that although most of the tagged fish migrated into the Sacramento and Mokelumne basins when Vernalis flows were less than about 56.7 $m^3\ s^{-1}$ (2,000 $ft^3\ s^{-1}$) and total exports exceeded 150% of Vernalis flows, there is uncertainty as to whether these were San Joaquin fish that strayed or Sacramento River fish that were captured in the San Joaquin River on their way to the Sacramento River via the Mokelumne River and Delta Cross Channel (Figure 2). He recommended that further studies were needed to refine the CWT return data in terms of the number of fish examined for tags during the carcass surveys and additional surveys for tags in all major tributaries of the Sacramento River Basin, particularly the mainstem Sacramento River.

Building on Mesick's (2001) work, we evaluated relationships between fall Delta flow conditions and San Joaquin salmon stray rates using coded-wire-tag (CWT) data collected from 1979 to 2007. We analyzed the data to determine the probability of an adult SJR salmon straying to the Sacramento River basin, given fall Delta flow conditions during their escapement. Pending analytical results, recommendations for controls that could be implemented as south Delta water quality control standards to provide a reasonable level of protection for returning adult SJR salmon could be considered and implemented. The specific hypothesis assessed, framed as a null hypothesis, is: fall south Delta inflow, export flow level, and barrier installation are not significantly correlated with SJR salmon stray rates.

METHODS

We developed three data sets in order to evaluate potential relationships between Delta flow patterns and SJR salmon stray rates. The data sets cover the years 1979 to 2007 and include those parameters we believe may significantly influence straying. The first data set includes coded wire tagged (CWT) salmon releases and recoveries of Central Valley fall-run Chinook salmon from which stray rates were determined. The second data set includes fall Delta flow and export conditions. The third data set contains south Delta Barrier (SDB) annual construction dates and operational periods. The 1979 to 2007 time-period represents the principal time-period when Central Valley salmon were coded wire tagged and released, and covers the period having complete brood-year production cohorts. Methods used to develop the stray rate data are complicated and are only summarized here. For a full description of methods used to develop the stray rate data, and to see the stray, hydrodynamic, and barrier data sets used in our analyses, please refer to the Methods Appendix.

Stray rates of ocean-escaping SJR salmon were compared with two fall south Delta inflow indices: the first using average October and November flow (base flow) and the second using a 10-day pulse flow occurring in mid-October to late October into early November. We also looked at Delta export flow levels over the same time periods. Stray rates for SJR salmon were developed from adult inland recoveries of coded-wire-tagged, hatchery-origin juvenile releases into the San Joaquin and Sacramento river basins, Delta, and Bay over a 29-year period (1979 to 2007).

Adult Salmon Stray Rates

We define salmon strays as the SJR basin fish that returned to the Sacramento River basin to spawn and the Sacramento River basin fish that returned to the SJR basin to spawn. Central Valley fall-run Chinook salmon stray rates were estimated based on CWT recoveries of adult salmon during the spawning surveys that were conducted to estimate escapement. The juvenile salmon with CWTs were produced in Central Valley hatcheries including the Merced River Hatchery (MRH) and the Mokelumne River Fish Installation (MRFI) in the San Joaquin River basin, and the Nimbus Fish Hatchery (NFH), Feather River Hatchery (FRH), and Coleman National Fish Hatchery (CNFH) in the Sacramento River basin (Figure 1). The MRH, MRFI, NFH, FRH, and CNFH are located 271, 120, 134, 236, and 446 km upstream of the Sacramento–San Joaquin River confluence respectively. Juvenile hatchery fish are trucked from the hatchery to various release locations and are not barged as occur in other river systems.

These hatchery-raised juveniles were released into three broad geographical areas identified as the Bay, Delta, and Inland release points. Bay releases occurred between Jersey Point on the San Joaquin and Collinsville on the Sacramento River, westward to the Golden Gate Bridge (Figure 1). Delta releases were made between Durham Ferry and Jersey Point on the SJR, and between the "I" Street Bridge (City of Sacramento) and Collinsville on the Sacramento River (Figure 1). Inland releases were made upstream of Durham Ferry and the "I" Street Bridge. To reduce the confounding effects of stray results caused by differences in juvenile release location (e.g. the farther downstream juveniles are released, the greater the stray probability (Quinn 1997; CDFG and NOAA Fisheries 2001; Newman 2008), only recoveries from inland releases were used to test our hypothesis.

MRH releases used in our analyses did not include any transfers of eggs or juveniles from other hatcheries; whereas, eggs and/or fry were routinely transferred from the FRH and NFH to the MRFI. In general, the MRH released juveniles as yearling-sized fish from 1978 to 1985 during October (mean weight 56 g) and November (mean weight 60 g) and as sub-yearling-sized fish from 1986 to 2006 during April (mean weight 6 g) and May (mean weight 7 g). The FRH primarily released juveniles as yearling-sized fish from 1980 to 2002 during October (mean weight 42 g) and November (mean weight 60 g) and as sub-yearling-sized fish from 1975 to 2006 during April (mean weight 6 g), May (mean weight 6 g), and June (mean weight 8 g). The CNFH primarily released juveniles as sub-yearling-sized fish from 1975 to 2006 during March (mean weight 2 g), April (mean weight 5 g), and May (mean weight 6 g).

Developing stray rate data for Central Valley fall-run salmon required a multi-step approach: (1) assembling inland escapement estimates for each Central Valley river, (2) assembling the expanded number of CWT's recovered within each Central Valley fall-run escapement survey, and (3) identifying the proportion of each CWT code recovered in each Central Valley river. We used the California Department of Fish and Game's (CDFG) fall-run escapement summary (GrandTab) for annual, river-by-river escapement data. We obtained CWT release data from the Pacific States Marine Fisheries Commission's (PSMFC's) Regional Mark Processing Center's Regional Mark Information System (RMIS) (data downloaded in 2011). We utilized CWT recovery data from annual escapement reports and/or personal contact with escapement survey crew leaders when additional information was necessary. The final form of the stray data consisted of annual summaries of the expanded number of fish that homed and strayed. Included in these expanded estimates were adjustments for number of fish that shed their tags, number of ad-clipped fish where tags were not recovered, and recovery number of untagged juvenile fish that were released alongside CWT marked juvenile releases. Annual summaries of hydrological data were also provided as discussed below.

To conduct this analysis, we assumed that CWT salmon recovery trends from juvenile salmon produced by the CDFG's MRH would also represent recoveries from naturally produced fish originating in the Merced, Tuolumne and Stanislaus rivers. Likewise, we assumed that the U.S. Fish and Wildlife Service's CNFH and the CDFG's FRH hatchery release–recovery trends would mirror those for all Sacramento Basin fall-run stocks. We believe this assumption is valid because Pacific salmon primarily home based on freshwater chemical olfactory cues imprinted when, as juveniles, they make their seaward migration (Quinn 1997; Williams 2006) and that water-borne odors would be similar for rivers within the same basin when compared with other basins. This assumption was indirectly corroborated by Barnett–Johnson and others (2008), who characterized Central Valley watersheds by Strontium isotope (^{87}Sr:^{86}Sr) ratios for purposes of identifying otolith markers for fall-run salmon, then by Miller and others (2010), who compared the water Sr:Ca (mmol mol^{-1}) and Ba:Ca (μmol mol^{-1}) ratios for Central Valley rivers to assess juvenile salmon river of origin via otolith Sr:Ca and Ba:Ca ratios. Collectively Barnett–Johnson and others (2008) and Miller and others (2010) found that water chemistry differed between the Sacramento and SJR basins. We did not include the MRFI CWT release–recovery data in our analyses for two reasons. First, the flows in the lower Mokelumne are mixed with Sacramento River basin flows (because of the Delta Cross Channel and Georgiana Slough), which can allow Mokelumne River juvenile salmon to imprint upon both Mokelumne and Sacramento basin water, thus enabling the adults to "correctly" choose either the Sacramento or Mokelumne rivers upon return. Second, egg and/or fry transfers to the MRFI from the FRH and NFH may affect the homing behavior of the MRFI releases.

Delta Flow Conditions

Delta flow data for the fall period were obtained from Dayflow, which is a program developed, operated and maintained by the California Department of Water Resources (CDWR). The program was initially developed in 1978 to serve "as an accounting tool for determining historical Delta boundary hydrology" (CDWR 2011b). CDWR significantly updated the program in 2000 using Java, enabling input data stored as a HEC-DSS file, and output presented in an ASCII file. The computational scheme was modified in February 2002 based on a better understanding of the complex Delta conveyance system.

According to CDWR, "the Dayflow program presently provides the best estimate of historical mean daily flows: (1) through the Delta Cross Channel and Georgiana Slough; (2) past Jersey Point; and (3) past Chipps Island to San Francisco Bay (net Delta outflow). The degree of accuracy of Dayflow output is affected by the Dayflow computational scheme and the accuracy and limitations of the input data. The input data include the principal Delta stream inflows, Delta precipitation, Delta exports, and Delta gross channel depletions" ("Dayflow").

All Dayflow calculations use daily flows and do not consider the travel time required for the water to move through the various channels in the Delta. The Dayflow computational scheme develops three types of quantities; net Delta outflow estimates at Chipps Island, interior Delta flow estimates at significant locations, and summary and fish-related parameters and indices.

Table 1 Delta Dayflow variables

SAC	Measured Sacramento flows at the "I" Street Bridge in Sacramento
SJR	Measured San Joaquin River flows at Vernalis
RIO	Calculated Sacramento River flows past Rio Vista
XGEO	Calculated flows of both the Delta Cross Channel and Georgiana Slough
QWEST	Calculated San Joaquin River flows at Jersey Point where reverse flows are indicated by a negative number
CCC	Measured Contra Costa Water District diversions at Rock Slough and Old River
SWP	Measured State Water Project exports from the Banks Pumping Plant or Clifton Court Intake
CVP	Measured Central Valley Project exports at Tracy
Exports	Sum of CCC + SWP + CVP

The time-period associated with the quantities generated by Dayflow range from October 1, 1955 through September 30, 2010. Our analyses included quantities from the years 1979 through 2007, to compare the results with fall-run Chinook salmon return data. The Dayflow variables are presented in Table 1 and the flow estimates are available at *http://www.water.ca.gov/dayflow/*.

Dayflow includes data representing total Delta exports (EXPORTS), which includes North Bay Aqueduct exports (NBAQ) along with the Contra Costa Water District Canal (CCC), State Water Project (SWP) and Central Valley Project (CVP) exports. NBAQ data were not used because these exports leave the Delta from the north. Therefore, in evaluating total exports for our analyses, we combined the CCC, SWP and CVP exports only. We also considered Old and Middle SJR (OMR) flows as measured at two U.S. Geological Survey (USGS) gaging stations: USGS 11312676 MIDDLE R AT MIDDLE RIVER CA and USGS 11313405 OLD R AT BACON ISLAND CA. The river at these locations is highly affected by both the SWP and CVP pumps that create reverse or upstream flows during the majority of the year. We gathered

a Table showing co-linearity comparison between various Delta flow metrics, including Sacramento River at Freeport (SAC), combined South Delta Exports (Exports), San Joaquin River at Vernalis (SJR), Delta Cross Channel and Georgiana Slough flow (XGEO), San Joaquin River flow past Jersey Point (QWEST), Sacramento River flow past Rio Vista (QRIO). Pulse metrics equal the average flow during the fall pulse flow time period. Non-pulse flow metrics are average flows for the October and November time period.

OMR flow data for both the October–November base flow period and the 10-day pulse flow period.

Fall Delta base flow (mean October and November flow) and pulse flow (10-day average of highest flow in October–November) data is provided in the Methods Appendix. In addition to average base and pulse flows, flow ratios (by example: the ratio of Delta exports to SJR inflow at Vernalis) are also presented in the Methods Appendix. We also developed a cross-correlation matrix table to identify co-linearity between any flow variables (Table 2).

South Delta Barriers

We obtained south Delta barrier (SDB) operational data from CDWR’s South Delta Temporary Barriers Project (CDWR 2011a). Four barriers comprise CDWR’s SDB Project: Head of Old River (HORB), Grant Line Canal, Middle River, and Old River at Tracy. As stated by CDWR, the objectives of the SDB program are three-fold: (1) increase south Delta water levels (e.g., elevation) and circulation patterns to improve agricultural diversion water quality; (2) enhance the operational flexibility of the SWP and CVP; and (3) reduce effects on native and anadromous fish species.

The Head of Old River (HORB) barrier is a rock barrier—and the primary barrier, because it is intended to prevent SJR south Delta inflow from entering the Old River channel, which leads to the Delta export pumping facilities (i.e., the SWP and CVP), and maintains flow within the mainstem SJR and the SDWSC. The tidal effect and Sacramento River Basin flow contribution are greater downstream of the SDWSC than at the Head of the Old River and so the HORB reduces the amount of SJR flows that are diverted at the Delta pumping facilities relative to the amount of Sacramento River Basin flows diverted. Without the HORB, the majority of the SJR inflow enters the Old River depending on the diversion rate at the SWP and CVP (Jassby 2005; SJRGA 2009; ICF 2010). From a fisheries management perspective, the purpose of the HORB is to concentrate flow into the main channel to attract adult immigrating salmon into the main SJR channel during the fall (fall HORB), to deter salmon from using non-main river channels, and keep springtime (spring HORB) emigrating juvenile salmon out of the Old River channel where entrainment into the south Delta pumps is possible.

The fall HORB is installed in most years and typically operates from September 15th to November 30th, which is intended to coincide with the SJR fall Chinook immigration time-period. The remaining three barriers, also temporary rock barriers, serve as agricultural barriers designed to improve water quality and operate during the agricultural irrigation season from April 15 through September 30 each year. From 1979 to 2007, the HORB operated in 19 years, the Old River at Tracy in 15 years, the Middle River in 20 years, and the Grant Line Canal in 11 years. State (CDWR) and federal (U.S. Bureau of Reclamation) agency regulatory requirements—both landowner and local reclamation district entry permits—and physical conditions determine barrier installation and removal dates (CDWR 2011a). By example, high SJR flows that occur in wetter years when upstream reservoir storage must be evacuated might preclude installation and operation of the HORB.

To analyze the influence SDB's have on SJR salmon stray rates we used an ordinal date format to make the SDB's fall operating dates consistent across years. (The SDB operating dates are provided in the Methods Appendix.) To further ensure SDB operational consistency across years, the earliest date a barrier was considered to have been installed was September 1st (ordinal day 245). This date was chosen as the start date to coincide with Delta salmon immigration timing as described in Hallock and others (1970).

Statistical Analysis

The goals of the statistical analyses include estimating the independent associations of flow and exports upon SJR stray rates (explanatory analysis), as well as determining whether any particular combination of predictors was significantly better at predicting stray rates. The objective of the explanatory analysis was to examine the probability of escaping salmon straying relative to Delta flow conditions. Specifically, given the denominator as adjusted estimates of the number of CWT fish retrieved, we examined whether the probability of being a stray (specifically, a SJR fish returning to the Sacramento River Basin) was a function of various flows: SAC (Sacramento River at Freeport), SJR (San Joaquin River flow at Vernalis), Exports (Delta Exports), QRIO (Sacramento River flow past Rio Vista), QWEST (SJR flow past Jersey Point), and XGEO (Delta Cross Channel and Georgiana Slough flow), and OMR (combined Old and Middle River flow). The individual adult return rates for each CWT code were adjusted by (1) observed carcasses with adipose fin clips but no information for the tag code and (2) releases of unmarked juveniles with CWT marked juveniles that may have affected CWT return rates (see Methods Appendix). They also include stray rate estimates for rivers that lacked direct CWT recovery data, such as the mainstem Sacramento River from 1986 to 2000 (see Methods Appendix). The mean annual return rate for individual tag codes for each adult age was used as the unit of the statistical analysis.

As mentioned above, there is very high correlation among many of the average and pulse flow annual summaries. Due to this co-linearity, we included only pulse flows for the SJR and the corresponding SJR pulse flow period for the exports in our analysis. Also because of the co-linearity of flow variables, we did not analyze ratios between these explanatory variables—not because the other variables are not causally important, but only because the covariance among them is such that it is impossible, given the available data, to distinguish (estimate) the relative effects with the modest sample size (number of years) available. In addition, we examined the number of operating days for each barrier and its association with stray rates. (We note that the number of days and the start day for barrier operations cannot be examined independently in the same model, so we used the number of days as a proxy for both variables).

For each paired analysis between either SJR or export pulse flow level and stray rate we: (1) performed LOWESS smoothing (Cleveland 1979) on the proportions to examine (semi-parametrically) the stray response and provide in visual form the variability of stray rates around the predicted mean; (2) examined the logistic regressions of average trends (in the logit scale) of the probability of being a stray versus these flow levels, adjusting for the age of fish; and (3) derived our *P*-value for resulting trends (relative to flow independence and stray probability) via an age-conditioned pseudo-exact permutation test.

For the multivariable regression models, we used the nonparametric bootstrap (Efron and Tibshirani 1993) to derive inference, treating the year as the unit. We note that sometimes the bootstrap-based *P*-values can be quite different from the corresponding permutation ones (for analyses that are equivalent), suggesting that the dispersion can be so great relative to sample size that even robust inference can be potentially biased, which is why we emphasize the permutation method when appropriate.

For both SJR fall pulse and export flow levels, we (1) performed LOWESS smoothing on the stray proportions (Figures 3 and 4); (2) examined the logistic regressions of "average" trends in the logit scale) of the probability of being a stray versus these flow variables; and (3) derived our *P*-value for these trends (relative to flow independence and stray probability) via bootstrapping. For the bootstrapping, one thousand bootstrapped re-samplings of the data were generated. Coefficients for each re-sampling were estimated and their dispersion was used to calculate the standard error of the estimates. Such bootstrapped estimates are to some level robust when data does not necessarily fully conform to the assumptions of the normal linear regression model. In this case, the data was overdispersed (i.e., there was greater variance than would be predicted by a binomial model) and significance estimates that did not take this into account would have resulted in a high overestimation of statistical significance.

Finally for the pure prediction model procedure we compared the fit of competing models in predicting future stray rates by using a cross-validation technique, with known theoretical properties related to selecting the "optimal" model (Van der laan and others 2007), to compare five simple models (all of them containing indicators for age groups): (1) including log (SJR Pulse Flow) and log (Exports); (2) log(SJR Pulse Flow) and log (pulse OMR flows); (3) log (exports/SJR Pulse Flows) ratio; (4) log (SJR Pulse Flow) alone; and (5) log (Exports) alone. We note that both Models 4 and 5 are sub-models of 1 (for Model 4, it assumes the coefficient associated with log (SJR pulse flow) equals the negative of that on log (exports), whereas for Model 5, it just assumes the coefficient on exports is 0). Thus, under the typical assumptions, a likelihood ratio test could provide a measure of the relative fits of the model. However, in this case, we examine it empirically via 10-fold cross-validation. Specifically, the sample is divided into 10 equal parts (say validation samples) and for each of these, one (a) removes them from the data, (b) fits Models 1 through 5 on the other portion (the so-called training sample), and (c) uses these fits to predict on the left out sample. Thus, the procedure results in a column of observed stray rates, and five predicted stray rates (one for each model) where the predictions were derived independently of the corresponding outcome.

RESULTS

Stray Rates in General

Our analysis indicates that the stray rates for Sacramento Basin hatchery origin salmon, released upstream of the Delta, average less than 1% (range = 0 to 6%). Comparatively, for SJR Basin hatchery-origin salmon, stray rates average 18% (range = 0 to 70%). When stray results are considered for Delta and Bay releases, the average Sacramento hatchery-origin stray rates are 0.5% and 1%, respectively. SJR basin hatchery-origin stray rates, corresponding with Delta and Bay releases, are 35% and 85%, respectively.

Cross Correlation of Delta Flow Variables

Exports correlate negatively to the OMR flows (Old and Middle SJR). As exports increase OMR flows become more negative. All non-export Delta flow variables are highly positively correlated with one another (Table 2). That is, as one variable rises in value so do the others. The positive correlation results indicate that any of the non-export flow variables can be used to some extent as a proxy for all the flow variables. Since SJR fall pulse flow is, biologically speaking, the flow variable of importance it is used as the variable to determine if Delta inflow is significantly correlated with stray rate probability. Due to the extreme co-linearity between fall base flows and 10-day pulse flows (correlation = 0.97), we cannot determine which has the most important influence. If SJR base flow was used as the flow metric instead of pulse flow, the results for pulse flow presented below could be applied to base flow using the following linear regression equation between base and pulse flow levels:

$$SJRBaseFlow = 0.786 \text{ X } SJRPulseFlow,\ R^2 = 0.97$$

Delta Flow Variables and Stray Rates

Graphical comparisons of the probability of SJR salmon straying as a function of SJR fall pulse flow, south Delta exports, and the ratio (E:I) of south Delta exports (E) to SJR fall pulse flow (I) are provided in Figures 3, 4 and 5, respectively. Though there is a significant amount of variability between years, general trends are identifiable. For SJR fall pulse flow, salmon stray rate probability peaks (~50%) when flow levels are less than 30 m^3 s^{-1} (1,060 ft^3 s^{-1}) and are reduced substantially (~5%) when pulse flow levels increase to 150 m^3 s^{-1} (5,297 ft^3 s^{-1}). For south Delta exports, salmon stray rate probability peaks (20%) when export levels exceed 141.6 m^3 s^{-1} (5,000 ft^3 s^{-1}) and are substantially lower (~3%)

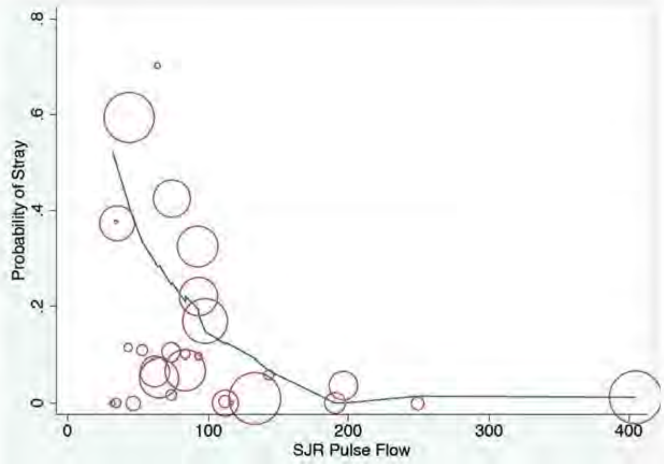

Figure 3 Plot showing the smooth of probability of San Joaquin River salmon straying as a function of San Joaquin River inflow level (m^3 s^{-1}) to the South Delta. Bubble size reflects relative number of coded-wire-tag recoveries across years. Smooth line is weighted by total recapture size.

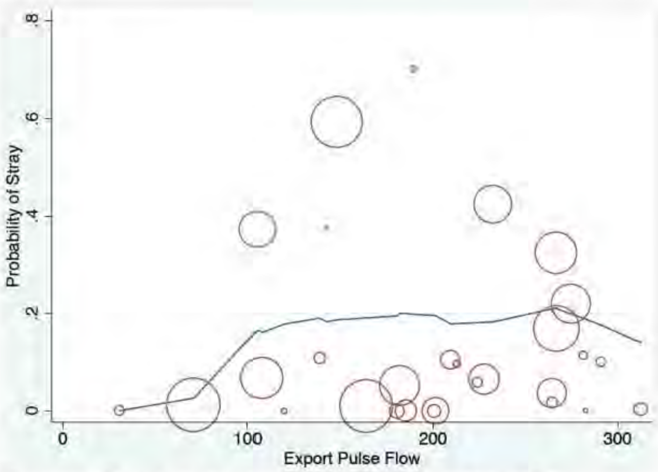

Figure 4 Plot showing the smooth of probability of San Joaquin River salmon straying as a function of South Delta export level (m^3 s^{-1}). Bubble size reflects relative number of coded-wire-tag recoveries across years. Smooth line is weighted by total recapture size.

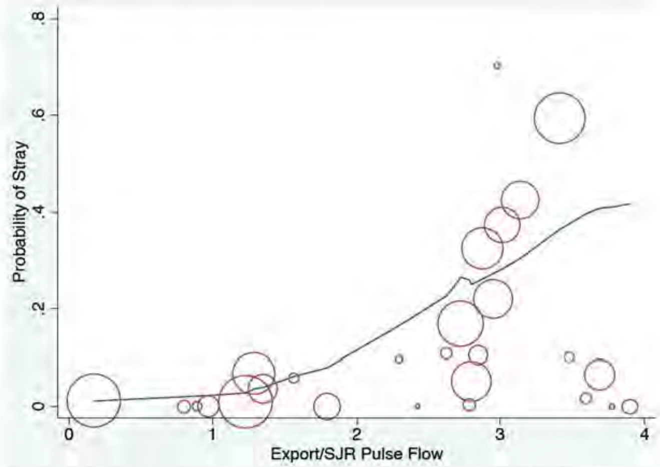

Figure 5 Plot showing the smooth of probability of San Joaquin River salmon straying as a function of South Delta export (E) (m^3 s^{-1}) to San Joaquin River Pulse Flow (I) level (m^3 s^{-1}) ratio (E:I). Bubble size reflects relative number of coded-wire-tag recoveries across years. Smooth line is weighted by total recapture size.

Table 3 Results of Delta flow variables and San Joaquin River salmon stray rate

	Coefficient[a]	Standard error[b]	*p*-value	95% confidence interval for coefficient	Unadjusted coefficient[c]	Unadjusted *p*-value[c]
Constant	5.349	9.231	0.562	−12.74 – 23.44		
ln(SJR)	−2.568	0.786	0.001	−4.108 – −1.029	−1.9	0.016
ln(Exports)	1.570	0.868	0.07	−0.131 – 3.271	0.53	0.56
Age 3[d]	−0.596	0.628	0.343	−1.827 – 0.636		
Age 4[d]	−0.846	0.726	0.244	−2.268 – 0.577		

a Example calculation using most likely coefficients. Assume a SJR pulse flow of 8,000 and an Export pulse flow of 6,000 (in cfs; U.S.) for a group of salmon aged 3. The following is used to calculate the probability of straying for this group:

$$\text{logit}\,(PStray) = 5.35 + (-2.57\ln(8{,}000) + 1.57\ln(6{,}000) + (-0.596 \times 1) + (-0.846 \times 0)$$

$$\text{logit}\,(PStray) = \ln\left(\frac{PStray}{1 - PStray}\right) = -4.68$$

$$PStray = 0.0092$$

b Standard Error calculated using nonparametric bootstrapping, randomly re-sampling years with replacement (Efron and Tibshirani 1993).

c Coefficient based on unadjusted logistic regression, p-value based on the permutation distribution of corresponding Wald Statistic.

d Age is a dummy variable that is 1 when the salmon is that age and 0 otherwise.

when export flow levels are reduced to 56.6 $m^3\ s^{-1}$ (2,000 $ft^3\ s^{-1}$). For E:I ratio, salmon stray rate probability peaks (~40%) when the ratio approaches a 4:1 level, and is substantially reduced (~10%) when the ratio is less than 2:1.

Table 3 contains the results of the logistic regression that predicts stray rates as a function of SJR fall pulse flow, export flow and salmon age. Of the independent fall Delta pulse inflow variables analyzed, only SJR flow was significant ($P = 0.05$), according to the bootstrapping estimate of error, and has a negative association with SJR salmon stray rate (Figure 3). Combined south Delta export pulse flow was close to significant ($P = 0.10$) and has a positive association with SJR salmon stray rate (Figure 4). The smooth lines depicted in Figures 3 and 4 are weighted by the proportional number of CWT recoveries. Equation 1 determines SJR salmon stray rate, by age, as a function of SJR pulse flow magnitude and south Delta combined export level in non-ratio format.

When the five competing models previously discussed—(1) log (SJR Pulse Flow) and log (Exports), (2) log (SJR Pulse Flow) and log (pulse OMR flows), (3) log (Exports/SJR Pulse Flows), (4) log (SJR Pulse Flow), and (5) log (Exports)—were compared via cross-validation, the results, given the relatively large residual variation seen in all the observed versus the cross-validated predictions (for all the competing models) were quite large, one can not definitely rank the predictive accuracy of any of them versus the others. It appears that models including either SJR flow and exports or both do relatively well, still with relatively modest cross-validated R^2 values of around 0.2. It is important to note that we repeated this analysis with many different splits, and also with different cross-validation folds (up to 40-fold) to avoid

Equation 1

$$StrayRate = \frac{1}{1 + e^{-(1.790 - 2.568\ln(SJRPulseFlow) + 1.570\ln(ExportPulseFlow) - (0.5956Age3) - (0.8455Age4)}}$$

NOTE: To calculate stray rate for age-2 salmon, set both the age-3 and the age-4 terms to zero. For age-3 salmon stray rates, set the age-3 term to 1 and the age-4 term to zero. For age-4 salmon stray rates, set the age-3 term to zero and the age-4 term to 1. For cubic feet per second (cfs; U.S.) units, simply substitute the intercept value of 1.790 with 5.349. The equation beneath Table 3 is the same equation described here but it is converted, for convenience, to standard units.

making conclusions based on any cross-validation configuration. These results suggest that, based on existing data, models that include exports and pulse flow, either as a ratio, or separate terms, appear to be as good or better than competing models with other hydrological measures. It is important to note that these cross validation results, which were intended to evaluate competing model prediction accuracy, do not contradict results obtained from a robust analysis assessing what is a significant association of stray rate. The single factor that is controlling stray rate, from a statistically significant perspective, is SJR flow.

In conclusion, since the biology of salmon indicates that a model including SJR flow is biologically necessary (salmon navigate based upon juvenile river imprinting), we must include SJR flow in a management model. There are several ways to link flow and exports to stray rates. Whether or not to include either co-variate (flow and exports), and how, depends entirely upon the objective. If the objective is explanation, then a model that includes both flow and exports independent of one another is warranted (Model 1). Alternatively, if the goal is pure prediction, then a model that has flow alone (Model 4) is acceptable given that flow is the only variable associated with SJR salmon stray rates at a statistically significant level. However, since we cannot say with statistical certainty whether flow or exports is the primary determinant influencing SJR salmon stray rates, exports can also be included in the management model in the form of an E:I ratio (Model 3). Equation 2 determines SJR salmon stray rate, by age, as a function of south Delta combined export to SJR inflow ratio (E:I).

South Delta Barriers and SJR Salmon Stray Rate

We also examined the operating days for each of the barriers and their association with stray rates. The total operating days and the initial operating day for each barrier cannot be examined independently in the same model, so we used the total barrier operating days as a proxy for both variables. None of the barriers produced a significant effect on salmon stray rates at either the $P = 0.05$ or 0.10 levels. This indicates that, for south Delta Barriers, neither barrier construction date, nor total operating days, are positively or negatively influencing SJR salmon stray rates in a statistically significant manner. The implication of this finding is that barrier operation for whatever purpose, even if to influence SJR salmon stray rate, is not reducing—or increasing—SJR salmon stray rate at a statistically detectable level.

DISCUSSION

Our results suggest that the percentage of SJR fall-run Chinook salmon straying into the Sacramento River Basin (1979 to 2007) was as high as 70% (fall 2007). Straying was inversely correlated with pulsed flows in the mainstem SJR at Vernalis ($P = 0.05$) and directly correlated with Delta export levels at a nearly significant level ($P = 0.10$). Our estimated stray rates were more than twice as high as those reported by Mesick (2001), because Mesick did not have complete estimates of the number of adult salmon carcasses that were examined for CWTs during the Sacramento River Basin surveys.

Although stray rates were most highly correlated with pulsed SJR flows, we cannot differentiate between the 10-day pulse flows in October–November and mean

Equation 2

$$StrayRate = \frac{1}{1 + e^{-(-3.25 + 2.41\ln(ExportPulseFlow/SJRPulseFlow) - (0.64\,Age3) - (1.01\,Age4))}}$$

NOTE: To calculate stray rate for age-2 salmon, set both the age-3 and the age-4 terms to zero. For age-3 salmon stray rates, set the age-3 term to 1 and the age-4 term to zero. For age-4 salmon stray rates, set the age-3 term to zero and the age-4 term to 1. No modifications to this equation are required for cubic feet per second (cfs; U.S.) unit calculations.

October and November base flows. Mean and pulse fall SJR flows are positively cross correlated to a very high degree (adjusted R-square of 0.97 at $P = 0.05$). Fall flows are highly regulated (controlled) in the SJR basin and are tied to SJR basin water year type (critical, dry, below normal, above normal, wet); whereby, annual flow schedules are derived pursuant to regulatory instream flow requirements. Thus, as water year type increases as a result of greater snowmelt runoff, both fall base and pulse flows increase concurrently. The cross correlation between mean and pulse flows makes it uncertain which of the two flow metrics is responsible for attracting SJR salmon to their natal river. However, it is logical that since adult salmon migrate over several months that the mean flow rate in September through November would affect the largest number of salmon.

It is uncertain whether SJR flows or Delta exports have the greatest effect on SJR stray rates, because exports were so high in most years that it appears that little if any SJR flow (i.e., olfactory migration cue) was conveyed to the Bay during the fall (Figure 6). The calculated QWEST (SJR flow past Jersey Point and the Central Delta outflow point) flow levels can be strongly negative even in wetter years (2005 and 2006). A negative QWEST flow means that the SJR is flowing 'backward' (i.e. upstream) and tends to occur when the combined SWP and CVP exports exceed the flow in the SJR. October and November QWEST flows for the years from 1979 through 2007 ranged from –70.8 $m^3 s^{-1}$ (–2,500 $ft^3 s^{-1}$; 2005) to 651.3 $m^3 s^{-1}$ (23,000 $ft^3 s^{-1}$; 1983). Negative fall base and pulse flows at QWEST occurred in 14 (48%) of years analyzed. Even in some years when QWEST is positive for the fall base and pulse flow period, exports may exceed SJR flow but Sacramento flow that has been diverted into the Central Delta (identified as XGEO: flow through the Cross-Delta Canal and the Georgiana Slough) adds to the QWEST. Median XGEO flows (150.4 $m^3 s^{-1}$; 5,310 $ft^3 s^{-1}$) from 1979 through 2007 are nearly double the SJR flows (66.1 $m^3 s^{-1}$; 2,333 $ft^3 s^{-1}$). Median fall pulse flows show a similar disparity between XGEO flows (145.9 $m^3 s^{-1}$; 5,152 $ft^3 s^{-1}$) and SJR flows (83.6 $m^3 s^{-1}$; 2,951 $ft^3 s^{-1}$).

Exports and SJR flow are not correlated; thus, both should be included as potential model parameters. A permutation test is the best statistical method to evaluate the individual linkage of each parameter with stray rate, which reveals flow is significant (0.05) and exports are nearly so (0.10). The permutation method does not allow simultaneous assessment of both parameters to get the best inference so another test is used (bootstrapping). The bootstrap method reveals flow is still significant but exports are not. However, we cannot say that exports are not truly significant, given the limited sample size, and, according to the competing model evaluation, a model with exports performed as well as one with SJR pulse flow alone. Therefore both flow and export parameters can be included in a single model in the form of an E:I ratio.

An example of daily SJR fall flow for a single year (2009) is provided in Figure 6 where SJR flow is measured at four gaging stations in the Delta. SJR flows, as measured at Vernalis, indicate that pulse flows experienced at Vernalis (rkm 118; rm 73) are barely detectable at Garwood Bridge (rkm 68; rm 42) and are non-detectable at both Prisoner's Point (rkm 40; rm 25) and Jersey Point (rkm 16; rm 10). In fact, not only did the SJR fall pulse flows in late October not make it to both Prisoner's Point and Jersey Point in 2009, both of these locations had strong negative flows occurring at the same time pulse flows were supposed to be flowing through the south Delta. Note that the flows depicted in Figure 6 give the impression that all SJR pulse flow is constrained within the main SJR channel, but it is not. Given the labyrinthine nature of the south Delta (Figure 2), and the ability of SJR pulse flow to enter and proceed through the SJR Old River channel, SJR pulse flow can re-enter the main SJR channel between Jersey Point (rkm 16; rm 10) and Prisoner's Point (rkm 40; rm 25). If SJR pulse flows that enter the Old River contribute to flow in the SJR at Jersey Point, it may be that SJR salmon that successfully migrate through the south Delta may be detecting the SJR via Old River, rather than mainstem SJR flow. It is also unknown how tidal influence affects fall pulse flow hydraulic continuity and ability of escaping salmon to detect the SJR. Further research is needed to determine whether SJR fall pulse flows do, or do

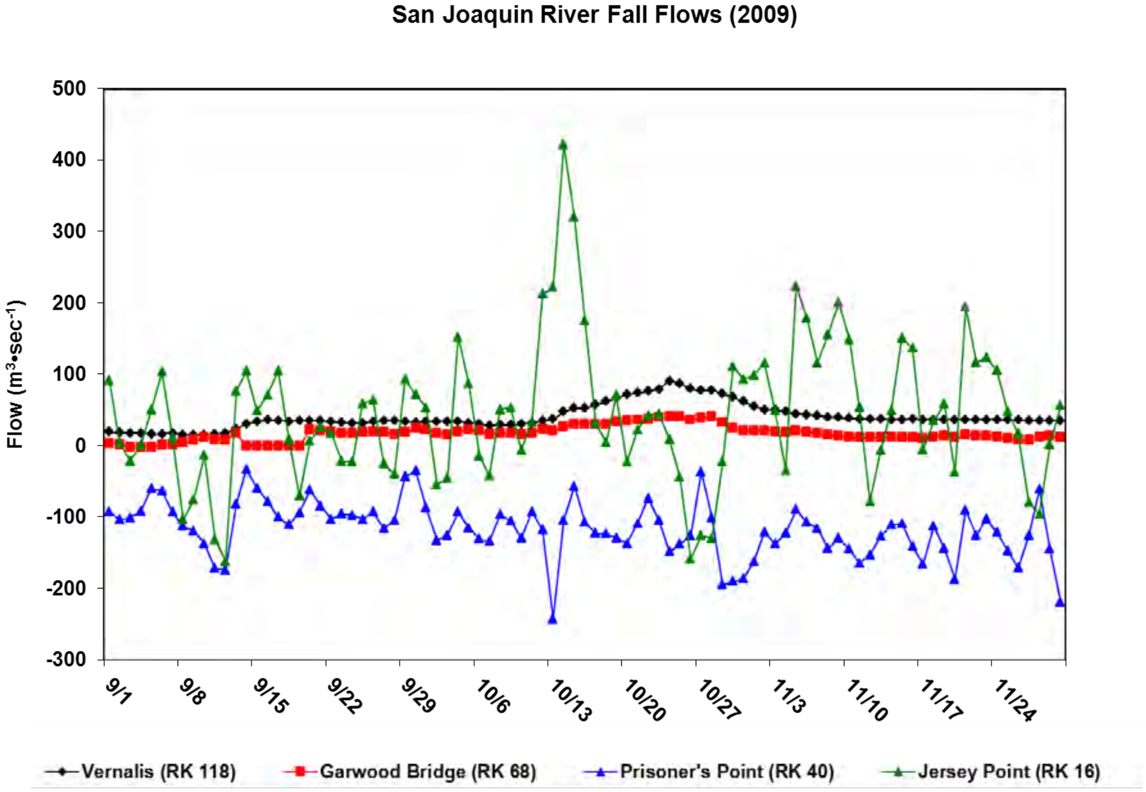

Figure 6 San Joaquin River flows at four locations from the entrance to the South Delta (Vernalis), through the interior of the Delta (Prisoner's Point and Garwood Bridge), and near the exit point of the Delta (Jersey Point). River kilometer (RK) is the distance measured from the San Joaquin-Sacramento River confluence to each location.

not, make their way to the SJR main river channel upstream of the confluence of the San Joaquin River and Sacramento River.

Our results also indicated that the south Delta barriers, including the fall HORB, have little if any influence on reducing SJR salmon stray rates. Although, the flow through the main SJR channel was reduced if the HORB was not installed, and the majority of the flow was conveyed towards the CVP and SWP pumping facilities via the Old River (Jassby 2005; SJRGA 2009; ICF 2010), the statistical analyses suggest that SJR stray rates were unaffected by whether SJR water flowed in the SDWSC or through the Old and Middle rivers. This is logical because SJR origin migrating adults would need to detect their natal SJR flow at the confluence of the San Joaquin and Sacramento Rivers to home successfully.

Juvenile Release Location and Stray Rates

Comparing stray rates for Sacramento River and SJR basin hatchery releases by broad geographical location (Figure 7) indicates that there is a ten-fold difference in stray rate for SJR salmon compared to that for Sacramento Basin salmon. Adult salmon stray rates for Sacramento Basin origin juvenile releases made upstream of the Delta averaged 0.1%; whereas, adult salmon stray rates for San Joaquin origin juvenile salmon releases made upstream of the Delta averaged 18%. For both Sacramento and San Joaquin adult salmon, straying increased sharply the farther downstream juvenile salmon were released. Sacramento salmon straying by release location averaged 0.1% (0 to 6.1%), 0.5% (0 to 3.4%), and 1.1% (0 to 7.8%), respectively for inland, Delta, and Bay releases. For San Joaquin salmon, adult straying by juvenile release location averaged 18% (0 to 70.1%), 35% (0 to 75%), and 85% (37.4% to 100%), respectively for inland, Delta, and Bay releases.

The coded-wire-tag release-recovery data indicate that releasing juvenile salmon farther downstream substantially increases juvenile-to-adult survival rates. This practice is called out-planting and while it increases survival, it appears to come at a cost in the form of higher stray rates than if releases occurred upstream at or near the hatchery (Ebel and others 1973; Slatick and others 1975; Ebel 1980). There is conflicting information in the literature about whether or not transportation of juveniles, from point of capture or rearing, to downstream locations, increases straying. Ebel and others (1973), Slatick and others (1975), and Ebel (1980), represent three separate studies documenting the effect of transporting juveniles on their survival and homing success as adult fish. Observed adult recoveries for both transported (barged) and non-transported fish in the Snake–Columbia River system, found that the homing ability of Chinook salmon was not impaired even when juveniles were transported 400 km (249 miles) downstream. Conversely, in a more recent study Keefer and others (2008), who also reported stray results from a long distance juvenile transportation study conducted in the Snake–Columbia River system, found that stray rates were higher for transported (barge) juveniles than for non-transported juveniles. Vreeland and others (1975) and Solazzi and others (1991), who conducted separate juvenile transportation studies using coho salmon (*Onchorhynchus kisutch*), found that transported (trucked) juveniles had lower homing (i.e. higher stray) rates than non-transported juveniles. These studies suggest that transportation of juveniles to downstream locations increases juvenile-to-adult survival but provide contradictory results for influ-

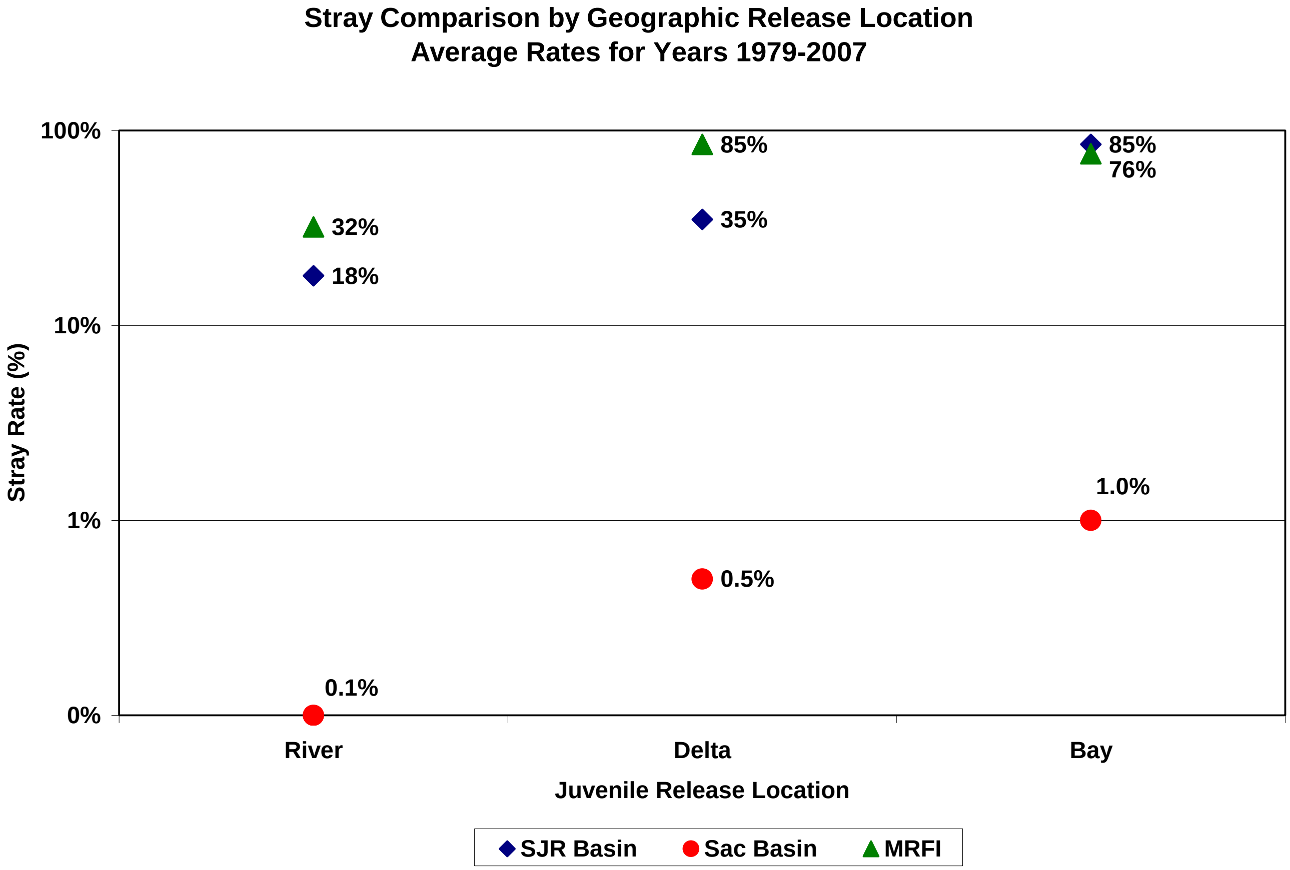

Figure 7 Plot showing stray rates for Sacramento River and San Joaquin River basin origin fall-run Chinook salmon by geographic location of release (River, Delta, and Bay) from the hatchery of origin during their juvenile emigration

ence upon adult homing. Our results indicate that juveniles released farther downstream will stray at greater rates (Figure 7).

One consequence arising from transporting hatchery juveniles to downstream releases locations is that hatchery fish from the MRH, and MRFI stray throughout the Central Valley at high rates. Though Sacramento River basin salmon exhibited relatively low stray rates (1% or less), regardless of release location in comparison to SJR basin salmon, the straying of Sacramento River basin salmon to the SJR could still be problematic given the order-of-magnitude difference in fall-run escapement between the two basins. For example, from 1979 to 2007, average annual escapement for Sacramento River and SJR adult salmon was 288,313 (ranging from 86,698 to 834,900) and 16,160 (ranging from 590 to 69,847), respectively (CDFG GrandTab 2010). If we assume a 1% stray rate and an escapement of 500,000 spawners for Sacramento River basin salmon, this would result in 5,000 salmon straying into the SJR basin. This level of Sacramento River basin salmon straying into the SJR can swamp SJR escapement, given that the combined SJR escapement has been less than 5,000 spawners in several years during the 1979 through 2007 time-period. This may have significant implications for Central Valley salmon management and may help explain why recent genetic testing indicates that the Central Valley fall-run Chinook salmon population is homogeneous (Banks and others 2000; Williamson and May 2005; Garza and others 2008; California HSRG 2012).

Stray Rate Comparisons

What is a "normal" (i.e., natural) stray rate for fall-run Chinook salmon? According to Quinn (1997), background levels of between 2% to 5% appear to be normal stray rates for hatchery salmon, but not many studies have been conducted for wild salmon. Williams (2006) reported a Mokelumne River wild fall-run Chinook stray rate of 7.3%, with the caveat that this population is heavily influenced by hatchery production and receives eggs and fry transferred from Sacramento River Basin hatcheries (FRH and NFH). CDFG Mokelumne River Hatchery annual reports confirm that large numbers of eggs and juveniles have been transported from Sacramento River Basin hatcheries (FRH and NFH) to the Mokelumne River Hatchery (Estey 1988; Anderson 2010). What a "normal" stray rate is depends on the definition of stray rate being referenced. There can be a wide range of stray rates for Chinook salmon depending on how straying is defined. Looking closely into the factors that influence straying, such as environmental conditions at the time of return (water temperature and flow rates in both natal rivers and rivers located adjacent to the natal river [Quinn 1997]), there is near unanimous agreement—from studies conducted in the lower Columbia River Basin, U.S. (Quinn 1993), Puget Sound and Strait of Georgia, Southern Canada (Candy and Beacham 2000), and New Zealand (Unwin and Quinn 1993)—that it is relatively rare that adult Chinook salmon stray into non-natal river basins to spawn. For reference and context, in this case the entire Central Valley is a single river basin. In other words, it would be a relatively rare event to have a naturally produced Central Valley salmon stray to a non-Central Valley river basin (say the Klamath River).

Whether or not there exists a difference in stray tendency for wild versus hatchery-reared salmon is largely unknown given the few homing studies conducted using wild salmon. Comparisons of straying between wild and hatchery-reared salmon, though few, have shown results indicating that tagged wild juveniles strayed less as returning adults than hatchery reared-released salmon; although, these results are not consistent. In one study, rearing of juvenile wild fall-run Chinook in a hatchery for a short time period increased their adult straying rate relative to wild fish not reared in the hatchery (McIsaac 1990). However, wild and hatchery-reared juvenile salmon showed similar stray rates in studies with coho salmon (Labelle 1992) and Atlantic salmon (*Salmo salar*; Jonsson and others 1991, as cited in Quinn 1997).

Straying by Age

The age of adults returning may contribute to stray rate variability in salmon. In some studies, older Chinook salmon strayed more than younger fish

(Quinn and Fresh 1984; McIsaac and Quinn 1988; Quinn and others 1991; Unwin and Quinn 1992; Pascual and Quinn 1994). In contrast, Hard and Heard (1999, as cited in Candy and Beacham 2000) studied stray rates among transplanted Alaskan hatchery populations of Chinook salmon and found that straying is highest for younger fish (jack males). They hypothesized that these fish may stray at higher rates in order to expand their population by straying into non-natal rivers and spawning with uncontested females. We also found that younger age SJR salmon strayed at higher rates than did older salmon though these differences in stray rates were not statistically significant. Candy and Beacham (2000) found no consistent trend of increased stray rate with age.

Coded Wire Tag Recovery Effort

Candy and Beacham (2000) reported that recovery effort influenced stray rates with the highest stray rates and number of fish recovered occurring in regions where the highest recovery effort occurred. Their finding was consistent with Pascual and others (1995) who found that the highest stray rates occurred in the lower Columbia River and attributed this finding to this area having the highest number of potential recovery sites. Development of the Central Valley fall-run Chinook salmon CWT database uncovered similar findings. Both number of fish tagged (CWT) and CWT recovery effort in the Central Valley has fluctuated widely over time. This variability in both tagging and recovery effort results in high levels of analytical uncertainty because, as described in the Methods Appendix, missing CWT data gaps need to be filled in. That said, both Central Valley CWT tagging and recovery effort have improved over time as resources to conduct monitoring (funding and staffing) have been made available. The constant fractional marking (CFM) program of hatchery produced Central Valley fall-run Chinook salmon initiated in 2007 (PSMFC 2008) will provide more reliable results as CFM continues (Newman and others 2004) and consistent recovery effort throughout the Central Valley occurs (Hicks 2003; Hankin and others 2005).

Policy and Management Implications

Although this statistical analysis shows that both south Delta exports and SJR flow affect SJR salmon stray rates, the relative role of flow and exports is uncertain, as is the period when flow management affects stray rates. Based on our statistical results alone, the SJR flow metric (either base or pulse) is more predictive metric than one that includes exports. However, since Delta exports can cause severe negative flows in the south Delta, and occurrence of negative flows are likely to negatively affect (disorient) escaping salmon populations that migrate through the Delta because of reduced chemical olfaction cue signals (Keefer and others 2006), further study is warranted to determine whether negative flows make it more difficult for returning SJR salmon to successfully locate and migrate into the SJR.

Since the Merced River (Mesick 2010), Tuolumne River (Mesick 2009), and Stanislaus River (Carl Mesick, USFWS, pers. comm., 2012) salmon populations have been identified as being at a high risk of extinction, we further suggest evaluating whether or not increasing fall south Delta inflows (pulse or base) from each of the tributaries in the SJR could reduce SJR salmon stray rates to a natural level (<5%). Each stream's fall flow contribution might also be managed to be proportional to its unimpaired watershed runoff size (i.e., ecological fair share contribution). This could ensure that each river provides equitable homing cues. Further research on such tributary effects is probably just as important as further monitoring of the effects of exports. Further research is also needed regarding the implementation of the SJR mainstem Friant Restoration Program (SJRRP 2011) and how these new fall flows influence SJR salmon straying.

The state and federal fish agencies should consider studies to determine how the following pairing of factors influences SJR salmon stray rates: (1) the relative roles of south Delta exports and SJR flow; (2) the timing of pulse flows and export reductions; and (3) the role of pulse flows versus base flows. Because of the large number of study factors involved, it may be necessary to test a different set of conditions each year until a statistically valid model can be developed (e.g., ~20 years). The test conditions should include the timing, duration, and magnitude of flow releases, including source of SJR tributary flow releases, and Delta exports. It would be important to hold these conditions constant through the migratory period each year to the extent possible. The homing success and movement timing of adult SJR salmon into and through the Delta and SJR tributaries should also be monitored. The analysis of salmon migration patterns and stray rates should include water quality indices such as water temperature and dissolved oxygen concentration as well as for flow and exports in the Delta. The role of tidal action influence upon stray rates should also be considered.

Lastly, we recommend developing a stray rate target that could consist of a single number, or range, that can be used to evaluate the effectiveness of management actions to achieve the biological management goal. An example goal could be to reduce SJR salmon stray rates to levels that are comparable with Sacramento River fall-run stray rates (i.e. <1% for river releases, see Figure 7). Equalizing salmon stray rates among the Sacramento and SJR basins would facilitate progress toward achieving SJR salmon restoration goals (i.e. reduce genetic homogenization, increase natural spawner abundance, and reduce migration barriers that impede upstream movement of spawners). The recommendation to do the aforementioned studies should not be used as a reason to defer taking action now to improve Delta flow conditions to reduce straying of SJR salmon, given that SJR flow, whether it be base or pulse, has been identified as a controlling factor. Furthering our understanding about how the above mentioned factors influence straying of SJR salmon should be built upon the premise of increasing SJR flow, base and/or pulse, into the south Delta during the fall time-period.

ACKNOWLEDGMENTS

We wish to thank the following individuals who provided Central Valley fall-run Chinook salmon data and/or information making this research paper possible: Robert Kano, Tracy McReynolds, Doug Killam, Kevin Niemela, Bob Null, Kyle Hartwigsen, Colleen Harvey–Arrison, Mike Healey, Steve Khirihara, Duane Massa, Stephanie Theis, Michelle Workman, Bill Mitchell, George Neillands, and Rick Burmester. In addition, we thank Wayne Getz and Andy Gordus for their willingness to review and provide valuable edits on a draft version of the paper, Sam Luoma and two anonymous reviewers who greatly added to the substance and quality of the paper, Bill Loudermilk who championed use of coded-wire-tag studies for salmon in the SJR basin, and Lauren Muscatine (and her editorial team) who facilitated final preparations for this paper.

Abstract

The loss of genetic and life history diversity has been documented across many taxonomic groups, and is considered a leading cause of increased extinction risk. Juvenile salmon leave their natal rivers at different sizes, ages and times of the year, and it is thought that this life history variation contributes to their population sustainability, and is thus central to many recovery efforts. However, in order to preserve and restore diversity in life history traits, it is necessary to first understand how environmental factors affect their expression and success. We used otolith $^{87}Sr/^{86}Sr$ in adult Chinook salmon (*Oncorhynchus tshawytcha*) returning to the Stanislaus River in the California Central Valley (USA) to reconstruct the sizes at which they outmigrated as juveniles in a wetter (2000) and drier (2003) year. We compared rotary screw trap-derived estimates of outmigrant timing, abundance and size with those reconstructed in the adults from the same cohort. This allowed us to estimate the relative survival and contribution of migratory phenotypes (fry, parr, smolts) to the adult spawning population under different flow regimes. Juvenile abundance and outmigration behavior varied with hydroclimatic regime, while downstream survival appeared to be driven by size- and time-selective mortality. Although fry survival is generally assumed to be negligible in this system, >20% of the adult spawners from outmigration year 2000 had outmigrated as fry. In both years, all three phenotypes contributed to the spawning population, however their relative proportions differed, reflecting greater fry contributions in the wetter year (23% vs. 10%) and greater smolt contributions in the drier year (13% vs. 44%). These data demonstrate that the expression and success of migratory phenotypes vary with hydrologic regime, emphasizing the importance of maintaining diversity in a changing climate.

Introduction

Life history diversity is often cited as a crucial component of population resilience, based on theoretical and empirical evidence that asynchrony in local population dynamics reduces long-term variance and extinction risk at both regional and metapopulation scales [1]. Pacific salmon are recognized for their complex life histories, having evolved alongside the shifting topography of the Pacific Rim [2]. In the California Central Valley (CCV), four runs of imperilled Chinook salmon (*Oncorhynchus tshawytscha*) coexist, exhibiting asynchronous spatial and temporal distributions that allow them to exploit a range of ecological niches [3,4]. The maintenance of multiple and diverse salmon stocks that fluctuate independently of each other has been shown to convey a stabilizing 'portfolio effect' to the overall the stock-complex [5,6]. Such 'risk spreading' can also act at finer scales [7,8], such as within-population variation in the timing of juvenile emigration. Preserving and restoring life history diversity remains an integral goal of many salmonid conservation programs [9], yet baseline monitoring data with which to detect and respond to changes in trait expression are scarce and difficult to relate directly to population abundance.

The expression and success of certain traits can be largely driven by hydroclimatic conditions experienced during critical periods of development [10]. CCV Chinook salmon are at the southern margin of their species range, and are subjected to highly variable patterns in precipitation and ocean conditions [4,11]. It is also a highly modified system, with >70% of spawning habitat lost or degraded as a result of mining activities, dam construction, and water diversions [4,12]. The majority of salmon rivers in the CCV experience regulated flows according to 'water year type' (WYT). Optimization of reservoir releases presents considerable challenges, given often limited availability and multiple uses of the water resource, inability to predict annual precipitation, and uncertainty surrounding the direct and indirect effects of flow on salmon survival [13]. Such challenges are particularly critical for the more southerly San Joaquin basin, whose salmon populations fluctuate considerably with river flows experienced during juvenile rearing (Fig 1).

Juvenile Chinook salmon exhibit significant variation in the size, timing and age at which they outmigrate from their natal rivers [3,14]. Selection for one strategy over another may vary as a function of freshwater and/or marine conditions [10,15]. In the CCV, fall-run juveniles typically rear in freshwater for one to four months before smoltification prompts downstream migration toward the ocean [16]. In this system, contributions of the smaller fry and parr outmigrants to the adult population are often assumed to be negligible, as survival tends to correlate with body size [17,18] and there is little evidence for downstream rearing in the San Francisco estuary [19]. However, this has never been explicitly tested for smaller size classes. Indeed, salmon fry are frequently observed rearing in tidal marsh and estuarine habitats in other systems [3], and have been observed in non-natal habitats in the CCV, such as the mainstem Sacramento and San Joaquin Rivers, freshwater delta, and estuary [20]. Juvenile salmon that enter the ocean at a larger size and have faster freshwater growth have demonstrated a survival advantage when faced with poor ocean conditions [18]. Yet intermediate size classes can be better represented in the adult population [21,22], and size-selective mortality can be moderated by a variety of other processes [23]. In a regulated system such as the CCV, identifying the relationships between observable traits, hydroclimatic regime and survival would be invaluable for reducing uncertainty and predicting how populations may respond to climate change and management actions related to water operations.

Quantifying the relative contribution of fry, parr and smolt outmigrants to the adult population has, until now, been largely limited by the methodological challenges associated with reconstructing early life history movements of the adults. Mark-recapture studies using acoustic and coded wire tags (CWT) have provided empirical indices of juvenile survival through stretches of the Sacramento-San Joaquin River Delta (hereafter, "the Delta") [24,25], but are hindered by low rates of return and tend to utilize hatchery fish that may exhibit different rearing behavior and sea-readiness to their wild counterparts [26]. Furthermore, 'fry pulses' tend to be dominated by individuals <45mm FL, which are difficult to mark externally without causing damage or behavioral modifications. No study to date has tracked habitat use of individual salmon over an entire lifecycle to estimate the relative success of juvenile outmigration phenotypes under different flow conditions. Previous studies have tended to rely on correlations between environmental conditions (e.g. flow) experienced during outmigration and the abundance of returns (Fig 1) [27]. Recent advances in techniques using chemical markers recorded in biomineralised tissues provide rare opportunity to retrospectively "geolocate" individual fish in time and space [28]. Given their incremental growth and metabolically inert

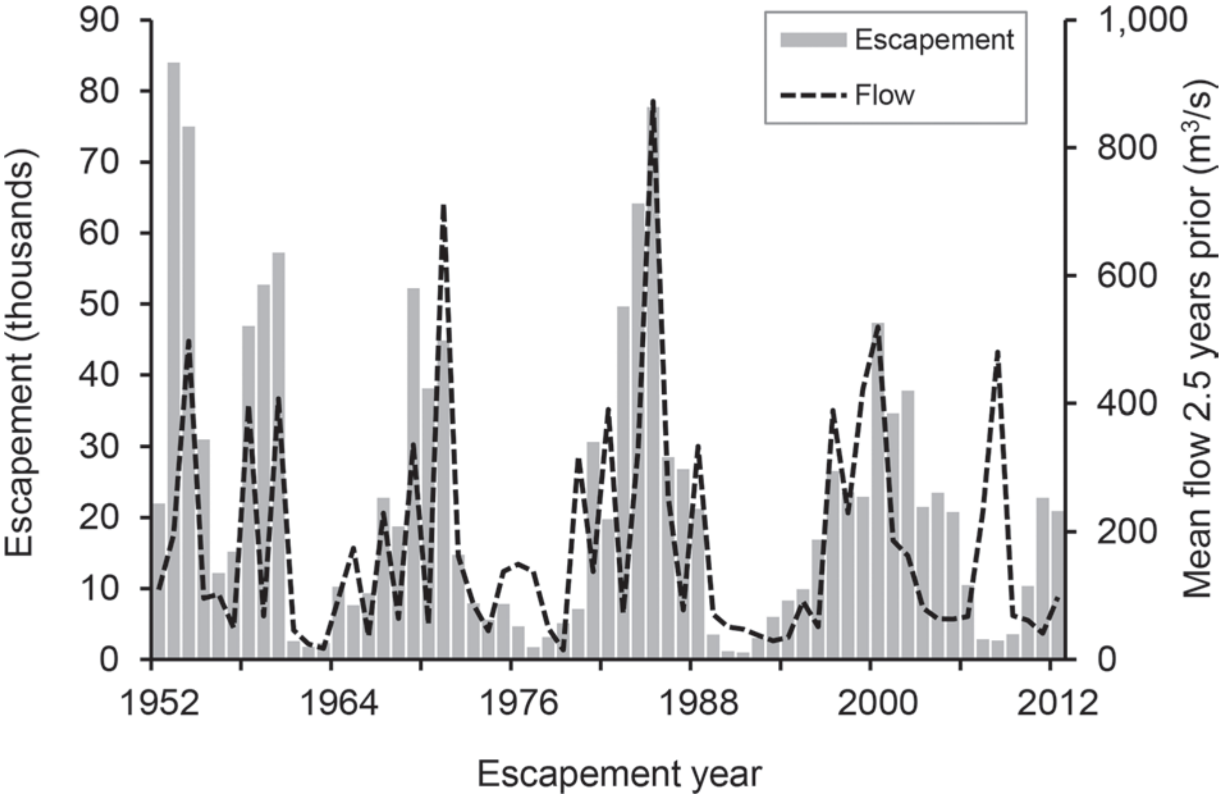

Fig 1. Relationship between adult salmon returns to the San Joaquin basin and the river flows experienced as juveniles. Fall-run Chinook salmon returns ('escapement') to the San Joaquin basin from 1952 to 2011 (CDFW GrandTab, www.CalFish.org) relative to mean flows at Vernalis (USGS gauge 11303500, http://waterdata.usgs.gov/nwis) for the January to June outmigration period they experienced 2.5 years previous. Note that adult abundance estimates have not been corrected for age distributions (we assumed that all adults returned at age 3), inter-annual variation in harvest rates or out-of-basin straying. The large deviation in 2007 reflected poor returns that were attributed to poor ocean conditions [96] and resulted in the closure of the fishery. Adapted from [97].

doi:10.1371/journal.pone.0122380.g001

nature, otoliths ('ear stones') represent a unique natural tag for reconstructing movement patterns of individual fish [29]. The technique relies on differences in the physicochemical environment producing distinct and reproducible "fingerprints" in the otolith. In the CCV, strontium isotopes ($^{87}Sr/^{86}Sr$) are ideal markers because the water composition varies among many of the rivers and is faithfully recorded in the otoliths of Chinook salmon [30–32]. Changes in otolith $^{87}Sr/^{86}Sr$ values can be used to reconstruct time- and age-resolved movements as salmon migrate through the freshwater and estuarine environments [33]. Furthermore, otolith size is significantly related to body size [34,35], allowing back-calculation of individual fork length (FL) at specific life history events [36].

Here, we document metrics of juvenile life history diversity (phenology, size, and abundance) of fall-run Chinook salmon as they outmigrated from the Stanislaus River during an 'above normal' (2000) and 'below normal' (2003) WYT. We used otolith $^{87}Sr/^{86}Sr$ and radius measurements to reconstruct the size at which returning (i.e. "successful") adults from the same cohort had outmigrated, then combined juvenile and adult datasets to estimate the relative contribution and survival of fry, parr and smolt outmigrants. Our main objectives were to determine (1) if a particular phenotype contributed disproportionately to the adult spawning population, (2) whether this could be attributed to selective mortality, and (3) if patterns in phenotype expression and success varied under contrasting flow regimes.

Study Area

The Stanislaus River (hereafter, "the Stanislaus") is the northernmost tributary of the San Joaquin River, draining 4,627 km^3 on the western slope of the Sierra Nevada (Fig 2) [37]. The basin has a Mediterranean climate and receives the majority of its annual rainfall between November and April. Contrasting with the Sacramento watershed in the north, the hydrology of the San Joaquin basin is primarily snowmelt driven [4]. There are over 40 dams in the Stanislaus, which collectively have a capacity of 240% of the average annual runoff [38]. Historically, the Stanislaus contained periodically-inundated floodplain habitat and supported spring- and fall-run Chinook salmon; however, spring-run salmon were extirpated by mining and dam construction, reducing habitat quality and preventing passage to higher elevation spawning grounds [4].

Materials and Methods

Ethics statement

This research was conducted in strict accordance with protocols evaluated and approved by the University of California, Santa Cruz Institutional Animal Care and Use Committee for this specific study (permit number BARNR1409). Otolith and scale samples were collected by California Department of Fish and Wildlife (CDFW) staff from adult salmon carcasses (i.e. already expired) as part of their annual carcass survey, permitted under the State legislative mandate to perform routine management actions. No tissue collections were taken from any state- or federally-listed endangered or protected species for this study.

Juvenile sampling and hydrologic regime

Typically, fall-run Chinook salmon return to the San Joaquin basin from September to early January, and their offspring outmigrate the following January to June [16,39]. Juveniles were sampled as they left the Stanislaus using rotary screw traps (RST) at Caswell Memorial State Park (Fig 2, N 37°42'7.533", W 121°10'44.882). Sampling was terminated when no juveniles had been captured for at least seven consecutive days in June or July [40]. Here, we focused on

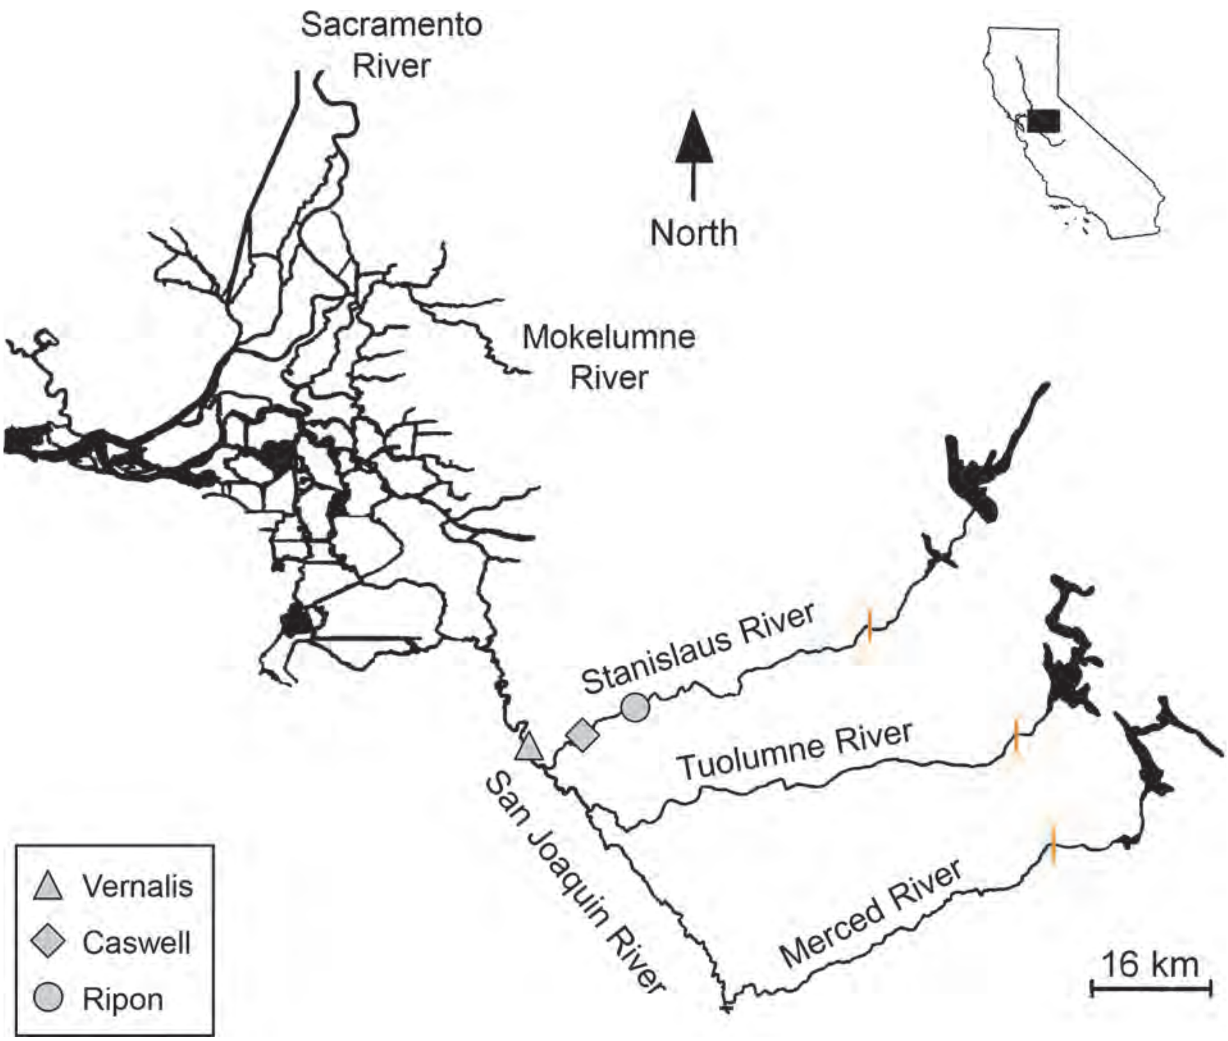

Fig 2. The San Joaquin basin of the Central Valley, California (inset). The upstream barriers to salmon migration in the three main tributaries are indicated by orange bars.

doi:10.1371/journal.pone.0122380.g002

an 'above normal' (2000) and 'below normal' (2003) WYT, and defined the outmigration period as January 1 to June 30, inclusive. When traps were checked, all fish were counted and up to 50 were randomly selected for fork length (FL) and weight measurements. Given potential subjectivity in visual staging criteria [41], we defined migratory phenotypes (fry, parr and smolt) by size: $\leq$55mm, $>$55 to $\leq$75mm, and $>$75mm FL, respectively (after [21]). Unmeasured fish were assigned to phenotype using the observed proportions in the measured fish for the same date. For each phenotype, we interpolated missing catch values with a triangular weighted mean [42].

Marked fish were periodically released to develop a statistical model of trap efficiency, which was used to expand counts of fry, parr and smolt-sized outmigrants. Trap efficiency was estimated using a GLM with a quasibinomial error distribution because of overdispersion in capture probabilities. We used the same efficiency model as [42], only using phenotype (fry, parr, smolt) to characterize fish size, rather than FL. We propagated uncertainty by deriving estimated expanded counts from repeated Monte Carlo draws (n = 2000) from the estimated sampling distribution of the estimated coefficients from the logistic efficiency model using R package mvtnorm [43]. Daily flow observations (USGS gauge no. 11303000 at Ripon, www.waterdata.usgs.gov/nwis) were used with the randomly-sampled model coefficients to simulate daily trap efficiency. Passage estimates were then simulated using daily catch and simulated trap efficiencies. We incorporated extra-binomial variation by generating simulated daily catch values from a beta-binomial distribution (based on the simulated efficiencies and passage estimates, as well as the dispersion estimated from the efficiency model). Finally, new daily passage estimates were calculated using simulated catch and trap efficiencies. Thus the final passage estimates incorporate both sampling error (catch) and estimation error (efficiency model). Annual passages estimates and confidence intervals (2.5% and 97.5% quantiles) were generated by summing daily passage estimates for the 6 month outmigration period (i.e. n = 2000 x 180 days).

Measured daily size-frequency distributions were applied directly to the expanded abundance estimates, then grouped into 2mm FL bins. We attempted to produce passage estimates by FL, but the distribution used in the uncertainty propagation procedure (see above) is asymmetric at low catches, resulting in zero-inflation and the median of the resampled distribution often being lower than the observed raw catch.

Turbidity was measured at Caswell using a LaMott turbidity meter [40]; mean daily flow and maximum daily temperature were measured at Ripon (gauge details above). Daily passage estimates, turbidity, flow and temperature were $\log_{10}$ transformed, then averaged for the 6-month outmigration period and compared among years by ANOVA, adjusting for temporal autocorrelation using the Durbin-Watson (DW) test [44]. Pearson's chi-squared test was used to identify differences in the proportion of phenotypes among years. Fry, parr and smolt phenology was summarized using three metrics associated with their date of passage past the trap: the range, interquartile range (IQR), and median (or "peak") outmigration date. Phenotype "migratory periods" were defined as the maximum IQR for both years combined.

Adult sampling and cohort reconstruction

To track outmigration cohorts 2000 and 2003 into the adult escapement, sagittal otoliths were extracted from Chinook salmon carcasses (aged 2–4 years, 45–112 cm FL) collected in the 2001–2006 CDFW Carcass Surveys (Table 1). Unmarked fish were sampled randomly, but in earlier years, known-hatchery fish with CWTs and clipped adipose fins ("adclipped") were preferentially sampled to assess the accuracy of age estimations. We utilized all otoliths collected from all unmarked fish, but included a subset of CWT fish from outmigration year 2000 (n = 27), which we analyzed blind to assess the accuracy of our natal assignments. Ages were estimated by counting scale annuli [45,46]. Each scale was aged by at least two independent readers and discrepancies resolved by additional reading(s).

Table 1. Adult sample sizes, age structure and collection periods.

	Outmigration cohort 2000 (wetter)			Outmigration cohort 2003 (drier)		
Age	N	%	Collection period	N	%	Collection period
2	6	7%	11/20/01–12/06/01	2	2%	11/08/04–11/12/04
3	80	87%	10/07/02–12/12/02	56	67%	11/02/05–12/15/05
4	6	7%	11/12/03–12/04/03	25	30%	11/15/06–12/06/06

Otoliths were analyzed from salmon carcasses belonging to adults that had outmigrated in 2000 and 2003, including 27 known-origin fish included as a blind test of our natal assignments.

doi:10.1371/journal.pone.0122380.t001

Otolith $^{87}Sr/^{86}Sr$ analyses

Otolith strontium isotope ratios ($^{87}Sr/^{86}Sr$) were measured along a standardized 90° transect [47] by multiple collection laser ablation inductively coupled plasma mass spectrometry (MC-LA-ICPMS; Nu plasma HR interfaced with a New Wave Research Nd:YAG 213 nm laser). Spot analyses were used to allow coupling of chemical data with discrete microstructural features, but otherwise preparation and analysis methods followed those of Barnett-Johnson et al. [32,48]. In brief, otoliths were rinsed 2–3 times with deionized water and cleaned of adhering tissue. Once dry, otoliths were mounted in Crystalbond resin and polished (600 grit, 1500 grit then 3 μm lapping film) until the primordia were exposed. Depending on sample thickness and instrument sensitivity, a 40–55μm laser beam diameter was used with a pulse rate of 10-20Hz, 3–7 J/cm^2 fluence, and a dwell time of 25–35 seconds, resulting in individual ablations roughly equivalent to 10–14 days of growth. Where individual ablations exhibited isotopic changes with depth (e.g. at habitat transition zones), only the start of the ablation was used (e.g. S1 Fig). Helium was used as the laser cell carrier gas (0.7–1.0 L/min) to improve sample transmission and was mixed with argon before reaching the plasma source. Krypton interference (^{86}Kr) was blank-subtracted by measuring background voltages for 30 s prior to each batch of analyses, and ^{87}Rb interferences were removed by monitoring ^{85}Rb. Isotope voltages were integrated over 0.2 s intervals then aggregated into 1 s blocks. Outliers (>2SD) were rejected. Marine carbonate standards ('UCD Vermeij Mollusk' and *O. tshawytscha* otoliths) were analyzed periodically to monitor instrument bias and drift, producing a mean mass-bias corrected $^{87}Sr/^{86}Sr$ ratio (normalized to $^{86}Sr/^{88}Sr = 0.1194$) within 1SD of the global marine value of 0.70918 (0.70922 ± 0.00008 2SD).

Strontium isotopes to reconstruct natal origin and size at outmigration

The baseline of natal $^{87}Sr/^{86}Sr$ signatures described in [32] was updated and expanded upon to increase sample sizes and among-year representation, resulting in an 'isoscape' that encompassed all major CCV sources, with many sampled across multiple years and hydrologic regimes. Linear discriminant function analysis (LDFA) was used to predict the natal origin of the sampled adult spawners, assuming equal prior probabilities for all sites (S1 Text). Differences in natal $^{87}Sr/^{86}Sr$ values were tested between years and sites (S1 Text, S1 Table and S2 Fig), and the performance of the LDFA was assessed using known-origin reference samples (S2 Table). Adults in this study were considered strays (not produced in the Stanislaus) when their natal $^{87}Sr/^{86}Sr$ were closer to other sources in the isoscape, and were excluded from further analysis.

For adults that had successfully returned to the Stanislaus, we monitored the change in $^{87}Sr/^{86}Sr$ across the otolith to identify the point at which they had outmigrated as juveniles. The Stanislaus has a significantly lower isotopic value (0.70660 ± 0.00008 SD) than the mainstem San Joaquin River immediately downstream from it (0.70716 ± 0.00013 SD), resulting in a clear increase and inflection point in otolith $^{87}Sr/^{86}Sr$ at natal exit (e.g. Fig 3B). If the inflection point was unclear, sequential spot analyses were analyzed by LDFA, and exit was defined as a >0.3 decrease in posterior probability of Stanislaus-assignment to a probability <0.5. Deviation from the mean $^{87}Sr/^{86}Sr$ Stanislaus value was assumed to reflect considerable time spent in non-natal water, as (1) the Stanislaus $^{87}Sr/^{86}Sr$ signature shows minor variation in otoliths (S1 Table) and water samples collected immediately upstream of the confluence, (2) the RST location is 13.8rkm upstream of the confluence (Fig 2) and (3) the length of time integrated by each laser spot is ~12 days. Therefore, the distance used to back-calculate exit size was from the otolith core to the last natal spot. To improve resolution and accuracy, additional ablations were performed around the transition zone, typically resulting in sub-weekly resolution.

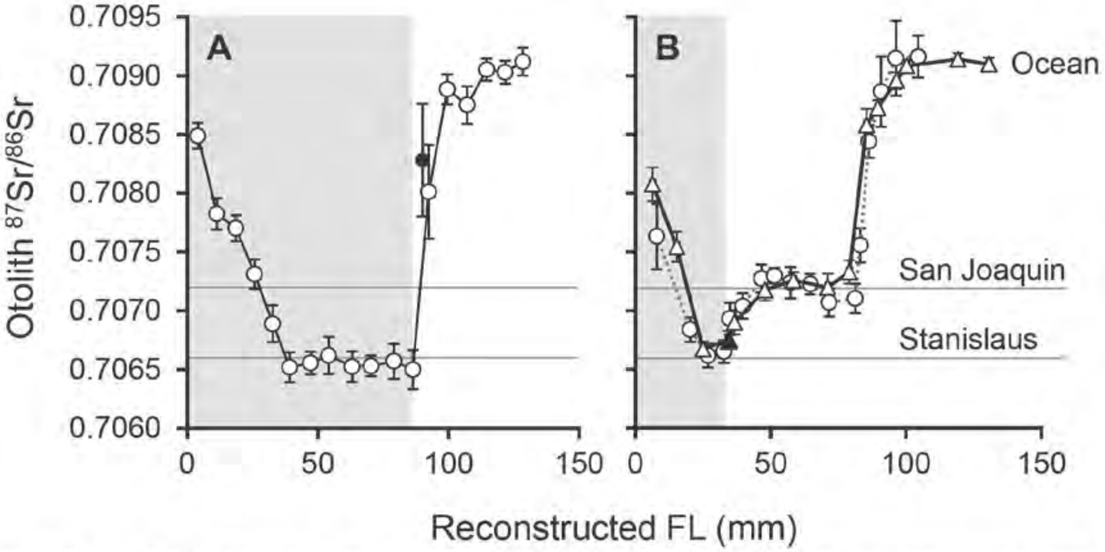

Fig 3. Otolith $^{87}Sr/^{86}Sr$ reconstructions of a smolt and fry outmigrant. Otolith $^{87}Sr/^{86}Sr$ profiles against back-calculated FL for two adult Chinook salmon that returned to the Stanislaus River having outmigrated as (A) a smolt and (B) a fry. The shaded box indicates the time spent rearing in the natal river. The fry outmigrant reared for several weeks downstream in the San Joaquin River before migrating out to the ocean, as indicated by both the left (triangles, solid line) and right (circles, dashed line) otolith (back-calculated FL = 33.3mm *vs.* 34.9mm). Mean $^{87}Sr/^{86}Sr$ signatures for the Stanislaus and San Joaquin Rivers, and modern-day ocean are displayed. Black filled symbols indicate 're-spots' carried out to improve sampling resolution. Error bars = 2SE.

doi:10.1371/journal.pone.0122380.g003

Reconstructed size at outmigration in the returning adults

The relationship between otolith radius (OR) and FL was first calibrated using juveniles collected from multiple sites in the CCV (S3 Table). All individuals belonged to the same Evolutionarily Significant Unit, which is critical for producing unbiased back-calculation models [49]. As there was no difference in the OR of paired otoliths from single individuals ($n = 30$, $\bar{x}\triangle =$ 2.5μm, 95% CI = -5.6–10.6μm), left and right otoliths were used interchangeably. OR was measured along the same 90° transect used for isotope analyses, using a Leica DM1000 microscope and Image Pro Plus (7.0.1).

Reconstructed sizes were grouped into 2mm FL bins and categorized as fry, parr or smolt outmigrants based on the criteria of [21]. Size-frequency distributions were compared between the juvenile and adult samples to identify trends indicative of size-selective mortality. The error around the OR-FL calibration line was used to estimate 95% CI around the proportions of fry, parr and smolt outmigrants using random resampling ($n = 5000$) of the residuals. This allowed us to derive the relative contribution of each phenotype to the adult spawning population.

Survival of juvenile migratory phenotypes

To generate survival indices, we normalized the contribution of each phenotype to the adult population by their abundance within each outmigration cohort based on RST sampling. To estimate spawner abundance ("natural escapement"), we removed adclipped strays from total escapement estimates (GrandTab, available at www.calfish.org) using river- and year-specific tag recovery rates (S4 Table), then separated cohorts using annual age distributions [50] and removed unmarked strays using our otolith natal assignments (see results and S4 Table). We evaluated the use of spawner abundance *vs.* "adult production" (after [51]). While production accounts for different harvest rates among years [52], the two metrics produced similar trends in survival ($r^2 = 0.98$), and we found that escapement, which includes harvest, bycatch and natural mortality between outmigration and spawning, to be more intuitive to interpret.

The otolith-derived proportions (±95% CI) of phenotype i in the escapement (β_i) were applied to our natural escapement estimates (E_n) to estimate the number of fry, parr and smolt spawners (E_i), then E_i was compared with the number of outmigrants of phenotype i (J_i) to estimate their relative survival (S_i):

$$E_i = E_n\beta_i \qquad S_i = E_i/J_i$$

To estimate 95% CI for S_i we combined error in β_i and J_i using the delta method. The 95% CI for S_i depends on the estimate and its standard error (SE): $\hat{S}_i,\ SE(\hat{S}_i)$. Assuming independence of β_i and J_i, we estimated variance as $SE(\log(\hat{S}_i)) \cong \sqrt{\left(\frac{1}{J_i}\right)^2 SE^2(\hat{J}_i) + \left(\frac{1}{\beta_i}\right)^2 SE^2(\hat{\beta}_i)}$. From this, we derived 95% CI for S_i as $\left(e^{\log(\hat{S}_i)-1.96\times SE(\log(\hat{S}_i))}, e^{\log(\hat{S}_i)+1.96\times SE(\log(\hat{S}_i))}\right)$. Note that uncertainties in adult escapement were not incorporated into these confidence intervals; however, the RST-expansions used to estimate J_i were deemed likely to introduce the largest amount of error.

Results

Juvenile outmigration relative to hydrologic regime

Mean flow and turbidity for the 6 month outmigration period were higher in 2000 than 2003 (DW-adjusted $F_{1,\ 361} = 7.52$, $p = 0.006$ and $F_{1,\ 257} = 14.53$, $p = 0.0002$, respectively) (Fig 4). In the drier year (2003) the river was warmer during the smolt migratory period (Apr 15-May 18: DW-adjusted $F_{1,\ 60} = 4.54$, $p = 0.037$) and peak daily temperatures first exceeded 15°C three weeks earlier (Fig 4).

Peak flows were about five times higher in 2000 than 2003, and accompanied by spikes in turbidity and juvenile migration (Fig 4). The number of outmigrants was an order of magnitude higher in 2000 (Table 2), reflecting significantly higher daily abundances of fry, parr and smolt outmigrants (DW adjusted $F_{1,\ 161} = 11.23$, $p < 0.001$; $F_{1,\ 196} = 47.99$, $p < 0.001$; $F_{1,\ 199} = 6.45$, $p = 0.0118$, respectively). While fry dominated in both years, phenotype contributions differed significantly between years ($X^2 = 223{,}683$, $p < 0.001$), with parr approximately twice as abundant as smolts in 2000, but vice versa in 2003 (Table 2). One yearling (FL = 140mm) was

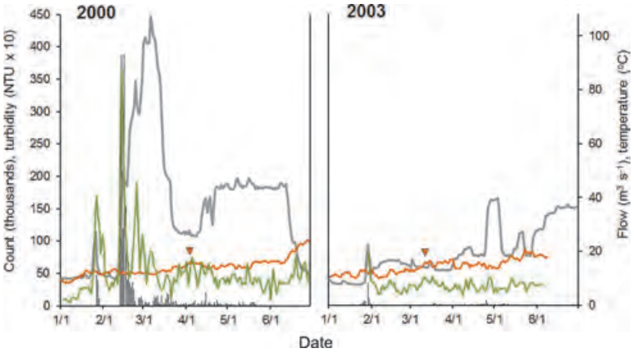

Fig 4. Daily abundance of juvenile salmon outmigrating in 2000 and 2003 relative to ambient environmental conditions. Juvenile salmon were sampled by rotary screw traps at Caswell as they outmigrated from the Stanislaus, and raw counts were expanded into daily abundance estimates (vertical bars) based on trap efficiency models. River flow (grey line) and maximum daily temperature (orange line) were measured at Ripon (data available at http://cdec.water.ca.gov/). Turbidity (green line) was measured at Caswell [40]. The first instance of temperatures reaching 15°C is indicated by an arrow on each plot.

	TOTAL	161,056 (119,868–209,151)				

The abundance and proportions of fry, parr and smolt outmigrants sampled by rotary screw traps, and the timing of their outmigration from the Stanislaus River in 2000 and 2003.

doi:10.1371/journal.pone.0122380.t002

captured in the RST in 2000, but none in 2003, otherwise the size range of outmigrants was similar between years (25-115mm in 2000 *vs*. 27-115mm in 2003).

Phenology varied between phenotypes and years (Table 2 and Fig 5). In general, migratory windows were shorter and earlier in the drier year, with smolt outmigration ceasing 15 days earlier in 2003 than in 2000. The peak migratory periods were similar across years for fry and parr, the former exhibiting a compressed interquartile range (4 d) that was tightly correlated with the start of winter flow pulses (Fig 5).

Natal origin of unmarked adults

The unmarked adults from outmigration cohorts 2000 and 2003 comprised 18% and 51% hatchery strays, respectively, primarily from the Mokelumne, Merced, and Feather River

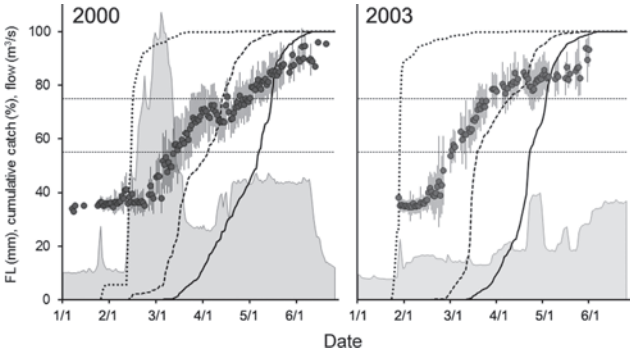

Fig 5. Size and phenology of juveniles outmigrants relative to river flow in 2000 and 2003. Mean (±SD) daily fork length (FL) of juvenile outmigrants, and cumulative percentage of fry (short dashed line), parr (long dashed line) and smolt (solid line) outmigrants relative to flow (filled area). Reference lines indicate the size categories used to define the migratory phenotypes: fry (≤55mm), parr (55-75mm) and smolts (>75mm).

Hatcheries (Table 3). These individuals were removed from subsequent analyses, ensuring that size back-calculations were calculated only for Stanislaus-origin fish that had experienced the same outmigration conditions as the RST-sampled juveniles.

Back-calculation of size at outmigration

A strong, positive relationship was observed between OR and FL ($r^2 = 0.92$, n = 224, $p < 0.001$; FL = 0.171 (±0.003 SE) x OR—12.76 (±1.54 SE)), remaining linear across the full range of FLs reconstructed in the current study. This relationship was used to reconstruct FLs for individual $^{87}Sr/^{86}Sr$ profiles (e.g. Fig 3). The back-calculated size at which returning adults had outmigrated from the Stanislaus ranged from 31.3mm to 86.6mm in 2000, and 46.0mm to 90.5mm in 2003 (Fig 6). No yearlings were detected in the adult returns in either year.

To explore reproducibility of the method, paired left and right otoliths were analyzed from a subset of adults (n = 3 fry and n = 1 smolt outmigrant). All fish were assigned to the same migratory phenotype using either otolith, and the mean difference between back-calculated FLs was 2.3mm (e.g. Fig 3B).

Contribution and survival of juvenile migratory phenotypes

The relative abundance of the migratory phenotypes in the escapement differed significantly to the outmigrating juvenile population in both 2000 ($X^2 = 20{,}931$, $p<0.0001$) and 2003 ($X^2 = 1{,}381$, $p<0.0001$). The phenotype composition of the adult population also differed significantly between years ($X^2 = 749$, $p<0.0001$), reflecting higher fry contributions in the wetter year (23% in 2000 *vs.*10% in 2003) and higher smolt contributions in the drier year (44% in 2003 *vs.* 13% in 2000). Despite representing only 10–16% of the outmigrating juveniles (Table 2), parr were the most commonly observed phenotype in the surviving adult populations (46–64%, Table 4), although parr and smolt contributions to the escapement were near-identical in 2003 (46% vs. 44%, respectively). Conversely, fry outmigrants represented 10–23% of the adult escapement, despite representing 50–85% of the juvenile sample (Tables 2 & 4). The lowest survival was observed in individuals <45mm, particularly in 2003, when the smallest outmigrant in the adult sample had left the river at 46mm FL, while the smallest individual captured in the RST was 27mm FL (Fig 6). Conversely, in 2000, 11% of the adults had left at FLs ≤46mm (the smallest at 31.3mm), compared with 80% of the original juvenile population (the smallest at 25mm; Fig 6).

In both years, fry survival downstream of the Stanislaus (S_{fry}) was significantly lower than parr or smolt survival ($p<0.05$). S_{parr} was approximately double S_{smolt} in both years, but the confidence intervals were overlapping (Table 4). Generally, outmigrant survival downstream of

Discussion

In this study we document the expression of juvenile salmon migratory phenotypes under two contrasting flow regimes and provide new insights into their contribution to the adult spawning population and ultimate survival. We observed variable expression and survivorship of fry, parr and smolt life histories within and between years, yet all three phenotypes consistently contributed to the adult spawning population. This result challenges the common perception in the CCV, that smolt outmigrants are the dominant phenotype driving adult population abundance. Our key findings in the context of the salmon life cycle in order to link the datasets, methods, and processes examined in the study (Fig 7). Overall, the wetter year (2000) was characterized by higher numbers of juvenile outmigrants and adult returns, despite fewer adult spawners contributing to the cohort the previous fall. Using the number of parental spawners as a coarse proxy for juvenile production, these trends suggest higher in-river mortality in the drier year (2003). Given similar downstream (outmigration-to-return) survival rates, these data suggest that for the two focus years of the study, cohort strength was primarily determined within the natal river, prior to juvenile outmigration.

Juvenile outmigration behavior and phenotype expression

Juvenile outmigration timing in salmonids is inextricably linked to large-scale patterns in hydroclimatic regime and local-scale patterns in the magnitude, variation, and timing of flows [14,42]. In the Stanislaus, increases in flow were accompanied by pulses of outmigrants in both years, though greatly amplified during the turbid storm events of 2000. Correlations between fry migration, flow, and turbidity are commonly reported in the literature [14,53,54], and are suggested to have evolved as a result of reduced predation from visual piscivores [14,27,55,56]. The peak in migration in late January 2003 contained 85% of the year's total fry outmigrants and coincided with a managed water release that resulted in mean river flows of 28.4 $m^3 s^{-1}$ [57]. This pulse flow appeared to stimulate fry migration, but comprised relatively clear water (~8 NTU) and contained outmigrants almost entirely <40mm FL (Fig 5). In both years, the larger parr- and smolt-sized fish also appeared to respond to instream flows, exhibiting smaller migration pulses from March through May, coincident with both natural and managed flows (Fig 4) [58,59].

The date and periods of peak migration were generally earlier and shorter in 2003, particularly for smolts. While warmer conditions can result in faster growth rates [60], smoltification in juvenile Chinook salmon is significantly impaired at temperatures above 15°C [61] and this critical temperature was reached at Ripon three weeks earlier in 2003, prior to the onset of peak parr migration. As the reduction in juvenile abundance in 2003 occurred in spite of greater

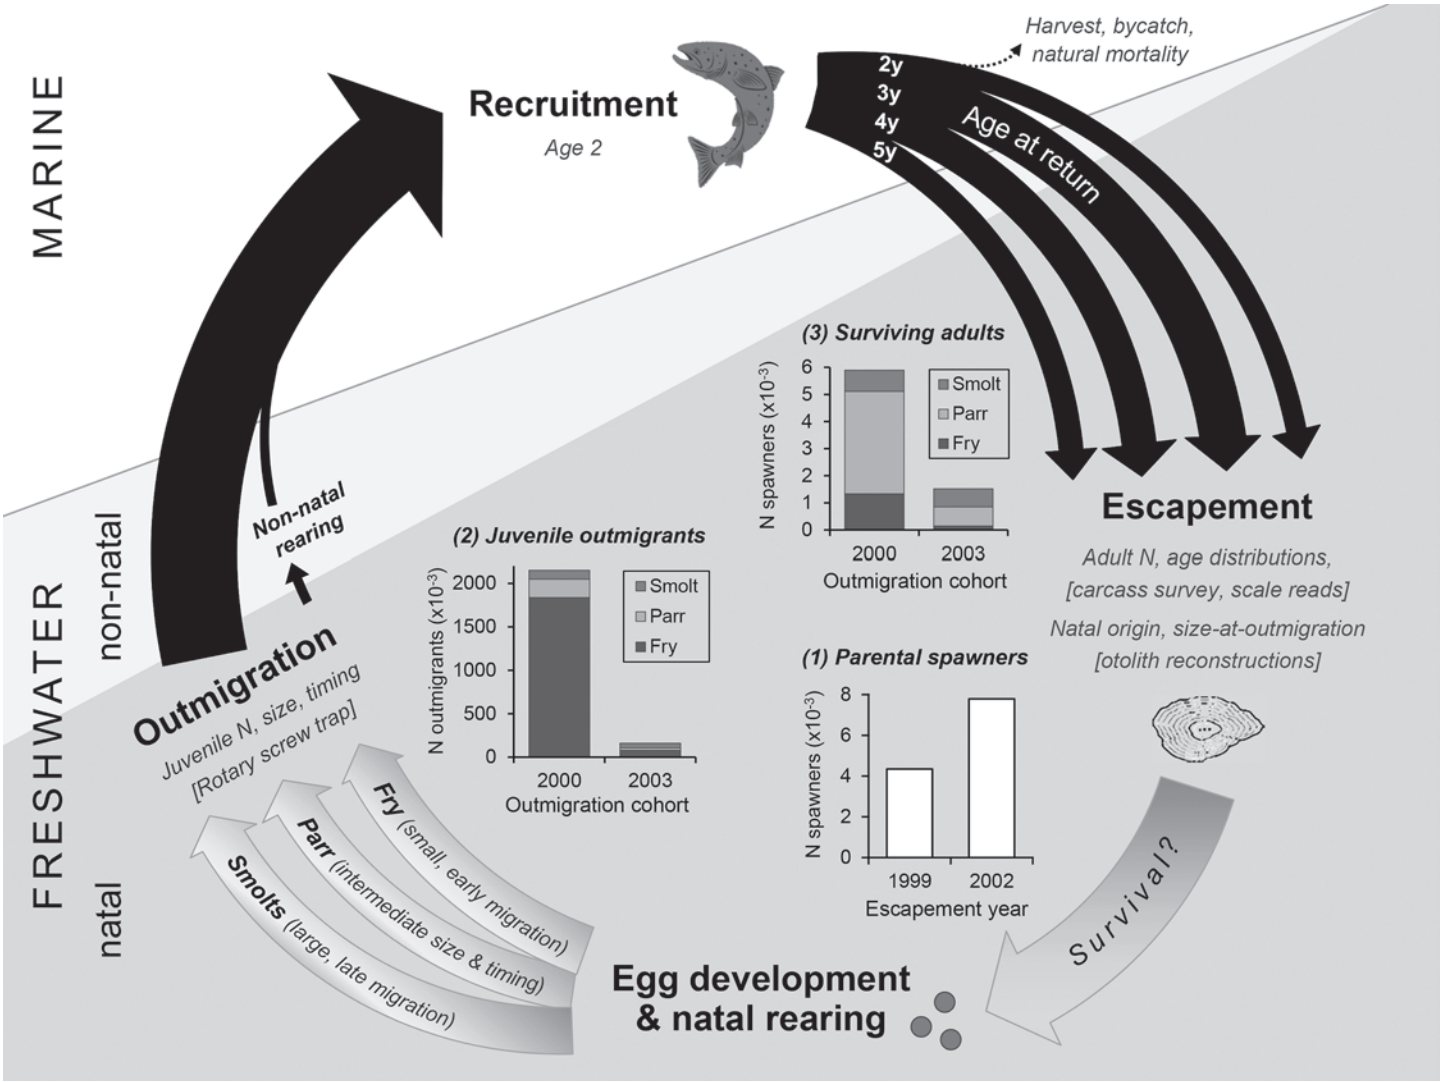

Fig 7. Schematic to conceptualize the data sources, methods and results presented in this study. This figure outlines the life cycle of fall-run Chinook salmon in the California Central Valley. Inset plot (1) demonstrates the abundance of parental spawners in the 1999 and 2002 escapement that contributed to the two focus years. Inset plots (2) and (3) illustrate the abundance and proportions of migratory phenotypes (fry, parr and smolts) observed in the juvenile sample (based on RST sampling) and in the adult escapement (based on otolith reconstructions), respectively. Arrow widths (not to scale) illustrate the typical proportions of 2, 3, 4 and 5 year olds observed in the adult escapement; note that age 5 fish tend to comprise <1% of the returns [50].

doi:10.1371/journal.pone.0122380.g007

numbers of parental spawners (Fig 7), we hypothesize that the truncation of migratory periods was driven by in-river mortality rather than altered migration timing or faster transitions between size classes. Juveniles tend to encounter less floodplain habitat, and increased predation rates and physiological stress in warmer, drier years [62], which likely resulted in a lower carrying capacity in the natal tributary [63] and increased density dependent mortality [64,65].

Survival of migratory phenotypes

Although lower flows and warmer temperatures in the Stanislaus may have contributed to the lower outmigrant production observed in 2003, our results suggest that after exiting the natal river, there was no significant difference in juvenile survival. Survival rates were, if anything, marginally higher in 2003, contradicting many tagging studies which find reduced salmon survival through the freshwater delta during low flow conditions [24,66–68]. This discrepancy is likely due to differences in the sampling design and the time period represented by the different indices. Tagging studies generally release larger hatchery fish in similar sized batches during the later months of the outmigration season, when warmer conditions likely increase their vulnerability to predation [62]. Conversely, our survival estimates were based on variable numbers of fish over a larger size spectrum and broader migratory window, incorporating mortality events in all habitats downstream of the natal river, including the mainstem river, delta, estuary and ocean. However, we assume that differences in our survival indices would be driven by selective mortality events occurring during outmigration and early ocean residence. In support of this, there was no relationship between back-calculated size at outmigration and return FL ($r^2 < 0.01$, $p > 0.05$), implying that size-selective mortality did not vary by phenotype in the adult fish. However, marine distributions of adult salmon can be non-random [69], and if driven by timing at ocean entry, the migratory phenotypes could have been subjected to different ocean processes and mortality rates even as adults.

Parr and smolt outmigrants. Life history theory predicts selection to favor different phenotypes under different hydrologic regimes, maintaining behavioral and phenotypic diversity [70]. Yet in the current study, parr consistently exhibited the greatest contribution to the adult population and the highest survival rates. Greater representation of intermediary-sized juveniles has also been observed in some years in the ocean fisheries of Chinook [21] and Atlantic salmon [22], contradicting the expected directionality of size-selective mortality. Generally, larger or faster-growing individuals within a population are thought to have a selective advantage as a result of greater feeding opportunities, lower vulnerability to predation and greater tolerance of environmental perturbations [71]. However, the strength of size-selection in juvenile CCV Chinook salmon can vary as a function of ocean productivity [18], highlighting the importance of maintaining life history diversity in outmigration strategies. Without large-scale field experiments, it is not possible to definitively ascertain why smolts were not the most successful phenotype, however the San Joaquin basin is at the southernmost reaches of the species distribution [3] and its salmon populations are exposed to high temperatures, poor water quality, and significant water diversions [72,73]. This frequently results in river conditions that could impair growth and smoltification, and increased vulnerability to predation and disease [62], particularly at the end of the season when smolt-sized fish are most prevalent. Thus, the survival advantage of parr is likely attributable to both size and migration timing, analogous to the marine-orientated "critical size and period hypothesis" proposed by Beamish and Mahnken [74]. Furthermore, current flow practices in the San Joaquin basin include managed releases in April and May, intended to improve the survival of smolts [75]. These managed flows typically occur after most parr have left their natal tributaries, potentially selecting for this phenotype by providing downstream benefits as they migrate through (or rear in) the San Joaquin River and freshwater Delta.

Fry outmigrants. Little is known about the factors driving fry behavior or survival, yet the numbers that outmigrated during the wetter year (2000) were orders of magnitude higher, when they also contributed more than double the number of adult survivors (23% in 2000 *vs.* 10% in 2003). While fry consistently exhibited lower survival rates than their conspecifics (Table 4), reflecting the typical direction for size-selective mortality [71], the fact that any survived to contribute to the adult population, let alone contributing >20% of the adult returns, is a significant finding. Based on these data, their sheer abundance during high flow conditions at least partially helps to explain the increases in returns following wet outmigration conditions in the San Joaquin watershed (Fig 1). Early-migrating fry and parr may represent a significant portion of the population that can access favorable downstream rearing habitats in high flow years and survive to contribute to the adult population. Indeed, our otolith reconstructions indicated that all of the smallest ($\leq$46mm FL) fry outmigrants in the surviving adult population (n = 4 in 2000, n = 1 in 2003) had spent several weeks rearing in the San Joaquin mainstem prior to leaving freshwater (e.g. Fig 3B). These data corroborate the extended transit times of CWT-tagged fish released in the San Joaquin basin and freshwater Delta in wetter years (averages of 16 d in 2000 vs. 6 d in 2003), although their mean size also differed (81mm vs. 87mm, respectively) [58]. Fry are observed in downstream freshwater and estuarine habitats in the CCV [20,76], and were probably more common when the Delta was a large tidal wetland [14,24,53]. This study confirms that these individuals can survive and contribute meaningfully to adult returns.

Currently there are no genetic data to support or refute a heritable component to early outmigration behavior, but it could otherwise meet the criteria of an adaptive trait, given that its expression is associated with "differential survival" and there is evidence for "a mechanism of selection" [77]. There is still some debate as to whether fry pulses during high flow events represent displacement due to reduced swimming ability or a deliberate behavior that might be considered a 'strategy' [3,14]. While catastrophic floods undoubtedly result in riverbed scouring and some fry displacement, not all individuals outmigrate during these events. Conversely, some fry migration is observed during periods with no pulse flows [78]. Given the frequency with which this phenotype is reported and the considerable rearing potential of downstream habitats, it is conceivable that fry dispersal is a heritable strategy, representing a 'migratory contingent' within the population [79,80]. Indeed, their consistent contribution to the adult population (observed here and in [21]) conclusively demonstrates that fry migration can be successful. If, however, early outmigration is purely an expression of phenotypic plasticity, it is likely that multiple factors are involved in stimulating the behavioral switch, including hydrology, intraspecific interactions [3] and density dependent mechanisms [65,81–83]. Irrespective of the underlying mechanisms, quantifying the relative success of migratory phenotypes across a broader range of hydrologic regimes is fundamental to understanding how environmental conditions and water operations contribute to salmon population dynamics.

Otolith strontium isotopes and sources of uncertainty

One of the most significant advances of the current study was the pairing of RST sampling with otolith reconstructions. This process enabled us to compare fish size at a specific time and location across life stages, and provided a unique method for generating survival estimates into adulthood. CWT studies and acoustic telemetry have provided valuable insights into survival through particular stretches of the CCV [25,75], but tend to focus on larger fish and provide no information about the long-term success of particular traits. In addition, acoustic tags have focused on understanding flow-survival relationships for smolts, which are physiologically ready for seaward migration and likely use the mainstem rivers, delta, and estuary differently than fry or parr, which may exhibit prolonged rearing. Otolith $^{87}Sr/^{86}Sr$ ratios are an ideal natural tag as they vary among many of the rivers in the CCV, resulting in high classification scores for natal assignments (S1 and S2 Tables) [30,32,84]. Sr isotopes also represent a unique and sensitive marker for reconstructing downstream movements and non-natal rearing patterns in the freshwater system (e.g. Fig 3B). While seasonal variation in $^{87}Sr/^{86}Sr$ values have been reported in certain systems [85] and interannual variations were detected for some sites (S1 Table), these were minor compared with most of the geographic differences, with the majority of sites exhibiting classification scores >70% even when pooled across years (S2 Table). Importantly, the Stanislaus exhibited a stable and distinct isotopic signature; with 96% of juveniles correctly classified using jack-knife resampling (S2 Table). Identification of natal origin represents a significant advantage of using otolith Sr isotopes over element concentrations. This was critical for pairing RST- and otolith-derived datasets and providing confidence that our size reconstructions were not skewed by hatchery smolts.

A high occurrence of straying of fall-run Chinook salmon occurs between the San Joaquin and Sacramento basins [86–88], potentially due to the relative outflows during the return migration as well as hatchery release practices [89]. However the extent to which hatchery fish are functioning to sustain the San Joaquin salmon populations has gone largely undetected until recently [86,87]. In the current study, hatchery strays represented 18–51% of the unmarked fish, reducing the number of samples available to inform outmigration strategies of wild fish and increasing analytical costs. However, the removal of strays was vital to ensure that FL reconstructions were only performed on individuals that had experienced the same conditions as the RST-sampled juveniles. The implementation of 100% visual identification of hatchery fish [90] would increase the feasibility and efficiency of future life history diversity studies in this system.

We attempted to reduce and account for sources of uncertainty, but the low number of focus years and sample sizes, and the potential for error propagation limit the strength of our inferences. With greater representation of 2 and 4 year olds in our adult sample, a more sophisticated analysis using age-specific natal assignments could have been carried out. While no yearlings were detected in the surviving adults, their rarity in the RST-sampled outmigrant population indicate that larger sample sizes would be required to ascertain the success of this strategy with any confidence. Similarly, our approach for assigning natal origin based on otolith chemistry following yolk sac absorption means that individuals that outmigrated as yolk sac fry could have been misclassified as strays. However, yolk sac fry are rarely observed in the outmigrant population (0.1% of the 2001–2011 RST catch at Caswell), so this was deemed unlikely to significantly influence our results.

Management implications

The complex biophysical properties of freshwater systems have led to the evolution of dynamic habitat mosaics [91] and diverse salmon life histories and distributions. The observed life history diversity likely provides within-population buffering, an as yet understudied component of the portfolio effect [5,6]. These data add to the mounting evidence that managing and conserving life history diversity is necessary to support resilient salmon populations, particularly in the face of climate change and projected human population growth [9,10]. Diversity in phenotypic traits is thought to produce a more stable population complex by decoupling population dynamics and buffering variance [6]. However, population resilience does not necessarily immediately translate into population abundance. In a highly regulated system such as the CCV, there is debate as to whether environmental unpredictability dictates a need to manage salmon stocks for diversity and resilience, or whether our understanding of (and control over) the relevant processes is sufficient to manage purely for abundance. Such topics are complicated by socio-economic and ecological trade-offs, however, by improving our understanding of how juvenile life history strategies are expressed and respond to different flow regimes, we may be able to optimize both. Currently, the portfolio effect for CCV salmon stocks is weak and deteriorating [92] and San Joaquin populations face serious future challenges, given predicted 25–40% reductions in snowmelt by 2050 [93]. CCV salmon exhibit diverse outmigration timings that have evolved over geological time scales in response to the unpredictable hydroclimatic conditions characteristic of the region [11]. Yet modern-day water and hatchery management practices tend to constrain outmigration timing. For example, alterations to the natural hydrograph, such as suppression of winter pulse flows, likely to truncate migratory windows, reduce the variability in outmigration timing, and significantly suppress the fry life history type. Such simplification and truncation of life history diversity could significantly reduce the resiliency of the stock-complex and exacerbate the risk of a temporal mismatch with favorable ocean conditions [94]. Indeed, the only clear deviation from the flow-driven relationship in Fig 1 was attributed to juveniles entering the ocean during a suboptimal period and resulted in the closure of the fishery in 2008. Perhaps with more diverse, resilient stocks, the consequences would have been less extreme. Largely without direct empirical support, hatchery and flow management practices tend to focus on optimizing the success of the largest, smolt-sized juveniles that are assumed to contribute the most to adult returns [14,21,24]. Here, we found that all phenotypes contributed to the reproductive adult population, with smolts comprising less than half of the surviving adults following two contrasting flow regimes. Without otolith reconstruction data for additional years, species, and watersheds, the broader inferences one can make regarding the influence of hydroclimatic regime on juvenile salmon survival are limited. However our data and a previous study [21] indicate that assumptions regarding size-selective mortality and smolt-focused management schemes need to be tested on a species, system and hydroclimatic basis.

This study has demonstrated the value of a combined RST and otolith geochemistry study to reconstruct patterns in the expression and survival of salmon migratory phenotypes. The results show that under paired years of low and high flow conditions, parr outmigrants comprised a significant portion of the returning adult population, while fry made smaller, but substantial contributions. Future efforts should focus on reducing the error in juvenile production estimates in order to produce more meaningful survival estimates, and understanding the demographic role that fry and parr play in salmon population dynamics. Management actions that promoted the expression and survival of fry in natal and downstream rearing habitats could result in demographic and genetic benefits to the population. Recognition of the importance of hydrodynamic regime and life history diversity should provide guidance to system managers when reassessing goals and future management strategies [5,95]. It is also important that management actions consider carefully-designed monitoring programs to detect changes in stock abundance and life history diversity at appropriate temporal and spatial scales.

State Water Resources Control Board
California Environmental Protection Agency

Development of Flow Criteria for the Sacramento-San Joaquin Delta Ecosystem

Prepared Pursuant to the Sacramento-San Joaquin Delta Reform Act of 2009

Report prepared by:

Phil Crader, Senior Environmental Scientist
Les Grober, Environmental Program Manager
Adam Ballard, Senior Environmental Scientist
Chris Foe, Staff Environmental Scientist
Diane Riddle, Staff Environmental Scientist
David La Brie, Engineering Associate
Mark Gowdy, Water Resources Control Engineer
Erin Mahaney, Senior Staff Counsel

With assistance from:

Barbara Leidigh, Senior Staff Counsel
Lucas Sharkey, Water Resources Control Engineer
Jean McCue, Water Resources Control Engineer
Dramy Saechao, Office Technician
Stephen Craig, Associate Information Systems Analyst
Duran Fiack, Student Assistant

Acknowledgements

The State Water Resources Control Board (State Water Board or Board) acknowledges the following for their contributions and participation in the Board's Delta Flow Criteria proceding:

- The professors, researchers, and staff from various resource agencies that comprise the Delta Environmental Flows Group (DEFG) for providing valuable information and insights that informed the Delta flow criteria informational proceeding, and whose work was cited liberally throughout this report
- The UC Davis Delta Solutions Group, a subset of the DEFG for providing additional insights in their reports on habitat variability, flow presecriptions, and ecosystem investments
- The California Department of Fish and Game for working collaboratively with the State Water Board on development of species life history requirements and for reviewing portions of the draft report
- The United States Fish and Wildflie Service and National Marine Fisheries Service for reviewing portions of the draft report
- All the participants of the proceeding for providing information and serving on panels to answer questions during the proceeding

The State Water Board, however, is responsible for any errors and for all interpretations of the information in this report.

STATE WATER RESOURCES CONTROL BOARD
RESOLUTION NO. 2010-0039

DETERMINING DELTA FLOW CRITERIA PURSUANT TO THE DELTA REFORM ACT

WHEREAS:

1. Water Code section 85086, contained in the Sacramento-San Joaquin Delta Reform Act of 2009 (Stats. 2009 (7th Ex. Sess.) ch. 5) (commencing with Wat. Code, § 85000), requires the State Water Resources Control Board (State Water Board) to develop, within nine months of enactment of the statute, new flow criteria for the Sacramento-San Joaquin Delta (Delta) ecosystem that are necessary to protect public trust resources. The purpose of the flow criteria is to inform planning decisions for the Delta Plan and the Bay Delta Conservation Plan. The statute specifies that the flow criteria shall not predetermine any issue that may arise in the State Water Board's subsequent consideration of a permit.

2. In accordance with Water Code section 85086, subdivision (c)(1), the State Water Board conducted a public process in the form of an informational proceeding to collect information used to develop the flow criteria. The State Water Board conducted the informational proceeding on March 22-24, 2010, and considered the information submitted in connection with that proceeding in developing the flow criteria.

3. The State Water Board has prepared a report determining flow criteria for the Delta ecosystem necessary to protect public trust resources. In developing the flow criteria, the State Water Board reviewed existing water quality objectives and used the best available scientific information. The flow criteria include the volume, timing, and quality of flow necessary under different hydrologic conditions.

THEREFORE BE IT RESOLVED THAT:

1. In accordance with the Delta Reform Act, the State Water Board approves the report determining new flow criteria for the Delta ecosystem that are necessary to protect public trust resources.

2. The Executive Director is directed to submit the Delta flow criteria report to the Delta Stewardship Council for its information within 30 days of the adoption of this resolution.

CERTIFICATION

The undersigned Clerk to the Board does hereby certify that the foregoing is a full, true, and correct copy of a resolution duly and regularly adopted at a meeting of the State Water Board held on August 3, 2010.

AYE: Chairman Charles R. Hoppin
Vice Chair Frances Spivy-Weber
Board Member Arthur G. Baggett, Jr.
Board Member Tam M. Doduc
Board Member Walter G. Pettit

1. Executive Summary

The Sacramento-San Joaquin Delta (Delta) is a critically important natural resource for California and the nation. It is both the hub of California's water supply system and the most valuable estuary and wetlands on the western coast of the Americas. The Delta is in ecological crisis, resulting in high levels of conflict that affect the sustainability of existing water policy in California. Several species of fish have been listed as protected species under the California Endangered Species Act (CESA) and under the federal Endangered Species Act (ESA). These two laws and other regulatory constraints have restricted water diversions from the Delta in an effort to prevent further harm to the protected species.

In November 2009, California enacted a comprehensive package of four policy bills and a bond measure intended to meet California's growing water challenges by adopting a policy of sustainable water supply management to ensure a reliable water supply for the State and to restore the Delta and other ecologically sensitive areas. One of these bills, Senate Bill No. 1 (SB 1) (Stats. 2009 (7th Ex. Sess.) ch 5, § 39) contains the Sacramento-San Joaquin Delta Reform Act of 2009 (Delta Reform Act), Water Code section 85000 et seq. The Delta Reform Act establishes a Delta Stewardship Council (Council), tasked with developing a comprehensive, long-term management plan for the Delta, known as the Delta Plan, and providing direction to multiple state and local agencies that take actions related to the Delta. The comprehensive bill package also sets water conservation policy, requires increased groundwater monitoring, and provides for increased enforcement against illegal water diversions.

The Delta Reform Act requires the State Water Board to use a public process to develop new flow criteria for the Delta ecosystem. During this process, participants cautioned the the State Water Board on the limitations of any flow criteria (Fleenor *et al*., 2010):

> "How much water do fish need?" has been a common refrain in Delta water management for many years… it is highly unlikely that any fixed or predetermined prescription will be a "silver bullet". The performance of native and desirable fish populations in the Delta requires much more than fresh water flows. Fish need enough water of appropriate quality over the temporal and spatial extent of habitats to which they adapted their life history strategies. Typically, this requires habitat having a particular range of physical characteristics, appropriate variability, adequate food supply and a diminished set of invasive species. While folks ask "How much water do fish need?" they might well also ask, "How much habitat of different types and locations, suitable water quality, improved food supply and fewer invasive species that is maintained by better governance institutions, competent implementation and directed research do fish need?" The answers to these questions are interdependent. We cannot know all of this now, perhaps ever, but we do know things that should help us move in a better direction, especially the urgency for being proactive. We do know that current policies have been disastrous for desirable fish. It took over a century to change the Delta's ecosystem to a less desirable state; it will take many decades to put it back together again with a different physical, biological, economic, and institutional environment."

The State Water Board concurs with this cautionary note. The State Water Board further cautions that flow and physical habitat interact in many ways, but they are not interchangeable.

The best available science suggests that current flows are insufficient to protect public trust resources.

1.1 Legislative Directive and State Water Board Approach

Legislative Directive

Water Code section 85086 (See Appendix B), contained in the Delta Reform Act, was enacted as part of the comprehensive package of water legislation adopted in November 2009. Water Code section 85086 requires the State Water Resources Control Board (State Water Board) to use the best available scientific information gathered as part of a public process conducted as an informational proceeding to develop new flow criteria for the Delta ecosystem to protect public trust resources. The purpose of the flow criteria is to inform planning decisions for the Delta Plan and the BDCP. The Legislature intended to establish an accelerated process to determine the instream flow needs of the Delta in order to facilitate the planning decisions required to meet the objectives of the Delta Plan. Accordingly, Water Code section 85086 requires the State Water Board to develop the flow criteria within nine months of enactment of the statute and to submit its flow criteria determinations to the Council within 30 days of their development.

State Water Board Approach

In determining the extent of protection to be afforded public trust resources through the development of the flow criteria, the State Water Board considered the broad goals of the planning efforts the criteria are intended to inform, including restoring and promoting viable, self-sustaining populations of aquatic species. Given the accelerated time frame in which to develop the criteria, the State Water Board's approach to developing criteria was limited to review of instream needs in the Delta ecosystem, specifically fish species and Delta outflows, while also receiving information on hydrodynamics and major tributary inflows. The State Water Board's flow criteria determinations are accordingly limited to protection of aquatic resources in the Delta.

Limitations of State Water Board Approach

When setting flow objectives with regulatory effect, the State Water Board reviews and considers all the effects of the flow objectives through a broad inquiry into all public trust and public interest concerns. For example, the State Water Board would consider other public trust resources potentially affected by Delta outflow requirements and impose measures for the protection of those resources, such as requiring sufficient water for cold water pool in reservoirs to maintain temperatures in Delta tributaries. The State Water Board would also consider a broad range of public interest matters, including economics, power production, human health and welfare requirements, and the effects of flow measures on non-aquatic resources (such as habitat for terrestrial species). The limited process adopted for this proceeding does not include this comprehensive review.

The State Water Board's Public Trust Responsibilities in this Proceeding

Under the public trust doctrine, the State Water Board must take the public trust into account in the planning and allocation of water resources, and to protect public trust uses whenever feasible. (*National Audubon Society v. Superior Court* (1983) 33 Cal.3d 419, 446.) Public trust values include navigation, commerce, fisheries, recreation, scenic, and ecological values. "[I]n determining whether it is 'feasible' to protect public trust values like fish and wildlife in a particular instance, the [State Water] Board must determine whether protection of those values, or what level of protection, is 'consistent with the public interest.'" (*State Water Resources*

Control Bd. Cases (2006) 136 Cal.App.4th 674, 778.) The State Water Board does not make any determination regarding the feasibility of the public trust criteria and consistency with the public interest in this report.

In this forum, the State Water Board has not considered the allocation of water resources, the application of the public trust to a particular water diversion or use, water supply impacts, or any balancing between potentially competing public trust resources (such as potential adverse effects of increased Delta outflow on the maintenance of coldwater resources for salmonids in upstream areas). Any such application of the State Water Board's public trust responsibilities, including any balancing of public trust values and water rights, would be conducted through an adjudicative or regulatory proceeding. Instead, the State Water Board's focus here is solely on identifying public trust resources in the Delta ecosystem and determining the flow criteria, as directed by Water Code section 85086.

Future Use of This Report

None of the determinations in this report have regulatory or adjudicatory effect. Any process with regulatory or adjudicative effect must take place through the State Water Board's water quality control planning, water rights processes, or public trust proceedings in conformance with applicable law. In the State Water Board's development of Delta flow objectives with regulatory effect, it must ensure the reasonable protection of beneficial uses, which may entail balancing of competing beneficial uses of water, including municipal and industrial uses, agricultural uses, and other environmental uses. The State Water Board's evaluation will include an analysis of the effect of any changed flow objectives on the environment in the watersheds in which Delta flows originate, the Delta, and the areas in which Delta water is used. It will also include an analysis of the economic impacts that result from changed flow objectives.

Nothing in either the Delta Reform Act or in this report amends or otherwise affects the water rights of any person. In carrying out its water right responsibilities, the State Water Board may impose any conditions that in its judgment will best develop, conserve, and utilize in the public interest the water to be appropriated. In making this determination, the State Water Board considers the relative benefit to be derived from all beneficial uses of the water concerned and balances competing interests.

The State Water Board has continuing authority over water right permits and licenses it issues. In the exercise of that authority and duty, the State Water Board may, if appropriate, amend terms and conditions of water right permits and licenses to impose further limitations on the diversion and use of water by the water right holder to protect public trust uses or to meet water quality and flow objectives in Water Quality Control Plans it has adopted. The State Water Board must provide notice to the water permit or license holder and an opportunity for hearing before it may amend a water right permit or license.

If the DWR and/or the USBR in the future request the State Water Board to amend the water right permits for the State Water Project (SWP) and/or the Central Valley Project (CVP) to move the authorized points of diversion for the projects from the southern Delta to the Sacramento River, Water Code section 85086 directs the State Water Board to include in any order approving a change in the point of the diversion of the projects appropriate Delta flow criteria. At that time, the State Water Board will determine appropriate permit terms and conditions. That decision will be informed by the analysis in this report, but will also take many other factors into consideration, including any newly developed scientific information, habitat conditions at the time, and other policies of the State, including the relative benefit to be derived from all beneficial uses of water. The flow criteria in this report are not pre-decisional in regard to any State Water Board action. (See e.g., Wat. Code, § 85086, subd. (c)(1).)

The information in this report illustrates to the State Water Board the need for an integrated approach to management of the Delta. Best available science supports that it is important to directly address the negative effects of other stressors, including habitat, water quality, and invasive species, that contribute to higher demands for water to protect public trust resources. The flow criteria highlight the continued need for the BDCP to develop an integrated set of solutions and to implement non flow measures to protect public trust resources.

1.2 Summary Determinations

This report contains the State Water Board's determinations as to the flows that protect public trust resources in the Delta, under the narrow circumstances analyzed in this report. As required, the report includes the volume, timing, and quality of flow for protection of public trust resources under different hydrologic conditions. The flow criteria represent a technical assessment only of flow and operational requirements that provide fishery protection under existing conditions. The flow criteria contained in this report do not represent flows that might be protective under other conditions. The State Water Board recognizes that changes in existing conditions may alter the need for flow. Changes in existing conditions that may affect flow needs include, but are not limited to, reduced reverse flows in Delta channels, increased tidal habitat, improved water quality, reduced competition from invasive species, changes in the point of diversion of the SWP and CVP, and climate change.

Flow Criteria and Conclusions

The numeric criteria determinations in this report must be considered in the following context:

- The flow criteria in this report do not consider any balancing of public trust resource protection with public interest needs for water.
- The State Water Board does not intend that the criteria should supersede requirements for health and safety such as the need to manage water for flood control.
- There is sufficient scientific information to support the need for increased flows to protect public trust resources; while there is uncertainty regarding specific numeric criteria, scientific certainty is not the standard for agency decision making.

The State Water Board has considered the testimony presented during the Board's informational proceeding to develop flow criteria and to support the following summary conclusions. Several of these summary conclusions rely in whole or in part on conclusions and recommendations made to the State Water Board by the Delta Environmental Flows Group (DEFG)[1] and the University of California at Davis Delta Solutions Group[2].

1. The effects of non-flow changes in the Delta ecosystem, such as nutrient composition, channelization, habitat, invasive species, and water quality, need to be addressed and integrated with flow measures.

---

[1] The Delta Environmental Flows Group of experts consists of William Bennett, Jon Burau, Cliff Dahm, Chris Enright, Fred Feyrer, William Fleenor, Bruce Herbold, Wim Kimmerer, Jay Lund, Peter Moyle, and Matthew Nobriga.

[2] The Delta Solutions Group consists of William Bennett, William Fleenor, Jay Lund, and Peter Moyle.

2. Recent Delta flows are insufficient to support native Delta fishes for today's habitats.[3] Flow modification is one of the immediate actions available although the links between flows and fish response are often indirect and are not fully resolved. Flow and physical habitat interact in many ways, but they are not interchangeable.

3. In order to preserve the attributes of a natural variable system to which native fish species are adapted, many of the criteria developed by the State Water Board are crafted as percentages of natural or unimpaired flows. These criteria include:

    - 75% of unimpaired Delta outflow from January through June;
    - 75% of unimpaired Sacramento River inflow from November through June; and
    - 60% of unimpaired San Joaquin River inflow from February through June.

    It is not the State Water Board's intent that these criteria be interpreted as precise flow requirements for fish under current conditions, but rather they reflect the general timing and magnitude of flows under the narrow circumstances analyzed in this report. In comparison, historic flows over the last 18 to 22 years have been:

    - approximately 30% in drier years to almost 100% of unimpaired flows in wetter years for Delta outflows;
    - about 50% on average from April through June for Sacramento River inflows; and
    - approximately 20% in drier years to almost 50% in wetter years for San Joaquin River inflows.

4. Other criteria include: increased fall Delta outflow in wet and above normal years; fall pulse flows on the Sacramento and San Joaquin Rivers; and flow criteria in the Delta to help protect fish from mortality in the central and southern Delta resulting from operations of the State and federal water export facilities.

5. The report also includes determinations regarding variability and the natural hydrograph, floodplain activation and other habitat improvements, water quality and contaminants, cold water pool management, and adaptive management:
    - Criteria should reflect the frequency, duration, timing, and rate of change of flows, and not just volumes or magnitudes. Accordingly, whenever possible, the criteria specified above are expressed as a percentage of the unimpaired hydrograph.

---

[3] This statement should not be construed as a critique of the basis for existing regulatory requirements included in the 2006 Bay-Delta Plan and biological opinions. Those requirements were developed pursuant to specific statutory requirements and considerations that differ from this proceeding. Particularly when developing water quality objectives, the State Water Board must consider many different factors including what constitutes reasonable protection of the beneficial use and economic considerations. In addition, the biological opinions for the SWP and CVP Operations Criteria and Plan were developed to prevent jeopardy to specific fish species listed pursuant to the federal Endangered Species Act; in contrast, the flow criteria developed in this proceeding are intended to halt population decline and increase populations of certain species.

- Inflows should generally be provided from tributaries to the Delta watershed in proportion to their contribution to unimpaired flow unless otherwise indicated.
- Studies and demonstration projects for, and implementation of, floodplain restoration, improved connectivity and passage, and other habitat improvements should proceed to provide additional protection of public trust uses and potentially allow for the reduction of flows otherwise needed to protect public trust resources in the Delta.
- The Central Valley and San Francisco Regional Water Quality Control Boards should continue developing Total Maximum Daily Loads (TMDLs) for all listed pollutants and adopting programs to implement control actions.
- The Central Valley Regional Water Quality Control Board should require additional studies and incorporate discharge limits and other controls into permits, as appropriate, for the control of nutrients and ammonia.
- Temperature and water supply modeling and analyses should be conducted to identify conflicting requirements to achieve both flow and cold water temperature goals.
- A strong science program and a flexible management regime are critical to improving flow criteria. The State Water Board should work with the Council, the Delta Science Program, BDCP, the Interagency Ecological Program (IEP), and others to develop the framework for adaptive management that could be relied upon for the management and regulation of Delta flows.
- The numeric criteria included in this report are all criteria that are only appropriate for the current physical system and climate; as other factors change the flow needs advanced in this report will also change. As physical changes occur to the environment and our understanding of species needs improves, the long-term flow needs will also change. Actual flows should be informed by adaptive management.
- Only the underlying principles for the numeric criteria and other measures are advanced as long term criteria.

6. Past changes in the Delta may influence migratory cues for some fishes. These cues are further scrambled by a reverse salinity gradient in the south Delta. It is important to establish seaward gradients and create more slough networks with natural channel geometry. Achieving a variable more complex estuary requires establishing seasonal gradients in salinity and other water quality variables and diverse habitats throughout the estuary. These goals in turn encourage policies which establish internal Delta flows that create a tidally-mixed upstream- downstream gradient (without cross-Delta flows) in water quality. Continued through-Delta conveyance is likely to continue the need for in-Delta flow requirements and restrictions to protect fish within the Delta.

7. Restoring environmental variability in the Delta is fundamentally inconsistent with continuing to move large volumes of water through the Delta for export. The drinking and agricultural water quality requirements of through-Delta exports, and perhaps even some current in-Delta uses, are at odds with the water quality and variability needs of desirable Delta species.

8. The Delta ecosystem is likely to dramatically shift within 50 years due to large scale levee collapse. Overall, these changes are likely to promote a more variable, heterogeneous estuary. This changed environment is likely to be better for desirable estuarine species; at least it is unlikely to be worse.

9. Positive changes in the Delta ecosystem resulting from improved flow or flow patterns will benefit humans as well as fish and wildlife.

10. In order to prevent further channelization of riparian corridors and infill of wetland habitats, the Delta Stewardship Council should consider developing a plan to coordinate land use policy within the Delta between the city, county, State, and federal governments.

Ecosystems are complex; there are many factors that affect the quality of the habitat that they provide. These factors combine in ways that can amplify the effect of the factors on aquatic resources. The habitat value of the Delta ecosystem for favorable species can be improved by habitat restoration, contaminant and nutrient reduction, changes in diversions, control of invasive species, and island flooding. Each of these non-flow factors has the potential to interact with flow to affect available aquatic habitat in Delta channels.

The State Water Board supports the most efficient use of water that can reasonably be made. The flow improvements that the State Water Board identifies in this report as being necessary to protect public trust resources illustrate the importance of addressing the negative effects of these other stressors that contribute to higher than necessary demands for water to provide resource protection. Future habitat improvements or changes in nutrients and contaminants, for example, may change the response of fishes to flow. Addressing other stressors directly will be necessary to assure protection of public trust resources and could change the demands for water to provide resource protection in the future. Uncertainty regarding the effects of habitat improvement and other stressors on flow demands for resource protection highlights the need for continued study and adaptive management to respond to changing conditions.

The flow criteria identified in this report highlight the need for the BDCP to develop an integrated set of solutions, to address ecosystem flow needs, including flow and non-flow measures. Although flow modification is an action that can be implemented in a relatively short time in order to improve the survival of desirable species and protect public trust resources, public trust resource protection cannot be achieved solely through flows – habitat restoration also is needed. One cannot substitute for the other; both flow improvements and habitat restoration are essential to protecting public trust resources.

1.3 Background and Next Steps

Informational Proceeding

The State Water Board held an informational proceeding on March 22, 23, and 24, 2010, to receive scientific information from technical experts on the Delta outflows needed to protect public trust resources. The State Water Board also received information at the proceeding on flow criteria for inflow to the Delta from the Sacramento and San Joaquin rivers and Delta hydrodynamics. The State Water Board did not solicit information on the need for water for other beneficial uses, including the amount of water needed for human health and safety, during the informational proceeding. Nor did the State Water Board consider other policy considerations, such as the state goal of providing a decent home and suitable living environment for every Californian.

Analytical Methods

The State Water Board received a wide range of recommendations for the volume, quantity and timing of flow necessary to protect public trust resources. Recommendations were also received on non-flow related measures. State Water Board determinations of flow criteria rely upon four types of information:

- Unimpaired flows
- Historical impaired inflows that supported more desirable ecological conditions
- Statistical relationships between flow and native species abundance
- Ecological functions-based analysis for desirable species and ecosystem attributes

The State Water Board emphasizes, however, information based on ecological functions, followed by information on statistical relationships between flow and native species abundance.

In all cases, the flow criteria contained in this report are those supported by the best available scientific information submitted into the record for this proceeding. The conceptual bases for all of the criteria in this report are supported by scientific information on function-based species or ecosystem needs. In other words, there is sufficiently strong scientific evidence to support the need for flows necessary to support particular functions. This does not necessarily mean that there is scientific evidence to support *specific* numeric criteria. Criteria are therefore divided into two categories: Category “A” criteria have more and better scientific information, with less uncertainty, to support specific numeric criteria than do Category “B” criteria. The State Water Board followed the following steps to develop flow criteria and other measures:

1. Establish general goals and objectives for protection of public trust resources in the Delta
2. Identify species to include based on ecological, recreational, or commercial importance.
3. Review and summarize species life history requirements
4. Summarize numeric and other criteria for each of: Delta outflow, Sacramento River inflow, San Joaquin River inflow, and Hydrodynamics, including Old and Middle River flows
5. Review other flow-related and non-flow measures that should be considered
6. Provide summary determinations for flow criteria and other measures

In developing its flow criteria, the State Water Board reviewed the life history requirements of the following pelagic and anadromous species:

- Chinook Salmon (various runs)
- American Shad.
- Longfin Smelt
- Delta Smelt
- Sacramento Splittail
- Starry Flounder
- Bay Shrimp
- Zooplankton

The flow criteria needed to protect public trust resources are more than just the sum of each species-specific flow need. The State Water Board also considered the following issues to make its flow criteria determinations:

- Variability, flow paths, and the natural hydrograph
- Floodplain activation and other habitat improvements

- Water quality and contaminants
- Cold water pool management
- Adaptive management

The Board also made other specific determinations for other measures based on review of these issues.

Regulatory Authority of the State Water Board

The State Water Board was established in 1967 as the State agency with jurisdiction to administer California's water resources. The State Water Board is responsible for water allocation as well as for water quality planning and water pollution control. In carrying out its water quality planning functions under both State and federal law, the State Water Board formulates and adopts state policy for water quality control, which includes water quality principles and guidelines for long-range resource planning, water quality objectives, and other principles and guidelines deemed essential by the State Water Board for water quality control. The State Water Board has adopted a Water Quality Control Plan for the Delta (Bay-Delta Plan). The plan is implemented in part through conditions imposed in both water quality and water right permits.

The State Water Board administers the water rights program for the State, including issuing water right permits. More than two-thirds of the residents of California and more than two million acres of highly productive farmlands receive water exported from the Delta, primarily, although not exclusively, through the SWP and CVP. In addition to the SWP and CVP, there are many other diversions from the Delta and from tributaries to the Delta including the East Bay Municipal Utilities District, the San Francisco Public Utilities Commission, and Contra Costa Water District, to name a few.

Regulatory Actions by Other Agencies

In addition to the State Water Board, other state and federal agencies have authority to take regulatory action that can affect Delta inflows, outflows, and hydrodynamics. As indicated below, the United States Fish and Wildlife Service (USFWS), the National Marine Fisheries Service (NMFS), and the California Department of Fish and Game (DFG) have authority to impose regulatory conditions that affect water diversions from the Delta. The Federal Energy Regulatory Commission (FERC) also has authority over non-federal hydropower projects that can change the timing and quantity of inflows to the Delta. Over the next six years, there are 16 hydropower projects on tributaries to the Sacramento and San Joaquin rivers with potential to affect Delta tributary flows that have ongoing or pending proceedings before the FERC.

Next Steps

The State Water Board will submit its flow criteria determinations to the Council for its information within 30 days of completing its determinations as required by Water Code section 85086.

The flow criteria contained in this report will be submitted to the Council to inform the Delta Plan. The Council is required to develop the Delta Plan to implement the State's co-equal goals of providing a more reliable water supply for California and protecting, restoring, and enhancing the Delta ecosystem. The Council is to develop the Delta Plan by January 2012.

The flow criteria will also inform the BDCP. The BDCP is a multispecies conservation plan being developed pursuant to the ESA and the State Natural Community Conservation Planning Act (NCCPA), administered by the USFWS and the NMFS and the DFG, respectively. The

CESA and the federal ESA generally prohibit the "take" of species protected pursuant to the acts. Both acts contain provisions that allow entities to seek approvals from the resources agencies, which approvals allow limited take of protected species under some circumstances. The BDCP is intended to meet all regulatory requirements necessary for USFWS and NMFS to issue Incidental Take Permits to allow incidental take of all proposed covered species as a result of covered activities undertaken by DWR, certain SWP contractors, and Mirant Corporation, and to issue biological opinions under the ESA to authorize incidental take for covered actions undertaken by USBR and CVP contractors. The BDCP is also intended to address all of the requirements of the NCCPA for aquatic, wetland, and terrestrial covered species of fish, wildlife, and plants and Delta natural communities affected by BDCP actions and is intended to provide sufficient information for DFG to issue permits under the CESA for the taking of the species proposed for coverage under the BDCP.

Finally, the flow criteria in this report will also inform the State Water Board's on-going and subsequent proceedings, including the review and development of flow objectives in the San Joaquin River, a comprehensive update to the 2006 Bay-Delta Plan, and the associated water rights proceedings to implement these Bay-Delta Plan updates.

2. Introduction

The purpose of this report is to identify new flow criteria for the Sacramento-San Joaquin Delta (Delta) ecosystem to protect public trust resources in accordance with the Delta Reform Act of 2009, Water Code § 85000 et seq. The flow criteria, which do not have any regulatory or adjudicative effect, may be used to inform planning decisions for the new Delta Plan being prepared by the newly created Delta Stewardship Council (Council) and the Bay Delta Conservation Plan (BDCP). The public trust resources that are the subject of this proceeding include those resources affected by flow, namely, native and valued resident and migratory aquatic species, habitats, and ecosystem processes. The State Water Resources Control Board (State Water Board or Board) has developed flow criteria to protect these resources that incorporate measures regarding Delta outflows and Delta inflows and has recommended other measures relevant to the protection of public trust resources. After approval by the State Water Board, this report will be submitted to the Council.

3. Purpose and Background

3.1 Background and Scope of Report

Pursuant to Water Code section 85086, subdivision (c), enacted on November 12, 2009, in Senate Bill No. 1 of the 2009-2010 Seventh Extraordinary Session (Stats. 2009 (7th Ex. Sess.) ch. 5, § 39) (SB 1), the State Water Board is required to "develop new flow criteria for the Delta ecosystem necessary to protect public trust resources." The purpose of this report is to comply with the Legislature's mandate to the State Water Board.

Given the limited amount of time the State Water Board had to develop the criteria, the Board initially focused on Delta outflow conditions as a primary driver of ecosystem functions in the Delta. In determining the extent of protection to be afforded public trust resources through the development of the flow criteria, the State Water Board considered the broad goals of the planning efforts the criteria are intended to inform, including restoring and promoting viable, self-sustaining populations of aquatic species. The specific goals for protection are discussed in more detail below.

The notice for this proceeding focused the proceeding on Delta outflows. During the proceeding, however, the State Water Board received useful information from participants regarding Sacramento River inflows, San Joaquin River inflows, and Delta hydrodynamics (including Old and Middle River flows, San Joaquin River at Jersey Point flows, and San Joaquin River inflow to export ratios) that is relevant to protection of public trust resources in the Delta ecosystem. The hydrodynamic criteria included in this reportare largely dependent on exports and on San Joaquin River inflows, and do not directly affect the outflows considered in this proceeding. The State Water Board believes, however, that this information should be transmitted to the Council for its use in informing the Delta Plan and BDCP. Because the notice for the proceeding focused on Delta outflows, and some of the participants did not submit scientific information on inflows and hydrodynamics for the State Water Board's consideration, the record for inflows and hydrodynamics may not be as complete, and the analyses for these flow parameters accordingly may be limited. As a result, these criteria do not constitute formal criteria within the scope of the informational proceeding as noticed, but instead are submitted to the Council with the acknowledgement that they are based on the limited information received by the State Water Board.

3.1.1 The Legislative Requirements

In November 2009, legislation was enacted comprising a comprehensive water package for California. In general, the legislation is designed to achieve a reliable water supply for future generations and to restore the Delta and other ecologically sensitive areas. The package includes a bond bill and four policy bills, one of which is SB 1.

In the Delta Reform Act, the Legislature found and declared, among other matters, that:

> "The Sacramento-San Joaquin Delta watershed and California's water infrastructure are in crisis and existing Delta policies are not sustainable. Resolving the crisis requires fundamental reorganization of the state's management of Delta watershed resources. (Wat. Code, § 85001, subd. (a).)
>
> By enacting this division, it is the intent of the Legislature to provide for the sustainable management of the Sacramento-San Joaquin Delta ecosystem, to provide for a more reliable water supply for the state, to protect and enhance the quality of water supply from the Delta, and to establish a governance structure that will direct efforts across state agencies to develop a legally enforceable Delta Plan." (Wat. Code, § 85001, subd. (c).)

Among other provisions, SB 1 establishes the Delta Stewardship Council, which is charged with responsibility to develop, adopt, and commence implementation of a Delta Plan, a comprehensive, long-term management plan for the Delta, by January 1, 2012. The legislation also establishes requirements for inclusion of the BDCP, a multispecies conservation plan, into the Delta Plan. For purposes of informing the planning efforts for the Delta Plan and BDCP, SB 1 requires the State Water Board, pursuant to its public trust obligations, to develop new flow criteria for the Delta ecosystem necessary to protect public trust resources. (Wat. Code, § 85086, subd. (c).) Regarding the flow criteria, the Legislature provided that the flow criteria shall:

- include the volume, quality, and timing of water necessary for the Delta ecosystem;
- be developed within nine months of enactment of SB 1;

- be submitted to the Council within 30 days of completion;
- inform planning decisions for the Delta Plan and the BDCP;
- be based on a review of existing water quality objectives and the use of the best available scientific information;
- be developed in a public process by the State Water Board as a result of an informational proceeding conducted under the board's regulations set forth at California Code of Regulations, title 23, sections 649-649.5, in which all interested persons have an opportunity to participate.
- not be considered predecisional with regard to any subsequent State Water Board consideration of a permit, including any permit in connection with a final BDCP;
- inform any State Water Board order approving a change in the point of diversion of the State Water Project or the federal Central Valley Project from the southern Delta to a point on the Sacramento River;

3.1.2 The State Water Board's Public Trust Obligations

As stated above, SB 1 requires the State Water Board to develop new flow criteria to protect public trust resources in the Delta ecosystem pursuant to the Board's public trust obligations. The purpose of the public trust is to protect commerce, navigation, fisheries, recreation, ecological values, and fish and wildlife habitat. Under the public trust doctrine, the State of California has sovereign authority to exercise continuous supervision and control over the navigable waters of the state and the lands underlying those waters. (*National Audubon Society v*. *Superior Court* (*Audubon*) (1983) 33 Cal.3d 419.) A variant of the public trust doctrine also applies to activities that harm a fishery in non-navigable waters. (*People v. Truckee Lumber Co.* (1897) 116 Cal. 397, see *California Trout, Inc. v. State Water Resources Control Board* (1989) 207 Cal.App.3d 585, 630.)

In *Audubon*, the California Supreme Court held that California water law is an integration of the public trust doctrine and the appropriative water right system. (*Audubon*, *supra*, 33 Cal.3d at p. 426.) The state has an affirmative duty to take the public trust into account in the planning and allocation of water resources. The public trust doctrine requires the State Water Board to consider the effect of a diversion or use of water on streams, lakes, or other bodies of water, and "preserve, so far as consistent with the public interest, the uses protected by the trust." (*Audubon*, *supra*, 33 Cal.3d at p. 447.) Thus, before the State Water Board approves a water diversion, it must consider the effect of the diversion on public trust resources and avoid or minimize any harm to those resources where feasible. (*Id.* at p. 426.) Even after an appropriation has been approved, the public trust imposes a duty of continuing supervision. (*Id.* at p. 447*.)*

The purpose of this proceeding is to receive scientific information and develop flow criteria pursuant to the State Water Board's public trust obligations. In this forum, the State Water Board will not consider the allocation of water resources, the application of the public trust to a particular water diversion or use, or any balancing between potentially competing public trust resources. The State Water Board has also not considered minimum or maximum flows needed to protect public health and safety. Any such application of the State Water Board's public trust responsibilities, including any balancing of public trust values and water rights, would be conducted through an adjudicative or regulatory proceeding. Instead, the State Water Board's focus here is solely on identifying public trust resources in the Delta ecosystem within the scope of SB 1 and determining the flows necessary to protect those resources.

3.1.3 Public Process

The Water Code directs the State Water Board to develop the flow criteria in a public process in the form of an informational proceeding conducted pursuant to the Board's regulations. (Wat. Code, § 85086, subd. (c)(1); Cal. Code Regs., tit. 23, §§ 649-649.5.) The State Water Board conducted this informational proceeding to receive the best available scientific information to use in carrying out its mandate to develop new flow criteria for the Delta ecosystem necessary to protect public trust resources. (Wat. Code, § 85086, subd. (c)(1).) On December 16, 2009, the State Water Board issued the notice for the public informational proceeding to develop the flow criteria. For the informational proceeding, the State Water Board required the participants to submit a Notice of Intent to Appear by January 5, 2010. The State Water Board received 55 Notices of Intent to Appear for the informational proceeding.

On January 7, 2010, the State Water Board conducted a pre-proceeding conference to discuss the procedures for the informational proceeding mandated by Water Code section 85086, subdivision (c). Topics for the pre-proceeding conference included coordination of joint presentations, use of presentation panels, time limits on presentations, and electronic submittal of written information. The conference was used only to discuss procedural matters and did not address any substantive issues.

On January 29, 2010, the State Water Board issued a revised notice amending certain procedural requirements and posted a preliminary list of reference documents. Written testimony, exhibits, and written summaries, along with lists of witnesses and lists of exhibits, were due on February 16, 2010. The State Water Board gave participants and interested parties an opportunity to submit written questions regarding the written testimony, exhibits, and written summaries by March 9, 2010. All submittals were posted on the State Water Board's website.

On March 22 through 24, the State Water Board held the public informational proceeding to develop flow criteria for the Delta ecosystem. The State Water Board received a technical introduction by the Delta Environmental Flows Group (DEFG)[4] at the beginning of the proceeding. The group prepared two documents and an associated list of references that were submitted as State Water Board exhibits:

- Key Points on Delta Environmental Flows for the State Water Resources Control Board, February 2010
- Changing Ecosystems: a Brief Ecological History of the Delta, February 2010

A subset of the group, the UC Davis Delta Solutions Group, prepared three additional papers (which were also submitted as State Water Board exhibits):

- Habitat Variability and Complexity in the Upper San Francisco Estuary
- On Developing Prescriptions for Freshwater Flows to Sustain Desirable Fishes in the Sacramento-San Joaquin Delta

---

[4] The Delta Environmental Flows Group consists of William Bennett, Jon Burau, Cliff Dahm, Chris Enright, Fred Feyrer, William Fleenor, Bruce Herbold, Wim Kimmerer, Jay Lund, Peter Moyle, and Matthew Nobriga. This group of professors, researchers, and staff from various resource agencies was assembled by State Water Board staff with the intent of informing the Delta flow criteria informational proceeding.

- Ecosystem Investments for the Sacramento-San Joaquin Delta: Development of a Portfolio Framework

Over the course of the hearing, the State Water Board received information from expert witnesses in response to questions posed by Board members. The expert witnesses, representing various participants, as well as experts from the DEFG, were grouped into five panels in order to focus the discussions on specific aspects of the Delta flow criteria. These panels addressed the following topics: hydrology, pelagic fish, anadromous fish, other stressors, and hydrodynamics.

At the conclusion of the informational proceeding, participants were given approximately 20 days to submit closing comments. On July 21, 2010, the draft report was released for public review and comment.

3.1.4 Scope of This Report

Due to the limited nine-month time period in which the State Water Board must develop new flow criteria, the notice for the informational proceeding requested information on what volume, quality, and timing of Delta outflows are necessary under different hydrological conditions to protect public trust resources pursuant to the State Water Board's public trust obligations and the requirements of SB 1. Delta outflows are of critical importance to various ecosystem functions, water supply, habitat restoration, and other planning issues. The effect of Delta outflows in protecting public trust resources necessarily involves complex interactions with other flows in the Delta and with non-flow parameters including water quality and the physical configuration of the Delta. This report recognizes the role of source inflows used to meet Delta outflows, Delta hydrodynamics, tidal action, hydrology, water diversions, water project operations, and cold water pool storage in upstream reservoirs, and relies upon information submitted on these related topics to inform its determinations.

The State Water Board intends that the flow criteria developed in this proceeding should meet the following general goal regarding the protection of public trust resources:

- Halt the population decline and increase populations of native species as well as species of commercial and recreational importance by providing sufficient flow and water quality at appropriate times to promote viable life stages of these species.

To meet this goal, the State Water Board also sought to develop criteria that are comprehensive and that can be implemented without undue complexity. This report is limited to consideration of flow criteria needed under the existing physical conditions, so therefore does not consider or anticipate changes in habitat or modification of water conveyance facilities. The State Water Board does, however, identify other measures that should be considered in conjunction with, and to complement, the flow criteria.

A number of factors outside the scope of the legislative mandate to develop new flow criteria could affect public trust resources and some other factors could affect the interaction of flows with the environment. These factors include contaminants, water quality parameters, future habitat restoration measures, water conveyance facilities modification, and the presence of non-native species.

3.1.5 Concurrent State Water Board Processes

The State Water Board has a number of ongoing proceedings that may be informed by the development of flow criteria. Some of these proceedings will result in regulatory requirements that affect flow, or otherwise affect the volume, quality, or timing of flows into, within, or out of the Delta. In July 2008, the State Water Board adopted a strategic work plan for actions to protect beneficial uses of the San Francisco Bay/Delta (Bay-Delta). In accordance with the work plan, the State Water Board recently completed a periodic review of the 2006 Water Quality Control Plan for the Bay-DeltaEstuary (Bay-Delta Plan) that recommended the Delta Outflow objectives, as well as other flow objectives, for further review in the water quality control planning process. Currently, the State Water Board is in the process of reviewing the southern Delta salinity and the San Joaquin River flow objectives contained in the Bay-Delta Plan.

Clean Water Act Water Quality Certifications

Several non-federal hydropower projects with potential to affect Delta tributary flows have ongoing or pending proceedings before the Federal Energy Regulatory Commission (FERC) that will result in the issuance of new licenses that will govern operations for the 30-50 year term. The relicensing process allows state and federal agencies to prescribe conditions to achieve certain objectives such as state water quality standards and the protection of listed species. New license conditions may include instreams flows requirements or other conditions to protect aquatic species. For example, the new license for the Oroville Dam will require changes in minimum flow requirements and changes in facilities and operations to meet certain water temperature requirements to protect Chinook salmon, steelhead, and green sturgeon. By 2016, more than 25 Delta tributary dams will go through the relicensing process.

The State Water Board will rely upon the FERC license application and the National Environmental Policy Act (NEPA) and California Environmental Quality Act (CEQA) documents prepared for the projects, and may require submittal of additional data or studies, to inform its Clean Water Act Section 401 Water Quality Certifications for the projects. The Board’s water quality certification will be issued as soon as possible after the environmental documents and any other needed studies are complete, after which FERC will issue a new license. The conditions in the water quality certification are mandatory and must be included in the FERC license.

Information developed as part of the relicensing of these projects will be used to inform on-going Bay Delta proceedings, and any information developed in the State Water Board’s Bay Delta proceedings will be used to inform the two water quality certifications.

Table 1 summarizes the dams, tributaries, and license expiration dates for FERC projects in the Delta watershed. Several of these projects are upstream of major dams and reservoirs in the Sacramento and San Joaquin river watershed so operational changes would have little or no direct effect upon Delta flows.

Table 1. Delta Watershed FERC Projects

River	Dam(s)	Storage Capacity (acre-feet)	Owner	Status of Proceeding	FERC License Expiration
Feather	Oroville	3.5 million	Department of Water Resources (DWR)	Near completion	January 2007
West Branch Feather	Philbrook, Round Valley	6,200	Pacific Gas and Electric Company (PG&E)	Near Completion	October 2009
South Feather	Little Grass Valley	90,000	South Feather Water and Power Agency	Near completion	March 2009
Upper North Fork Feather	Lake Almanor	1.1 million	PG&E	Near Completion	October 2004
Pit River	McCloud, Iron Canyon,Pit 6, 7	110,000	PG&E	Ongoing	July 2011
North Yuba	New Bullards Bar	970,000	Yuba County Water Agency	Pre-Licensing meetings started	March 2016
Middle and South Yuba, Bear	Yuba-Bear Project, 10+ dams	210,000	Nevada Irrigation District	Ongoing	April 2013
Middle & South Yuba, Bear	Drum-Spaulding Project, 10+ dams	150,000	PG&E	Ongoing	April 2013
Middle Fork American River	French Meadows, Hell Hole	340,000	Placer County Water Agency	Ongoing	February 2013
South Fork American River	Loon Lake, Slab Creek	400,000	Sacramento Municipal Utility District	Near completion	July 2007
South Fork American River	Chili Bar	1,300	PG&E	Near completion	July 2007
Tuolumne	New Don Pedro	2 million	Turlock Irrigation District	To commence late 2010	April 2016
Merced	New Exchequer/ McSwain	1 million	Merced Irrigation District	Ongoing	February 2014
Merced	Merced Falls	650	PG&E	Ongoing	February 2014
San Joaquin	Mammoth Pool	120,000	Southern California Edison	Near Completion	November 2007
San Joaquin	Huntington, Shaver, Florence	320,000	Southern California Edison	Near Completion	February 2009

3.1.6 Delta Stewardship Council and Use of This Report

In accordance with the legislative requirements described above, the State Water Board will submit this report, containing its Delta flow criteria determinations, to the Council within 30 days after this report has been completed. This report will be deemed complete on the date the State Water Board adopts a resolution approving transmittal of the report to the Council.

Additionally, SB 1 requires any order approving a change in the point of diversion of the State Water Project (SWP) or the Central Valley Project (CVP) from the southern Delta to a point on the Sacramento River to include appropriate flow criteria and to be informed by the analysis in this report. (Wat. Code, § 85086, subd. (c)(2).) The statute also specifies, however, that the criteria shall not be considered predecisional with respect to the State Water Board's subsequent consideration of a permit. (*Id.*, § 85086, subd. (c)(1).) Thus, any process with regulatory or adjudicative effect must take place through the State Water Board's water quality control planning or water rights processes in conformance with applicable law. Any person who wishes to introduce information produced during this informational proceeding, or the State Water Board's ultimate determinations in this report, into a later rulemaking or adjudicative proceeding must comply with the rules for submission of information or evidence applicable to that proceeding.

3.2 Regulatory Setting

3.2.1 History of Delta Flow Requirements

The State Water Rights Board (a predecessor to the State Water Board) first had an opportunity to consider flow requirements in the Delta when it approved water rights for much of the U.S. Bureau of Reclamation's (USBR) CVP in Water Right Decision 990 (D-990) (adopted in 1961), but it did not impose any fish protection conditions in D-990. In 1967, the State Water Rights Board included fish protections in D-1275 approving the water right permits for the SWP. Effective December 1, 1967, the State Water Rights Board and the State Water Quality Control Board were merged in a new agency, the State Water Board, which exercises both the water quality and water rights adjudicatory and regulatory functions of the state. The State Water Board adopted a new water quality control policy for the Delta and Suisun Marsh in October 1968, in Resolution 68-17. The resolution specified that the objectives would be implemented through conditions on the water rights of the CVP and SWP.

To implement the water quality objectives, the State Water Board adopted Water Right Decision 1379 (D-1379) in 1971[5]. D-1379 established new water quality requirements in both the SWP and CVP permits, including fish flows, and rescinded the previous SWP requirements from D-1275 and D-1291. D-1379 was stayed by the courts and eventually was superseded by Water Right Decision 1485 (D-1485).

In April 1973, in Resolution 73-16, the State Water Board adopted a water quality control plan to supplement the State water quality control policies for the Delta.

---

[5] In 1971, the State Water Board approved interim regional water quality control plans for the entire State, including the Delta and Suisun Marsh. Subsequently, the State Water Board approved long-term objectives for the Delta and Suisun Marsh in the regional plans for the Sacramento-San Joaquin Delta Basin and the San Francisco Bay Basin.

In August 1978, the State Water Board adopted both D-1485 and the 1978 Delta Plan. Together the 1978 Delta Plan and D-1485 revised existing objectives for flow and salinity in the Delta's channels and ordered USBR and DWR to meet the objectives. In 1987, the State Water Board commenced proceedings to review the 1978 Delta Plan and D-1485. The Board held a hearing at numerous venues in California and released a draft water quality control planin 1988, but subsequently withdrew it and resumed further proceedings.

In 1991, the State Water Board adopted the 1991 water quality control plan. This is the first Bay-Delta plan to adopt objectives for dissolved oxygen (DO) and temperature. The 1991 Bay-Delta plan did not amend either the flow or water project operations objectives adopted in the 1978 Delta Plan.[6] The United States Environmental Protection Agency (USEPA) approved the objectives in the plan for salinity for municipal, industrial, and agricultural uses, and approved the new DO objectives for fish and wildlife, but disapproved the Delta outflow objectives for the protection of fish and wildlife carried over from the 1978 Delta Plan. The USEPA adopted its own Delta outflow standards in 1994 to supersede the State's objectives.

In the summer of 1994, after the USEPA had initiated its process to develop standards for the Delta, the State and federal agencies with responsibility for management of Bay-Delta resources signed a Framework Agreement, agreeing that: (1) the State Water Board would update and revise its 1991 Bay-Delta Plan to meet federal requirements and would initiate a water right proceeding to implement the plan, after which the USEPA would withdraw its fish and wildlife objectives; (2) a group would be formed to coordinate operations of the SWP and CVP with all regulatory requirements in the Delta; and (3) the State and federal governments would undertake a joint long-term solution finding process to resolve issues in the Bay-Delta. In December 1994, representatives of the State and federal governments, water users, and environmental interests agreed to the implementation of a Bay-Delta protection plan. The plan and institutional documents to implement it are contained in a document titled "Principles for Agreement on Bay-Delta Standards between the State of California and the Federal Government." This is commonly referred to as the "Bay-Delta Accord" or "Principles Agreement."

In 1995 the State Water Board adopted the 1995 Bay-Delta Plan, which is consistent with the Principles Agreement.[7] In response to a water right change petition filed by DWR and USBR, the State Water Board then adopted Water Right orders that temporarily allowed DWR and USBR to operate the SWP and CVP in accordance with the 1995 Plan while the State Water Board conducted water right proceedings for a water right decision that would implement the 1995 Bay-Delta Plan. The hearing commenced in 1998 and concluded in 1999. During the 1998-99 water right hearing, DWR and USBR and their water supply contractors negotiated with a number of parties. In 1999, the State Water Board adopted Decision 1641 (D-1641) and subsequently revised D-1641 in 2000.

---

[6] After adopting the 1991 Plan, the State Water Board conducted a proceeding to establish interim water right requirements for the protection of public trust uses in the Delta. The State Water Board released a draft water right decision known as "Decision 1630" (D-1630), but did not adopt it.

[7] USEPA approved the 1995 Bay-Delta Plan. By approving the 1995 Bay-Delta Plan, the USEPA supplanted its own water quality standards with the standards in the 1995 Bay-Delta Plan. (*State Water Resources Control Board Cases* (2006) 136 Cal.App.4th 674,774-775 [39 Cal.Rptr.3d 189]; 33 U.S.C. § 1313(c)(2)(A),(c)(3).)

3.2.2 Current State Water Board Flow Requirements

The current Bay-Delta flow requirements are contained in the 2006 Bay-Delta Plan and in D-1641. D-1641 implements portions of the 1995 Bay-Delta Plan. D-1641 accepts the contribution that certain entities, through their agreements, will make to meet the flow-dependent water quality objectives in the 1995 Plan, and continues the responsibility of DWR and USBR for the remaining measures to meet the flow-dependent objectives and other responsibilities. In addition, D-1641 recognizes the San Joaquin River Agreement (SJRA) and approves, for a period of twelve years, the conduct of the Vernalis Adaptive Management Plan (VAMP) under the SJRA instead of meeting the San Joaquin River pulse flow objectives in the 1995 Plan. The 2006 Bay-Delta Plan is consistent with D-1641 and makes only minor changes to the 1995 Bay-Delta Plan, allowing the staged implementation of the San Joaquin River spring pulse flow objectives and other minor changes. The 2006 Bay-Delta Plan also identifies a number of issues requiring additional review and planning including: the pelagic organism decline (POD), climate change, Delta and Central Valley salinity, and San Joaquin River flows.

Current Delta outflow requirements, set forth in Tables 3 and 4 in both the 2006 Bay-Delta Plan and D-1641, take two basic forms based on water year type and season: 1) specific numeric Delta outflow requirements; and 2) position of X2, the horizontal distance in kilometers up the axis of the estuary from the Golden Gate Bridge to where the tidally averaged near-bottom salinity is 2 practical salinity units (psu). The Delta outflow requirements are expressed in Table 3 as a Net Delta Outflow Index (NDOI). The NDOI is a calculated flow expressed as Delta Inflow, minus net Delta consumptive use, minus Delta exports. Each component is calculated as described in the 2006 Bay-Delta Plan and D-1641. An electrical conductivity (EC) measurement of 2.64 mmhos/cm at Collinsville station C2 can be substituted for the NDOI during February through June. The most downstream location of either the maximum daily average or the 14-day running average of this EC level is commonly referred to as the position of "X2" in the Delta. Table 4 specifies EC measurements at two specific locations and alternatively allows an NDOI calculation at these locations.

3.2.3 Special Status Species

The California Endangered Species Act (CESA) states that all native species of fishes, amphibians, reptiles, birds, mammals, invertebrates, and plants, and their habitats, threatened with extinction and those experiencing a significant decline which, if not halted, would lead to a threatened or endangered designation, will be protected or preserved. The federal Endangered Species Act of 1973 (ESA) provides for the conservation of species that are endangered or threatened throughout all or a significant portion of their range, and the conservation of the ecosystems on which they depend. A number of species discussed in this report are afforded protections under CESA and ESA. These species and the protections are discussed below.

The longfin smelt (*Spirinchus thaleichthys*) is currently a candidate for threatened species status under the CESA. (DFG 1, p. 9.) In March 2009, the California Fish and Game Commission (Commission) made a final determination that the listing of longfin smelt as a threatened species was warranted and the rulemaking process to officially add the species to the CESA list of threatened species found in the California Code of Regulations was initiated. Upon completion of this rulemaking process, the longfin smelt's status will officially change from candidate to threatened. (DFG 1, p. 9.) Its status remains unresolved at the federal level. (USFWS 2009.) The delta smelt (*Hypomesus transpacificus*) is listed as endangered and threatened pursuant to the CESA and ESA, respectively. (DFG 1, p. 14; USFWS 1993.) In April 2010, the United States Fish and Wildlife Service (USFWS) considered a petition to reclassify the delta smelt from threatened to endangered. After review of all available scientific and commercial information, the USFWS found that reclassifying the delta smelt from a threatened to an endangered species is warranted, but precluded by other higher priority listing actions. (USFWS 2010.)

Sacramento winter-run Chinook salmon *(Oncorhynchus tshawytscha)* is listed as endangered pursuant to the CESA and ESA. (NMFS 1994; NMFS 2005; DFG 2010.) Central Valley spring-run Chinook salmon (*O. tshawytscha*) is listed as threatened pursuant to both the CESA and ESA. (NMFS 1999; NMFS 2005; DFG 2010.) Central Valley fall/late fall-run Chinook salmon (*O. tshawytscha*) are classified as species of special concern by the National Marine Fisheries Service (NMFS). (NMFS 2004.) Central Valley steelhead (*O. mykiss*) is listed as threatened under the ESA (NMFS 1998; NMFS 2006a.) Southern Distinct Population Segment of North American green sturgeon (*Acipenser medirostris*) is listed as threatened under the ESA. (NMFS 2006b.)

3.2.4 State Incidental Take Permit for Longfin Smelt

The CESA prohibits the take[8] of any species of wildlife designated as an endangered, threatened, or candidate species[9] by the Commission. The Department of Fish and Game (DFG), however, may authorize the take of such species by permit if certain conditions are met (Cal. Code Regs., tit 14, § 783.4). In 2009, DFG issued an Incidental Take Permit for Longfin Smelt to the DWR for the on-going and long-term operation of the SWP. The permit specifies a number of conditions, including two flow measures (Conditions 5.1 and 5.2) intended to minimize take of the longfin smelt and provide partial mitigation for the remaining take by: 1) minimizing entrainment; 2) improving estuarine processes and flow; 3) improving downstream transport of longfin smelt larvae; and 4) providing more water that is used as habitat (increasing habitat quality and quantity) by longfin smelt than would otherwise be provided by the SWP.

Longfin Smelt Incidental Take Permit (2009), p. 9-10, Condition 5.1.
This Condition is not likely to occur in many years. To protect adult longfin smelt migration and spawning during December through February period, the Smelt Working Group (SWG) or DFG SWG personnel staff shall provide Old and Middle River (OMR) flow advice to the Water Operations Management Team (WOMT) and to Director of DFG weekly. The SWG will provide the advice when either: 1) the cumulative salvage index (defined as the total longfin smelt salvage at the CVP and SWP in the December through February period divided by the immediately previous FMWT longfin smelt annual abundance index) exceeds five (5); or 2) when a review of all abundance and distribution survey data and other pertinent biological factors that influence the entrainment risk of adult longfin smelt indicate OMR flow advise is warranted. Permittee shall ensure the OMR flow requirement is met by maintaining the OMR flow 14-day running average is no more negative than -5,000 cfs and the initial 5-day running average is not more negative than -6,250 cfs. During any time OMR flow restrictions for the USFWS's 2008 Biological Opinion for delta smelt are being implemented, this condition (5.1) shall not result in additional OMR flow requirements for protection of adult longfin smelt. Once spawning has been detected in the system, this Condition terminates and 5.2 begins. Condition 5.1 is not required or would cease if previously required when river flows are 1) > 55,000 cfs in

---

[8] Pursuant to Fish and Game Code section 86, "'Take' means hunt, pursue, catch, capture, or kill, or attempt to hunt, pursue, catch, capture or kill."

[9] "Candidate species" are species of wildlife that have not yet been placed on the list of endangered species or the list of threatened species, but which are under formal consideration for listing pursuant to Fish and Game Code section 2074.2

the Sacramento River at Rio Vista; or 2) > 8,000 cfs in the San Joaquin River at Vernalis. If flows go below 40,000 cfs in the Sacramento River at Rio Vista or 5,000 cfs in the San Joaquin River at Vernalis, the OMR flow in Condition 5.1 shall resume if triggered previously. Review of survey data and other pertinent biological factors that influence the entrainment risk of adult longfin smelt may result in a recommendation to relax or cease an OMR flow requirement.

Longfin Smelt Incidental Take Permit (2009), p. 10-11, Condition 5.2.
To protect larval and juvenile longfin smelt during January -June period, the SWG or DFG SWG personnel shall provide OMR flow advice to the WOMT and the DFG Director weekly. The OMR flow advice shall be an OMR flow between -1,250 and -5,000 cfs and be based on review of survey data, including all of the distributional and abundance data, and other pertinent biological factors that influence the entrainment risk of larval and juvenile longfin smelt. When a single Smelt Larval Survey (SLS) or 20 mm Survey sampling period results in: 1) longfin smelt larvae or juveniles found in 8 or more of the 12 SLS or 20mm stations in the central and south Delta (Stations 809, 812, 901, 910, 912, 918, 919) or, 2) catch per tow exceeds 15 longfin smelt larvae or juveniles in 4 or more of the 12 survey stations listed above, OMR flow advice shall be warranted. Permittee shall ensure the OMR flow requirement is met by maintaining the OMR flow 14-day running average no more negative than the required OMR flow and the 5-day running average is within 25% of the required OMR. This Conditions OMR flow requirement is likely to vary throughout Jan through June. Based on prior analysis, DFG has identified three likely scenarios that illustrate the typical entrainment risk level and protective measures for larval smelt over the period: High Entrainment Risk Period - Jan through Mar OMR range from -1,250 to -5,000 cfs; Medium Entrainment Risk Period - April and May OMR range from -2000 to -5,000 cfs, and Low Entrainment Risk Period - June OMR -5,000 cfs. When river flows are: 1) greater than 55,000 cfs in the Sacramento River at Rio Vista; or 2) greater than 8,000 cfs in the San Joaquin River at Vernalis, the Condition would not trigger or would be relaxed if triggered previously. Should flows go below 40,000 cfs in Sacramento River at Rio Vista or 5,000 cfs in the San Joaquin River at Vernalis, the Condition shall resume if triggered previously. In addition to river flows, the SWG or DFG SWG personnel review of all abundance and distribution survey data and other pertinent biological factors that influence the entrainment risk of longfin smelt may result in a recommendation by DFG to WOMT to relax or cease an OMR flow requirement.

3.2.5 Biological Opinions

In 2008 and 2009, the USBR and the DWR concluded consultations regarding the effects of continued long-term operations of the Central CVP and SWP with the USFWS and the NMFS, respectively. Those consultations led to the issuance of biological opinions that require implementation of reasonable and prudent alternatives (RPAs) to avoid jeopardizing the continued existence and potential for recovery of delta smelt (*Hypomesus transpacificus*), Sacramento River winter-run Chinook salmon *(Oncorhynchus tshawytscha)*, Central Valley spring-run Chinook salmon (*O. tshawytscha*), Central Valley steelhead (*O. mykiss*), Southern Distinct Population Segment of North American green sturgeon (*Acipenser medirostris*), and Southern Resident killer whales *(Orcinus orca)*.

Pursuant to Section 7 of the ESA, federal agencies must insure that their actions do not jeopardize the continued existence of threatened or endangered species or adversely modify their designated critical habitat. The regulations (50 CFR 402.02) implementing Section 7 of the ESA define RPAs as alternative actions, identified during formal consultation, that: 1) can be implemented in a manner consistent with the intended purpose of the action; 2) can be implemented consistent with the scope of the action agency’s legal authority and jurisdiction; 3) are economically and technologically feasible; and, 4) would, the USFWS or NMFS believes, avoid the likelihood of jeopardizing the continued existence of listed species or resulting in the destruction or adverse modification of critical habitat. (USFWS 2008, p.279.)

Numerous anthropogenic and other factors (e.g., pollutants and non-native species) that may adversely affect listed fish species in the region are not under the direct control of the CVP or the SWP and as such are not addressed in the biological opinions.

USFWS Biological Opinion

On December 15, 2008, the USFWS issued a biological opinion on the Long-Term Operational Criteria and Plan (OCAP) for coordination of the CVP and SWP (UFWS Opinion). The RPA in the USFWS Opinion, divided into six actions, applies to delta smelt and focuses primarily on managing flow regimes to reduce entrainment of delta smelt and on the extent of suitable water conditions in the Delta, as well as on construction or restoration of habitat. (USFWS 2008, pp.329-381.) Flow related components of the RPA include:

- A fixed duration action to protect pre-spawning adult delta smelt from entrainment during the first flush, and to provide advantageous hydrodynamic conditions early in the migration period. This action limits exports so that the average daily net OMR flow is no more negative than -2,000 cubic-feet per second (cfs) for a total duration of 14 days, with a 5-day running average no more negative than -2,500 cfs (within 25 percent) (Action 1, p.329).

- An adaptive process to continue to protect pre-spawning adults from entrainment and, to the extent possible, from adverse hydrodynamic conditions after the action identified above. The range of net daily OMR flows will be more no more negative than -1,250 to -5,000 cfs. From the onset of this action through its termination, the Delta Smelt Working Group would provide weekly recommendations for specific net OMR flows based upon review of the sampling data, from real-time salvage data at the CVP and SWP, and utilizing the most up-to-date technological expertise and knowledge relating population status and predicted distribution to monitored variables of flow and turbidity. The USFWS will make the final determination (Action 2, p.352).

- Upon completion of Actions 1 and 2 or when Delta water temperatures reach 12°C (based on a 3-station average of daily average water temperature at Mossdale, Antioch, and Rio Vista) or when a spent female delta smelt is detected in the trawls or at the salvage facilities, the projects shall operate to maintain net OMR flows no more negative than -1,250 to -5000 cfs based on a 14-day running average with a simultaneous 5-day running average within 25% of the applicable 14-day OMR flow requirement. Action continues until June 30th or when Delta water temperatures reach 25˚C, whichever comes first (Action 3, p.357).

- Improve fall habitat, both quality and quantity, for delta smelt through increasing Delta outflow during fall (fall X2). Subject to adaptive management, provide sufficient Delta outflow to maintain average X2 for September and October no greater (more eastward) than 74 km in the fall following wet years and 81km in the fall following above normal years. The monthly average X2 must be maintained at or seaward of these values for each individual month and not averaged over the two month period. In November, the inflow to CVP/SWP reservoirs in the Sacramento Basin will be added to reservoir releases to provide an added increment of Delta inflow and to augment Delta outflow up

- To minimize entrainment of larval and juvenile delta smelt at the State and federal south Delta export facilities or from being transported into the south and central Delta, where they could later become entrained, do not install the Head of Old River Barrier (HORB) if delta smelt entrainment is a concern. If installation of the HORB is not allowed, the agricultural barriers would be installed as described in the Project Description of the biological opinion. If installation of the HORB is allowed, the Temporary Barrier Project flap gates would be tied in the open position until May 15 (Action 5, p. 377).

- Implement habitat restoration activities designed to improve habitat conditions for delta smelt by enhancing food production and availability to supplement the benefits resulting from the flow actions described above. DWR shall implement a program to create or restore a minimum of 8,000 acres of intertidal and associated subtidal habitat in the Delta and Suisun Marsh. The restoration efforts shall begin within 12 months of signature of this biological opinion and be completed within a 10 year period (Action 6, p. 379).

NMFS Biological Opinion

On June 4, 2009, NMFS issued its Biological and Conference Opinion on the OCAP (NMFS Opinion), which provides RPA actions to protect winter-run and spring-run Chinook salmon, Central Valley steelhead, green sturgeon, and killer whales from project effects in the Delta and upstream areas. (NMFS 3.) The RPA consists of five actions with a total of 72 subsidiary actions. Included within the RPA are actions related to: formation of technical teams, research and adaptive management, monitoring and reporting, flow management, temperature management, gravel augmentation, fish passage and reintroduction, gate operations and installation (Red Bluff Diversion Dam, Delta Cross Channel Gate, South Delta Improvement Program), funding for fish screening, floodplain and other habitat restoration, hatchery management, export restrictions, CVP and SWP fish collection facility modifications, and fish collection and handling. The flow related components of the opinion include:

- In the Sacramento River Basin – flow requirements for Clear Creek; release requirements from Whiskeytown Dam for temperature management; cold water pool management of Shasta Reservoir; development of flow requirements for Wilkins Slough; and restoration of floodplain habitat in the lower Sacramento River basin to better protect Chinook salmon, steelhead, and green sturgeon. (*Id at* pp.587-611.)

- In the American River - flow requirements and cold water pool management requirements to provide protection for steelhead. (*Id at* pp. 611-619.)

- In the San Joaquin River Basin – cold water pool management, floodplain inundation flows, and flow requirements for the Stanislaus River (NMFS 3, pp. 619-628, Appendix 2-E) and an interim minimum flow schedule for the San Joaquin River at Vernalis during April and May effective through 2011 for the protection of steelhead. (*Id at* pp. 641-645.)

- In the Delta – Delta Cross-Channel Gate operational requirements; net negative flow requirements toward the export pumps in Old and Middle rivers; and export limitations based on a ratio of San Joaquin River flows to combined SWP and CVP export during April and May for the protection of Chinook salmon and steelhead. (*Id. at* pp. 628-660.)

It is important to note that the flow protections described in the project description and RPA are the minimum flows necessary to avoid jeopardy. (NMFS written summary, p.3.) In addition, NMFS considered provision of water to senior water rights holders to be non-discretionary for purposes of the ESA as it applies to Section 7 consultation with the USBR, which constrained development of RPA Shasta storage actions and flow schedules. San Joaquin River flows at Vernalis were constrained by the NMFS Opinion's scope extending only to CVP New Melones operations. Operations on other San Joaquin tributaries were not within the scope of the consultation. (*Id.*)

Recent Litigation

Both the USFWS Opinion and the NMFS Opinion are the subject of ongoing litigation in the United States District Court for the Eastern District of California. Plaintiffs challenged the validity of the opinions under various legal theories, including claims under the ESA and the NEPA. Most recently, this year plaintiffs Westlands Water District and San Luis Delta Mendota Water Authority sought preliminary injunctions against the implementation of certain RPAs identified by NMFS and USFWS in their biological opinions for the protection of Delta smelt and Central Valley steelhead and salmonids. In May 2010, Judge Wanger issued a ruling concluding that injunctive relief was appropriate with respect to the NMFS biological opinion PRA Action IV.2.1, which limits pumping based on San Joaquin River inflow from April 1 through May 31, and RPA Action IV.2.3, which imposes restrictions on negative OMR flows in generally between January 1 and June 15. Later that month, he also ruled that injunctive relief was appropriate with respect to RPA Component 2 of Action 3 of the USFWS Opinion, which requires net OMR flows to remain between -1,250 and -5,000 cfs during a certain period for the protection of larval and juvenile delta smelt. The validity of the biological opinions likely will continue to be litigated in the foreseeable future, creating uncertainty about implementation of the RPAs.

3.3 Environmental Setting

Figure 1 is a map of the Bay-Delta Estuary that was included in the 2006 Bay-Delta Plan. The map depicts the location of monitoring stations used to collect baseline water quality data for the Bay-Delta Estuary and stations used to monitor compliance with water quality objectives set forth in the Bay-Delta Plan.

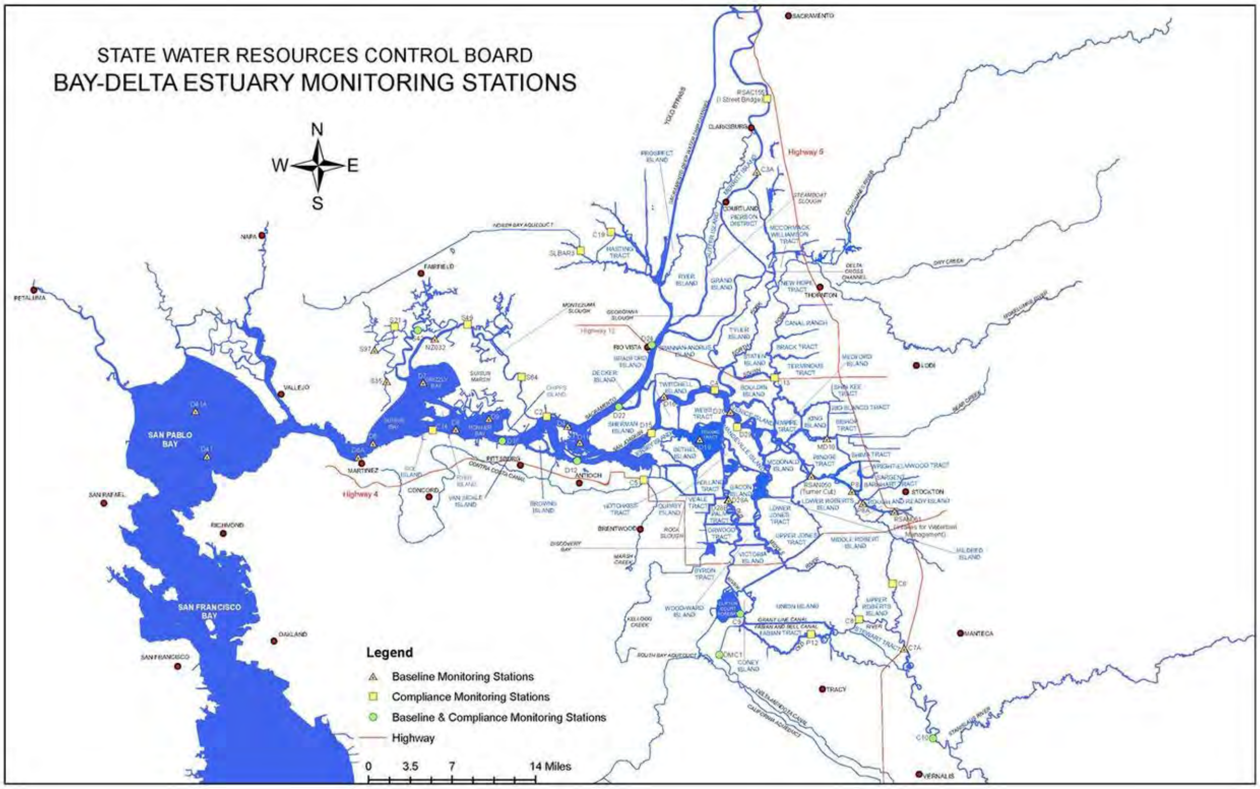

Figure 1. Map of the Bay-Delta Estuary

3.3.1 Physical Setting

The Delta is located where California's two major river systems, the Sacramento and San Joaquin rivers, converge from the north and south and are joined by several tributaries from the Central Sierras to the east, before flowing westward through the San Francisco Bay to the Pacific Ocean. The Sacramento and San Joaquin rivers drain water from the Central Valley Basin, which includes about 40 percent of California's land area.

Outflow from the Delta enters Suisun Bay just west of the confluence of the Sacramento and San Joaquin rivers. Suisun Marsh, which is located along the north shore of Suisun Bay, is one of the few major marshes remaining in California and is the largest remaining brackish wetland in Western North America. The marsh is subject to tidal influence and is directly affected by Delta outflow. Suisun Marsh covers approximately 85,000 acres of marshland and water ways and provides a unique diversity of habitats for fish and wildlife.

The Old Delta
The Delta formed as a freshwater marsh through the interaction of river inflow and the strong tidal influence of the Pacific Ocean and San Francisco Bay. The growth and decay of tules and other marsh plants resulted in the deposition of organic material, creating layers of peat that formed the soils of the marsh. Hydraulic mining during the Gold Rush era washed large amounts of sediment into the rivers, channels and bays, temporarily burying the wetlands. The former wetland areas were reclaimed into more than 60 islands and tracts that are devoted primarily to farming. A network of levees protects the islands and tracts from flooding, because most of the islands lie near or below sea level due to the erosion and oxidation of the peat soils.

As shown in Figure 2 (Courtesy, Chris Enright, DWR, using Atwater data), prior to reclamation, the channels in the Delta were connected in a dendritic, or tree-like, pattern and may have included 5 to 10 times as many miles of interconnected channels as it does today, with largely unidirectional flow.

Figure 2. The Old Delta (*ca.* 1860).

The Recent Delta

Today's Delta covers about 738,000 acres, of which about 48,000 acres are water surface area, and is interlaced with about 700 miles of waterways. As shown in Figure 3 (Courtesy, Chris Enright, DWR, using Atwater data), today's remaining Delta waterways have been greatly modified to facilitate the bi-directional movement of water and the river banks have been armored to protect against erosion, thus changing the geometry of the stream channels and eliminating most of the natural vegetation and habitat of the aquatic and riparian environment. The interconnected geometry and channelized sloughs of the present Delta result in much less variability in water quality than the past dendritic pattern, and today's mostly open ended sloughs results in water quality and habitat being relatively homogenous throughout the system. (Moyle et al. 2010.)

Figure 3. The Recent Delta

The Changing Delta

The Delta Environmental Flows Group (DEFG 2) describes in *Changing Ecosystems: a Brief Ecological History of the Delta* how the Delta has undergone significant physical and biological modification over the past 150 years. Initial development occurred during the Gold Rush when large amounts of sediment washed into the Delta, followed by diking and dredging of rivers. This was followed by increasing diversions and developments, including fixing of levees and channels, and most recently with large-scale dam development and diversions from the Delta. The Moyle et al. history also suggests what is likely to happen in the future:

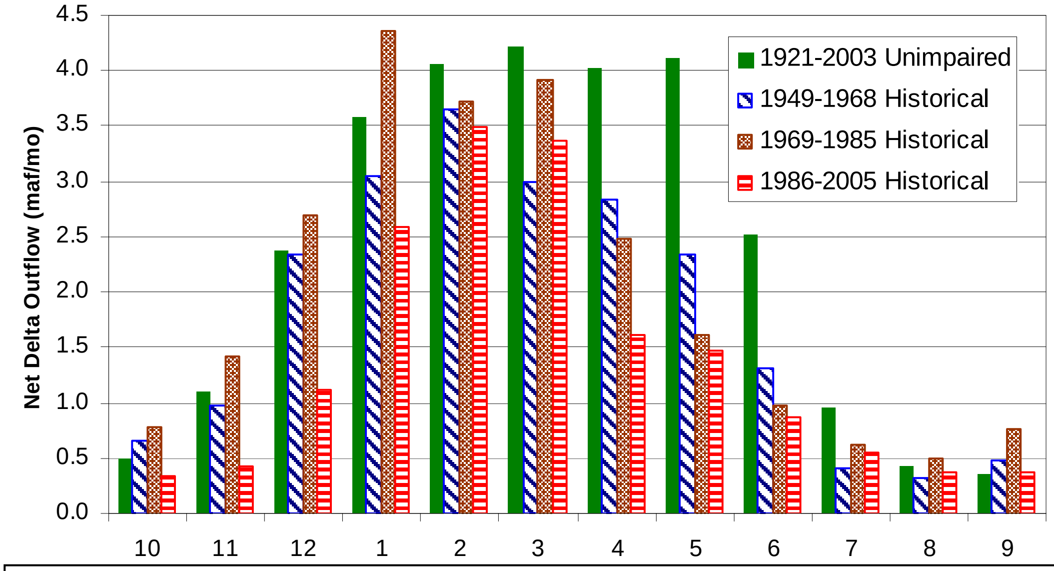
> "The Delta ecosystem is likely to dramatically shift again within 50 years due to large-scale levee collapse in the Delta and Suisun Marsh. Major levee failures are inevitable due to continued subsidence, sea level rise, increasing frequency of large floods, and high probability of earthquakes. These significant changes will create large areas of open water and increased salinity intrusion, as well as new tidal and subtidal marshes. Other likely changes include reduced freshwater inflow during prolonged droughts, altered hydraulics from reduced export pumping, and additional alien invaders (e.g., zebra and quagga mussels). The extent and effects of all these changes are unknown but much will depend on how the estuary is managed in response to change or even before change takes place. Overall, these major changes in the estuary's landscape are likely to promote a more variable, heterogeneous estuary, especially in the Delta and Suisun Marsh. This changed environment is likely to be better for desirable estuarine species; at least it is unlikely to be worse."

3.3.2 Hydrology/Hydrodynamics

California's climate and hydrology are Mediterranean, which is characterized by most precipitation falling during the winter-spring wet season, a dry season extending from late spring through early fall, and high inter-annual variation in total runoff. The life history strategies of all native estuarine Delta fishes are adapted to natural variability. (Moyle and Bennett 2008, as cited in Fleenor et al. 2010.) Although the unimpaired flow record does not indicate precise, or best, flow requirements for fish under current conditions, the general timing (e.g., seasonality), magnitudes, and directions of flows seen in the unimpaired flow record are likely to remain important for native species under contemporary and future conditions. (Fleenor et al. 2010.)

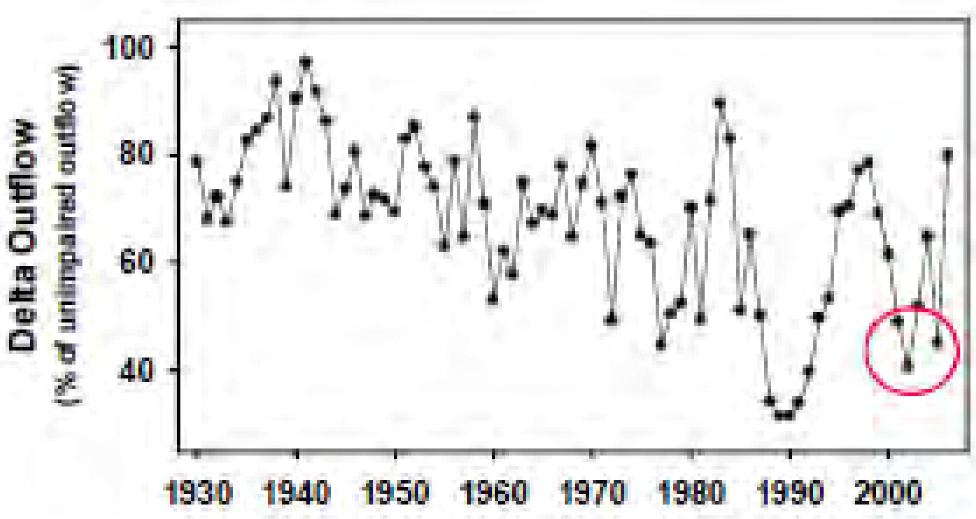
Inflow to the Delta comes primarily from the Central Valley Basin's Sacramento and San Joaquin river systems and is chiefly derived from winter and spring runoff originating in the Cascade and Sierra Nevada mountains, with minor amounts from the Coast Ranges. Precipitation totals vary annually with about 80 percent of the total occurring between the end of October and the beginning of April. Snow storage in the high Sierra delays the runoff from that area until the snow melts in April, May, and June. Normally, about half of the annual runoff from the Central Valley Basin occurs during this period. In recent years, the Sacramento River contributed roughly 75 to 80% of the Delta inflow in most years, while the San Joaquin River contributed about 10 to 15%. The minor flows of the Mokelumne, Cosumnes, and Calaveras rivers, which enter into the eastern side of the Delta, contributed the remainder of the inflow to the Delta.

Net Delta outflow represents the difference between the sum of freshwater inflows from tributaries to the Delta and the sum of exports and net in-Delta consumptive uses. (Kimmerer 2004, DOI 1, p.17.) As noted above, the majority of the freshwater flow into the Delta occurs in winter and spring; however, upstream storage and diversions have reduced the winter-spring flow and increased flow in summer and early fall. (Figure 4, Kimmerer 2002b; Kimmerer 2004; DOI 1, p. 16.) The April-June reductions are largely the result of the San Joaquin River diversions. (Fleenor et al. 2010.) During the summer-fall dry season the Delta channels essentially serve as a conveyance system for moving water from reservoirs in the north to the CVP and SWP export facilities, as well as the smaller Contra Costa Water District facility, for subsequent delivery to farms and cities in the San Joaquin Valley, southern California, and/or other areas outside the watershed. (Kimmerer 2002b.) Figure 5 shows the reduction in annual Delta outflow as a percentage of unimpaired outflow. The combined effects of water exports and upstream diversions reduced average annual net outflow from the Delta from unimpaired conditions by 33% and 48% during the 1948 – 1968 and 1986 – 2005 periods, respectively. (Fleenor et al. 2010.)



This figure shows monthly average net delta outflows (in million acre-feet per month) compared to the unimpaired flows from 1921-2003. Unimpaired flow data is from DWR (2006) and other from Dayflow web site. (Source: Fleenor et al. 2010, Figure 7.)

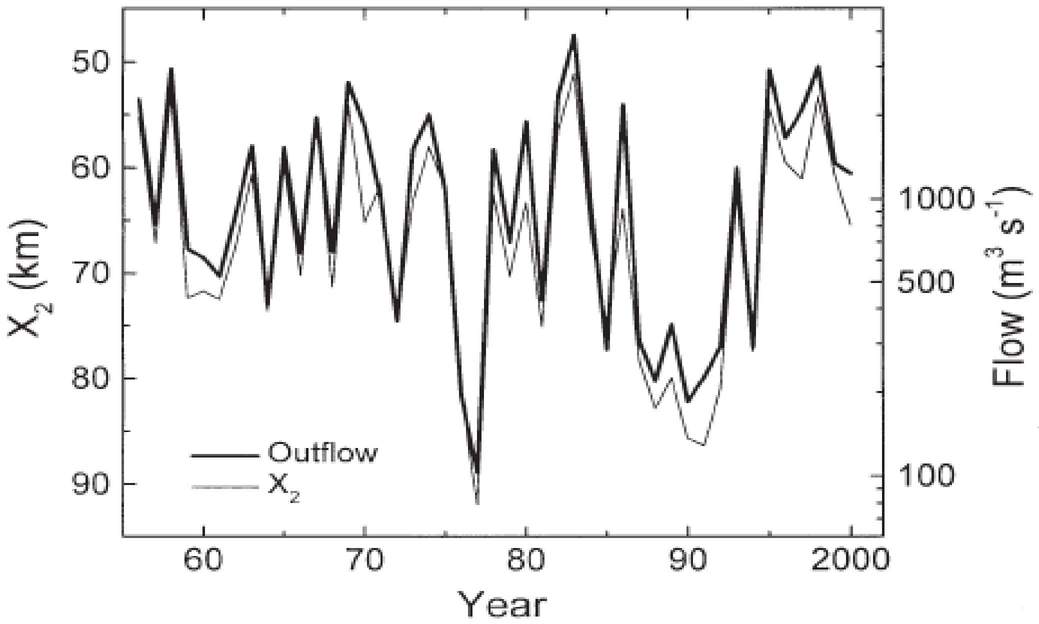
Figure 4. Monthly Average Net Delta Outflows from Fleenor et al. 2010



Delta outflow shown as a percentage of unimpaired outflow (1930-2005); in the last decade annual outflow is reduced by more than 50% in 2001, 2002, and 2005. (Source: TBI 2007, as cited in DOI 1, p. 17.)

Figure 5. Delta Outflow as a Percent of Unimpaired Outflow from TBI 2007

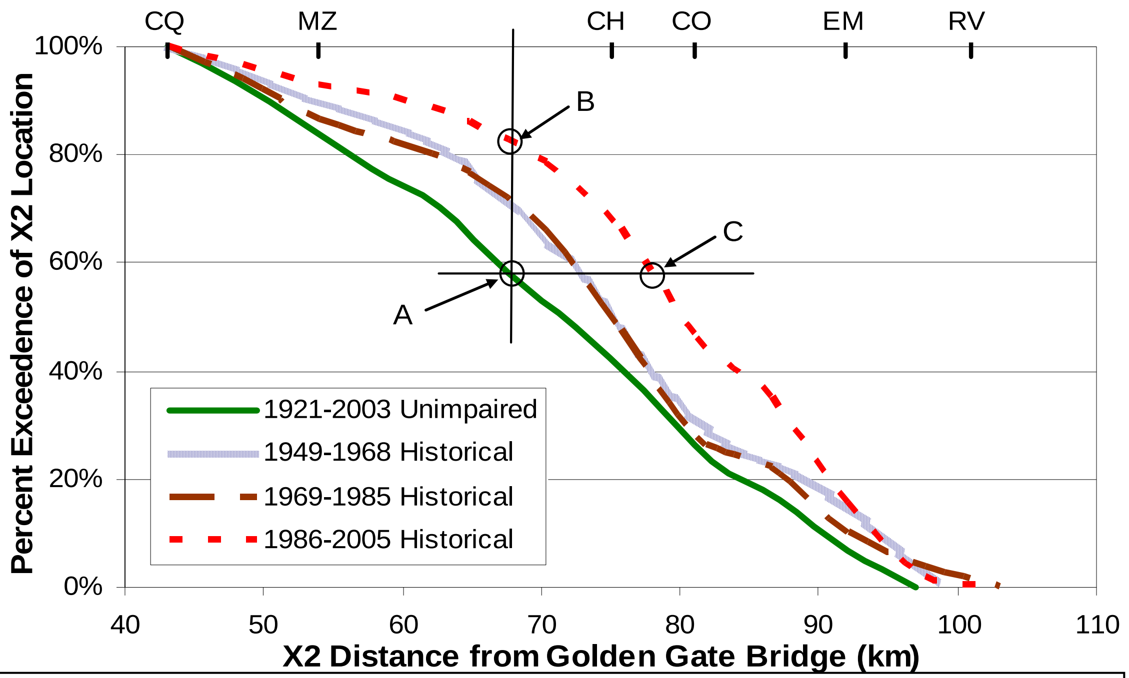
Delta outflows and the position of X2 are closely and inversely related, with a time lag of about two weeks. (Jassby et al. 1995; Kimmerer 2004.) A time series of the annual averages for January to June of X2 and Delta outflow is depicted in Figure 6. X2 is defined as the horizontal distance in kilometers up the axis of the estuary from the Golden Gate Bridge to where the tidally averaged near-bottom salinity is 2 practical salinity units (psu). (Jassby et al. 1995, Kimmerer 2002a.) The position of X2 roughly equates to the center of the low salinity zone (defined as salinity of 0.5 to 6 psu). (Kimmerer 2002a.) The X2 objectives in the 2006 Bay-Delta Plan were designed to restore a more natural hydrograph and salinity pattern by requiring maintenance of the low salinity zone at specified points and durations based on the previous month's Eight River Index. (State Water Board 2006a.) The relationships between outflow and several measures of the health of the Bay-Delta Estuary have been known for some time (Jassby *et al*. 1995) and are the basis for the current X2 objectives.



Time series of X2 (thin line, left axis, scale reversed) and flow (heavy line, right axis, log scale), annual averages for January to June; flow data from DWR; X2 calculated as in Jassby et al. (1995) (Source: Kimmerer 2002a, Figure 3).

Figure 6. X2 and Delta Outflow for January to June from Kimmerer 2002a

Both Delta outflow and the position of X2 have been altered as a result of numerous factors including development and operation of upstream storage and diversions, land use changes, and increasing water demand. Hydrodynamic simulations conducted by Fleenor et al. (2010) indicate that the position of X2 has been skewed eastward in the recent past, as compared to unimpaired conditions and earlier impaired periods, and that the variability of salinity in the western Delta and Suisun Bay has been significantly reduced (Figure 7). The higher X2 values shown in this figure (refer to Point 'B') indicate the low salinity zone is farther upstream for a more prolonged period of time. Point 'B' demonstrates that during the period from 1986 to 2005 the position of X2 was located upstream of 71 km nearly 80% of the time, as opposed to unimpaired flows which were equally likely to place X2 upstream or downstream of the 71 km location (50% probability). (Fleenor *et al*. 2010.) Historically, X2 exhibited a wide seasonal range tracking the unimpaired Delta outflows; however, seasonal variation in X2 range has been reduced by nearly 40%, as compared to pre-dam conditions. (TBI 2003, as cited in DOI 1, pp. 21-22.)



This graph shows the cumulative probability distributions of daily X2 locations showing unimpaired flows (green solid line) and three historical periods, 1949-1968 (light solid blue line), 1969-1985 (long-dashed brown line) and 1986-2005 (short-dashed red line), illustrating progressive reduction in salinity variability from unimpaired conditions. Paired letters indicate geographical landmarks: CQ, Carquinez Bridge; MZ, Martinez Bridge; CH, Chipps Island; CO, Collinsville; EM, Emmaton; and RV, Rio Vista (Source: Fleenor et al. 2010, Figure 8).

Figure 7. Cumulative Probability of Daily X2 Locations from Fleenor *et al*. 2010

In their key points on Delta environmental flows for the State Water Board, the DEFG (DEFG 1) noted that the recent flow regimes both harm native species and encourage non-native species and provided the following justification:

> “The major river systems of the arid western United States have highly variable natural flow regimes. The present-day flow regimes of western rivers, including the Sacramento and San Joaquin, are highly managed to increase water supply reliability for agriculture, urban use, and flood protection (Hughes et al. 2005, Lund et al. 2007). Recent Delta inflow and outflow regimes appear to both harm native species and encourage non-native species. Inflow patterns from the Sacramento River may help riverine native species in the north Delta, but inflow patterns from the San Joaquin River encourage non-native species. Ecological theory and observations overwhelmingly support the argument that enhancing variability and complexity across the estuarine landscape will support native species. However, the evidence that flow stabilization reduces native fish abundance in the upper estuary (incl. Delta) is circumstantial:
>
> 1) High winter-spring inflows to the Delta cue native fish spawning migrations (Harrell and Sommer 2003; Grimaldo et al. 2009), improve the reproductive success of resident native fishes (Meng et al. 1994; Sommer et al. 1997; Matern et al. 2002; Feyrer 2004), increase the survival of

juvenile anadromous fishes migrating seaward (Sommer *et al*. 2001; Newman 2003), and disperse native fishes spawned in prior years (Feyrer and Healey 2003; Nobriga et al. 2006).

2) High freshwater outflows (indexed by X2) during winter and spring provide similar benefits to species less tolerant of freshwater including starry flounder, bay shrimp, and longfin smelt (Kimmerer 2002; Kimmerer *et al*. 2009). Freshwater flows provide positive benefits to native fishes across a wide geographic area through various mechanisms including larval-juvenile dispersal, floodplain inundation, reduced entrainment, and increased up-estuary transport flows. Spring Delta inflows and outflow have declined since the early 20th century, but average winter-spring X2 has not had a time trend during the past 4-5 decades (Kimmerer 2004).

3) The estuary's fish assemblages vary along the salinity gradient (Matern et al. 2002; Kimmerer 2004), and along the gradient between predominantly tidal and purely river flow. In tidal freshwater regions, fish assemblages also vary along a gradient in water clarity and submerged vegetation (Nobriga et al. 2005; Brown & Michniuk 2007), and smaller scale, gradients of flow, turbidity, temperature and other habitat features (Matern et al. 2002; Feyrer & Healey 2003). Generally, native fishes have their highest relative abundance in Suisun Marsh and the Sacramento River side of the Delta, which are more spatially and temporally variable in salinity, turbidity, temperature, and nutrient concentration and form than other regions.

4) In both Suisun Marsh and the Delta, native fishes have declined faster than non-native fishes over the past several decades (Matern et al. 2002; Brown and Michniuk 2007). These declines have been linked to persistent low fall outflows (Feyrer et al. 2007) and the proliferation of submerged vegetation in the Delta (Brown and Michniuk 2007). However, many other factors also may be influencing native fish declines including differences in sensitivity to entrainment (sustained or episodic high "fishing pressure" as productivity declines), and greater sensitivity to combinations of food-limitation and contaminants, especially in summer-fall when many native fishes are near their thermal limits.

The weight of the circumstantial evidence summarized above strongly suggests flow stabilization harms native species and encourages non-native species, possibly in synergy with other stressors such as nutrient loading, contaminants, and food limitation."

Diversion and Use

Irrigation is the primary use of water in the Sacramento and San Joaquin river watershed. Water is used to a lesser extent to meet municipal, industrial, environmental, and instream needs. Water is also exported from the Central Valley Basin for many of these same purposes. Local irrigation districts, municipal utility districts, county agencies, private companies and corporations, and State and federal agencies have developed surface water projects throughout the basin to control and conserve the natural runoff and provide a reliable water supply for beneficial uses. Many of these projects are used to produce hydroelectric power and to enhance recreational opportunities. Flood control systems, water storage facilities, and diversion works exist on all major streams in the basin, altering the timing, location, and quantity of water and the habitat associated with the natural flow patterns of the basin. (State Water Board 1999.)

The major surface water supply developments of the Central Valley include the CVP, other federal projects built by the USBR and the U.S. Army Corps of Engineers (USACE), the SWP, and numerous local projects (including several major diversions). The big rim dams, developed mostly since the 1940s, dramatically changed river flow patterns. The dams were built to provide flood protection and a reliable water supply. Collection of water to storage decreased river flows in winter and spring, and changed the timing of high flow periods (except for extreme flood flows). The San Joaquin River has lost most of its natural summer flows because the majority of the water is exported via the Friant project or diverted from the major tributaries for use within the basin. Even though natural flows have been substantially reduced, agricultural return flows during the summer have actually resulted in higher flows than would have occurred under unimpaired conditions at times. Winter and spring flows collected to storage by the State and federal projects in the Sacramento Basin are released in the late spring and throughout the summer and fall, largely to be rediverted from the Delta for export. The federal pumping plants in the southern Delta started operating in the 1950s, exporting water into the Delta-Mendota Canal. The State pumps and the California Aqueduct started operating in the late 1960s, further increasing exports from the Delta. (Moyle, et al. 2010.)

In-Delta Diversions and Old and Middle River Reverse Flows

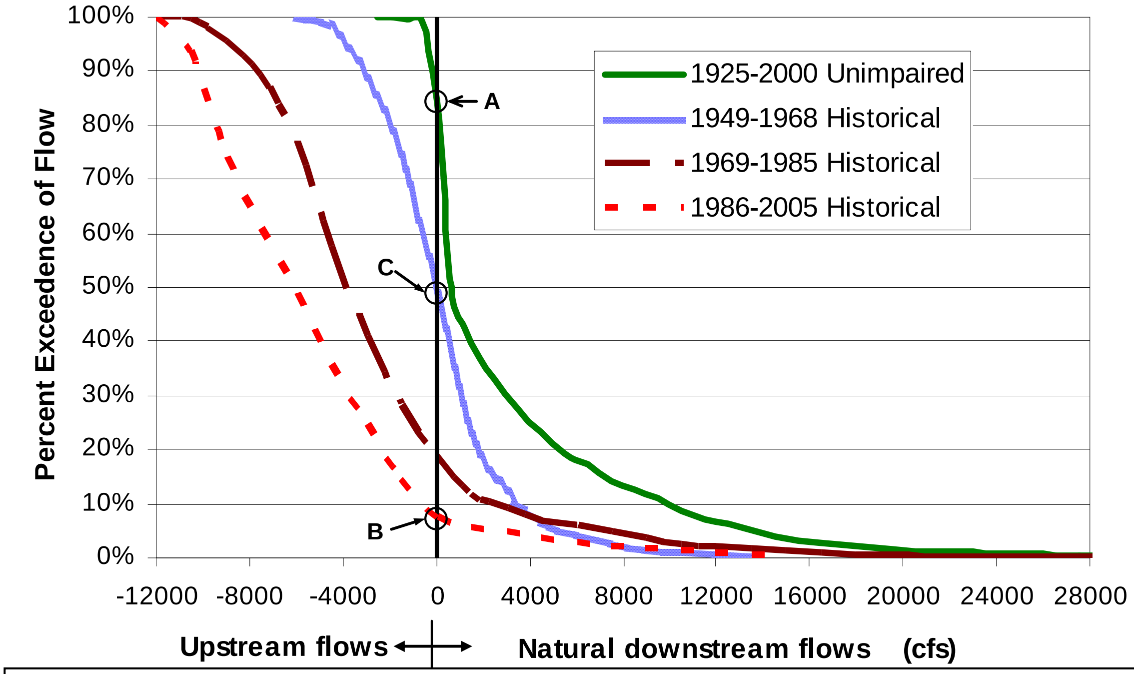
The USBR and the DWR are the major diverters in the Delta. The USBR exports water from the Delta at the Tracy Pumping Plant and the Contra Costa Water District diverts CVP water at Rock Slough and Old River under a water supply contract with the USBR. The DWR exports from the Delta at the Banks Delta Pumping Plant and Barker Slough to serve the SWP contractors. Operation of the CVP and SWP Delta export facilities are coordinated to meet water quality and flow standards set by the Board, the USACE, and by fisheries agencies. In addition, there are approximately 1,800 local diversions within the Delta that amount to a combined potential instantaneous flow rate of more than 4,000 cfs. (State Water Board 1999.)

Net OMR reverse flows are now a regular occurrence in the Delta (Figure 8). Net OMR reverse flows are caused by the fact that the major freshwater source, the Sacramento River, enters on the northern side of the Delta while the two major pumping facilites, the SWP and CVP, are located in the south (Figure 1). This results in a net water movement across the Delta in a north-south direction along a web of channels including Old and Middle rivers instead of the more natural pattern from east to west or from land to sea. Net OMR is calculated as half the flow of the San Joaquin River at Vernalis minus the combined SWP and CVP pumping rate. (CCWD closing comments, p. 2.) A negative value, or a reverse flow, indicates a net water movement across the Delta along Old and Middle river channels to the State and Federal pumping facilities. Fleenor *et al* (2010) has documented the change in both the magnitude and frequency of net OMR reverse flows as water development occurred in the Delta (Figure 8). The 1925-2000 unimpaired line in Figure 8 represents the best estimate of “quasi-natural” or net OMR values before most modern water development. (Fleenor et al. 2010.) The other three lines represent changes in the frequency and magnitude of net OMR flows with increasing development. Net OMR reverse flows are estimated to have occurred naturally about 15% of the time before most modern water development, including construction of the major pumping facilities in the South Delta (point A, Figure 8). The magnitude of net OMR reverse flows was seldom more negative than a couple of thousand cfs. In contrast, between1986-2005 net OMR reverse flows had become more frequent than 90 percent of the time (Point B). The magnitude of net OMR reverse flows may now be as much as -12,000 cfs. High net OMR reverse flows have several negative ecological consequences. First, net reverse OMR flows draw fish, especially the weaker swimming larval and juvenile forms, into the SWP and CVP export facilities. The export facilities have been documented to entrain most species of fish present in the upper estuary. (Brown *et al*. 1996,.) Approximately 110 million fish were salvaged at the SWP pumping facilities and returned to the Delta over a 15 year period, (Brown et al. 1996.) However, this number underestimates the actual number of fish entrained, as it does not include losses at the CVP nor does it account for fish less than 20 mm in length which are not collected and counted at the fish collection facilities. Second, net OMR reverse flows reduce spawning and rearing habitat for native species, like delta smelt. Any fish that enters the Central or Southern Delta has a high probability of being entrained and lost at the pumps. (Kimmerer and Nobriga, 2008.) This has restricted their habitat to the western Delta and Suisun and Grizzly bays. Third, net OMR reverse flows have led to a confusing environment for migrating juvenile salmon leaving the San Joaquin Basin. Through-Delta exports reduce salinity in the central and southern Delta and as a result juvenile salmon migrate from higher salinity in the San Joaquin River to lower salinity in the southern Delta, contrary to the natural historical conditions and their inherited migratory cues. Finally, net OMR reverse flows reduce the natural variability in the Delta by drawing Sacramento River water across and into the Central Delta. The UC Davis Delta Solutions Group recommends:

> “Achieving a variable, more complex estuary requires establishing seaward gradients in salinity and other water quality variables…These goals in turn encourage policies which… establish internal Delta flows that create a tidally-mixed, upstream-downstream gradient (without cross-Delta flows) in water quality… and … restoring environmental variability in the Delta is fundamentally inconsistent with continuing to move large volumes of water through the Delta for export. The drinking and agricultural water quality requirements of through-Delta exports, and perhaps even some current in-Delta uses, are at odds with the water quality and variability needs of desirable Delta species.”
> (Moyle et al., 2010.)

Net OMR reverse flow restrictions are included in the USFWS Opinion (Actions 1 through 3), the NMFS Opinion (Action IV.2.3), and the DFG Incidental Take Permit (Conditions 5.1 and 5.2) for the protection of delta smelt, salmonids, and longfin smelt, respectively. (NMFS 3. p. 648; USFWS 2008, DFG 2009.) Additional net OMR reverse flow restrictions are recommended in this report for protection of longfin and delta smelt and Chinook salmon.

Further north in the Delta, the Delta Cross Channel is used to divert a portion of the Sacramento River flow into the interior Delta channels. The purpose of the Delta Cross Channel is to preserve the quality of water diverted from the Sacramento River by conveying it to southern Delta pumping plants through eastern Delta channels rather than allowing it to flow through more saline western Delta channels. The Delta Cross Channel is also operated to protect fish and wildlife beneficial uses (specifically Chinook salmon), while recognizing the need for fresh water to be moved through the system. With a capacity of 3,500 cfs, the Delta Cross Channel can divert a significant portion of the Sacramento River flows into the eastern Delta, particularly in the fall.



Cumulative probability distribution of sum of Old and Middle River flows (cfs) resulting from through Delta conveyance showing unimpaired flows (green solid line) and three historical periods, 1949-1968 (solid light blue line), 1969-1985 (long-dashed brown line) and 1986-2005 (short-dashed red line) (Source: Fleenor et al. 2010, Figure 9).

Figure 8. OMR Cumulative Probability Flows from Fleenor et al. 2010

3.3.3 Water Quality

Water quality in the Delta may be negatively impacted by contaminants in sediments and water, low DO levels, and blue green algal blooms. Additionally, changes in hydrology and hydrodynamics affect water quality. The conversion of tidal wetlands to leveed Delta islands has altered the tidal exchange and prism. These changes can contribute to spatial and temporal shifts in salinity and other physical and chemical water quality parameters (temperature, DO, contaminants, etc.).

Contaminants

The Delta and San Francisco Bay are listed under section 303(d) of the Federal Clean Water Act as impaired for a variety of toxic contaminants that may contribute to reduced population abundance of important fish and invertebrates. The contaminants include: organophosphate and pyrethrin pesticides, mercury, selenium and unknown toxicity. In addition, low DO levels periodically develop in the San Joaquin River in the Stockton Deep Water Ship Channel (DWSC) and in Old and Middle rivers. The low DO levels in the DWSC inhibit the upstream migration of adult fall-run Chinook salmon and adversely impact other resident aquatic organisms. The Central Valley and San Francisco Regional Boards are systematically developing Total Maximum Daily Loads (TMDLs) for all listed pollutants and adopting programs to implement control actions.

There is concern that a number of non-303(d) listed contaminants, such as ammonia, pharmaceuticals, endocrine disrupting compounds and blue-green algal blooms could also limit biological productivity and impair beneficial uses. More work is needed to determine their impact on the aquatic community. Sources of these contaminants include: agricultural, municipal, and industrial wastewater; urban storm water discharges; discharges from wetlands; and channel dredging activities.

Ammonia has emerged as a contaminant of special concern in the Delta. Recent hypotheses are that ammonia is causing toxicity to delta smelt, other local fish, and zooplankton, and is reducing primary production rates in the Sacramento River below the Sacramento Regional Wastewater Treatment Plant (SRWTP) and in Suisun Bay. A third, newer, hypothesis is that ammonia and nitrogen to phosphorus ratios have altered phytoplankton species composition, and these changes have had a detrimental effect on zooplankton and fish population abundance. (Glibert, 2010.)

The SRWTP is the primary source of ammonia to the Delta. (Jassby 2008.) The SRWTP has converted the Delta from a nitrate to an ammonia dominated nitrogen system. (Foe et al. 2010.) Seven-day flow-through bioassays by Werner et al. (2008, 2009) have demonstrated that ammonia concentrations in the Delta are not acutely toxic to delta smelt. Monthly nutrient monitoring by Foe *et al*. (2010) has demonstrated that ammonia concentrations are below the recommended USEPA (1999) chronic criterion for the protection of juvenile fish. Results from the nutrient monitoring suggest that ammonia-induced toxicity to fish is not regularly occurring in the Delta.

Elevated ammonia concentrations inhibit nitrate uptake and that appears to be one factor preventing spring diatom blooms from developing in Suisun Bay. (Dugdale et al. 2007; Wilkerson et al. 2006.) One of the primary hypotheses for the POD is a decrease in the availability of food at the base of the food web. (Sommer et al. 2007.) Staff from the San Francisco Regional Board has informed the Central Valley Regional Board that ammonia may be impairing aquatic life beneficial uses in Suisun Bay (letter to Kathy Harder with the Central Valley Regional Board from Bruce Wolfe of the San Francisco Regional Board dated June 4, 2010).

Ammonia concentrations are higher in the Sacramento River below the SRWTP than in Suisun Bay. This led to a hypothesis that ammonia might be inhibiting nitrate uptake and reducing primary production rates in the Sacramento River and downstream Delta, as occurs in Suisun Bay. Experimental results for the Sacramento River are more ambiguous than for Suisun Bay. (Parker *et al*., 2010.) Five-day cubitainer grow out experiments conducted using water collected above and below the SRWTP usually demonstrated more chlorophyll in water collected below the SRWTP. Short-term bottle primary production rate measurements conducted using water collected above and below the SRWTP also demonstrate no decrease in the rate when normalized by the amount of chlorophyll in the bottle. However, effluent dosed into upstream Sacramento River water at environmentally realistic concentrations does show a decrease in primary production. Elevated ammonia concentrations consistently decrease nitrate uptake. Whether the shift in nitrogen utilization indicates that different algal species are beginning to grow in the ammonia rich water is not known. A recent paper by Glibert (2010) demonstrates significant correlations between the form and concentration of nutrients discharged by the SRWTP, and changes in phytoplankton, zooplankton, and fish abundance in the Delta.

Salinity

Elevated salinity can impair the uses of water by municipal, industrial, and agricultural users and by organisms that require lower salinity levels. There are at least three factors that may cause salinity levels to exceed water quality objectives in the Delta: saltwater intrusion from the Pacific

Ocean and San Francisco Bay moving into the Delta on high tides during periods of relatively low flows of fresh water through the Delta; salts from agricultural return flows, municipalities, and other sources carried into the southern and eastern Delta with the waters of the San Joaquin River; and localized increases in salinity due to irrigation return flows into dead-end sloughs and low-capacity channels (null zones). The effects of saltwater intrusion are seen primarily in the western Delta. Due to the operation of the State and federal export pumping plants near Tracy, the higher salinity areas caused by salts in the San Joaquin River tend to be restricted to the southeast corner of the Delta. Null zones, and the localized areas of increased salinity associated with them, exist predominantly in three areas of the Delta: Old River between Sugar Cut and the CVP intake; Middle River between Victoria canal and Old River; and the San Joaquin River between the head of Old River and the City of Stockton.

Suspended Sediments and Turbidity

Turbidity in the Delta is caused by factors that include suspended material such as silts, clays, and organic matter coming from the major tributary rivers; planktonic algal populations; and sediments stirred up during dredging operations to maintain deep channels for shipping. Turbidity affects large river and estuarine fish assemblages because some fishes survive best in turbid (muddy) water, while other species do best in clear water. Studies suggest that changes in specific conductance and turbidity are associated with declines in upper estuary habitat for delta smelt, striped bass, and threadfin shad. Laboratory studies have shown that delta smelt require turbidity for successful feeding.

Turbidity in the Delta has decreased through time. The primary hypotheses to explain the turbidity decrease are: (1) reduced sediment supply; (2) sediment washout from very high inflows during the 1982 to 1983 El Nino; and (3) trapping of sediment by submerged aquatic vegetation. (Wright and Schoellhamer 2004, Jassby et al. 2005, Nobriga et al. 2005, and Brown and Michniuk 2007 as cited in Nobriga et al. 2008.)

Dissolved Oxygen

Low DO levels are found along the lower San Joaquin River and in certain localized areas of the Delta. Dissolved oxygen impairment is caused, in part, by loads of oxygen demanding substances such as dead algae or waste discharges. Low DO in the Delta occurs mainly in the late summer and coincides with low river flows and high temperatures. Fish vary greatly in their ability to tolerate low DO concentrations, based on the environmental conditions the species has evolved to inhabit. Salmonids are relatively intolerant of low DO concentrations. Within the lower San Joaquin River, DO concentrations can become sufficiently low to impair the passage and/or cause mortality of migratory salmonids. (DFG 3, p. 3; DOI 1, p. 25; TBI/NRDC 3, p. 26.)

The DWSC is a portion of the lower San Joaquin River between the City of Stockton and the San Francisco Bay that has been dredged to allow for the navigation of ocean-going vessels to the Port of Stockton. A 14-mile stretch of the DWSC, from the City of Stockton to Disappointment Slough, is listed as impaired for DO and, at times, does not meet the objectives set forth in the San Joaquin Riverwater quality control plan. Studies have identified three main contributing factors to the problem: loads of oxygen demanding substances that exert an oxygen demand (particularly the death and decay of algae); DWSC geometry, which reduces the assimilative capacity for loads of oxygen demanding substances by reducing the efficiency of natural re-aeration mechanisms and by magnifying the effect of oxygen demanding reactions; and, reduced flow through the DWSC, which reduces the assimilative capacity by reducing upstream inputs of oxygen and increasing the residence time for oxygen demanding reactions. (Central Valley Regional Board 2003.)

3.3.4 Biological Setting

The Bay-Delta Estuary is one of the largest, most important estuarine systems for fish and waterfowl production on the Pacific Coast of the United States. The Delta provides habitat for a wide variety of freshwater, estuarine, and marine fish species. Channels in the Delta range from dead-end sloughs to deep, open water areas that include several flooded islands that provide submerged vegetative shelter. The complex interface between land and water in the Delta provides rich and varied habitat for wildlife, especially birds. The Delta is particularly important to waterfowl migrating via the Pacific Flyway as these birds are attracted to the winter-flooded fields and seasonal wetlands. (State Water Board 1999.)

Existing Setting

A wide variety of fish are found throughout the waterways of the Central Valley and the Bay-Delta Estuary. About 90 species of fish are found in the Delta. Some species, such as the anadromous fish, are found in particular parts of the Bay-Delta Estuary and the tributary rivers and streams only during certain stages of their life cycle. The Delta's channels serve as a migratory route and nursery area for Chinook salmon, striped bass, white and green sturgeon, American shad, and steelhead trout. These anadromous fishes spend most of their adult lives either in the lower bays of the estuary or in the ocean, moving inland to spawn. Resident fishes in the Bay-Delta Estuary include delta smelt, longfin smelt, threadfin shad, Sacramento splittail, catfish, largemouth and other bass, crappie, and bluegill.

Food supplies for Delta fish communities consist of phytoplankton, zooplankton, benthic invertebrates, insects, and forage fish. The entrapment zone, where freshwater outflow meets and mixes with the more saline water of the Bay, concentrates sediments, nutrients, phytoplankton, some fish larvae, and other fish food organisms. Biological standing crop (biomass) of phytoplankton and zooplankton in the estuary has generally been highest in this zone. However, the overall productivity at the lower trophic levels has decreased over time. (State Water Board 1999.)

Non-Native and Invasive Species

Invasive aquatic organisms are known to have deleterious effects on the Delta ecosystem. These effects include reductions in habitat suitability, reductions in food supply, alteration of the aquatic food-web, and predation on or competition with native species. There are many notable examples of exotic species invasions in the Bay-Delta, so much so, that the Delta has been labeled “the most invaded estuary on earth.”

Of particular importance potentially in the recent decline in pelagic organisms is the introduction of the Asian clam, *Corbula amurensis*. The introduction of the clam has lead to substantial declines in the lower trophic production of the Bay-Delta Estuary. In addition to reductions in planktonic production caused by *Corbula*, the planktonic food web composition has changed dramatically over the past decade or so. Once dominant copepods in the food web have declined leading to speculation that estuarine conditions have changed to favor alien species. The decrease in these desirable copepods may further increase the likelihood of larval fish starvation or result in decreased growth rates. (State Water Board 2008.)

The proliferation of invasive, aquatic weeds, such as *Egeria densa*, which filter out particulate materials and further reduce planktonic growth, are also having a impact on the Bay-Delta. Areas with low or no flow, such as warm, shallow, dead-end sloughs in the eastern Delta also support objectionable populations of plants during summer months including planktonic blue-green algae and floating and semi-attached aquatic plants such as water primrose, water hyacinth, and *Egeria densa*. All of these plants contribute organic matter that reduces DO levels in the fall, and the floating and semi-attached plants interfere with the passage of small boat traffic. In addition, native fishes in the Bay-Delta face growing challenges associated with competition and predation by non-native fish. (State Water Board 1999; State Water Board 2008.)

Recent Species Declines

Historical fisheries within the Central Valley and the Bay-Delta Estuary were considerably different than the fisheries present today. Many native species have declined in abundance and distribution, while several introduced species have become well established. The Sacramento perch is believed to have been extirpated from the Delta; however, striped bass and American shad are introduced species that, until recently, have been relatively abundant and have contributed substantially to California's recreational fishery. (State Water Board 1999.)

In 2005, scientists with the Interagency Ecological Program (IEP) announced observations of a precipitous decline in several pelagic organisms in the Delta, beginning in 2002, in addition to declining levels of zooplankton. Zooplankton are the primary food source for older life stages of species such as delta smelt. The decline in pelagic organisms included delta smelt, striped bass, longfin smelt, and threadfin shad. Scientists hypothesized that at least three general factors may be acting individually, or in concert, to cause this recent decline in pelagic productivity: 1) toxic effects; 2) exotic species effects; and 3) water project effects. Scientists and resources agencies have continued to investigate the causes of the decline, and have prepared plans that identify actions designed to help stabilize the Delta ecosystem and improve conditions for pelagic fish species. (State Water Board 2008.)

In January of 2008, the Pacific Fisheries Management Council reported unexpectedly low Chinook salmon returns to California, particularly to the Central Valley, for 2007. Adult returns to the Sacramento River, the largest of Central Valley Chinook salmon runs, failed to meet resource management goals (122,000-180,000 spawners) for the first time in 15 years. (State Water Board 2008.) The Sacramento River fall Chinook salmon escapement to the Central Valley was estimated to be 88,000 adults in 2007; 66,000 in 2008; and 39,530 – the lowest on record -- in 2009. (PCFFA 2.) The NMFS concluded that poor ocean conditions were a major factor contributing to the low fall-run abundance; however, other conditions may exacerbate these effects. (State Water Board 2008.)

In April 2008, the Pacific Fisheries Management Council and the Commission adopted the most restrictive ocean and coastal salmon seasons ever for California by closing the ocean and coastal fishery to commercial and recreation fishing for the 2008 fishing season. The Commission further banned salmon fishing in all Central Valley rivers, with the exception of limited fishing on a stretch of the Sacramento River. (State Water Board 2008.) The ban on all salmon fishing was extended through the 2009 season, but the restrictions were eased somewhat for 2010.

3.3.5 How Flow-Related Factors Affect Public Trust Resources

Flow is important to sustaining the ecological integrity of aquatic ecosystems, including the public trust resources that are the subject of this proceeding. Flow affects water quality, food resources, physical habitat, and biotic interactions. Alterations in the natural flow regime affect aquatic biodiversity and the structure and function of aquatic ecosystems.

In its key points on Delta environmental flows for the State Water Board, the DEFG (DEFG 1) noted that:

- Flow related factors that affect public trust resources include more than just volumes of inflow and outflow and no single rate of flow can protect all public trust resources at all times. The frequency, timing, duration, and rate of change of flows, the tides, and the occurrence of overbank flows, all are important. Seasonal, interannual, and spatial variability in flows, to which native species are adapted, are as important as the quantity of flow. Biological responses to flows rest on combinations of quantity, timing, duration, frequency and how these inputs vary spatially in the context of a Delta that is geometrically complex, highly altered by humans, and fundamentally tidally driven.

- Recent flow regimes in the Delta have contributed to the decline of native species and encouraged non-native species. Flows into and within the estuary affect turbidity, salinity, aquatic plant communities, and nutrients that are important to both native and non-native species. However, flows and habitat structure are often mismatched and now favor non-native species.

- Flow is a major determinant of habitat and transport. The effects of flow on transport and habitat are controlled by the geometry of the waterways. Further, because the geometry of the waterways will change through time, flow regimes needed to maintain desired habitat conditions will also change through time. Delta inflow is an important factor affecting the biological resources of the Delta because inflow has a direct effect on flood plain inundation, in-Delta net channel flows, and net Delta outflows.

- Flow modification is one of the few immediate actions available to improve conditions to benefit native species. However, habitat restoration, contaminant and nutrient reduction, changes in diversions, control of invasive species, as well as flood plain inundation and island flooding all interact with flow to affect aquatic habitats.

4. Methods and Data

The notice for the informational proceeding requested scientific information on the volume, quality, and timing of water needed for the Delta ecosystem under different hydrologic conditions to protect public trust resources pursuant to the State Water Board's public trust obligations and the requirements of SB 1. Specifically, the notice focused on Delta outflows, but also requested information concerning the importance of the source of those flows and information concerning adaptive management, monitoring, and special study programs. In addition to the requested information concerning Delta outflows, the State Water Board also received information on Sacramento River inflows, San Joaquin River inflows, hydrodynamics including Old and Middle River flows, and other information that is relevant to protection of public trust resources in the Delta ecosystem. This section presents the recommendations received by the State Water Board and discusses approaches used to evaluate the recommendations and develop flow criteria responsive to SB1.

4.1 *Summary of Participants' Submittals*

Information submitted by interested parties over the course of this proceeding has resulted in the development of a substantive record; submittals are available on the State Water Board's website at:
http://www.waterboards.ca.gov/waterrights/water_issues/programs/bay_delta/deltaflow/entity_index.shtml

The exhibits include discussions pertaining to: the State Water Board's public trust obligations; methodologies that should be used to develop flow criteria; the importance of the source of flows when determining outflows; means by which uncertainty should be addressed; and specific recommendations concerning Delta outflows, Sacramento and San Joaquin river inflows, hydrodynamics, operation of the Delta Cross Channel Gates, and floodplain activation.

The State Water Board received a wide range of recommendations for the volume, quantity and timing of flow necessary to protect public trust resources. Delta outflow recommendations ranged from statements that the current state of scientific understanding does not support development of numeric Delta flow criteria that differ from the current outflow objectives included in D-1641 (DWR closing comments; SFWC closing comments) to flow volumes during above normal and wet water year types that are two to four times greater than currently required under D-1641 (TBI/NRDC closing comments; AR/NHI closing comments; EDF closing comments, CSPA closing comments; CWIN closing comments). Appendix A: Summary of Participant Recommendations, provides summary tables of the recommendations received for Delta outflows, Sacramento River inflows, San Joaquin River inflows, hydrodynamics, floodplain inundation, and Delta Cross Channel Gate closures.

4.2 *Approach to Developing Flow Criteria*

Fleenor et al. (2010) examined the following four approaches for prescribing environmental flows for the Delta:

- Unimpaired (quasi-natural) inflows
- Historical impaired inflows that supported more desirable ecological conditions
- Statistical relationships between flow and native species abundance
- The appropriate accumulation of flows estimated to provide specific ecological functions for desirable species and ecosystem attributes based on available literature.

Fleenor *et al*. (2010) concludes:

> "Generally, approaches that rely on data from the past will become more risky as the underlying changes in the Delta accumulate. However, since the objective is to provide flows for species which evolved under past conditions, information on past flows and life history strategies of fish provide considerable insight and context. Aggregate statistical approaches, which essentially establish correlations between past conditions and past species abundance, are likely to be less directly useful as the Delta changes. However, statistical approaches will continue to be useful, especially if developed for causal insights. More focused statistical relationships can be of more enduring value in the context of more causal models, even given underlying changes. In the absence of more process-based science, empirical relationships might be required for some locations and functions on an interim basis. Insights and information can be gained from each approach. Given the importance of the problem and the uncertainties involved,

> the strengths of each approach should be employed to provide greater certainty or improve definition of uncertainties."

Among other things, the Fleenor report recommends:

1. Flow prescriptions should be supported preferably by causally or process-based science, rather than correlative empirical relationships or other statistical relationships without supporting ecological basis. Having a greater causal basis for flow prescriptions should make them more effective and readily adapted to improvements in knowledge and changing conditions in the Delta. A more explicit causal basis for flow prescriptions will also create incentives for improved scientific understanding of this system and its management as well as better integration of physical, chemical, and biological aspects of the problem.
2. Ongoing managed and unmanaged changes in the Delta will make any static set of flow standards increasingly irrelevant and obsolete for improving conditions for native fishes. Flows should be tied to habitat, fish, hydrologic, and other management conditions, as well as our knowledge of the system. Flows needed for fish native to the Delta will change.

Information received during this proceeding supports these conclusions and recommendations. The record for this proceeding contains a mix of data and analyses that uses the four approaches identified by Fleenor et al. (2010):

- Unimpaired flows
- Historical impaired inflows that supported more desirable ecological conditions
- Statistical relationships between flow and native species abundance
- Ecological functions-based analysis for desirable species and ecosystem attributes

All four types of information are relied upon to develop the flow criteria in this report. Emphasis, however, is placed on ecological function-based information, followed by information on statistical relationships between flow and native species abundance. In all cases, the criteria are supported by the best available scientific information submitted into the record for this proceeding. The species and ecosystem function-based needs assessments and criteria in this report are supported by references to specific scientific and empirical evidence, and cite to exhibits and testimony in the record or conclusions in published and peer reviewed articles. Criteria based upon statistical relationships between flow and native species abundance are also supported by references to specific scientific and empirical evidence, and cite to exhibits and testimony in the record or conclusions in published and peer reviewed articles.

Furthermore, the conceptual bases for all of the criteria in this report are supported by scientific information on function-based species or ecosystem needs. In other words, there is sufficiently strong scientific evidence to support the need for functional flows. This does not necessarily mean that there is scientific evidence to support *specific* numeric criteria. Recommendations are therefore divided into two categories: Category "A" criteria have more and better scientific information, with less uncertainty, to support specific numeric criteria than do Category "B" criteria. In all cases, the assumptions upon which the criteria are based are identified and discussed. The following steps were followed to develop flow criteria and other recommendations:

1. Establish general goals and objectives for protection of public trust resources in the Delta
2. Identify species to include based on ecological, recreational, or commercial importance
3. Review and summarize species life history requirements, including description of:
    - general life history and species needs
    - population distribution and abundance
    - population abundance and relationship to flow
    - specific population goals
    - species-specific basis for flow criteria
4. Summarize numeric and other criteria for each of: Delta outflows, Sacramento River inflows, San Joaquin River inflows, and hydrodynamics
5. Review other flow-related and non-flow measures that should be considered
6. Provide summary determinations for flow criteria and other measures

The following information was assembled and considered for each species, if available in the record for this proceeding:

- Life history information including timing of migrations
- Seasons or time periods when flow characteristics are most important
- Relationships of species abundance or habitat to Delta outflows, Delta inflows, hydrodynamics, or water quality parameters linked to flow, etc.
- Species environmental requirements (e.g., DO, temperature preferences, salinity, X2 location, turbidity, toxicity to specific pollutants, etc.)
- Relationship of species abundance to invasive species, to the extent possible
- Key quantifiable population responses or habitat characteristics linked to flow
- Mechanisms or hypotheses about mechanisms that link species abundance, habitat, and other metrics to flow or other variables

4.2.1 Biological and Management Goals

The goal of this report is discussed in Section 3.1.4 (Scope of this Report). The following biological and management goals are used to guide the development of criteria that support species life history requirements.

Biological Goals

- Depending on water year type or hydrologic condition, provide sufficient flow to increase abundance of desirable species that depend on the Delta (longfin smelt, delta smelt, starry flounder, bay shrimp, American shad, and zooplankton).

- Create shallow brackish water habitat for longfin smelt, delta smelt, starry flounder, bay shrimp, American shad, and zooplankton in Suisun Bay (and farther downstream).

- Provide floodplain inundation of appropriate timing and sufficient duration to enhance spawning and rearing opportunities to support Sacramento splittail, Chinook salmon, and other native species.

- Manage net OMR reverse flows and other hydrodynamic conditions to protect sensitive life stages of desirable species.

- Provide sufficient flow in the San Joaquin River to transport salmon smolts through the Delta during spring in order to contribute to attainment of the State Water Board's salmon protection water quality objective. (2009 Bay-Delta Plan, p. 14.)

- Provide sufficient flow in the Sacramento River to transport salmon smolts through the Delta during the spring in order to contribute to the attainment of the salmon protection water quality objective. (*Id.*)

- Provide sufficient flow in eastside streams that flow to the Delta, including the Mokelumne and Consumes rivers, to transport salmon smolts to the Delta during the spring in order to contribute to the attainment of the salmon protection water quality objective.

- Maintain water temperatures and DO in mainstem rivers that flow into the Delta and their tributaries at levels that will support adult Chinook salmon migration, egg incubation, smolting, and early-year and late-year juvenile rearing.

Management Goals

- Combine freshwater flows needed to protect species and ecosystem functions in a manner that is comprehensive, does not double count flows, uses an appropriate time step, and is well-documented

- Establish mechanisms to evaluate Delta environmental conditions, periodically review underpinnings of the biological objectives and flow criteria, and change biological objectives and flow criteria when warranted

- Periodically review new research and monitoring to evaluate the need to modify biological objectives and flow criteria

- Do not recommend overly complex flow criteria so as not to infer a greater understanding of specific numeric flow criteria than the available science supports

4.2.2 Selection of Species[10]

Information received during the informational proceeding links the abundance and habitat of several key species that live in, move through, or otherwise depend upon for their survival, the Delta and its ecosystem. DFG Exhibits 1 through 4 present information on the relationship between abundance and the quantity, quality, and timing of flow for the following species: (1) Chinook salmon, (2) Pacific herring, (3) longfin smelt, (4) prickly sculpin, (5) Sacramento splittail, (6) delta smelt, (7) starry flounder, (8) white sturgeon, (9) green sturgeon, (10) Pacific lamprey, (11) river lamprey, (12) bay shrimp, (13) mysid shrimp and a copepod, *Eurytemora affinis*, and (14) American shad. In general, the available data and information indicates:

- For many species, abundance is related to timing and quantity of flow (or the placement of X2).
- For many species, more flow translates into greater species production or abundance.
- Species are adapted to use the water resources of the Delta during all seasons of the year, yet for many species, important life history stages or processes consistently

---

[10] This section is largely drawn from DFG exhibits 1 through 4.

coincide with the winter-spring seasons and its associated increased flows because this is the reproductive season for most native fishes, and the time that most salmonid fishes are emigrating.

- The source, quantity, quality, and timing of Central Valley tributary outflow affects the same characteristics of mainstem river flow into and through the Delta. Flows in all three of these areas, Delta outflows, tributary inflows, and hydrodynamics, influence production and survival of Chinook salmon in both the San Joaquin River and Sacramento River basins.
- Some invasive species negatively influence native species abundance.

This report is consistent with DFG's recommendation to establish flow criteria for species of priority concern that will benefit most by improving flow conditions. (DFG closing comments, p. 3.) Table 2 (from DFG closing comments p.4) identifies select species that have the greatest ecological, commercial, or recreational importance and are influenced by Delta inflows (including mainstem river tributaries) or Delta outflows. The table identifies the species life stage most affected by flows, the mechanism most affected by flows, and the time when flows are most important to the species.

Table 2. Species of Importance (from DFG closing comments p.4)

Priority Species	Life Stage	Mechanism	Time When Water Flows are Most Important	Reference
Chinook salmon (San Joaquin River basin)	Smolt	Outmigration	March – June	DFG Exhibit 1 – page 2; DFG Exhibit 3 – pages 7-10, 21-35.
Chinook salmon (Sacramento River basin)	Juvenile	Outmigration	November – June	DFG Exhibit 1 – page 1-2, 6-8
Chinook salmon (San Joaquin River tributaries)	Egg/fry	Temperature, DO, upstream barrier avoidance	October – March	DFG Exhibit 3, pages 2-4; DFG Exhibit 4
Longfin smelt	Egg	Freshwater-brackish habitat	December – April	DFG Exhibit 1 – page 2, 9-12
Longfin smelt	Larvae	Freshwater-brackish habitat; transport; turbidity	December – May	DFG Exhibit 1 – page 2, 9-12
Sacramento Splittail	Adults	Floodplain inundating flows	January – April	DFG Exhibit 1 – page 2, 13-14
Sacramento Splittail	Eggs and larvae	Floodplain habitat persistence	January – May	DFG Exhibit 1 – page 3, 13-14

Priority Species	**Life Stage**	**Mechanism**	**Time When Water Flows are Most Important**	**Reference**
Delta smelt	Larvae and Pre-adult	Transport; habitat	March – November September – November	DFG Exhibit 1 – page 2,14-15
Starry flounder	Settled juvenile; Juvenile-2 yr old	Estuary attraction; habitat	February – May	DFG Exhibit 1 – page 3, 15-16
Bay shrimp	Late-stage larvae and small juveniles	Transport	February – June	DFG Exhibit 1 – page 4; 22-25
Bay shrimp	Juveniles	Nursery habitat	April – June	DFG Exhibit 1 – page 4; 22-25
Mysid shrimp (zooplankton)	All	Habitat	March – November	DFG Exhibit 1 – page 5; 25-26
Eurytemora affinis (zooplankton)	All	Habitat	March – May	DFG Exhibit 1 – page 5; 25-26
American shad	Egg/larvae	Transport; dispersal; habitat	March – June	DFG Exhibit 1 – page 5; 26-28

While many species found in the Delta are of ecological, commercial, and/or recreational interest, specific flow needs for some of those species may not be directly addressed in this report because: they overlap with the needs of more sensitive species otherwise addressed in the report; the relationships between flow and abundance of those species are not well understood; or the needs of those species may be outside the scope of this report. For example, placement of X2 at certain locations in the Delta to protect longfin smelt or starry flounder will also protect striped bass (*Morone saxatilis*). Striped bass survival from egg to 38 mm is significantly increased as X2 shifts downstream in the estuary. (Kimmerer 2002a.) Kimmerer et al. (2009) showed that as X2 location moved downstream, several measures of striped bass survival and abundance significantly increased, as did several measures of striped bass habitat. Similarly, it is assumed that improved stream flow conditions for Chinook salmon will benefit steelhead, but additional work is needed to assure that these flow criteria are adequate for the protection of steelhead. Adult steelhead in the Central Valley migrate upstream beginning in June, peaking in September, and continuing through February or March. (Hallock *et al*. 1961, Bailey 1954, McEwan and Jackson 1996, as cited in SJRRP FMWG 2009.) Spawning occurs primarily from January through March, but may begin as early as December and may extend through April. (Hallock et al. 1961, as cited in McEwan and Jackson 1996.) Steelhead also rear in tributaries to the Delta throughout the year. Consequently, additional inflow criteria may be needed to protect steelhead at times when flows are not specifically recommended to protect Chinook salmon. As will be discussed in the species needs section for Chinook salmon, additional flow criteria may also be needed to protect various runs and life-stages of Chinook salmon. Adequate information is not currently available, however, upon which to base criteria.

Other species are influenced by very high and infrequent flows, far in excess of what could be provided by the State and federal water projects because they occur only during very wet years when project operations are not controlling. For example, white sturgeon are influenced by high winter and spring Delta and river flows (March-June Delta outflow greater than 60,000 cfs) that attract migrating adults, cue spawning, transport larvae, and enhance nursery habitat. These types of flows occur episodically in very wet years. Historical flow patterns combined with the unique life history (long-lived, late maturing, long intervals between spawning, high fecundity) result in infrequent strong recruitment.

There is adequate information in the record, and adequate time to evaluate life history requirements and develop species-specific flow criteria for the following species:

- Chinook Salmon (various runs) (primarily mirgration flows)
- American Shad
- Longfin Smelt
- Delta Smelt
- Sacramento Splittail
- Starry Flounder
- Bay Shrimp
- Zooplankton

4.2.3 Life History Requirements – Anadromous Species

Following are life history and species-specific requirements for Chinook Salmon (including Sacramento River winter-run, Central Valley spring-run, Central Valley fall-run, and Central Valley late fall-run) and American shad.

Chinook Salmon (Sacramento River Winter-Run, Central Valley Spring-Run, Central Valley Fall-Run, and Central Valley Late Fall-Run)

Status

Sacramento River winter-run Chinook salmon is listed as endangered pursuant to the ESA and the CESA. Central Valley spring-run Chinook salmon is listed as threatened pursuant to both the ESA and the CESA. Central Valley fall/late fall-run Chinook salmon are classified as species of special concern pursuant to the ESA.[11]

Life History[12]

Chinook salmon exhibit two generalized freshwater life history types (Healey 1991). Adult "stream-type" Chinook salmon enter freshwater up to several months before spawning, and juveniles reside in freshwater for a year or more, whereas "ocean-type" Chinook salmon spawn soon after entering freshwater and migrate to the ocean as fry or parr within their first year. Adequate instream flows and cool water temperatures are more critical for the survival of Chinook salmon exhibiting a stream-type life history due to over-summering by adults and/or juveniles.

---

[11] Source: http://www.dfg.ca.gov/fish/Resources/Chinook/index.asp

[12] This section was largely extracted from NMFS 3, pages 76 through 79.

Chinook salmon typically mature between 2 and 6 years of age (Myers et al. 1998). Freshwater entry and spawning timing generally are thought to be related to local water temperature and flow regimes. Runs are designated on the basis of adult migration timing. However, distinct runs also differ in the degree of maturation of the fish at the time of river entry, thermal regime, and flow characteristics of their spawning sites, and the actual time of spawning (Myers et al. 1998). Both winter-run and spring-run tend to enter freshwater as immature fish, migrate far upriver, and delay spawning for weeks or months. Fall-run enter freshwater at an advanced stage of maturity, move rapidly to their spawning areas on the mainstem or lower tributaries of the rivers, and spawn within a few days or weeks of freshwater entry (Healey 1991).

During their upstream migration, adult Chinook salmon require streamflows sufficient to provide olfactory and other orientation cues used to locate their natal streams. Adequate streamflows are necessary to allow adult passage to upstream holding habitat. The preferred temperature range for upstream migration is 38ºF to 56ºF (Bell 1991, DFG 1998). Boles (1988) recommends water temperatures below 65ºF for adult Chinook salmon migration, and Lindley et al. (2004) report that adult migration is blocked when temperatures reach 70ºF, and that fish can become stressed as temperatures approach 70ºF.

Information on the migration rates of adult Chinook salmon in freshwater is scant and primarily comes from the Columbia River basin (Matter and Sanford 2003). Keefer et al. (2004) found migration rates of Chinook salmon ranging from approximately 10 kilometers (km) per day to greater than 35 km per day and to be primarily correlated with date, and secondarily with discharge, year, and reach, in the Columbia River basin. Matter and Sanford (2003) documented migration rates of adult Chinook salmon ranging from 29 to 32 km per day in the Snake River.

Adult Chinook salmon inserted with sonic tags and tracked throughout the Delta and lower Sacramento and San Joaquin rivers were observed exhibiting substantial upstream and downstream movement in a random fashion, for several days at a time, while migrating upstream (CALFED 2001). Adult salmonids migrating upstream are assumed to make greater use of pool and mid-channel habitat than channel margins (Stillwater Sciences 2004), particularly larger salmon such as Chinook salmon, as described by Hughes (2004). During their upstream migration, adults are thought to be primarily active during twilight hours.

Spawning Chinook salmon require clean, loose gravel in swift, relatively shallow riffles or along the margins of deeper runs, and suitable water temperatures, depths, and velocities for redd construction and adequate oxygenation of incubating eggs. Chinook salmon spawning typically occurs in gravel beds that are located at the tails of holding pools (USFWS 1995). The range of water depths and velocities in spawning beds that Chinook salmon find acceptable is very broad. The upper preferred water temperature for spawning Chinook salmon is 55ºF to 57ºF (Chambers 1956, Smith 1973, Bjornn and Reiser 1991, and Snider 2001).

Incubating eggs are vulnerable to adverse effects from floods, siltation, desiccation, disease, predation, poor gravel percolation, and poor water quality. Studies of Chinook salmon egg survival to hatching conducted by Shelton (1995) indicated 87% of fry emerged successfully from large gravel with adequate subgravel flow. The optimal water temperature for egg incubation ranges from 41ºF to 56ºF [44ºF to 54ºF (Rich 1997), 46ºF to 56ºF (NMFS 1997), and 41ºF to 55.4ºF (Moyle 2002)]. A significant reduction in egg viability occurs at water temperatures above 57.5ºF and total embryo mortality can occur at temperatures above 62ºF (NMFS 1997). Alderdice and Velsen (1978) found that the upper and lower temperatures resulting in 50% pre-hatch mortality were 61ºF and 37ºF, respectively, when the incubation temperature was held constant. As water temperatures increase, the rate of embryo malformations also increases, as well as the susceptibility to fungus and bacterial infestations. The length of development for Chinook salmon embryos is dependent on the ambient water temperature surrounding the egg pocket in the redd. Colder water necessitates longer development times as metabolic processes are slowed. Within the appropriate water temperature range for embryo incubation, embryos hatch in 40 to 60 days, and the yolk-sac fry remain in the gravel for an additional 4 to 6 weeks before emerging from the gravel.

During the 4 to 6 week period when alevins remain in the gravel, they utilize their yolk-sac to nourish their bodies. As their yolk-sac is depleted, fry begin to emerge from the gravel to begin exogenous feeding in their natal stream. Fry typically range from 25 mm to 40 mm at this stage. Upon emergence, fry swim or are displaced downstream (Healey 1991). The post-emergent fry disperse to the margins of their natal stream, seeking out shallow waters with slower currents, finer sediments, and bank cover such as overhanging and submerged vegetation, root wads, and fallen woody debris, and begin feeding on zooplankton, small insects, and other microcrustaceans. Some fry may take up residence in their natal stream for several weeks to a year or more, while others are displaced downstream by the stream's current. Once started downstream, fry may continue downstream to the estuary and rear there, or may take up residence in river reaches farther downstream for a period of time ranging from weeks to a year (Healey 1991).

Fry then seek nearshore habitats containing riparian vegetation and associated substrates important for providing aquatic and terrestrial invertebrates, predator avoidance, and slower velocities for resting (NMFS 1996). The benefits of shallow water habitats for salmonid rearing have been found to be more productive than the main river channels, supporting higher growth rates, partially due to higher prey consumption rates, as well as favorable environmental temperatures (Sommer et al. 2001).

When juvenile Chinook salmon reach a length of 50 to 57 mm, they move into deeper water with higher current velocities, but still seek shelter and velocity refugia to minimize energy expenditures (Healey 1991). Catches of juvenile salmon in the Sacramento River near West Sacramento exhibited larger-sized juveniles captured in the main channel and smaller-sized fry along the margins (USFWS 1997). When the channel of the river is greater than 9 to 10 feet in depth, juvenile salmon tend to inhabit the surface waters (Healey 1982). Migrational cues, such as increasing turbidity from runoff, increased flows, changes in day length, or intraspecific competition from other fish in their natal streams, may spur outmigration of juveniles from the upper Sacramento River basin when they have reached the appropriate stage of maturation (Kjelson et al. 1982, Brandes and McLain 2001).

As fish begin their emigration, they are displaced by the river's current downstream of their natal reaches. Similar to adult movement, juvenile salmonid downstream movement is crepuscular. Juvenile Chinook salmon migration rates vary considerably presumably depending on the physiological stage of the juvenile and hydrologic conditions. Kjelson *et al*. (1982) found Chinook salmon fry to travel as fast as 30 km per day in the Sacramento River, and Sommer et *al.* (2001) found travel rates ranging from approximately 0.5 miles up to more than 6 miles per day in the Yolo Bypass. As Chinook salmon begin the smoltification stage, they prefer to rear further downstream where ambient salinity is up to 1.5 to 2.5 parts per thousand (ppt, Healey 1980, Levy and Northcote 1981).

Fry and parr may rear within riverine or estuarine habitats of the Sacramento River, the Delta, and their tributaries (Maslin et al. 1997, Snider 2001). Within the Delta, juvenile Chinook salmon forage in shallow areas with protective cover, such as intertidal and subtidal mudflats, marshes, channels, and sloughs (McDonald 1960, Dunford 1975, Meyer 1979, Healey 1980). Cladocerans, copepods, amphipods, and larvae of diptera, as well as small arachnids and ants are common prey items (Kjelson et al. 1982, Sommer et al. 2001, MacFarlane and Norton 2002). Shallow water habitats are more productive than the main river channels, supporting higher growth rates, partially due to higher prey consumption rates, as well as favorable environmental temperatures (Sommer et al. 2001). Optimal water temperatures for the growth of juvenile Chinook salmon in the Delta are between 54ºF to 57ºF (Brett 1952). In Suisun and San Pablo bays, water temperatures reach 54ºF by February in a typical year. Other portions of the Delta (*i.e*., South Delta and Central Delta) can reach 70ºF by February in a dry year. However, cooler temperatures are usually the norm until after the spring runoff has ended.

Within the estuarine habitat, juvenile Chinook salmon movements are dictated by the tidal cycles, following the rising tide into shallow water habitats from the deeper main channels, and returning to the main channels when the tide recedes (Levings 1982, Levy and Northcote 1982, Levings et al. 1986, Healey 1991). As juvenile Chinook salmon increase in length, they tend to school in the surface waters of the main and secondary channels and sloughs, following the tides into shallow water habitats to feed (Allen and Hassler 1986). In Suisun Marsh, Moyle et al. (1989) reported that Chinook salmon fry tend to remain close to the banks and vegetation, near protective cover, and in dead-end tidal channels. Kjelson et al. (1982) reported that juvenile Chinook salmon demonstrated a diel migration pattern, orienting themselves to nearshore cover and structure during the day, but moving into more open, offshore waters at night. The fish also distributed themselves vertically in relation to ambient light. During the night, juveniles were distributed randomly in the water column, but would school up during the day into the upper 3 meters of the water column. Available data indicate that juvenile Chinook salmon use Suisun Marsh extensively both as a migratory pathway and rearing area as they move downstream to the Pacific Ocean. Juvenile Chinook salmon were found to spend about 40 days migrating through the Delta to the mouth of San Francisco Bay and grew little in length or weight until they reached the Gulf of the Farallones (MacFarlane and Norton 2002). Based on the mainly oceantype life history observed (*i.e.*, fall-run), MacFarlane and Norton (2002) concluded that unlike other salmonid populations in the Pacific Northwest, Central Valley Chinook salmon show little estuarine dependence and may benefit from expedited ocean entry.

Population Distribution and Abundance

Four seasonal runs of Chinook salmon occur in the Central Valley, with each run defined by a combination of adult migration timing, spawning period, and juvenile residency and smolt migration periods. (Fisher 1994 as cited in Yoshiyama et al. 2001 p. 73.) The runs are named after the season when adults move upstream to migrate-- winter, spring, fall, and late-fall. The Sacramento River basin supports all four runs resulting in adult salmon being present in the basin throughout the year. (Stone 1883a; Rutter 1904; Healey 1991; Vogel and Marine 1991 as cited in Yoshiyama *et. al,* 2001 p. 73.) Historically, different runs occurred in the same streams staggered in time to correspond to the appropriate stream flow regime for which that species evolved, but overlapping. (Vogel and Marine 1991; Fisher 1994 as cited in Yoshiyama et al*.,* 2001, p. 73.) Typically, fall and late-fall runs spawn soon after entering natal streams and spring and winter runs typically “hold” for up to several months before spawning. (Rutter 1904; Reynolds and others 1993 as cited in Yoshiyama *et. al,* 2001, p. 73.) These runs and their life-cycle timing are summarized in Table 3 and described in more detail below.

Winter-Run - Due to a need for cool summer flows, Sacramento River winter-run originally likely only spawned in the upper Sacramento River tributaries, including the McCloud, Pit, Fall, and Little Sacramento rivers and Battle Creek. (NMFS 5, p. 16.) As a result of construction of

Shasta and Keswick Dams, today all spawning habitat above Keswick Dam has been eliminated and approximately 47 of the 53 miles of habitat in Battle Creek has been eliminated. (Yoshiyama et al. 1996, as cited in NMFS 5, p. 16.) Currently, winter-run habitat is likely limited to the Sacramento River reach between Keswick Dam downstream of the Red Bluff Diversion Dam. (NMFS 5, p. 16.)

The winter-run population is currently very vulnerable due to its low population numbers and the fact that only one population exists. (Good et al. 2005, as cited in NMFS 5, p. 16.) In the late 1960s escapement was near 100,000 fish declining to fewer than 200 fish in the 1990s. (*Id*.) Recent escapement estimates from 2004 to 2006 averaged 13,700 fish. (DFG Website 2007, as cited in NMFS 5, p. 16.) However, in 2007 and 2008 escapements were less than 3,000 fish. Since 1998, hatchery produced winter-run have been released likely contributing to the observed increased escapement numbers. (Brown and Nichols 2003 as cited in NNFS 5, p. 16.) In addition, a temperature control device was installed on Shasta Dam in 1997 likely improving conditions for winter-run. (NMFS 5, p. 18.)

<u>Spring-Run</u> - Historically, spring-run were likely the most abundant salmonid in the Central Valley inhabiting headwater reaches of all major river systems in the Central Valley in the absence of natural migration barriers. (NMFS 5, p. 28.) Since the 1880s, construction of dams and other factors have significantly reduced the numbers and range of spring-run in the Central Valley. (*Id*.) Currently, the only viable populations occur on Mill, Deer, and Butte creeks, but those populations are small and isolated. (DFG 1998, as cited in NMFS 5, p. 28.) In addition, the Feather River Fish Hatchery which opened in 1967 produces spring-run salmon. However, significant hybridization of these hatchery fish with fall-run has occurred. (NMFS 5, p. 28-31.)

Historically, Central Valley spring-run numbers were estimated to be as large as 600,000 fish. (DFG 1998 as cited in NMFS 5, p. 28.) Nearly 50,000 spring-run adults were counted on the San Joaquin River prior to construction of Friant Dam. (Fry 1961 as cited in NMFS 5, p. 28.) Shortly after construction of Friant Dam, spring-run were extirpated on the San Joaquin River. (Yoshiyama et al. 1998 as cited in NMFS 5, p. 28.) Since 1970, estimates of spring-run populations in the Sacramento River have been as high as 30,000 fish and as low as 3,000 fish. (NMFS 5, p. 28.)

<u>Fall-Run</u> - Historically, fall run likely occurred in all Central Valley streams that had adequate flows during the fall months, even if the streams were intermittent during other parts of the year. (Yoshiyama *et. al* 2001, p. 74.) Due to their egg-laden and deteriorating physical condition, fall-run likely historically spawned in the valley floor and lower foothill reaches and probably were limited in their upstream migration. (Rutter 1904 as cited in Yoshiyama *et. al* 2001, p. 74.)

Currently, fall-run Chinook inhabit both the Sacramento and San Joaquin river basins and are currently the most abundant of the Central Valley races, contributing to large commercial and recreational fisheries in the ocean and popular sportfisheries in the freshwater streams. Fall-run Chinook are raised at five major Central Valley hatcheries which release more than 32 million smolts each year. In the past few years, there have been large declines in fall-run populations with escapements of 88,0000 and 66,000 fish in 2007 and 2008. (NMFS 2009, p. 4.) NMFS concluded that the recent declines were likely primarily due to poor ocean conditions in 2005 and 2006. (*Id*.) Other factors contributing to the decline of fall-run include: loss of spawning grounds due to dams and other factors, degradation of spawning habitat from water diversions, introduced species, altered sediment dynamics, hatchery practices, degraded water quality, and loss of riparian and estuarine habitat. (*Id*.)

Late-Fall Run - Historically, late fall-run probably spawned in the mainstem Sacramento River and major tributary reaches and possibly in the San Joaquin River upstream of its tributaries. (Hatton and Clark 1942; Van Cleve 1945; Fisher 1994 as cited in Yoshiyama *et. al* 2001.) Today, late-fall run are mostly found in the upper Sacramento River where the river remains deep and cool enough in the summer for juvenile rearing. (Moyle 2002, p. 254.) The late fall-run has continued low, but potentially stable abundance. (NMFS 2009, p. 4.) Estimates from 1992 ranged from 6,700 to 9,700 fish and in 1998 were 9,717 fish. However, changes in estimation methods, lack of data, and hatchery influences make it difficult to accurately estimate abundance trends for this run. (*Id.*)

Table 3. Generalized Life History Timing of Central Valley Chinook Salmon Runs

	Migration Period	**Peak Migration**	**Spawning Period**	**Peak Spawning**	**Juvenile Emergence Period**	**Juvenile Stream Residency**
Sacramento River Basin Late Fall-Run	October–April	December	Early January–April	February–March	April-June	7-13 months
Winter-Run	December-July	March	Late April-early August	May-June	July-October	5-10 months
Spring-Run	March-September	May- June	Late August-October	Mid-September	November-March	3-15 months
Fall Run	June-December	September-October	Late September-December	October-November	December-March	1-7 months
San Joaquin (Tuolumne River) Fall-Run	October-early January	November	Late October-January	November	December-April	1-5 months

Population Abundance and Relationship to Flow

Delta outflows and inflows affect rearing conditions and migration patterns for Chinook salmon in the Delta watershed. Freshwater flow serves as an important cue for upstream adult migration and directly affects juvenile survival and abundance as they move downstream through the Delta. (DOI 1, p. 23.) Decreased flows may decrease migration rates and increase exposure to unsuitable water quality and temperature conditions, predators, and entrainment at water diversion facilities. (DFG 1, p. 1.) For the most part, relationships between salmon survival and abundance have been developed using tributary inflows rather than Delta outflows, however, the Delta is an extension of the riverine environment until salmon reach the salt water interface. (DOI 1, p. 29.) Prior to development and channelization, the Delta provided hospitable habitat for salmon. With channelization and other development, the environment is no longer hospitable for salmon. As a result, the most beneficial Delta outflow pattern for salmon may currently be one that moves salmon through the Delta faster. (*d.*)

Salmon respond behaviorally to variations in flows. Monitoring shows that juvenile and adult salmon begin migrating during the rising limb of the hydrograph. (DOI 1, p. 30.) For juveniles, pulse flows appear to be more important than for adults. (*Id.*) For adults, continuous flows through the Delta and up to each of the natal tributaries appears to be more important. (*Id.*) Flows and water temperatures are also important to maintain populations with varied life history strategies in different year types to insure continuation of the species over different hydrologic and other conditions. For salmon migrating as fry within a few days of emigration from redds, increased flows provide improved transport downstream and improved rearing habitat, and for salmon that stay in the rivers to rear, increased flows provide for increased habitat and food production. (DOI 1, 30.)

Population Abundance Goal

The immediate goal is to significantly improve survival of all existing runs of Chinook salmon that migrate through the Delta in order to facilitate positive population growth in the short term and subsequently achieve the narrative salmon protection objective identified in the 2006 Bay-Delta Plan to double the natural production of Chinook salmon from the average production from 1967 to 1991 consistent with the provisions of State and federal law. (State Water Board 2006a, p. 14.)

Species- Specific Recommendations

Delta Outflow

No specific Delta outflow criteria are recommended for Chinook salmon. Any flow needs would generally be met by the following inflow criteria and by the Delta outflow criteria determined for estuarine dependant species discussed elsewhere in this report.

Sacramento River Inflows

The 2006 Bay-Delta Plan includes flow objectives for the Sacramento River at Rio Vista for the protection of fish and wildlife beneficial uses from September through December ranging from 3,000 to 4,500 cfs. (State Water Board 2006a, p. 15.) These flow objectives are in part intended to provide attraction and transport flows and suitable habitat conditions for Chinook salmon. (State Water Board 2006b, p. 49.) The 2006 Bay-Delta Plan includes Delta outflow objectives for the remainder of the year, which effectively provide Sacramento River inflows. However, the Bay-Delta Plan does not include any specific Sacramento River flow requirements for the remainder of the year, including the critical spring period.

Habitat alterations in the Delta limit Sacramento River salmon production primarily through reduced survival during the outmigrant (smolt) stage. Decreases in flow through the estuary, increased temperatures, and the proportion of flow diverted through the Delta Cross Channel and Georgiana Slough on the Sacramento River are associated with lower survival in the Delta of marked juvenile fall-run Sacramento River salmon. (DOI 1, p. 24.) In 1981 (p. 17-18) and 1982 (p. 404), Kjelson et al. reported that flow was positively correlated with juvenile fall-run Chinook salmon survival through the Delta and that temperature was negatively correlated with survival. In testimony before the State Water Board in 1987 Kjelson presented additional analyses that again showed that survival of fall-run Chinook salmon smolts through the Delta between Sacramento and Suisun Bay was found to be positively correlated to flow and negatively correlated to water temperature. (p. 36.) Smolt survival increased with increasing Sacramento River flow at Rio Vista, with maximum survival observed at or above about 20,000 and 30,000 cfs from April through June (p. 36), while no apparent relationship was found at flows between 7,000 and 19,000 cfs (p. 27), suggesting a potential threshold response to flow. Smolt survival was also found to be highest when water temperatures were below 66ºF. (p. 61.) In addition to increased survival, juvenile abundance has also been found to be higher with greater Sacramento River flow. (DFG 3, pp. 1 and 6.) The abundance of juvenile Chinook salmon leaving the Delta at Chipps Island was found to be highest when Rio Vista flows averaged above 20,000 cfs from April through June. (*Id*.)

Dettman et al. (1987) reanalyzed data from the 1987 Kjelson experiments and found a positive correlation between an index of spawning returns, based on coded-wire tagged fish, and both

June and July outflow from the Delta. (p. 1.) In 1989, Kjelson and Brandes updated and confirmed Kjelson's 1987 findings again reporting that survival of smolts through the Delta from Sacramento to Suisun Bay was highly correlated to mean daily Sacramento River flow at Rio Vista. (p. 113.) In the State Water Board's 1992 hearings, USFWS (1992) presented additional evidence, based on data collected from 1988 to 1991, that increased flow in the Delta may increase migration rates of both wild and hatchery fish migrating from the North Delta (Sacramento and Courtland) to Chipps Island. (DOI 1, p. 26.)

In 2001, Brandes and McLain confirmed the relationships between water temperature, flow, and juvenile salmonid survival. (p. 95.) In 2006, Brandes et al. updated findings regarding the relationship between Sacramento River flows and survival and found that the catch of Chinook salmon smolts surveyed at Chipps Island between April and June of 1978 to 2005 was positively correlated with mean daily Sacramento River flow at Rio Vista between April and June. (p. 41-46.)

In addition to the flow versus juvenile fall-run Chinook salmon survival relationships discussed above, several studies show that loss of migrating salmonids within Georgiana Slough and the interior Delta is approximately twice that of fish remaining in the mainstem Sacramento River. (Kjelson and Brandes 1989; Brandes and McLain 2001; Vogel 2004, 2008; and Newman 2008 as cited in NMFS 3, p. 640). Recent studies and modeling efforts have found that increasing Sacramento River flow such that tidal reversal does not occur in the vicinity of Georgiana Slough and at the Cross Channel Gates would lessen the proportion of fish diverted into channels off the mainstem Sacramento River. (Perry et al. 2008, 2009.) Thus, closing the Delta Cross Channel and increasing the flow on the Sacramento River to levels where there is no upstream flow from the Sacramento River entering Georgiana Slough on the flood tide during the juvenile salmon migration period (November to June) will likely reduce the number of fish that enter the interior Delta and improve survival. (DOI 1, p. 24.) To achieve no bidirectional flow in the mainstem Sacramento River near Georgiana Slough, flow levels of 13,000 (personal communication Del Rosario) to 17,000 cfs at Freeport are needed. (DOI 1, p. 24.)

Monitoring of emigration of juvenile Chinook salmon on the lower Sacramento River near Knights Landing also indicates a relationship between timing and magnitude of flow in the Sacramento River and the migration timing and survival of Chinook salmon approaching the Delta from the upper Sacramento River basin. (Snider and Titus 1998, 2000a, 2000b, 2000c, and subsequent draft reports and data as cited in DFG 1, p. 7.) The emigration timing of juvenile late fall, winter, and spring-run Chinook salmon from the upper Sacramento River basin depends on increases in river flow through the lower Sacramento River in fall, with significant precipitation in the basin by November to sustain downstream migration of juvenile Chinook salmon approaching the Delta. (Titus 2004 as cited in DFG 1, p. 7.) Sacramento River flows at Wilkins Slough of 15,000 to 20,000 cfs following major precipitation events are associated with increased emigration. (DFG 1, p. 7 and NMFS 7, p. 2-4.)

Delays in precipitation producing flows result in delayed emigration which may result in increased susceptibility to in-river mortality from predation and poor water quality conditions. (DFG 1, p. 7.) Allen and Titus (2004) suggest that the longer the delay in migration, the lower the survival of juvenile salmon to the Delta. (as cited in DFG 1, p. 7.) DFG indicates that juvenile Chinook salmon appear to need increases in Sacramento River flow that correspond to flows in excess of 20,000 cfs at Wilkins Slough by November with similar peaks continuing past the first of the year. (DFG 1, p. 7.) Pulse flows in excess of 15,000 to 20,000 cfs may also be necessary to erode sediment in the upper Sacramento River downstream of Shasta to create turbid inflow pulses to the Delta. (AR/NHI 1, p. 32.)

Salmon are the only species considered for the Sacramento River inflow criteria; discussion of the flow criteria for Sacramento River inflows is therefore continued in Section 5.2, Sacramento River Inflow criteria.

San Joaquin River Inflows

Currently the Merced, Tuolumne, and Stanislaus river tributaries to the San Joaquin River support fall-run Chinook salmon. Historically spring-run also inhabited the basin. Pursuant to the San Joaquin River Restoration effort, there are plans to reintroduce spring-run Chinook salmon to the main-stem river beginning in 2012. Since the 1980s (1980-1989), San Joaquin basin fall-run Chinook salmon escapement numbers have declined from approximately 26,000 fish to 13,000 fish in the 2000s (2000-2008). (TBI/NRDC 3, p. 22.) Flow related conditions are believed to be a significant cause of this decline.

The 2006 Bay-Delta Plan includes flow objectives for the San Joaquin River at Vernalis, largely for the protection of fall-run Chinook salmon. The plan includes base flows during the spring (February through June with the exception of mid-April through mid-May) that vary between 700 and 3,420 cfs based on water year type and required location of X2. To improve juvenile fall-run Chinook salmon outmigration, the Plan also includes spring pulse flows (mid-April through mid-May) that vary between 3,110 and 8,620 cfs, however, those flows have never been implemented and have instead been replaced with the Vernalis Adaptive Management Plan (VAMP) flow targets for the past 10 years. The VAMP flows are lower than the pulse flow objectives and vary between 2,000 and 7,000 cfs based on existing flows and other conditions. (State Water Board 2006a, p. 24-26.) The 2006 Bay-Delta Plan also includes a flow objective of 1,000 to 2,000 cfs during October to support adult fall-run Chinook salmon migration. (State Water Board 2006b, p. 15-16.) The 2006 Bay-Delta Plan does not include any specific flow requirements during the remainder of the year. (State Water Board 2006b, pg. 50.)

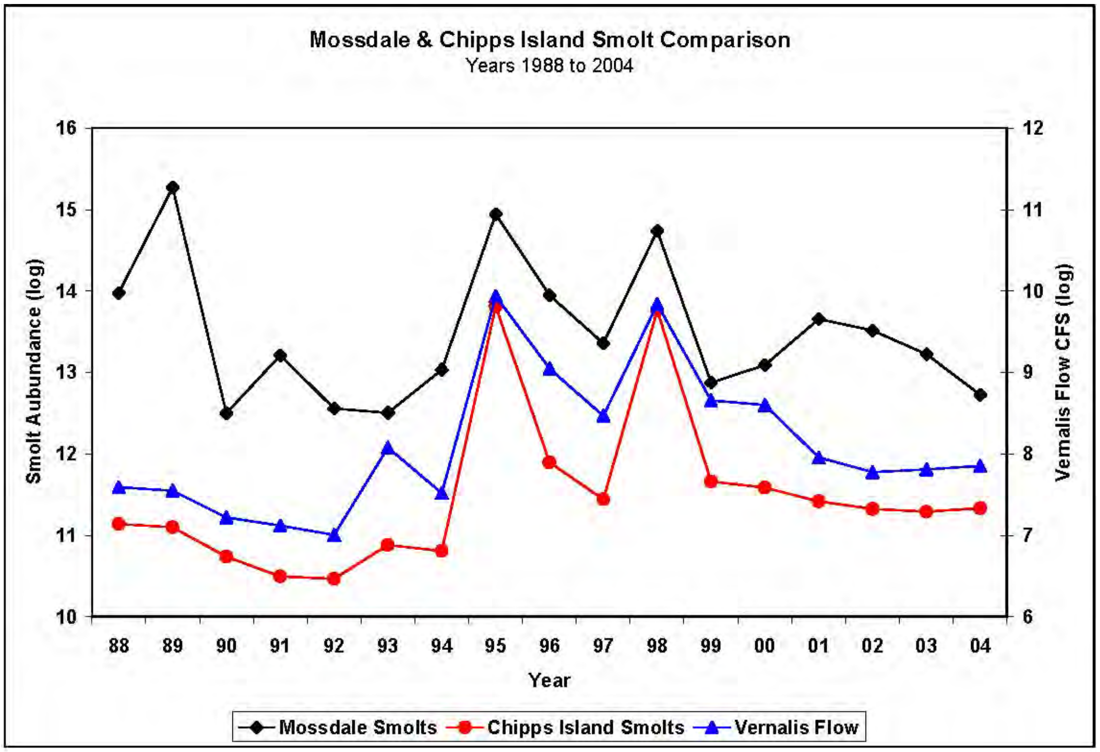
Inflows from the San Joaquin River affect various life stages of Chinook salmon including adult migration, spawning, egg incubation, juvenile rearing, and juvenile emigration to the ocean. Evidence indicates that to maintain a viable Chinook salmon population, escapements should not decline below approximately 833 adult salmon per year (a total of 2,500 salmon in 3 years), and fluctuations in escapement between wet and dry years should be reduced by increasing dry year escapements and the percentages of hatchery fish should be reduced to no more than 10%. (Lindley and others 2007, as cited in CSPA 14, p. 3-4.) Mesick estimates that the Tuolumne River population is currently at a high risk of extinction (Mesick 2009); and that the Stanislaus and Merced river populations are also likely soon to be at a high risk of extinction due to high percentages of hatchery fish. (CSPA 7, p.4.)

Mesick estimates that the decline in escapement on the Tuolumne River from 130,000 salmon in the 1940s to less than 500 in recent years is primarily due to inadequate minimum instream flow releases from La Grange Dam in late winter and spring during non-flood years. (CSPA 14, p. 1.) Mesick suggests that escapement has been primarily determined by the rate of juvenile survival, which is primarily determined by the magnitude and duration of late winter and spring flows since the 1940s. (CSPA 14, p. 2.) Mesick indicates that other analyses show that spawner abundance, spawning habitat degradation, and the harvest of adult salmon in the ocean have not caused the decline in escapement. (CSPA 14, p. 1.)

Successful adult Chinook salmon migration depends on environmental conditions that cue the response to return to natal streams. Optimal conditions help to reduce straying and maintain egg viability and fecundity rates. (DFG 3, p. 2 and CSPA 7, p. 1.) Analyses of flow needs for the protection of adult fall-run migration conducted by Hallock and others from 1964 to 1967 indicate that the presence of Sacramento River water in the central and south Delta channels results in migration delays for both San Joaquin River and Sacramento River basin salmon. (Hallock et al*.,* 1970 as cited in DOI 1, p. 25.) These analyses also show that reverse flows on the San Joaquin River delay and potentially hamper migration. (*Id.*) In addition, analyses by Hallock show that water temperatures in excess of 65˚ F and low DO conditions of less than 5 mg/l in the San Joaquin River near Stockton act as a barrier to adult migration. (as cited in AFRP 2005, p. 11.) Delayed migration may result in reduced gamete viability under elevated temperatures and mortality to adults prior to spawning. (AFRP 2005, p. 12.)

Mesick found that up to 58% of Merced River Hatchery Chinook salmon strayed to the Sacramento River Basin when flows in the San Joaquin River were less than 3,500 cfs for ten days in late October, but stray rates were less than 6% when flows were at least 3,500 cfs. (CSPA 14, p. 15 and CSPA 7, p. 1.) Mesick indicates that providing 1,200 cfs flows from the tributaries to the San Joaquin River (Merced, Tuolumne, and Stanislaus) for ten days in late October increases escapement by an average of 10%. (Mesick 2009 as cited in CSPA 7, p. 1.) The 2005 AFRP includes similar recommendations for flows of 1,000 cfs from each of the San Joaquin River tributaries. (AFRP, p. 12.) Such flows would likely improve DO conditions, temperatures, and olfactory homing fidelity for San Joaquin basin salmon. (Harden Jones 1968, Quinn et al. 1989, Quinn 1990 as cited in EDF 1, p. 48.) To achieve olfactory homing fidelity and continuous flows for adult migration, the physical source of this water is at least as important as the volume or rate of flow, especially given that the entire volume of the San Joaquin River during the fall period is typically diverted at the southern Delta export facilities. (EDF 1. p. 48.) Even in the absence of exports, it is necessary for the scent of the San Joaquin basin watershed to enter the Bay in order for adult salmonids to find their way back to their natal rivers. (NMFS 2009, p.407 as cited in EDF 1, p. 48.)

Outmigration success of juvenile Chinook salmon is affected by multiple factors, including water diversions and conditions related to flow. Data show that smolt survival and resulting adult production is better in wet years. (Kjelson and Brandes, 1989, SJRGA, 2007 as cited in DOI 1, p. 24.) VAMP analyses indicate that San Joaquin River flow at Vernalis is positively associated with the probability of survival for outmigrating smolts from Dos Reis (downstream of the Old River bifurcation) to the Delta (Jersey Point). (Newman, 2008 as cited in DOI 1, p. 24.) A positive relationship has also been shown between salmon survival indices and flow at Jersey Point for fish released at Jersey Point. (USFWS 1992, p. 21 as cited in DOI 1, p. 24.) Data indicate that maximum San Joaquin basin adult fall-run chinook salmon escapement may be achieved with flows exceeding 20,000 cfs at Vernalis during the smolt emigration period of April 15 through June 15. (2006 VAMP report page 65; DOI 1, p. 25.) As indicated below in Figure 9, DFG found that more spring flow from the San Joaquin River tributaries results in more juvenile salmon leaving the tributaries, more salmon successfully migrating to the South Delta, and more juvenile salmon surviving through the Delta. (DFG 3, p. 17.) DFG concludes that the primary mechanism needed to substantially produce more smolts at Jersey Point is to substantially increase the spring Vernalis flow level (magnitude, duration, and frequency) which will produce more smolts leaving the San Joaquin River tributaries, and produce more smolts surviving to, and through, the South Delta. (DFG 3, p. 17-18.) DFG indicates that random rare and unpredictable poor ocean conditions may cause stochastic high mortality of juvenile salmon entering the ocean, but that the overwhelming evidence is that more spring flow results in higher smolt abundance, and higher smolt abundance equates to higher adult production. (DFG 3, p.17.)



Note: This figure shows the relationship of smolt abundance (log transformed) at Mossdale to estimate smolt abundance at Chipps Island by average spring (3/15 to 6/15) Vernalis flow level (log transformed). To estimate the number of smolts at Chipps Island the smolt survival vs. flow level relationship developed by Dr. Hubbard was applied on a daily basis to the Mossdale smolt abundance and out-migration pattern. Smolt abundance at Chipps Island (or stated differently smolt survival through the Delta on an annual basis) can change by an order of magnitude pending Vernalis flow rate. (DFG 3, p. 16.)

Figure 9. Salmon Smolt Survival and San Joaquin River Vernalis Flows

Elevated flows during the smolt outmigration period function as an environmental cue to trigger migration, facilitate transport of juveniles downstream, improve migration corridor conditions to inundate floodplains, reduce predation and improve temperature and other water quality conditions; these are all functions that are currently extremely impaired on the San Joaquin River. (e.g., “Steelhead stressor matrix,” NMFS 2009 as cited in TBI/NRDC 3, p. 7.) Under the 2006 Bay-Delta Plan, elevated flows are limited to approximately the mid-April to mid-May period. However, outmigration timing in the San Joaquin River basin occurs over a prolonged time frame from mid-March through June. (TBI/NRDC 3, p. 12-13.) This restricted window may impair population viability by limiting survival of fish that migrate outside of this time period, thus reducing the life history diversity and the genetic diversity of the population. (TBI/NRDC 3, p. 11-12.) Diverse migration timing increases population viability by making it more likely that at least some portion of the population is exposed to favorable ecological conditions in the Delta and into the ocean. (Smith et al. 1995 as cited in TBI/NRDC 3, p. 12.)

Temperature conditions in the San Joaquin River basin may limit smolt outmigration and survival. Lethal temperature thresholds for Pacific salmon depend, to some extent, on acclimation temperatures. (Myrick and Cech 2004 as cited in TBI/NRDC 3, p. 18.) Central Valley salmonids are generally temperature-stressed through at least some portion of their freshwater life-cycle. (e.g. Myrick and Cech 2004, 2005 as cited in TBI/NRDC 3, p. 18.) Lethal temperature effects commence in a range between 71.6° and 75.2° F (Baker et al.1995 as cited in TBI/NRDC 3, p. 18), with sub-lethal effects occurring at lower temperatures. Access to food also affects temperature responses. When fish have adequate access to food, growth increases with increasing temperature, but when food is limited (which is typical), optimal growth occurs at lower temperatures. (TBI/NRDC 3, p 18.) Marine and Cech (2004) observed decreased growth, smoltification success, and predator avoidance at temperatures above 68˚ F and that fish reared at temperatures between 62.6˚ and 68˚ F experienced increased predation compared to fish reared at between 55.4˚ and 60.8˚ F. (as cited in TBI/NRDC 3, p. 18.) Several studies indicate that optimal rearing temperatures for Chinook salmon range from 53.6˚ to 62.6F (Richter and Kolmes 2005 as cited in TBI/NRDC 3, p. 18.) Mesick found that Tuolumne River smolt outmigration rates and adult recruitment were highest when water temperatures were at or below 59˚F when smolts were migrating in the lower river. (Mesick 2009, p. 25.) Elevated temperatures may also affect competition between different species. (Reese and Harvey 2002 as cited in TBI/NRDC 3, p. 18.)

Temperature is determined by a number of factors including reservoir releases, channel geometry, and ambient air temperatures. As a result, a given flow may achieve different water temperatures depending on the other conditions listed above. Cain estimates that flows over 5,000 cfs in late spring (April to May) generally provide water temperatures (below 65˚ F) suitable for Chinook salmon, but that flows less than 5,000 cfs may be adequate to provide sufficient temperature conditions. (Cain 2003 as cited in TBI/NRDC 3, p 13-14.) Mesick indicates that salmon smolt survival can be improved by maintaining water temperatures near 59˚F from March 15 to May 15 and as low as practical from May 16 to June 15. (CSPA 7, p. 2-3.) To maintain mean water temperatures near 59˚F and maximum temperatures below 65˚F from March 15 to May 15 in the tributaries downstream to the confluence with the San Joaquin River, Mesick indicates that flows need to be increased in response to average air temperature. (CSPA 7, p. 3.)

There are several different estimates for flow needs on the San Joaquin River during the spring period to improve or double salmon populations on the San Joaquin River. The USFWS's 2005 *Recommended Streamflow Schedules to Meet the AFRP Doubling Goal in the San Joaquin River Basin* (2005 AFRP) concludes that the declines in salmon in the San Joaquin River basin primarily resulted from reductions in the frequency and magnitude of spring flooding in the basin from 1992-2004 compared to the baseline period of 1967-1991. (2005 AFRP, p. 1.) The AFRP states that the most likely method to increase production of fall-run Chinook salmon is to increase flows from February to March to increase survival of juveniles in the tributaries and smolts in the mainstem and then to increase flows from April to mid-June to increase smolt survival through the Delta. (*Id.*) Using salmon production models for the San Joaquin River Basin, the AFRP provides recommendations for the amount of flow at Vernalis that would be needed to double salmon production in the San Joaquin River basin. On average, over the four month period of February to May, the AFRP recommends that flows range from less than 4,000 cfs in critical years to a little more than 10,000 cfs in wet years. From March through June, AFRP recommends that flows average between about 4,500 cfs in critical years to more than 12,000 cfs in wet years. (2005 AFRP, p. 8-10.)

Using a non-linear regression empirical data driven fall-run Chinook salmon production model, DFG developed flow recommendations for the San Joaquin River from March 15 through June 15 to double Chinook salmon smolt production. DFG developed a variety of modeling scenarios to evaluate the effects of various combinations of flow magnitudes and durations in order to identify the combination of flow levels varied by water year type to achieve doubling of juveniles. Base flows for the March 15 through June 15 period vary between 1,500 cfs in critical years to

6,315 cfs in wet years. Pulse flow recommendations vary between 7,000 cfs and 15,000 cfs for durations of 31 to 70 days depending on water year type. (DFG 3, p. 34.)

In analyzing the relationship between Vernalis flow and cohort return ratios of San Joaquin River Chinook salmon, TBI/NRDC found that Vernalis average March through June flows of approximately 4,600 cfs corresponded to an equal probability for positive population growth or negative population growth. (TBI/NRDC 3, p. 24.) TBI/NRDC found that average March through June flows exceeding 5,000 cfs resulted in positive population growth in 84% of years with only 66% growth in years with flows less than 5,000 cfs. (*Id.)* TBI/NRDC found that flows of 6,000 cfs produced a similar response as the 5,000 cfs flows and flows of 4,000 cfs or lower resulted in significantly reduced population growth of only 37% of years. (*Id*.) The TBI/NRDC analysis suggests that 5,000 cfs may represent an important minimum flow threshold for salmon survival on the San Joaquin River. (*Id*.) Based on abundance to prior flow relationships, TBI/NRDC estimates that average March through June inflows of 10,000 cfs are likely to achieve the salmon doubling goal. (TBI/NRDC 3, p. 16-17.)

In addition to fall pulse flows for adult migration and spring flows to support juvenile emigration, additional flows on the San Joaquin River may be needed at other times of year to support Chinook salmon and their habitat. The 2006 Bay-Delta Plan does not include base flow objectives for the San Joaquin River. However, the Central Valley Regional Board's Water Quality Control Plan for the Sacramento and San Joaquin River Basins does include a year round DO objective of 5.0 mg/l at all times on the San Joaquin River within the Delta. (Central Valley Regional Board 2009,. III-5.0). The 2006 Bay-Delta Plan and the Central Valley Basin Plan also include a DO objective of 6.0 mg/L between Turner Cut and Stockton from September 1 through November 30. (*Id*.)

Current flow conditions on the San Joaquin River result in DO conditions below the existing DO objectives in the fall and winter in lower flow years. These conditions may result in delayed migration and mortality to San Joaquin River Chinook salmon, steelhead and other species. Increased flows would improve DO levels in the lower San Joaquin River. Additional flows at other times of year in the tributaries to the San Joaquin River would also provide improved conditions for steelhead inhabiting tributaries to the San Joaquin River (NMFS 3, p. 105) and would have additional benefits by reducing nutrients pollution and biological oxygen demand. (TBI/NRDC 3, p. 27.)

To reduce crowding of spawning adults during the fall, increased flows in the tributaries may also be needed from November through January to ensure protection of Chinook salmon. (AFRP, p. 12.) However, there is no evidence that increased flows would reduce spawner crowding or improve juvenile production. (*Id*.) Habitat modeling indicates that flows of up to 300 cfs on the San Joaquin River tributaries may provide optimum physical habitat during the fall. (AFRP 2005, p. 14.)

To maintain the ecosystem benefits of a healthy riparian forest, minimum flows and ramping rates for riparian recruitment may also be needed during late spring and early summer. (AFRP 2005, p. 14.) To protect over-summering steelhead and salmon, flows in the tributaries during the summer and fall are needed. To maintain minimal habitat of a suitable temperature (less than 65° F), flows between 150 and 325 cfs may be needed on each of the tributaries to the San Joaquin River. (AFRP 2005, pp. 14-15.)

The magnitude, duration, timing, and source of San Joaquin River inflows are important to San Joaquin River Chinook salmon migrating through the Delta and several different aspects of their life history. Inflows are needed to provide appropriate conditions to cue upstream adult migration to the San Joaquin River and its tributaries, adult holding, egg incubation, juvenile rearing, emigration from the San Joaquin River and its tributaries, and other functions. San Joaquin River inflows are important during the fall to provide attraction flows and are especially important during juvenile emigration periods. Flows on tributaries to the San Joaquin River are also important for egg incubation and rearing, in addition to migration.

As with the Sacramento River inflows, Chinook salmon are the only species considered for the San Joaquin River inflow criteria; discussion of flow criteria for San Joaquin River inflows is therefore continued in Section 5.3, San Joaquin River inflow criteria.

Hydrodynamics

All Central Valley Chinook salmon must migrate out of the Delta as juveniles and back through the Delta as adults returning to spawn. In addition, many Central Valley Chinook salmon also rear in the Delta for a period of time. (DOI 1, p. 53.) Delta exports affect salmon migrating through and rearing in the Delta by modifying tidally dominated flows in the channels. It is, however, difficult to quantitatively evaluate the direct and indirect effects of these hydrodynamic changes. Delta exports can cause a false attraction flow drawing fish to the export facilities where direct mortality from entrainment may occur. (DOI 1, p. 29.) More important than direct entrainment effects, however, may be the indirect effects caused by export operations increasing the amount of time salmon spend in channelized habitats where predation is high. (*Id*.) Steady flows during drier periods (as opposed to pulse flows that occur during wetter periods) may increase these residence time effects. (DOI 1.)

Direct mortality from entrainment at the south Delta export facilities is most important for San Joaquin River and eastside tributary salmon (and steelhead). (DOI 1, p. 29.) Juvenile salmonids emigrate downstream on the San Joaquin River during the winter and spring. Salmonids from the Calaveras River basin and the Mokelumne River basin also use the lower San Joaquin River as a migration corridor. This lower reach of the San Joaquin River between the Port of Stockton and Jersey Point has many side channels leading toward the export facilities that draw water through the channels to the export pumps. (NMFS 3, p. 651.) Particle tracking model (PTM) simulations and acoustic tagging studies indicate that migrating fish may be diverted into these channels and may be affected by flow in these channels. (Vogel 2004, SJRGA 2006, p. 68, SJRGA 2007, pp. 76-77, and NMFS 3, p. 651.) Analyses indicate that tagged fish may be more likely to choose to migrate south toward the export facilities during periods of elevated diversions than when exports are reduced. (Vogel 2004.)

Similarly, salmon that enter the San Joaquin River through Georgiana Slough from the Sacramento River may also be vulnerable to export effects. (NMFS 3, p. 652.) While fish may eventually find their way out of the Central Delta channels after entering them, migratory paths through the Central Delta channels increase the length and time that fish take to migrate to the ocean increasing their exposure to predation, increased temperatures, contaminants, and unscreened diversions. (NMFS 3, p. 651-652.)

PTM analyses indicate that as net reverse flows in Old and Middle rivers increase from -2,500 cfs to -3,500 cfs, particle entrainment changes from 10% to 20% and then again to 40% when flows are -5,000 cfs and 90% when flows are -7,000 cfs. (*Id*.) Based on these findings, NMFS's Opinion includes requirements that exports be reduced to limit negative net Old and Middle river flows to -2,500 cfs to -5,000 cfs depending on the presence of salmonids from January 1 through June 15. (NMFS 3, p. 648.)

In addition to effects of net reverse flows in Old and Middle rivers, analyses concerning the effects of net reverse flows in the San Joaquin River at Jersey Point were also conducted and documented in the USFWS, 1995 *Working Paper on Restoration Needs, Habitat Restoration Actions to Double the Natural Production of Anadromous Fish in the Central Valley California* (1995Working Paper). These analyses show that net reverse flows at Jersey Point decrease the survival of smolts migrating through the lower San Joaquin River. (USFWS 1992b as cited in USFWS 1995b, p. 3Xe-19.) Net reverse flows on the lower San Joaquin River and diversions into the central Delta may also result in reduced survival for Sacramento River fall-run Chinook salmon. (USFWS 1995b, p. 3Xe-19) Based on these factors, the 1995 Working Paper includes a recommendation to maintain positive flows at Jersey Point of 1,000 cfs in critical and dry years, 2,000 cfs in below- and above-normal years, and 3,000 cfs in wet years from October 1 through June 30 to improve survival for all races and stocks of juvenile salmon and steelhead migrating through and rearing in the Delta. (*Id*.)

In addition to relationships between reverse flows and entrainment effects, flows on the San Joaquin River versus exports also appear to be an important factor in protecting San Joaquin River Chinook salmon. Various studies show that, in general, juvenile salmon released downstream of the effects of the export facilities (Jersey Point) have higher survival out of the Delta than those released closer to the export facilities. (NMFS 3-Appendix 3, p. 74.) Studies also indicate that San Joaquin basin Chinook salmon production increases when the ratio of spring flows to exports increases. (DFG 2005, SJRGA 2007 as cited in NMFS 3-Appendix 3, p. 74.) However, it should be noted that flow at Vernalis appears to be the controlling factor. Increased flows in the San Joaquin River in the Delta may also benefit Sacramento basin salmon by reducing the amount of Sacramento River water that is pulled into the central Delta and increasing the amount of Sacramento River water that flows out to the Bay. (NMFS 3, Appendix 3, p. 74-75.) Based on these findings, the NMFS Opinion calls for export restrictions from April 1 through May 31 with Vernalis flows to export ratios ranging from 1.0 to 4.0 based on water year type, with unrestricted exports above flows of 21,750 cfs at Vernalis, in addition to other provisions for health and safety requirements. (NMFS 3, Appendix 3, p.73-74.)

Analyses by TBI/NRDC indicate that Vernalis flow to export ratios above 1.0 during the San Joaquin basin juvenile salmon outmigration period in the spring consistently correspond to higher escapement estimates two and half years later, with more than 10,000 fish in 76% of years. (TBI/NRDC 4, p. 11.) Vernalis flows to export ratios of less than 1.0 correspond to lower escapement estimates two and half years later, with more than 10,000 fish in only 33% of years. (*Id*.) TBI/NRDC estimates that Vernalis flows to export ratios of greater than 4.0 would reach population abundance goals. (TBI/NRDC 4, pp. 11-12.)

Vernalis flows to export ratios also appear to be important during the fall period to provide improved migration conditions for adult fall-run San Joaquin basin Chinook salmon. Adult fall-run San Joaquin basin Chinook salmon migrate upstream through the Delta primarily during October when San Joaquin River flows are typically low. (AFRP 2005, p. 12.) As a result, when exports are high, little if any flow from the San Joaquin basin may make it out to the ocean to help guide San Joaquin basin salmon back to the basin to spawn. (*Id*.) Analyses indicate that increased straying occurs when more than 400% of the flow at Vernalis is exported at the Delta pumping facilities (equivalent to a Vernalis flow to export ratio of 0.25). (*Id*.) Straying rates decreased substantially when export rates were less than 300% of Vernalis flow. (*Id.*)

Export related criteria for salmon are provided in section 5.4, Hydrodynamic Recommendations.

Floodplain Flows

Juvenile salmon will rear on seasonally inundated floodplains when available. Such rearing in the Central Valley, in the Yolo Bypass and the Cosumnes River floodplain, has been found to have a positive effect on growth and apparent survival of juvenile Central Valley salmon through the Delta. (Sommer *et al*. 2001 and Jeffres *et al*. 2005 as cited in DOI 1, p. 27 and Sommer *et al*. 2005 and Jeffres *et al*. 2008 as cited in NMFS 3, p. 609.) The increased growth rates may be due to increased temperatures and increased food supplies. (DOI 1, p. 27, DFG 3, p. 3.) Floodplain rearing provides conditions that promote larger and faster growth which improves outmigration, predator avoidance, and ultimately survival. (Stillwater Science 2003 as cited in DFG 3, p. 6.) Increased survival may also be related to the fact that ephemeral floodplain habitat and other side-channels provide better habitat conditions for juvenile salmon than intertidal river channels during high flow events when, in the absence of such habitat, juvenile salmon may be displaced to these intertidal areas. (Grosholz and Gallo 2006 as cited in DOI 1, p. 27 and Stillwater Science as cited in DFG 3, p. 6.) The improved growing conditions provided by floodplain habitat are also believed to improve ocean survival resulting in higher adult return rates. (Healy 1982, Parker 1971 as cited in DOI 1, p. 28.)

While floodplain habitat is generally beneficial to salmon, it may also be detrimental under certain conditions. Areas with engineered water control structures have comparatively higher rates of stranding. (Sommer *et al*. 2005 as cited in DOI 1, p. 28.) In addition, high temperatures, low DO, and other water quality conditions that may occur on floodplains may adversely affect salmon. (DFG 3, p. 6.) Reduced depth may also make salmon more susceptible to predation. (*Id*.) Water depths of 30 cm or more are believed to reduce the risk of avian predation. (Gawlik 2002 as cited in DFG 3, p. 6.) Further, the most successful native fish are those that use the floodplain for rearing, but leave before the floodplain becomes disconnected to the river. (Moyle *et al*. 2007, DFG 3, p. 6.) From a restoration perspective, projects should be designed to drain completely to minimize formation of ponds in order to avoid stranding. (Jones and Stokes, 1999 as cited in DOI 1, p. 28.) Bioenergetic modeling indicates that with regard to increased temperatures, increased food availability may be sufficient to offset increased metabolic demands from higher water temperatures. (DFG 3, p. 6.) However, as temperatures increase, juveniles may be unable to migrate to areas of lower temperatures due to reduced swimming ability. (DFG 3, p. 7.) As a result, as summer temperatures increase, floodplain habitat should also decrease. (*Id*.)

The timing of floodplain inundation for the protection of Central Valley Chinook salmon should generally occur from winter to mid-spring to coincide with the peak juvenile Chinook salmon outmigration period (which itself generally coincides with peak flows) and to avoid non-native access to the floodplain (which would generally occur in late-spring). (AR/NHI 1, p. 25.) The benefits of floodplain inundation generally increase with increasing duration, with even relatively short periods of two-weeks providing potential benefits to salmon. (Jeffres *et al*., 2008 as cited in AR/NHI 1, p. 25.) Benefits to salmon may also increase with increasing inter-annual frequency of flooding. Repeated pulse flows and associated increased residence times may be associated with increased productivity which would benefit salmon growth rates and potentially reduce stranding. (*Id*.)

Table 4, developed by AR/NHI, provides estimated thresholds for inundating floodplain habitat under existing and potentially modified conditions. Inundation threshold refers to the discharge when floodwaters begin to inundate the floodplain. Target discharge is the amount of water necessary to produce substantial inundation and flow across the floodplain. (Source: AR/NHI 1, p. 30.)

Floodplain inundation criteria for protection of salmon are provided in section 5.6.2, Floodplain Activation, under Other Measures.

Table 4. Inundation Thresholds for Floodplains and Side Channels at Various Locations Along the Sacramento River

American Shad (*Alosa sapidissima*)

Status

This species is not listed pursuant to either the ESA or CESA.

Life History[13]

The American shad (*Alosa sapidissima*) is an anadromous fish, introduced into California in the late 1880s, that has become an important sport fish within the San Francisco Estuary. American shad range from Alaska to Mexico and use major rivers between British Columbia and the Sacramento watershed for spawning. (Moyle 2002.)

American shad adults, at 3 to 5 years of age, return from the ocean and migrate into the freshwater reaches of the Sacramento and San Joaquin rivers during March through May, with peak migration occurring in May (Stevens *et al*. 1987). Within California, the major spawning run occurs in the Sacramento River up to Red Bluff and in the adjoining American, Feather, and Yuba rivers with lesser use of the Mokelumne, Cosumnes, and Stanislaus rivers and the Delta (Moyle 2002). Spawning takes place from May through early July (Stevens *et al*. 1987). Following their first spawning event, American shad will return annually to spawn up to seven years of age (Stevens *et al*. 1987). It is believed that river flow will affect the distribution of first time spawners, with numbers of newly mature adults spawning in rivers proportional to flows at the time of arrival (Stevens *et al*. 1987). Spawning takes place in the main channels of the rivers with flows washing negatively buoyant eggs downstream. Depending upon temperature, larvae hatch from eggs in 3 to 12 days and will remain planktonic for 4 weeks (Moyle 2002).

---

[13] This section was largely extracted from DFG Exhibit 1, pages 26-27.

The lower Feather River and the Sacramento River from Colusa to the northern Delta provide the major summer nursery for larvae and juveniles. Flows drive the transport of young downstream, with wet years changing the location of the concentration of young and their nursery area further downstream into the northern Delta (Stevens *et al*. 1987). Out migration of young American shad through the Delta occurs from June through November (Stevens 1966). American shad spawned and rearing in the Delta and those that travel through the Delta during out migration are vulnerable to entrainment at the State and federal pumping facilities; catches at the facilities in some years have numbered in the millions (Stevens and Miller 1983). During migration to the ocean, young fish feed upon zooplankton, including copepods, mysids, and cladocerans, as well as amphipods (Stevens 1966, Moyle 2002). Most American shad migrate to the ocean by the end of their first year, but some remain in the estuary (Stevens *et al*. 1987).

Population Abundance and its Relationship to Flow

Year class strength correlates positively with river flow during the spawning and nursery period (April-June). (Stevens and Miller 1983.) American shad exhibit a weak but significant relationship to X2, (Kimmerer 2002a). After 1987, the relationship changed such that abundance increased per unit flow. (Kimmerer 2002a, Kimmerer 2009.) The X2 versus abundance relationship has remained intact into recent years. (Kimmerer *et al*. 2009.) In addition, Kimmerer *et al*. (2009) found that American shad had a habitat relationship (defined by salinity and Secchi depth) to X2 that appeared consistent with its relationship of abundance to X2 (i.e., slopes for abundance versus X2 and habitat versus X2 were similar), which provides some support for the idea that increasing quantity of habitat could explain the X2 relationship for this species (a possible causal mechanism for the abundance versus X2 relationship). Stevens and Miller (1983) determined that the apparent general effect of high flow on all of the species they examined, including American shad, is to increase the quality and quantity of nursery habitat and more widely disperse the young fish, thus reducing density-dependent mortality.

Population Goal

The immediate goal is to maintain viable populations of this species by providing sufficient flows to facilitate attraction of spawners, survival of eggs and larvae, and dispersal of young fish to suitable nursery habitats.

Species-Specific Recommendations

Delta Outflow

The DFG's current science-based conceptual model is that placement of X2 in Suisun Bay represents the best interaction of water quality and landscape for fisheries production given the current estuary geometry. (DFG 2, p. 6.) Maintaining X2 at 75 km and 64 km corresponds to net Delta outflows of approximately 11,400 cfs and 29,200 cfs, respectively. As noted by DFG, X2, in this instance, is a surrogate for tributary and mainstem river inflows to the Delta that support egg and larval survival. The species specific flow criteria to protect American shad shown in Table 5 are consistent with those submitted by DFG. (closing comments, p. 7.)

Inflows

No explicit recommendations for inflows to support American shad were identified in the record. The DFG provided outflow criteria for this species based on positioning X2 in Suisun Bay (DFG closing comments, p. 7); noting that in this instance X2 is a surrogate for tributary and mainstem river inflows. As noted above, year class strength correlates positively with river flow during the spawning and nursery period (April to June). (Steven and Miller 1983.) Flows must be sufficient to attract American shad spawners into Sacramento River tributaries, transport and disperse the young fish to suitable nursery habitat, and reduce the probability of entrainment of young fish and their food organisms in water diversions. (DFG 1987 [Exh 23, p. 23].) Water development has reduced flows during the spring and early summer periods which are most critical in this respect. (*Id.*) The spawning and nursery period, during which inflows appear to be most critical for this species, generally correspond to important periods for other more sensitive species (e.g., salmon outmigration, longfin smelt spawning and rearing). It is anticipated that by providing sufficient flows to meet the outflow criteria recommended above, favorable river conditions will be provided to support American shad spawning and rearing.

Old and Middle River Flows

American shad spawned and rearing in the Delta and those that travel through the Delta during out migration are vulnerable to entrainment at the State and Federal export facilities; in some years catches at the facilities have numbered in the millions. (Stevens and Miller 1983.) Although evaluations of screening efficiency comparable to studies for striped bass and salmon had not been completed for American shad, DFG believed in 1987 that larger fish in the fall were screened fairly efficiently, while screening efficiencies for newly metamorphosed juveniles in the late spring and early summer were quite low. (DFG 1987 [Exh 23, p. 20].) American shad are notoriously intolerant of handling. Tests have shown that losses of American shad that were successfully screened exceeded 50%during the summer months, with slightly lower mortalities during the cooler fall months. (DFG 1987 [Exh 23, p. 22].) These high handling mortalities suggest the only practical strategy for reducing losses may be pumping schedules that minimize shad entrainment. (*Id.*). However, no recommendations specific to American shad for net OMR flows or pumping restrictions were identified in the record. Net OMR flow criteria are intended to protect salmon, delta smelt, and longfin smelt populations and are also likely to reduce the number of American shad entrained at the export facilities. In addition, restrictions stipulated in the OCAP Biological Opinions (NMFS 3, pp. 648-653; USFWS 2008) will also reduce entrainment of American shad.

Table 5. Delta Outflows to Protect American Shad

Effect or Mechanism	Water Year	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec

[1] For this species, X2 is a surrogate for tributary and mainstem river inflows to the Delta that support egg and larval survival. Source: DFG 1, p. 26; DFG 2, p. 6, DFG closing comments, p. 7.

4.2.4 Life History Requirements – Pelagic Species

Following are life history and species-specific requirements for longfin smelt, Delta smelt, Sacramento splittail, starry flounder, Bay shrimp, and zooplankton

Longfin Smelt (*Spirinchus thaleichthys*)

Status

Longfin smelt is listed as a candidate for threatened status under the CESA. (DFG 2010.)

Life History

Longfin smelt are a native species that live two years with females reproducing in their second year. Both juveniles and adults feed on zooplankton. Longfin smelt is an anadromous, open water species moving between fresh and salt water. Adults spend time in San Francisco Bay and may go outside the Golden Gate for short periods. Adults aggregate in Suisun Bay and the western Delta in late fall and migrate upstream to spawn in freshwater as water temperatures drop below 18˚C. (Baxter *et al*. 2009.) The spawning habitat is between the confluence of the Sacramento and San Joaquin rivers (around Point Sacramento) to Rio Vista on the Sacramento side and Medford Island on the San Joaquin River. Spawning activity appears to decrease with distance from the low salinity zone, so the location of X2 influences how far spawning migrations extend into the Delta. (Baxter *et al*. 2009.) Spawning takes place between November and April with peak reproduction in January. Eggs are deposited on the bottom and hatch between December and May into buoyant larvae. Peak hatch is in February. Net Delta outflow transports the larvae and juvenile fish to higher salinity water.

Population Abundance and its Relationship to Flow

The population abundance of longfin smelt is positively correlated with spring Delta outflow and inversely related to net OMR spring reverse flows. The correlations are interpreted to mean that net Delta outflow and net reverse OMR flows are, at least partially, responsible for controlling the abundance of longfin smelt. Modifications in the two flow regimes are intended to begin to stabilize and increase the population abundance of longfin smelt. Each correlation is discussed below.

The population abundance of longfin smelt is positively related to Delta outflow during winter and spring. (Jassby *et al*. 1995; Rosenfield and Baxter 2007; Kimmerer 2002a; Kimmerer *et al*. 2009.) The statistically strongest outflow averaging period is January-June. The abundance relationships are from the fall mid-water trawl (FMWT) survey, the bay study mid-water trawl, and the bay study otter trawl. All three surveys show statistically significant positive relationships between the abundance of juveniles/adults and Delta outflow. There has been a decrease in the carrying capacity of the estuary since 1988, presumably because of the invasion of the clam *Corbula*, but the overall winter spring relationship is still statistically significant. More spring outflow results in more smelt as measured by all three indices. The biological basis for the spring outflow relationship is not known. Baxter et al. (2009) speculate that the larvae may benefit from increased downstream transport, increased food production, and a reduction in entrainment losses at the SWP and CVP pumps.

The population abundance of juvenile and adult longfin smelt, as measured by the FMWT index, is also inversely related to the number of fish salvaged at the SWP and CVP pumping facilities. (TBI/NRDC 4, pp. 19-20.) High pumping rates at the two facilities cause net OMR reverse flows which passively move all age groups of longfin smelt toward entrainment at the pumps. A subset of the juvenile and adult populations are counted at the pumping facilities. Larval longfin smelt (<20 mm) pass through the louvers and are not counted. Peak adult and juvenile longfin smelt salvage occurs in January and April to May, respectively. (Baxter *et al*. 2009.) Entrainment of larval smelt, although not counted, are likely greatest between March and April. (TBI/NRDC 4, p.16.) Adult and juvenile longfin smelt salvage is an inverse logarithmic function of net OMR flows. (Grimaldo *et al*. 2009.) Increasing OMR reverse flows results in an exponential increase in salvage loss. Juvenile longfin smelt salvage is a negative function of Delta outflow between March and May. (TBI/NRDC 4, p.17.) Higher outflow in these three months results in lower entrainment loss. This may result from the fact that during low outflow years spawning occurs higher in the system, placing adults and subsequent larvae and juveniles closer to the pumps. Also, negative net OMR flows can either passively draw fish to the pumps or at high levels mis-cue them as to the direction of higher salinity. A consequence is that juvenile longfin smelt are most in danger of entrainment at the CVP and SWP pumping facilities during low outflow years with high net negative OMR flows.

The OMR flow results discussed above are consistent with the findings of Baxter *et al* (2009). The authors used the Delta Simulation Model (DSM2, PTM subroutine) to predict the fate of larval longfin smelt. The PTM predicted that larval entrainment at the SWP might be substantial (2 to10%), particularly during the relatively low outflow conditions modeled. Baxter *et al*. (2009) also identified a significant negative relationship between spring (April to June) net negative OMR flows and the sum of combined SWP and CVP juvenile longfin smelt salvage. Juvenile longfin smelt salvage increased rapidly as OMR became more negative than -2,000 cfs. However, as winter-spring or just spring outflows increased, shifting the position of X2 downstream, the salvage of juvenile longfin smelt decreased significantly. Also, particle entrapment decreased, even with a high negative net OMR, when the flow of the Sacramento River at Rio Vista increased above 40,000 cfs. Entrainment of particles almost ceased at flows of 55,000 cfs.

TBI/NRDC (TBI/NRDC 2, pp. 15-19) conducted a generation to generation population abundance analysis for longfin smelt versus Delta outflow. The authors found that the probability of an increase in the FMWT longfin smelt index was greater than 50% in years when Delta outflow averaged 51,000 and 35,000-cfs between January to March and March to May, respectively. The analysis is important because it suggests a potential outflow trigger for growing the population.

There is also evidence that longfin smelt is food limited. (SFWC 1, p.59.) The FMWT index for longfin smelt is positively correlated in a multiple linear regression with the previous spring's *Eurytemora affinis* abundance (an important prey organism) after weighting the data by the proportion of smelt at each *Eurytemora* sampling station and normalizing by the previous years FMWT index. The spring population abundance of *Eurytemora* has itself been positively correlated with outflow between March and May since the introduction of *Corbula.* (Kimmerer, 2002a.) The positive correlation between *Eurytemora* abundance and spring outflow provides further support for a spring outflow criterion.

Longfin smelt populations are at an all time low. The average FMWT index for years 2001-2009 are only 3 percent of the average value for 1967 to 1987, a time period when pelagic fish did better in the estuary. The FMWT index for two of the last three years is the lowest on record.

Delta outflow recommendations to protect longfin smelt received from participants are summarized in Table 6. The DFG (DFG closing comments, p.7) recommended a Delta outflow between 12,400 and 28,000 cfs from January to June of all water year types to help transport larval/juvenile longfin smelt seaward in the estuary. TBI/NRDC (TBI/NRDC 2, pp. 19-26; TBI/NRDC Closing Comments, pp. 6-7) also made spring Delta outflow recommendations based on five sets of hydrologic conditions for the Central Valley. The TBI/NRDC recommendations range between 14,000 and 140,000 cfs for January through March and 10,000 to 110,000 cfs between April and May. The TBI/NRDC recommendations are based on their longfin smelt population abundance analysis which demonstrated positive growth in years with high spring outflow.

The four sets of OMR recommendations to protect longfin smelt received from participants are summarized in Table 7. TBI/NRDC (TBI/NRDC 4, pp. 21 and 30; TBI/NRDC closing comments, p. 11) recommended reducing entrainment losses of longfin smelt in dry years (March to May when outflow is less than 18,000 cfs) and population abundance is low (FMWT index less than 500) by maintaining positive net OMR flows in April and May. Alternatively, if the index is greater than 500 and Delta outflow is low, then net OMR flows should not be more negative than -1,500 cfs. The DOI (DOI 1, p.53) made a non-species specific recommendation that OMR flows should be positive in all months between January and June. CSPA/CWIN made a non-species specific recommendations that combined export rates equal zero from mid-March through June. (CSPA 1, p.8; CWIN 2, p. 26.) Finally, the DFG has issued an Incidental Take Permit for longfin smelt (2081-2009-001-03) that restricts net OMR flows in some years based on the recommendations of the Delta Smelt Workgroup. (Baxter *et al*. 2009.)

Table 6. Participant Recommendations for Delta Outflow to Protect Longfin Smelt

Organization	**Water Year**	**Jan**	**Feb**	**Mar**	**April**	**May**	**Jun**
TBI/NRDC	81-100% (driest years)	14,000 – 21,000			10,000 – 17,500		3000 – 4200
	61-80%	21,000 – 35,200			17,500 – 29,000		4200 – 5000
	41-60%	35,200 – 55,000			29,000 – 42,000		5000 – 8500
	21-40%	55,000 – 87,500			42,000 – 62,500		8500 – 25000
	0-20% (wettest years)	87,500 – 140,000			62,500 – 110,000		25000 – 50000
DFG	all	12,400 to 28,000					

Population Goal

The immediate goal is to stabilize the longfin smelt population, as measured by the FMWT index, and to begin to grow the population. The long-term goal is to achieve the objective of the Recovery Plan for the Sacramento/San Joaquin Delta Native Fishes (USFWS 1996). The plan states that longfin smelt will be considered recovered when its abundance is similar to the 1967 to 1984 period.

Species- Specific Recommendations

Table 8 contains the species-specific flow criteria to protect longfin smelt. The purpose of the Delta outflow criteria is to stabilize and begin to grow the longfin smelt population; positive population growth is expected in half of all years with these flows. The net OMR flow criteria are intended to protect the longfin smelt population from entrainment in the CVP and SWP pumping facilities during years with limited Delta outflow (dry and critically dry years). As noted above, longfin smelt spawn in the Delta on both the Sacramento and San Joaquin rivers. Longfin smelt optimally need positive flow on both river systems to move buoyant larvae downstream and away from the influence of the pumps.

Table 7. Participant Recommendations for Net OMR Reverse Flows to Protect Longfin Smelt

Organization	Water Year	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sept	Oct	Nov	Dec
2006 Bay-Delta Plan	all	Some restrictions, given in terms of E/I ratios											
DFG Take Permit	all	-1,250 to -5,000[1]											
TBI/NRDC	C/D				>0[2] or -1,500[3]								
DOI	all	>0											
CSPA/CWIN	all			Combined export rates = 0									

[1] This condition is not likely to occur in many years and is based on requirements in the DFG Incidental Take Permit 2081-2009-001-03 and the advice of the Smelt Working Team. The condition is most likely to occur in dry or critical years when longfin smelt spawn higher in the Delta and hydrology does not rapidly transport hatched larvae from the central and south Delta.

[2] If FMWT index is less than 500

[3] If FMWT index is greater than 500

Table 8. Delta Outflows to Protect Longfin Smelt

Flow Type	Water Year Type	Jan	Feb	Mar	April	May	Jun
Net Delta Outflow	C	14,000 – 21,000			10,000 – 17,500		3,000 – 4,200
	D	21,000 – 35,200			17,500 – 29,000		4,200 – 5,000
	BN	35,200 – >50,000			29,000 – 42,000		5,000 – 8,500
	AN	>50,000			>42,000		8,500 – 25,000
	W	>50,000			>42,000		25,000 – 50,000

[2] If FMWT index is greater than 500

Delta Smelt (*Hypomesus transpacificus*)

Status

Delta smelt is listed as endangered under the CESA and threatened under the ESA. (DFG 2010.)

Life History

Delta smelt are endemic to the Delta. Delta smelt have an annual, one-year life cycle although some females may live and reproduce in their second year. (Bennett 2005.) Delta smelt complete their entire life cycle in the Delta and upper estuary. Delta smelt feed primarily on planktonic copepods, cladocerans, and amphipods. (Baxter *et al*. 2008.) In September or October delta smelt begin a slow upstream migration toward their freshwater spawning areas in the upper Delta, a process that may take several months. (Moyle 2002.) The upstream migration may be triggered by Sacramento River flows in excess of 25,000 cfs. (DSWG 2006.) Spawning can occur from late February to July, although most reproduction appears to take place between early April and mid-May. (Moyle 2002.) Spawning areas include the lower Sacramento, Mokelumne, and San Joaquin rivers, the west and south Delta, Suisun Bay, Suisun Marsh, and occasionally in wet years, the Napa River. (Wang 2007.) Eggs are negatively buoyant and adhesive with larvae hatching in about 13 days. (Wang, 1986; Mager 1996.) Upon hatching, the larvae are semi-buoyant staying near the bottom. Within a few weeks, larvae develop an air bladder and become pelagic, utilizing vertical water column movement to maintain their longitudinal position in the estuary. (Moyle 2002.)

Freshwater outflow during spring (March to June) affects the distribution of larvae by transporting them seaward toward the low salinity zone. (Dege and Brown 2004.) High Delta outflow during spring can carry some smelt downstream of their traditional rearing areas in the west Delta and Suisun Bay and into San Pablo Bay where long-term growth and survival may not be optimal. Conversely, periods of low outflow increase residence time in the Delta. Increasing residence time in the Delta probably prolongs the exposure of delta smelt to higher water temperatures and increased risk of entrainment at the State and Federal pumping facilities. (Moyle 2002.) Ideal rearing habitat conditions are believed to be shallow water areas most commonly found in Suisun Bay. (Bennett 2005.) When the mixing zone was located in Suisun Bay, it may in the past have provided optimal conditions for algal and zooplankton growth, an important food source for delta smelt. (Moyle 2002.) However, the quality of habitat in Suisun Bay appears to have deteriorated with the introduction of the clam *Corbula* which now consumes much of the phytoplankton that previously supported large populations of zooplankton. Since 2005, approximately 40% of the delta smelt population now remains in the Cache Slough complex north of the Delta. This may represent an alternative life history strategy in which the fish stay upstream of the low salinity zone (LSZ) through maturity. (Sommer et al., 2009.)

Population Abundance and Relationship to Flow

Delta smelt population abundance is measured in the summer tow net survey, the FMWT survey and the 20-mm spring-summer survey of juvenile fish. (Kimmerer et al. 2009.) All three indices indicate that delta smelt populations are at an all time low and may be in danger of extinction. The average FMWT index for 2001-2009 is only 20% of the value measured between 1967 and 1987, a time period when pelagic fish did better in the estuary. FMWT indices for the last six years (2004 to 2009) include all of the lowest values on record. The cause of the decline is unclear but likely includes some combination of flow, export pumping, food limitation, and introduced species.

Three types of flow have been hypothesized to affect delta smelt abundance. These are spring and fall Delta outflow and net OMR reverse flow. Testimony was received at the public proceeding recommending management changes to all three types of flow (Table 9 and Table 10). In the past, there has been a weak negative relationship between spring Delta outflow and delta smelt abundance as measured by the FMWT, however, the relationship has now disappeared. (Kimmerer *et al*. 2009.) The cause for the disappearance of the spring outflow-abundance relationship is not known but may result from the deterioration of rearing habitat in Suisun Bay because of colonization by the clam *Corbula.*

Several organizations recommend fall Delta outflow criteria for protection of delta smelt (Table 9). The primary purpose of a fall Delta outflow criterion is to increase the quality and quantity of rearing habitat for Delta smelt. (Nobriga et al. 2008; Feyrer et al. 2007; Feyrer et al., in review.) Rearing habitat is hypothesized to increase when the fall LSZ is downstream of the confluence of the Sacramento and San Joaquin rivers. This corresponds to Delta outflows greater than about 7,500 cfs between September and November, which would have to be achieved by release of water from upstream reservoirs in most years. Grimaldo et al. (2009) found that X2 was a predictor for salvage of adult delta smelt at the intra-annual scale when net OMR flows were negative. Moving X2 westward in the fall serves to increase the geographic and hydrologic distance of delta smelt from the influence of the export facilities and therefore likely reduces the risk of entrainment. (DOI 1, p. 34.) The USFWS (2008) recommended in their Opinion that the LSZ be maintained in the fall of above normal and wet water year types in Suisun Bay (Action 4). The action was restricted to above average water years to insure that sufficient cold water pool resources remained for steelhead and salmon and because these are the years in which SWP and CVP operations have most significantly affected fall conditions. (USFWS 2008.) The National Academy of Sciences (NAS) (2010) commented on this action in their review:

> ”The statistical relationship is complex. When the area of highly suitable habitat …is low, either high or low FMWT indices can occur. In other words, delta smelt can be successful even when habitat is restricted. More important, however, is that the lowest abundances all occurred when the habitat-area index was less than 6,000 ha. This could mean that reduced habitat area is a necessary condition for the worst population collapses, but it is not the only cause of the collapse… The … action is conceptually sound … to the degree that the amount of habitat available for smelt limits their abundance… however…the weak statistical relationship between the location of X2 and the size of smelt populations makes the justification for this action difficult to understand.” The National Academy of Sciences noted approvingly that the U.S. Fish and Wildlife Service (2008) required “additional studies addressing elements of the habitat conceptual model to be formulated … and … implemented promptly.”

[1] 2006 Bay-Delta Plan and USFWS Opinion flows shown for comparative purposes.

[2] All water year types - Increase to 6000 if the December Eight River Index is > than 800 thousand acre-feet (TAF).

[3] Minimum Delta outflow calculated from a series of rules that are described in Tables 3 and 4 of the 2006 Bay-Delta Plan.

[4] USFWS Opinion (RPA concerning Fall X2 requirements [pp282-283] - improve fall habitat [quality and quantity] for delta smelt) (references USFWS 2008, Feyrer *et al* 2007, Feyrer *et al* in revision) - September-October in years when the preceding precipitation and runoff period was wet or above normal, as defined by the Sacramento Basin 40-30-30 Index, USBR and DWR shall provide sufficient Delta outflow to maintain monthly average X2 no greater than 74 km and 81 km in Wet and Above Normal years, respectively. During any November when the preceding water year was wet or above normal, as defined by Sacramento Basin 40-30-30 index, all inflow into the CVP/SWP reservoirs in the Sacramento Basin shall be added to reservoir releases in November to provide additional increment of outflow from Delta to augment Delta outflow up to the fall X2 of 74 km and 81 km for wet and above normal water years, respectively. In the event there is an increase in storage during any November this action applies, the increase in reservoir storage shall be released in December to augment the December outflow requirements in the 2006 Bay-Delta Plan.

Table 10. Participant Recommendations for Net OMR Flows to Protect Delta Smelt

	Water Year	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sept	Oct	Nov	Dec
2006 Bay-Delta Plan	all	Some restrictions, given in terms of exports to inflow ratios											
USFWS - Opinion	all	Action 1: -2000 cfs for 14 days once turbidity or salvage trigger has been met; Action 2: range btw -1250 and -5000 cfs [1]			Range between -1,250 and -5,000 [2]								See Jan-Mar
USFWS	all	>0 [3]											
CSPA/ CWIN				Combined Export Rates = 0[3]									
TBI/ NRDC	all	>-1,500 cfs											>-1500 cfs

[1] USFWS Opinion - RPA re: net OMR flows. Component 1 - Adults (December - March) - Action 1 (protect upmigrating delta smelt) - once turbidity or salvage trigger has been met, -2000 cfs OMR flow for 14 days to reduce flows towards the pumps. Action 2 (protect delta smelt after migration prior to spawning) – Net OMR flow range between -1250 and -5000 cfs determined using adaptive process until spawning detected. (pp.280-282.)

[2] USFWS Opinion - RPA re: net OMR flows. Component 2 - Larvae/juveniles - action starts once temperatures hit 12° C at three Delta monitoring stations or when spent female is caught. Net OMR flow range between -1250 and -5000 cfs determined using adaptive process. OMR flow restrictions continue until June 30 or when Delta water temperatures reach 25° C, whichever comes first. (pp. 280-282.)

[3] Recommendations by the USFWS and CSPA/CWIN were not species specific.

It should be reiterated that this measure should be implemented within an adaptive framework, including completing studies designed to clarify the mechanism(s) underlying the effects of fall habitat on the delta smelt population, and a comprehensive review of the outcomes of the action and its effectiveness. Until additional studies are conducted demonstrating the importance of fall X2 to the survival of delta smelt, additional fall flows, beyond those stipulated in the fall X2criteria, for the protection of delta smelt are not recommended if it will compete with preservation of cold water pool resources needed for the protection of salmonids.

Net negative OMR flows can affect delta smelt by pulling them into the central Delta where they are at risk of entrainment in the SWP and CVP pumps. Recent studies have shown that entrainment of delta smelt and other pelagic species increases as net OMR flows become more negative. (Grimaldo et al. 2009; Kimmerer 2008.) Delta smelt are at risk as juveniles in the spring during downstream migration to their rearing area, and as adults between the fall and early spring as they move upstream to spawn. Salvage of age-0 delta smelt at the SWP /CVP fish collection facilities at the intra-annual scale has been found to be related to the abundance of these fish in the Delta, while net OMR flows and turbidity were also strong predictors. (Grimaldo et al. 2009.) This suggests that within a given year, the mechanism influencing entrainment is probably a measure of the degree to which their habitat overlaps with the hydrodynamic “footprint” of net negative OMR flows. (Grimaldo et al. 2009.) PTM results suggest that entrainment is a function of both net OMR flows and river outflows. (Kimmerer and Nobriga 2008.) PTM results may be more applicable to neutrally buoyant larvae and poorly swimming juveniles than adult delta smelt. Particle entrainment increased as a logarithmic function of increasing net negative OMR flows and decreases in river outflows. The highest entrainment was observed at high net negative OMR flows and low outflows. PTM results suggest that entrainment losses might be as high as 40% of the total delta smelt population in some years. (Kimmerer 2008.) Similar results were obtained by Baxter et al. (2009) when evaluating entrainment of longfin smelt using PTM. Juvenile longfin smelt salvage increased rapidly as net OMR flows became more negative than -2,000 cfs. Also, particle entrapment decreased, even with high net negative OMR flows, when the flow of the Sacramento River at Rio Vista increased above 40,000 cfs. Entrainment of particles almost ceased at flows of 55,000 cfs.

Field population investigations support some of the spring PTM results. Gravid females and larvae are present in the Delta as early as March and April. (Bennett 2005.) However, analysis of otolith data on individuals collected later in the year by Bennett *et al*. (unpublished data) show that few of the early progeny survived if spawned prior to the VAMP time period (typically April 15 to May 15). The hydrodynamic data showed high net negative OMR flows in the months preceding and after the VAMP, leading the researchers to conclude that high winter and early spring net negative OMR flows were selectively entraining the early spawning and/or early hatching cohort of the delta smelt population. However, Baxter *et al*. (2008) stated that “under this hypothesis, the most important result of the loss of early spawning females would manifest itself in the year following the loss, and would therefore not necessarily be detected by analyses relating fall abundance indices to same-year predictors.” No statistical relationships have been found between either OMR flows or CVP and SWP pumping rates and Delta smelt population abundance. (Bennett 2005.)

Entrainment of adult delta smelt occurs following the first substantial precipitation event (“first flush”), characterized by sudden increases in river inflows and turbidity, in the estuary as they begin their migration into the tidal freshwater areas of the Delta. (Grimaldo *et al*. 2009.) Patterns of adult entrainment are distinctly unimodal, suggesting that migration is a large population-level event, as opposed to being intermittent or random. (DOI 1, p. 36.) Grimaldo *et al*. (2009) provided evidence suggesting that entrainment during these "first flush" periods could be reduced if export reductions were made at the onset of such periods.

The USFWS Opinion identifies turbidity criteria for which to trigger first flush export reductions, but total Delta outflow greater than 25,000 cfs could serve as an alternate or additional trigger since such flows are highly correlated with turbidity. (Grimaldo *et al*. 2009, DOI 1, p. 36.) Managing OMR flows to thresholds at which entrainment or populations losses increase rapidly, represents a strategy for providing additional protection for adult delta smelt in the winter period (Dec-Mar). (DOI 1, p.36.). The USFWS Opinion identified the lower net OMR flow threshold as - 5000 cfs based on observed OMR flow versus salvage relationships from a longer data period (USFWS 2008) and additional data summarized over a more recent period. (Grimaldo et al. 2009.) The -5000 cfs OMR flow threshold is appropriate because it is the level where population losses consistently exceed 10%. (USFWS 2008, DOI 1, p. 36.) Adult delta smelt entrainment varies according to their distribution in the Delta following their upstream migration. The population is at higher entrainment risk if the majority of the population migrates into the south Delta, which may require net OMR flows to be more positive than -5000 cfs to reduce high entrainment. Conversely, if the majority of the population migrates up the lower Sacramento River or north Delta, a smaller entrainment risk is presumed, which would allow for OMR flows to be more negative than -5000 cfs for an extended period of time, or until conditions warrant a more protective OMR flow. (DOI 1, p.36.)

The USFWS Opinion for delta smelt includes net negative OMR flow restrictions to protect both spawning adult and out-migrating young. Component 1 of the USFWS Opinion has two action items; both are to protect adult delta smelt. Action 1 restricts OMR flow in fall to -2,000 cfs for 14 days when a turbidity or salvage trigger has been met. Both triggers have previously been correlated with the upstream movement of spawning adult smelt. Action 2 commences immediately after Action 1. Action 2 is to protect adult delta smelt after migration, but prior to spawning, by restricting net OMR flows to between -1250 and -5,000 cfs based on the recommendations of the Delta Smelt Workgroup. Component 2 of the USFWS Opinion is to protect larval and juvenile fish. Component 2 actions start once water temperatures hit 12°C at three monitoring stations in the Delta or when a spent female is caught. OMR flows during this phase are to be maintained more positive than -1,250 to -5000 cfs based on a 14-day running average. Component 2 actions are to continue until June 30 or when the 3-day-mean water temperature at Clifton Court Forebay is 25°C. The Delta Smelt Working Group is to make recommendations on the specific OMR flow restrictions between -1250 and -5000 cfs.

The NAS (2010) reviewed the USFWS Opinion OMR flow restrictions and concluded:

> "…it is scientifically reasonable to conclude that high negative OMR flows in winter probably adversely affect smelt populations. Thus, the concept of reducing OMR negative flows to reduce mortality of smelt at the SWP and CVP facilities is scientifically justified … but the data do not permit a confident identification of the threshold values to use … and … do not

> permit a confident assessment of the benefits to the population…As a result, the implementation of this action needs to be accompanied by careful monitoring, adaptive management and additional analyses that permit regular review and adjustment of strategies as knowledge improves."

The negative impact of negative OMR flows on delta smelt, like on longfin smelt, is likely to be greatest during time periods with high negative OMR flows and low Sacramento River outflow. (Baxter *et al*. 2009; Kimmerer and Nobriga 2008.) The work of Grimaldo *et al*, (2009) suggests that impacts associated with the export facilities can be mitigated on a larger scale by altering the timing and magnitude of exports based on the biology of the fishes and changes in key physical and biological variables.

For the protection of longfin smelt, Delta outflow criteria between January and March range from 35,000 cfs in below normal water years to greater than 50,000 cfs in wet water years (Table 8). For the protection of longfin smelt, flow criteria between April and May range from 29,000 cfs to more than 42,000 cfs. These flows should also afford protection for larval delta smelt from excessive negative OMR flows and entrainment at the CVP and SWP pumping facilities. Under this criterion, lower outflows will still likely occur during critically dry and dry water year types (Table 6). These outflows may not be sufficient to prevent longfin and delta smelt entrainment at the pumping facilities. Therefore, the recommended criterion for longfin smelt specifies that net OMR flows should not be more negative than -1500 cfs in April and May of dry and critically dry water years to protect longfin smelt. The State Water Board determines that this criterion should be extended to include March and June of dry and critically dry water years to protect early and late spawning delta smelt (Table 11).

Minimizing net negative OMR flows during periods when adult delta smelt are migrating into the Delta could also substantially reduce mortality of the critical life stage. For example, one potential strategy is to reduce exports during the period immediately following the "first flush", based on a turbidity or flow trigger. (Grimaldo et al. 2009.) This supports a recommendation that net OMR flows be more positive than -5000 cfs during the period between December and March. Additional OMR flow restrictions may be warranted during periods when a significant portion of the adult delta smelt population migrates into the south or central Delta. In such instances, the determination of specific thresholds should be made through an adaptive approach that takes into account a variety of factors including relative risk (e.g., biology, distribution and abundance of fishes), hydrodynamics, water quality, and key physical and biological variables. The State Water Board agrees with the NAS (2010) that the data, as currently available, do not permit a confident assessment of the threshold OMR flow values nor of the overall benefit to the delta smelt population. Development of a comprehensive life-cycle model for delta smelt would be valuable in that it would allow for an assessment of population level impacts associated with entrainment. Such life-cycle models for delta smelt are currently under development. Therefore, net OMR flow criteria need to be accompanied by a strong monitoring program and adaptive management to adjust OMR flow criteria as more knowledge becomes available.

Delta smelt are food limited. Delta smelt survival is positively correlated with zooplankton abundance. (Feyrer et al., 2007; Kimmerer 2008; Grimaldo et al., 2009.) A new analysis by the SFWC (SFWC 1, p.60) also demonstrates a positive relationship between FMWT delta smelt indices and the previous spring and summer abundance of

Eurytemora and *Psuedodiaptomus.* There are several hypotheses for the cause of the decline in zooplankton abundance. First, zooplankton abundance in Suisun and Grizzly bays, prime habitat for delta smelt, declined after the introduction of the invasive clam *Corbula. Corbula* is thought to compete directly with zooplankton for phytoplankton food and lower phytoplankton levels may limit zooplankton abundance. A second hypothesis is that changes in nutrient loading and nutrient form in the Delta that result from the SRWTP discharge can have major impacts on food webs, from primary producers through secondary producers to fish. (Glibert, 2010.) Changes in nutrient concentrations and their ratios may have caused the documented shift in phytoplankton species composition from large diatoms to smaller, less nutritious algal forms for filter feeding organisms like zooplankton. If true, both of the above hypotheses could indirectly result in lower densities of delta smelt. Therefore, all recommended flow modifications should be accompanied by a strong monitoring and adaptive management process to determine whether changes in OMR flows result in an improvement in delta smelt population levels.

Population Abundance Goal

The immediate goal is to stabilize delta smelt populations, as measured by the FMWT index, and begin to grow the population. The long term goal should be to achieve the objective of the Recovery Plan for the Sacramento/San Joaquin Delta Native Fishes (USFWS 1996.)

Species-Specific Recommendations

Although a positive correlation between Delta outflows and delta smelt is lacking, Delta outflows do have significant positive effects on several measures of delta smelt habitat. (Kimmerer *et al*. 2009), and spring outflow is positively correlated with spring abundance of *Eurytemora affinis* (Kimmerer 2002a), an important delta smelt prey item. No specific spring Delta outflow criteria are therefore recommended for delta smelt. Flow criteria to protect longfin smelt in the spring of wetter years (Table 8) may, however, afford some additional protection for the Delta smelt population.

The State Water Board advances the OMR flow criteria in Table 11 for dry and critically dry years to protect the delta smelt population from entrainment in the CVP and SWP pumping facilities during years with limited Delta outflow. The OMR flow restrictions are an extension of the criteria for longfin smelt. In addition, the State Water Board includes criteria for OMR flows to be more positive than -5,000 cfs between December and February of all water year types to protect upstream migrating adult delta smelt. The -5,000 cfs criteria may need to be made more protective in years when delta smelt move into the central Delta to spawn. The more restrictive OMR flows would be recommended after consultation with the USFWS's Delta Smelt Working Group. In the absence of any other specific information, the State Water Board determines that the existing 2006 Bay-Delta Plan Delta outflow objectives for July through December are needed to protect delta smelt.

Table 11. Net OMR Flows for the Protection of Delta Smelt

Flow Type	Water Year Type	Dec	Jan	Feb	Mar - June
Net OMR flows	C/D				> -1,500 cfs
Net OMR flows	All	> - 5000 cfs (thresholds determined through adaptive management)			

Sacramento Splittail (*Pogonichthys macrolepidotus*)

Status

Sacramento splittail is currently recognized by the DFG as a species of special concern. Splittail was listed as a threatened species pursuant to the ESA in 1999; however, its status was remanded in 2003 on the premise of recent increases in abundance and population stability. This decision was subsequently challenged and the USFWS is revisiting the status of splittail and will make a new 12-month finding on whether listing is warranted by September 30, 2010.

Life History

Sacramento splittail (*Pogonichthys macrolepidotus*) is a cyprinid native to California that can live seven to nine years and has a high tolerance to a wide variety of water quality parameters including moderate salinity levels. (Moyle 2002, Moyle et al. 2004.)

Adult splittail are found predominantly in Suisun Marsh, Suisun Bay, and the western Delta, but are also found in other brackish water marshes in the San Francisco Estuary as well as the fresher Delta. Splittail feed on detritus and a wide variety of invertebrates; non-detrital food starts with cladocerans and aquatic fly larvae on the floodplains, progresses to insects and copepods in the rivers, and to mysid shrimps, amphipods and clams for older juveniles and adults. (Daniels and Moyle 1983, Feyrer et al. 2003, Feyrer et al. 2007a, as cited in DFG 1, p. 13.) In winter and spring when California's Central Valley experiences increased runoff from rainfall and snowmelt, adult splittail move onto inundated floodplains to forage and spawn. (Meng and Moyle 1995; Sommer et al. 1997, Moyle et al. 2004, as cited in DFG 1, p. 13.) Spawning takes place primarily between late February and early July, and most frequently during March and April (Wang 1986, Moyle 2002) and occasionally as early as January. (Feyrer et al. 2006a.) Splittail eggs, laid on submerged vegetation, begin to hatch in a few days and the larval fish grow fast in the warm and food rich environment. (e.g., Moyle et al. 2004, Ribeiro et al. 2004.) After spawning, the adult fish move back downstream.

Once they have grown a few centimeters, the juvenile splittail begin moving off of the floodplain and downstream into similar habitats as the adults. These juveniles become mature in two to three years. In the Yolo Bypass, two flow components appear necessary for substantial splittail production (Feyrer et al. 2006a): (1) inundating flows in winter (January to February) to stimulate and attract migrating adults; and (2) sustained floodplain inundation for 30 or more days from March through May or June to allow successful incubation through hatching (3 to 7 days, see Moyle 2002), and extended rearing until larvae are competent swimmers (10 to 14 days; Sommer et al. 1997) and beyond to maximize recruitment. (DFG 1, p. 13.)

Large-scale spawning and juvenile recruitment occurs only in years with significant protracted (greater than or equal to 30 days) floodplain inundation, particularly in the

Sutter and Yolo bypasses. (Meng and Moyle 1995, Sommer et al. 1997, Feyrer et al. 2006a, as cited in DFG 1, p. 13.) Some spawning also occurs in perennial marshes and along the vegetated edges of the Sacramento and San Joaquin rivers. (Moyle et al. 2004.) During periods of low outflow, splittail appear to migrate farther upstream to find suitable spawning and rearing habitats. (Feyrer et al. 2005.) Moyle et al. (2004) noted that though modeling shows splittail to be resilient, managing floodplains to promote frequent successful spawning is needed to keep them abundant.

Population Abundance and its Relationship to Flow

Age-0 splittail abundance has been significantly correlated to mean February through May Delta outflow and days of Yolo Bypass floodplain inundation, representing flow/inundation during the incubation and early rearing periods. (Meng and Moyle 1995, Sommer et al. 1997.) The flow-abundance relationship is characterized by increased abundance (measured by the FMWT) as mean February–May X2 decreases, indicating a significant positive relationship between FMWT abundance and flow entering the estuary during February–May. (Kimmerer 2002a.)

Feyrer et al. (2006a) proposed the following lines of evidence to suggest the mechanism supporting this relationship for splittail lies within the covarying relationship between X2 and flow patterns upstream entering the estuary: the vast majority of splittail spawning occurs upstream of the estuary in freshwater rivers and floodplains (Moyle et al. 2004); the averaging time frame (February–May) for X2 coincides with the primary spawning and upstream rearing period for splittail; the availability of floodplain habitat, as indexed by Yolo Bypass stage, is directly related to X2 during February–May ($y = 4.38 - 2.21x$; $p<0.001$; $r^2 = 0.97$); the center of age-0 splittail distribution does not reach the estuary until summer (Feyrer et al. 2005); and the splittail X2-abundance relationship has not been affected by dramatic food web changes (Kimmerer 2002a) that have significantly altered the diet of young splittail in the estuary. (Feyrer et al. 2003.)

Population Abundance Goal

The immediate goal is to stabilize the Sacramento Splittail population, as measured by the FMWT index, and to begin to grow the population. The long-term goal is to maintain population abundance index as measured by FMWT in half of all years above the long term population index value.

Species- Specific Recommendations

Delta Outflow - Upstream covariates of X2, such as the availability of suitable floodplain and off-channel spawning and nursery habitat, appear to be the attributes supporting the flow-abundance relationship for splittail. Therefore, the flow needs of this species, with respect to spawning and rearing habitat, are most effectively dealt with through establishment of flow criteria that address the timing, duration, and magnitude of floodplain inundation from a river inflow standpoint.

Delta Inflow - Information in the record on conditions conducive to successful spawning and recruitment of splittail shows that the species depends on inundation of off-channel areas. Sufficient flows are therefore needed to maintain continuous inundation for at least 30 consecutive days in the Yolo Bypass, once floodplain inundation has been achieved based on runoff and discharge for ten days between late-February and May, during above normal and wet years (Table 12). (DFG closing comments, p. 7.)

Opportunities to provide floodplain inundation in other locations (e.g., the San Joaquin River) warrant further examination.

Feyrer *et al* (2006a) noted that manipulating flows entering Yolo Bypass such that floodplain inundation is maximized during January through June will likely provide the greatest overall benefit for splittail, especially in relatively dry years when overall production is lowest. Within the Yolo Bypass, floodplain inundation of at least a month appears to be necessary for a strong year class of splittail (Sommer *et al*. 1997); however, abundance was highest when the period of inundation extended 50 days or more. (Meng and Moyle 1995.) Floodplain inundation during the months of March, April, and May appears to be most important. (Wang 1986, Moyle 2002.) Managing the frequency and duration of floodplain inundation during the winter and spring, followed by complete drainage by the end of the flooding season, could favor splittail and other native fish over non-natives. (Moyle et al. 2007, Grimaldo et al. 2004.) Duration and timing of inundation are important factors that influence ecological benefits of floodplains.

<u>Yolo Bypass Inundation</u> – The Fremont Weir is a passive facility that begins to spill into the Yolo Bypass when the Sacramento River flow at Verona exceeds 55,000 to 56,000 cfs. (AR/NHI 1, p. 21; EDF 1, p. 50; TBI/NRDC 3, p. 35; Sommer et al. 2001b.) Water also enters the bypass at the Sacramento Weir and from the west via high flow events in small west-side tributaries. (Feyrer et al. 2006b.) Each of these sources joins the Toe Drain, a perennial channel along the east side of the Yolo Bypass floodplain, and water spills onto the floodplain when the Toe Drain flow exceeds approximately 3,500 cfs. (Feyrer et al. 2006b.) The Yolo Bypass typically floods in winter and spring in about 60% of years (DOI 1, p. 54; Sommer et al. 2001a; Feyrer et al. 2006a), with inundation occurring as early as October and as late as June, with typical peak period of inundation during January-March. (Sommer et al. 2001b.) In addition, studies suggest phytoplankton, zooplankton, and other organic material transported from the Yolo Bypass enhances the food web of the San Francisco Estuary. (Jassby and Cloern 2000; Mueller-Solger et al. 2002; Sommer et al. 2004.) Much of the water diverted into the bypass drains back into the north Delta near Rio Vista. Besides the Yolo Bypass, the only other Delta region with substantial connectivity to portions of the historical floodplain is the Cosumnes River, a small undammed watershed. (Sommer et al. 2001b.)

Multiple participants provided recommendations concerning the magnitude and duration of floodplain inundation along the Sacramento River, lower San Joaquin River, and within the Yolo and Sutter bypasses. (AR/NHI 1, p. 32; DFG closing comments; DOI 1, p. 54, EDF 1, pp. 50-52, 53-55; SFWC closing comments; TBI/NRDC 3, p. 36.) In addition, the draft recovery plan for the Sacramento River winter-run Chinook salmon, Central Valley spring-run Chinook salmon, and Central Valley Steelhead (NMFS 2009) calls for the creation of annual spring inundation of at least 8,000 cfs to fully activate the Yolo Bypass floodplain. (NMFS 5, p.157.)

Overtopping the existing weirs and flooding the bypasses (e.g., Yolo and Sutter) to achieve prolonged periods (30 to 60 days) of floodplain inundation in below normal and dry water years would require excessive amounts flows given the typical runoff patterns during those year types. (AR/NHI 1, p. 29.) From a practical standpoint, it is probably only realistic to achieve prolonged inundation during drier water year types by notching the upstream weirs and possibly implementing other modifications to the existing system. (AR/NHI 1, p. 29.)

The BDCP is currently evaluating structural modifications to the Fremont Weir (e.g., notch the weir and install operable “inundation gates”), as a means of increasing the interannual frequency and duration of floodplain inundation in the Yolo Bypass. (BDCP 2009.) TBI/NRDC (TBI/NRDC 3, p. 36) and AR/NHI (AR/NHI 1, p. 32) provided floodplain inundation recommendations for the Yolo Bypass assuming structural modifications to the Fremont Weir were implemented. A potential negative impact of notching the Fremont Weir is that it will affect stage height and Sutter Bypass flooding, and the resulting spawning and rearing of splittail and spring-run Chinook salmon. (personal communication R. Baxter.)

The NMFS Opinion stipulates that USBR and DWR, in cooperation with DFG, USFWS, NMFS, and USACE, shall, to the maximum extent of their authorities (excluding condemnation authority), provide significantly increased acreage of seasonal floodplain rearing habitat, with biologically appropriate durations and magnitudes, from December through April, in the lower Sacramento River basin, on a return rate of approximately one to three years, depending on water year type. (NMFS 3, p.608.) USBR and DWR are to submit a plan to implement this action to NMFS by December 31, 2011. (NMFS 3, p. 608.) This plan is to include an evaluation of options to, among other things, increase inundation of publicly and privately owned suitable acreage within the Yolo Bypass and modify operations of the Sacramento Weir or Fremont Weir to increase rearing habitat. (NMFS 3, p. 608.) The NMFS Opinion specifies that in the event that this action conflicts with Shasta Operations Actions I.2.1 to I.2.3 (e.g., carryover storage requirements), the Shasta Operations Actions shall prevail. (NMFS 3, p. 608.)

<u>OMR Flows</u> - Entrainment of splittail at the SWP and CVP export facilities is highest during adult spawning migrations and periods of peak juvenile abundance in the Delta. (Meng and Moyle 1995, Sommer et al. 1997.) The incidence of age-0 splittail entrainment increased during wet years when abundance was also high (Sommer et al. 1997.) However, analyses conducted by Sommer et al. (1997) suggested that entrainment at the export facilities did not have an important population-level effect. However, Sommer et al. (1997) noted that their evidence does not demonstrate that entrainment never affects the species. For example, if the core of the population’s distribution were to shift toward the south Delta export facilities during a dry year, there could be substantial entrainment effects to a year-class. (Sommer et al. 1997.) Criteria for net OMR flows intended to protect salmon, delta smelt, and longfin smelt populations, as well as restrictions stipulated in the Opinions (NMFS 3, pp. 648-653; USFWS 2008) are likely to reduce the number of splittail entrained at the export facilities.

Table 12. Floodplain Inundation Criteria for Sacramento Splittail

Mechanism	Water Year	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec

Starry Flounder (*Platichthys stellatus*)

Status

Starry flounder is not listed pursuant to either the ESA or CESA.

Life History

Starry flounder is a native to the Bay-Delta Estuary. The geographic distribution of flounder is from Santa Barbara, California, to Alaska and in the western Pacific as far south as the Sea of Japan. (Miller and Lea 1972.) Starry flounder are important in both the recreational and commercial catch in both central and northern California. (Haugen 1992; Karpov et al. 1995.)

Starry flounder is an estuarine dependent species. (Emmett et al. 1991.) Spawning occurs in the Pacific Ocean near the entrance to estuaries and other freshwater sources between November and February. (Orcutt 1950.) Juveniles migrate from marine to fresh water between March and June and remain through at least their second year of life before returning to the ocean. (Baxter 1999.) Young individuals are found in Suisun Bay and Marsh and in the Delta. Older individuals range from Suisun to San Pablo bays. Maturity is reached by males at the end of their second year and by females in their third or fourth years. (Orcott 1950.)

Population abundance of young of the year and one year old starry flounder have been measured by the San Francisco Otter Trawl Study since 1980 and reported as an annual index. (Kimmerer et al. 2009.) The index declined between 2000 and 2002 but has since recovered to values in the 300 to 500 range. The median index value for the 29 years of record is 293.

Population Abundance Relationship to Flow

Starry flounder age-1 abundance in the San Francisco Bay otter trawl study is positively correlated with the March through June outflow of the previous year. (Kimmerer et al. 2009.) The mechanism underlying the abundance outflow relationship is not known but may be increased passive transport of juvenile flounder by strong bottom currents during high outflow years. (Moyle 2002.) There has been a decline in the abundance of flounder for any given outflow volume since 1987, presumably because of the invasion by the clam Corbula, however, the overall abundance-flow relationship is still statistically significant. (Kimmerer 2002a.)

Population Abundance Goal

The goal is to maintain the starry flounder population abundance index, as measured by the San Francisco Otter Trawl Study, in half of all years above the long term population median index value of 293.

Species-Specific Recommendations

Outflow recommendations were only received from the DFG. (DFG 1, p. 16.) DFG recommends maintaining X2 between 65 and 74 km between February and June. This corresponds to an average outflow of 11,400 to 26,815 cfs. Table 13 contains the criteria needed for protection of starry flounder. The purpose of this outflow criteria is to maintain population abundance near the long term median index value of 293. This net Delta outflow criteria is similar to those proposed for the protection of longfin smelt, delta smelt, and *Crangon sp*. The State Water Board's criteria for Delta outflow for the protection of both longfin and delta smelt and *Crangon* will also protect starry flounder. The proposed outflow is consistent with DFG's recommendation for starry flounder. There is no information in the record to support criteria for inflows or hydrodynamics to protect starry flounder.

Table 13. Criteria for Delta Outflow to Protect Starry Flounder

Flow Type	**Water Year Type**	**Jan**	**Feb**	**Mar**	**April**	**May**	**Jun**
Net Delta Outflow	C	14,000 – 21,000			10,000 – 17,500		
	D	21,000 – 35,200			17,500 – 29,000		
	BN	35,200 – >50,000			29,000 – 42,000		
	AN	>50,000			>42,000		
	W	>50,000			>42,000		

California Bay Shrimp (*Crangon franciscorum*)

Status

The California bay shrimp is not listed pursuant to either ESA or CESA.

Life History

There are three native species of Crangon, collectively known as bay shrimp or grass shrimp, common to the San Francisco Estuary: *Crangon franciscorum, C. nigricauda*, and *C. nigromaculata.* (Hieb 1999.) Bay shrimp are fished commercially in the lower estuary and sold as bait. (Reilly et al. 2001.) *C. franciscorum* species is targeted by the commercial fishery because of its larger size. Bay shrimp are also important prey organisms for many fish in the estuary. (Hatfield, 1995.)

The California bay shrimp (*Crangon franciscorum*) is an estuary dependent species that is distributed along the west coast of North America from Alaska to San Diego. Larvae hatch from eggs carried by females in winter in the lower estuary or offshore in the Pacific Ocean. Most late-stage larvae and juvenile *C. franciscorum* migrate into the estuary and upstream to nursery areas between April and June. Juvenile shrimp are common in San Pablo and Suisun bays in high outflow years. Their center of distribution moves upstream to Honker Bay and the lower Sacramento and San Joaquin rivers during low flow years. (Hieb 1999.) Mature shrimp migrate back down to higher salinity waters after a four to six month residence in the upper estuary. (Hatfield 1985.) *C. franciscornum* mature at one year and may live up to two years. Some females hatch more than one brood of eggs during a breeding season.

Population abundance of juvenile *C. franiscorum* is measured by DFG's San Francisco Bay Study and is reported as an annual index. (Jassby et al. 1995, Hieb 1999.) Indices over the 29 years of record have varied from 31 to 588 with a median value of about 103.

Population Abundance and Relationship to Flow

There is a positive correlation between the abundance of *C. franciscorum* and net Delta outflow from March to May of the same year. (Jassby et al. 1995; Kimmerer et al. 2009.) The statistical relationship has remained constant since the early years of the San Francisco Bay Study, which began in 1980. The mechanism underlying the abundance relationship is not known but may be an increase in the passive transport of juvenile shrimp up-estuary by strong bottom currents during high outflows years. (Kimmerer et al. 2009, Moyle 2002, DFG 1992.) Other potential mechanisms include the effects of freshwater outflow on the amount and location of habitat, the abundance of food organisms and predators, and the timing of the downstream movement of mature shrimp. (DFG 1, p. 23.)

Delta outflow recommendations (Table 14) were received from both the DFG (DFG 1, p. 23) and TBI/NRDC. (TBI/NRDC 2, p. 17). TBI/NRDC analyzed the productivity of *C. franciscorum* as a function of net Delta outflow between March and May. The analysis suggests that estuary populations increased in about half of all years when flows between March and May were approximately 5 million acre-feet (MAF), or about 28,000 cfs per month. TBI/NRDC recommended that flow be maintained in most years above 28,000 cfs during these three months to insure population growth about half the time. The DFG recommended a net Delta outflow criterion of 11,400 to 26,800 cfs between February and June of all water years to aid immigration of late stage larvae and small juveniles.

Table 14. Participant Recommendations for Delta Outflows to Protect Bay Shrimp

	Water Year	**Feb**	**Mar**	**Apr**	**May**	**Jun**
TBI/NRDC Exhibit 2	Most years		28,000			
Fish and Game Exhibit 1	all	11,400 to 26,815				

Population Abundance Goal

The goal is to maintain the juvenile C*. franciscorum* population abundance index, as measured by the San Francisco Bay Study otter trawl, in half of all years above a target value of 103. An index of 103 is the median longterm index value for this species in the San Francisco Estuary.

Species-Specific Recommendations

The State Water Board determines the Delta outflow criteria in Table 15 are needed to protect C*rangon franciscorum*. The purpose of the outflow criteria is to maintain population abundance at a long term median index value of 103. Positive population growth is expected in half of all years under these flow conditions. The Delta outflow criteria are similar to those proposed for protection of both longfin smelt and delta smelt. The nursery area for C*. franciscorum* is usually downstream of the influence of the pumps, therefore no OMR flow recommendations were received and no review was conducted.

Table 15. Criteria for Delta Outflows to Protect Bay Shrimp

Flow Type	Water Year Type	Jan	Feb	Mar	April	May
Net Delta Outflow	C	14,000 – 21,000			10,000 – 17,500	
	D	21,000 – 35,200			17,500 – 29,000	
	BN	35,200 – >50,000			29,000 – 42,000	
	AN	>50,000			>42,000	
	W	>50,000			>42,000	

Zooplankton (*E. affinis* and *N. mercedis*)

Status

Eurytemora affinis is a non-native species that is not listed pursuant to either the ESA or CESA. *Neomysis mercedis* is a native species that is not listed pursuant to either the ESA or CESA.

Life History[14]

Zooplankton is a general term for small aquatic animals that constitute an essential food source for fish, especially young fish and all stages of pelagic fishes that mature at a small size, such as longfin smelt and delta smelt (DFG 1987b). Although DFG follows trends of numerous zooplankton taxa (e.g., Hennessy 2009), two upper estuary zooplankton taxa of particular importance to pelagic fishes have exhibited abundance relationships to Delta outflow. The first is the mysid shrimp *Neomysis mercedis*, which before its decline, beginning in the late 1980s, was an important food of most small fishes in the upper estuary (see Feyrer et al. 2003). Prior to 1988, *N. mercedis* mean summer abundance (June through October) increased significantly as X2 moved downstream (mean March through November location, Kimmerer 2002a. Table 1). After 1987, *N. mercedis* abundance declined rapidly and is currently barely detectable (Kimmerer 2002a, Hennessy 2009). The second is a calanoid copepod, *Eurytemora affinis*, which also declined sharply after 1987, but more so in summer than in spring (Kimmerer 2002a). Before 1987, *E. affinis* was abundant in the low salinity habitat (0.8-6.3 ‰) throughout the estuary (Orsi and Mecum 1986). *E. affinis* is an important food for most small fishes, particularly those with winter and early spring larvae, such as longfin smelt, delta smelt and striped bass (Lott 1998, Nobriga 2002, Bryant and Arnold 2007, DFG unpublished).

Population Abundance and Relationship to Flow

E. affinis was historically abundant throughout the year, particularly in spring and summer, but after 1987 abundance declined in all seasons, most notably in summer and fall. (Hennessy 2009, as cited in DFG 1, p. 26.) After 1987, *E. affinis* spring abundance (March through May) has significantly increased as spring X2 has moved downstream. (Kimmerer 2002a. Table 1, as cited in DFG 1, p. 26.) Relative abundance in recent years is highest in spring and persistence of abundance is related to spring outflow. As flows decrease in late spring, abundance decreases to extremely low levels throughout the estuary. (Hennessey 2009, as cited in DFG 1, p. 26.)

---

[14] This section was largely extracted from DFG Exhibit 1, page 25.

The only outflow recommendation identified in the record specifically for *E. affinis* and *N. mercedis* was submitted by DFG, in their closing comments (Table 16). According to DFG, their current science-based conceptual model is that placement of X2 in Suisun Bay represents the best interaction of water quality and landscape for fisheries production given the current estuary geometry. (DFG 2, p. 6.) Maintaining X2 at 75 km and 64 km corresponds to net Delta outflows of approximately 11,400 cfs and 29,200 cfs, respectively. The Bay Institute provided flow recommendations for a suite of species, including *E. affinis (*Table 17*).*

Table 16. DFG's Delta Outflow Recommendation to Protect *E. affinis* and *N. mercedis* (DFG Closing Comments)

Species	**Parameter**	**Effect or Mechanism**	**Timing**	**Minimum**	**Maximum**	**Reference**
Zooplankton	Flows	Habitat	February - June	X2 at 75 km	X2 at 64 km	DFG Exhibit 1, p.25-26; Exhibit 2, p.6

Table 17. The Bay Institute's Delta Outflow Recommendations to Protect Zooplankton Species Including *E. affinis*

Species	Mechanism	Water Year	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
Eurytemora affinis	Habitat	81-100% (driest years)	14000-21000 cfs		10000-17500 cfs			3000-4200 cfs						
		61-80%	21000-35000 cfs		17500-29000 cfs			4200-5000 cfs						
		41-60%	35200-55000 cfs		29000-42500 cfs			5000-8500 cfs						
		21-40%	55000-87500 cfs		42500-62500 cfs			8500-25000 cfs						
		0-20% (wettest years)	87500-140000 cfs		62500-110000 cfs			25000 - 50000 cfs						

Species-Specific Recommendations

Table 18 shows the State Water Board's determination for Delta outflows needed to protect zooplankton. These recommendations are consistent with those submitted by DFG. (closing comments, p. 7.) The State Water Board concurs with DFG's current science-based conceptual model which concludes that placement of X2 in Suisun Bay represents the best interaction of water quality and landscape for fisheries production given the current estuary geometry. (DFG 2, p. 6.) Maintaining X2 at 75 km and 64 km corresponds to net Delta outflows of approximately 11,400 cfs and 29,200 cfs, respectively. No explicit recommendations concerning zooplankton and inflow or hydrodynamic requirements were identified in the record.

Table 18. Criteria for Delta Outflows to Protect Zooplankton

Effect or Mechanism	Water Year	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
Habitat	All	--	X2[1] – 75 to 64 km (~11400 – 29200 cfs)					--	--	--	--	--	--

4.3 Other Measures

Information in the record for this proceeding broadly supports the five key points submitted by the DEFG of experts (DEFG 1):

1) Environmental flows are more than just volumes of inflows and outflows
2) Recent flow regimes both harm native species and encourage non-native species
3) Flow is a major determinant of habitat and transport
4) Recent Delta environmental flows are insufficient to support native Delta fishes for today’s habitats
5) A strong science program and a flexible management regime are essential to improving flow criteria

These key points recognize that although adequate environmental flows are a necessary element to protect public trust resources in the Delta ecosystem, flows alone are not sufficient to provide this protection. These key points and other information in the record warrant a brief summary discussion of other information in the record that should be considered in the development of flow criteria, consistent with the charge of SB1 that “the flow criteria include the volume, quality, and timing of water necessary for the Delta ecosystem. “ Based on review of the information in the record this charge is expanded to include specific consideration of:

- Variability, flow paths, and the hydrograph
- Floodplain activation and other habitat improvements
- Water quality and contaminants
- Cold water pool management
- Adaptive management

4.3.1 Variability, Flow Paths, and the Hydrograph

The first of the five key points submitted by the DEFG of experts stated, in part: “There is no one correct flow number. Seasonal, interannual, and spatial variability, to which our native species are adapted, are as important as quantity.“ Species and biological systems respond to combinations of quantity, timing, duration, frequency and how these inputs vary spatially. (DEFG 1.) Based on their review of the literature in *Habitat Variability and Complexity in the Upper San Francisco Estuary*, Moyle *et al* (2010) find:

> “… unmodified estuaries are highly variable and complex systems, renowned for their high production of fish and other organisms (McClusky and Elliott 2004). The San Francisco Estuary, however, is one of the most highly modified and controlled estuaries in the world (Nichols et al. 1986). As a consequence, the

> estuarine ecosystem has lost much of its former variability and complexity and has recently suffered major declines of many of its fish resources (Sommer et al. 2007).
>
> …the concept of the "natural flow regime" (Poff et al. 1997) is increasingly regarded as an important strategy for establishing flow regimes to benefit native species in regulated rivers (Postel and Richter 2003; Poff et al. 2007; Moyle and Mount 2007). For estuaries worldwide, the degree of environmental variability is regarded as fundamental in regulating biotic assemblages (McLusky and Elliott 2004). Many studies have shown that estuarine biotic assemblages are generally regulated by a combination of somewhat predictable changes (e.g., tidal cycles, seasonal freshwater inflows) and stochastic factors, such as recruitment variability and large-scale episodes of flood or drought (e.g., Thiel and Potter 2001). The persistence and resilience of estuarine assemblages is further decreased by various human alterations, ranging from diking of wetlands, to regulation of inflows, to invasions of alien species (McLusky and Elliott 2004, Peterson 2003).
>
> …a key to returning the estuary to a state that supports more of the desirable organisms (e.g., Chinook salmon, striped bass, delta smelt) is increasing variability in physical habitat, tidal and riverine flows, and water chemistry, especially salinity, over multiple scales of time and space. It is also important that the stationary physical habitat be associated with the right physical-chemical conditions in the water at times when the fish can use the habitat most effectively (Peterson 2003)."

An example of a major change in the natural flow regime of the Delta is demonstrated by the increase in net OMR reverse flows just north of the SWP and CVP pumping facilities. Reverse flows are now a regular occurrence in the Delta channels because Sacramento River water enters on the northern side of the Delta while the two major pumping facilities, the SWP and CVP, are located in the south. This results in a net water movement across the Delta in a north-south direction along a web of channels including OMR instead of the more natural pattern from east to west or from land to sea. Positive net flows, connected flow paths, and salinity gradients are important features of an estuary. Natural net channel flows move water and some biota toward Suisun Bay and maintain downstream directed salinity gradients. Today, Delta gates and diversions can substantially redirect tidal flows creating net flow patterns and salinity and turbidity distributions that did not occur historically. These changes may influence migratory cues for some fishes. These cues are further scrambled by a reverse salinity gradient in the south Delta caused by higher salinity in agricultural runoff. (DEFG 1.)

Per the DEFG's paper, *Habitat Variability and Complexity in the Upper San Francisco Estuary* (Moyle et al., 2010), a more variable Delta has multiple benefits:

> "Achieving a variable, more complex estuary requires establishing seaward gradients in salinity and other water quality variables, diverse habitats throughout the estuary, more floodplain habitat along inflowing rivers, and improved water quality. These goals in turn encourage policies which: (1) establish internal Delta flows that create a tidally-mixed, upstream-downstream gradient (without cross-Delta flows) in water quality; (2) create slough networks with more natural channel

> geometry and less diked rip-rapped channel habitat; (3) improve flows from the Sacramento and San Joaquin rivers; (4) increase tidal marsh habitat, including shallow (1-2 m) subtidal areas, in both fresh and brackish zones of the estuary; (5) create/allow large expanses of low salinity (1-4 ppt) open water habitat in the Delta; (6) create a hydrodynamic regime where salinities in parts of the Delta and Suisun Bay and Marsh range from near-fresh to 8-10 ppt periodically (does not have to be annual) to discourage alien species and favor desirable species; (7) take species-specific actions that reduce abundance of non-native species and increase abundance of desirable species; (8) establish abundant annual floodplain habitat, with additional large areas that flood in less frequent wet years; (9) reduce inflow of agricultural and urban pollutants; and (10) improve the temperature regime in large areas of the estuary so temperatures rarely exceed 20°C during summer and fall months."

Similarly, reliance upon water year classification as a trigger for flow volumes has contributed to reduced flow variability in the estuary. The information received during this proceeding supports the notion that reliance upon water year classification as a trigger for flow volumes is an imperfect means of varying flows. Any individual month or season might have a dramatically different hydrology than the overall hydrology for the year. A critically dry year, for example, can have one or two very wet months, just as a wet year may have several disproportionately dry months. Figure 10 demonstrates how this actually occurs. Unimpaired Delta outflow for the month of June from 1922 through 2003 has historically been highly variable. Many June months that occur in years classified as wet have had much lower flows than June flows in years classified as below normal. The opposite is also true; several June flows in years classified as critically dry are higher than some years classified as above normal. Depending on the direction of this divergence of monthly flows (higher or lower) relative to the water year, reliance upon water year classification can provide less than optimal protection of the ecosystem or more than needed water supply impacts. The figure also shows the actual June flows for various periods of years, demonstrating how much lower actual flows have been than unimpaired flows. The primary reason for the lower historical flows is consumption of water in the watershed. The three periods shown, however, are not directly comparable to the unimpaired flow record because the shorter time frame may have been wetter or drier than the full historical record.

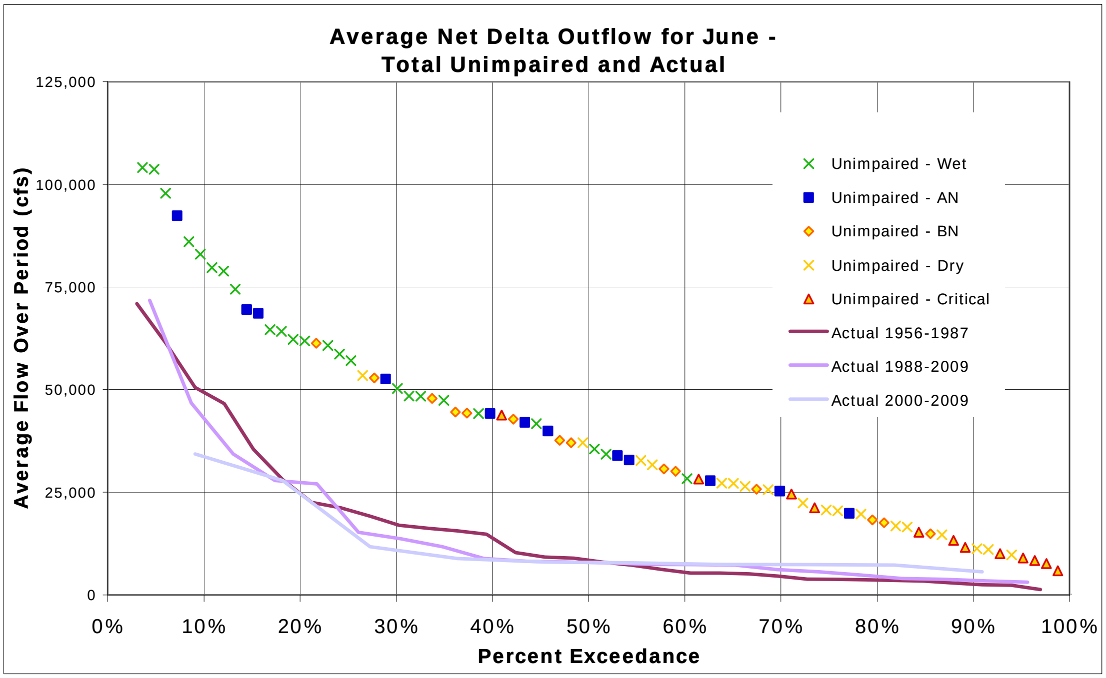

Figure 10. Actual and Unimpaired June Delta Outflow

Proportionality is one of the key attributes of restoring ecosystem functions by mimicking the natural hydrograph in tributaries to the Delta and providing for connectivity. Currently, inflows to the Delta are largely controlled by upstream water withdrawals and releases for water supply, power production, and flood control. As a result, inflows from tributaries frequently do not contribute flow to the Delta in the same proportions as they would have naturally, and to which native fish adapted. There is consensus in contemporary science that improving ecosystem function in the watershed, mainstem rivers, and the Delta is a means to improving productivity of migratory species. (e.g.,Williams 2005; NRC 1996, 2004a, 2004b as cited in NAS 2010, p. 42.) NAS found that, “Watershed actions would be pointless if mainstem passage conditions connecting the tributaries to, and through, the Delta were not made satisfactory.” (NAS 2010, p. 42.) “Propst and Gido (2004) support this hypothesis and suggest that manipulating spring discharge to mimic a natural flow regime enhances native fish recruitment (Propst and Gido, 2004 and Marchetti and Moyle, 2001).” (DOI, 1 p. 25.) Specifically, providing pulse flows to mimic the natural hydrograph could diversify ocean entry size and timing for anadromous fishes so that in many years at least some portion of the fish arrive in saltwater during periods favoring rapid growth and survival. (DOI 1, p. 30.) Food production may also be improved by maintaining the attributes of a natural hydrograph (EFG 1, p. 8.) Connectivity between natal streams and the Delta is critical for anadromous species that require sufficient flows to emigrate out of natal streams to the Delta and ocean, and sufficient flows upon returning, including flows necessary to achieve homing fidelity. Specifically, it is necessary for the scent of the river to enter the Bay in order for adult salmonids to find their way back to their natal river. (NMFS 2009, p.407 as cited in EDF 1, p. 48.) Further, insuring adequate flows from all of the tributaries that support native fish is important to maintain genetic diversity and species resilience in the face of catastrophic events.

4.3.2 Floodplain Activation and Other Habitat Improvements

Most floodplains in the Central Valley have been isolated from their rivers by levees. Due to the effects of levees and dams, side channel and floodplain inundating flows have been substantially reduced. At present, besides the Yolo Bypass, the only other Delta region with substantial connectivity to portions of the historical floodplain is the Cosumnes River, a small undammed watershed. (Sommer et al. 2001b.) Floodplains are capable of providing substantial benefits to numerous aquatic, terrestrial, and wetland species. (Sommer et al. 2001b.) Inundation of floodplains facilitates an exchange of organisms, nutrients, sediment, and organic material between the river and floodplain, and provides a medium in which biogeochemical processes and biotic activity (e.g., phytoplankton blooms, zooplankton and invertebrate growth and reproduction) can occur. (AR/NHI 1, p. 22.) This exchange of material can benefit downstream areas. For example, studies suggest phytoplankton, zooplankton, and other organic material transported from the Yolo Bypass enhances the food web of the San Francisco Estuary. (Jassby and Cloern 2000; Mueller-Solger et al. 2002; Sommer et al. 2004.)

Many fishes rear opportunistically on floodplains. (Moyle et al. 2007, as cited in Moyle et al. 2010), and juvenile salmon grow faster and become larger on floodplains than in the main-stem river channels. (Sommer et al. 2001a; Jeffres et al. 2008; DOI 1, p. 27; AR/NHI 1, p. 24.) Splittail require floodplains for spawning (Moyle et al. 2007), with large-scale juvenile recruitment occurring only in years with significant protracted (greater than or equal to 30 days) floodplain inundation, particularly in the Sutter and Yolo bypasses. (Meng and Moyle 1995, Sommer et al. 1997, Feyrer et al. 2006a.) Managing the frequency and duration of floodplain inundation during the winter and spring, followed by complete drainage by the end of the flooding season, could favor splittail and other native fish over non-natives. (Moyle et al. 2007, Grimaldo et al. 2004.) In addition, modeling conducted by Moyle et al. (2004) shows that while splittail are resilient, managing floodplains to promote frequent successful spawning is needed to keep them abundant. Improving management of the Yolo Bypass for fish, increasing floodplain areas along other rivers (e.g., Cosumnes and Mokelumne rivers), and developing floodplain habitat along the lower San Joaquin River, including a bypass in the Delta, represent opportunities to increase the frequency and extent of floodplain inundation. (Moyle et al. 2010.) The BDCP is currently evaluating structural modifications to the Fremont Weir (e.g., notch weir and install operable “inundation gates”), as a means of increasing the interannual frequency and duration of floodplain inundation in the Yolo Bypass. (BDCP 2009.)

The NMFS Opinion stipulates that USBR and DWR, in cooperation with DFG, USFWS, NMFS, and USACE, shall, to the maximum extent of their authorities (excluding condemnation authority), provide significantly increased acreage of seasonal floodplain rearing habitat, with biologically appropriate durations and magnitudes, from December through April, in the lower Sacramento River basin, on a return rate of approximately one to three years, depending on water year type. (NMFS 3, p. 608.) Per this NMFS Opinion, USBR and DWR are to submit a plan to implement this action to NMFS by December 31, 2011. (Id.) This plan is to include an evaluation of options to, among other things, increase inundation of publicly and privately owned suitable acreage within the Yolo Bypass, and modify operations of the Sacramento Weir or Fremont Weir to increase rearing habitat. (Id.)

Moyle et al. (2010) discuss the value of creating more slough networks with natural geometry and less diked, rip-rapped channel habitat, the value of tidal marsh habitat, and low salinity, open water habitat in the Delta:

> "Re-establishing the historical extensive dendritic sloughs and marshes is essential for re-establishing diverse habitats and gradients in salinity, depth and other environmental characteristics important to desirable fish and other organisms (e.g., Brown and May 2008). These shallow drainages are likely to increase overall estuarine productivity if they are near extensive areas of open water, because they can deliver nutrients and organic matter to the more open areas. Dendritic slough networks will develop naturally in Suisun Marsh after large areas become inundated following dike failures and they can be recreated fairly readily in the Cache Slough region by reconnecting existing networks. In the Delta, the present simplified habitat in the channels between islands needs to be made more suitable as habitat for desirable species. Many levees are maintained in a nearly vegetation-free state, providing little opportunity for complex habitat (e.g., marshes and fallen trees) to develop. Much of the low-value channel habitat in the western and central Delta will disappear as islands flood, but remaining levees in submerged areas should be managed to increase habitat complexity (e.g., through planting vegetation), especially in the cooler northern and eastern parts of the Delta.
>
> [Subtidal] habitat has been greatly depleted because marshes in the Delta and throughout the estuary have been diked and drained, mostly for farming and hunting (Figure 3). Unfortunately, most such habitat in shallow water today is dominated by alien fishes, including highly abundant species such as Mississippi silverside which are competitors with and predators on native fishes (Moyle and Bennett 1996; Brown 2003). Such habitat could become more favorable for native fishes with increased variability in water quality, especially salinity. In particular, increasing the amount of tidal and subtidal habitat in Suisun Marsh should favor native fishes, given the natural variability in salinity and temperature that occurs there. The few areas of the marsh with natural tidal channels tend to support the highest diversity of native fishes, as well as more striped bass (Matern et al. 2002; Moyle, unpublished data). With sea level rise, many diked areas of Suisun Marsh currently managed for waterfowl (mainly dabbling ducks and geese) will return to tidal marsh and will likely favor native fishes such as splittail and tule perch (Hysterocarpus traski), as well as (perhaps) migratory fishes such as juvenile Chinook salmon. Experimental (planned) conversions of some of these areas would be desirable for learning how to manage these inevitable changes to optimize habitat for desired fishes.
>
> Open water habitat is most likely to be created by the flooding of subsided islands in the Delta, as well as diked marshland 'islands' in Suisun Marsh (Lund et al. 2007, 2010; Moyle 2008). The depth and hydrodynamics of many of these islands when flooded should prevent establishment of alien aquatic plants while variable salinities in the western Delta should prevent establishment of dense populations of alien clams (Lund et al. 2007).

> Although it is hard to predict the exact nature of these habitats, they are most likely to be better habitat for pelagic fishes than the rock-lined, steep-sided and often submerged vegetation-choked channels that run between islands today (Nobriga et al. 2005). Experiments with controlled flooding of islands should provide information to help to ensure that these changes will favor desired species. Controlled flooding also has the potential to allow for better management of hydrodynamics and other characteristics of flooded islands (through breach location and size) than would be possible with unplanned flooding."

4.3.3 Water Quality and Contaminants

Toxic effects are one of three general factors identified by scientists with the IEP in 2005 as contributing to the decline in pelagic productivity. The life history requirements and water quality sections above identify specific species sensitivities to water quality issues.

Though the information received in this proceeding supports the recommendation that modification to flow through the Delta is a necessary first step in improving the health of the ecosystem, it also supports the recommendation that flow alone is insufficient. The Delta and San Francisco Bay are listed under section 303(d) of the Federal Clean Water Act as impaired for a variety of toxic contaminants that may contribute to reduced population abundance of important fish and invertebrates. The contaminants include organophosphate and pyrethrin pesticides, mercury, selenium and unknown toxicity. In addition, low DO levels periodically develop in the San Joaquin River at the DWSC and in OMR. The low oxygen levels in the DWSC inhibit the upstream migration of adult fall-run Chinook salmon and adversely impact other resident aquatic organisms.

There is concern that a number of non-303(d) listed contaminants, such as ammonia, pharmaceuticals, endocrine disrupting compounds, and blue-green algal blooms could also limit biological productivity and impair beneficial uses. Sources of these contaminants include agricultural, municipal and industrial wastewater, urban storm water discharges, discharges from wetlands, and channel dredging activities. More work is needed to determine their impact on the aquatic community.

Ammonia has emerged as a contaminant of special concern in the Delta. Recent hypotheses are that ammonia is causing toxicity to delta smelt, other local fish, and zooplankton and is reducing primary production rates in the Sacramento River below the SRWTP and in Suisun Bay. A newer hypothesis is that ammonia and nitrogen to phosphorus ratios have altered phytoplankton species composition and these changes have had a detrimental effect on zooplankton and fish population abundance. (Glibert 2010.) More experiments are needed to evaluate the effect of nutrients, including ammonia, on primary production and species composition in the Sacramento River and Delta.

4.3.4 Cold Water Pool Management

As mentioned in the specific flow criteria, the criteria contained in this report should be tempered by the additional need to maintain cold water resources in reservoirs on tributaries to the Delta until improved passage and other measures are taken that would reduce the need for maintaining cold water reserves in reservoirs. As discussed in the Chinook salmon section, salmon have specific temperature tolerances during various portions of their life-cycle. Historically salmonids were able to take advantage of cooler upstream temperatures for parts of their life-cycle to avoid adverse temperature effects. Since construction of the various dams in the Central Valley, access to much of the cooler historic spawning and rearing habitat has been blocked. To mitigate for these impacts, reservoirs must be managed to preserve cold water resources for release during salmonid spawning and rearing periods. As reservoir levels drop, availability of cold water resources also diminishes. Accordingly, it may not be possible to attain all of the identified flow criteria in all years and meet the thermal needs of the various runs of Chinook salmon and other sensitive species. Thorough temperature and water supply modeling analyses should be conducted to adaptively manage any application of these flow criteria to suit real world conditions and to best manage the competing demands for water needed for the protection of public trust resources, especially in the face of future climate change.

Specifically, these criteria should not be construed as contradicting existing and future cold water management requirements that may be needed for the protection of public trust resources, including those for the Sacramento River needed to protect the only remaining population of winter-run Chinook salmon. (see NMFS 3, p. 590-603.)

4.3.5 Adaptive Management

Any environmental flow prescription for native species in the Delta will be imperfect. The problem is too complex, uncertainties are too large, and the situation in the Delta is changing too rapidly in too many ways for any single flow prescription to be correct, or correct for long. (Fleenor et al. 2010.) Some degree of certainty regarding future conditions in the Delta is needed before long term flow criteria can be developed. Since it is unlikely that certainty will be achieved before actions or responses are required by geologic, biological, and legal processes, it might be valuable to provide substantial financial and water reserve resources, along with responsible institutional wherewithal to respond to changes and undertake necessary experiments for more successfully transitioning into the largely unexplored new Delta. (Fleenor et al. 2010.) This confounding need for certainty of operations and water supply at the same time there is uncertainty underlying ecosystem needs, provides good rationale to rely upon adaptive management to address this uncertainty.

The Delta is continually changing. Flow criteria developed for the present Delta ecosystem will become less reflective of ecosystem needs with the passage of time. Accordingly, it is important that flow criteria be adaptive to future changes. Flows, habitat restoration, and measures to address other stressors should be managed adaptively. (AR/NHI Closing Comments.)

Adaptive management is “an iterative process, based on a scientific paradigm that treats management actions as experiments subject to modification, rather than as fixed and final rulings, and uses them to develop an enhanced scientific understanding about whether or not and how the ecosystem responds to specific management actions.” (NRC 1999 as cited in DOI Ex.1.) This notion of treating actions as experiments is key, because information received in this proceeding indicates that the mechanisms underlying the relationship between flows and the health of the Delta ecosystem are, at times, unclear. Adaptive management is the most suitable approach for managing with uncertainty. (DEFG 1.)

Murray and Marmorek (2004) describe an adaptive management approach as:

- exploring alternative ways to meet management objectives
- predicting the outcomes of alternatives based on the current state of knowledge
- implementing one or more of these alternatives
- monitoring to learn about the impacts of management actions
- using the results to update knowledge and adjust management actions

An adaptive approach provides a framework for making good decisions in the face of critical uncertainties, and a formal process for reducing uncertainties so that management performance can be improved over time. (Williams et al. 2007.)

Adaptive management does not postpone action until "enough" is known but acknowledges that time and resources are too short to defer *some* action, particularly actions to address urgent problems. (Lee 1999.) Adaptive management provides a means of informing planning and management decisions in spite of uncertainty. Key point number 5 of the DEFG states: “a strong science program and a flexible management regime are essential to improving flow criteria. (DEFG 1.)

Adaptive management can be used to manage uncertainty in two ways, over two time frames. Over the short-term, adaptive management could allow for a specific response to real time conditions so long as the response is otherwise consistent with the constraints of some overarching regulatory framework. Over the longer term, adaptive management could allow for the more nimble modification of regulatory constraints, so long as these modifications fell within the clearly defined parameters of the overarching regulatory framework.

Short-term Adaptive Management

Per the DEFG’s assessment regarding the role of uncertainty…

> “…despite [our] extensive scientific understanding substantial knowledge gaps remain about the ecosystem's likely response to flows. First, ecosystem processes in a turbid estuary are mostly invisible, and can be inferred only through sampling. Second, monitoring programs only scratch the surface of ecosystem function by estimating numbers of fish and other organisms, whereas the system’s dynamics depend on birth, growth, movement, and death rates which can rarely be monitored. Third, this system is highly variable in space (vertical, cross-channel, along-channel, and larger-scale), time (tidal, seasonal, and interannual), flow, salinity, temperature, physical habitat type, and species composition. Each of the hundreds of species has a different role in the system, and these differences can be subtle but important. As a result, we have little ability to predict how the ecosystem will respond to the numerous anticipated deliberate and uncontrolled changes.” (DEFG 1.)

Flexible management can be designed into a regulatory framework so that any requirements rely upon real time information and real time decisions to guide specific real-time action. A current example of this is the Delta Smelt Working Group that provides information and analyses used to guide real time operation of export facilities so that these facilities can be operated in a manner that conforms with the current NMFS and USFWS opinions. Any such flexible management will need to consider the processes and governance structures required to make sound scienfically-based real-time decisions. The Delta Smelt Working Group is a good example of how scientific assessment of real-time data, including the presence of fish, can better inform the real-time operation of export facilities.

<u>Long-term Adaptive Management</u>
Over the longer term, adaptive management can be used to more nimbly modify regulatory constraints so that fishery and water resource agencies are not locked into prescriptive constraints well past the time that current scientific understanding can support. This longer term adaptive management has bearing on a number of the flow criteria being considered in this report because many of these criteria lack sufficiently robust information to support a specific numeric criterion. Although the functional basis for a beneficial flow may be understood, the basis for a specific numeric criteria may not. Some regulatory flows may therefore need to take the form of an informed experimental manipulation. Such flows would need to be implemented… "as if they were experiments, with explicit conceptual and simulation models, predicting outcomes, and feedback loops so that the course of management and investigation can change as the system develops and knowledge is gained. A talented group of people tasked to integrate, synthesize, and recommend actions based on the data being gathered are essential for making such a system work. Failure to implement an effective adaptive management program will likely lead to a continued failure to learn from the actions, and a lack of responsiveness to changing conditions and increased understanding." (DEFG 1.)

The Delta Science Program, IEP, and other institutions could be relied upon to evaluate experimental flows and make recommendations to be considered for modifications of such flows.

4.4 Expression of Criteria as a Percentage of Unimpaired Flow

In some cases, participants' recommendations were expressed as specific flows in specific months, to be applied during specific water year types or with specified probabilities of exceedance. Review of unimpaired hydrology shows there is great variability in the quantity of unimpaired flow during these specified months when categorized by water year type. Reliance upon monthly or seasonal flow prescriptions based on water year type would therefore result in widely ranging relative amounts of unimpaired flow depending upon the specific hydrology of the month or season. Also, the rather coarse division of the hydrograph into five water year types can lead to abrupt step-wise changes in flow requirements. In an attempt to more closely reflect the variation of the natural hydrograph, the State Water Board recommends that, when possible, the flow criteria be expressed as a percentage of unimpaired flow.

To develop criteria in this way, the unimpaired flow rate for a specified time period (e.g. average monthly flow over a range of months) was plotted on an exceedance probability graph (using the Weibull plotting position formula) along with the flow recommendations and desired return frequencies. The unimpaired flow rates were also plotted such that the associated water year type can be identified and their percent exceedance estimated. A percentage of unimpaired flow was selected by trial and error so that the desired flow rate and exceedance frequency was achieved. A separate exceedance plot was produced for each time period being evaluated.

The unimpaired flow estimates used in the development of these flow criteria are based on those developed in the DWR May 2007 document: *"California Central Valley Unimpaired Flow Data" Fourth Edition Draft.* (DWR 2007.) This report contains estimates of the monthly flow for 24 sub-basins in the Central Valley. Each sub-basin uses a separate calculation dependant on conditions specific to that sub-basin, available gauge data, and relationships to other sub-basins. In many cases the methods change over the period of record to incorporate changes to infrastructure within the sub-basins that need to be accounted for. Estimates are provided for 83 water years from 1922 through 2003. A water year begins in October of the previous calendar year through September of the named water year. The following describes the unimpaired flow estimates that are the basis for flow criteria for the Sacramento River at Rio Vista, the San Joaquin River at Vernalis, and Net Delta Outflow.

Sacramento Valley Unimpaired Total Outflow

Estimates of the unimpaired Sacramento Valley outflow were computed as the sum of estimates from 11 sub-basins in the watershed and are understood to represent the flow that would occur on the Sacramento River at approximately Freeport. These 11 sub-basins include the Sacramento Valley Floor, Putah Creek near Winters, Cache Creek above Rumsey, Stony Creek at Black Butte, Sacramento Valley West Side Minor Streams, Sacramento River near Red Bluff, Sacramento Valley East Side Minor Streams, Feather River near Oroville, Yuba River at Smartville, Bear River near Wheatland, and the American River at Fair Oaks.

The unimpaired Sacramento Valley outflow from DWR 2007 is used as the basis for flow criteria on the Sacramento River at Rio Vista, even though it is understood they are more representative of unimpaired flows expected at Freeport. This is a necessary simplification as such estimates do not exist at Rio Vista, but should be adequate for the purpose of these criteria. If future flow requirements are to be established at Rio Vista based on a percentage of unimpaired flow, it is recommended that new estimates of unimpaired flow be developed specific for this location.

San Joaquin Valley Unimpaired Total Outflow

Estimates of the unimpaired San Joaquin Valley outflow were computed as the sum of estimates from nine sub-basins in the watershed and are understood to represent the flow that would occur on the San Joaquin River at Vernalis. These nine sub-basins include the Stanislaus River at Melones Reservoir, San Joaquin Valley Floor, Tuolumne River at Don Pedro Reservoir, Merced River at Exchequer Reservoir, Chowchilla River at Buchanan Reservoir, Fresno River near Daulton, San Joaquin River at Millerton Reservoir, Tulare Lake Basin Outflow, San Joaquin Valley West Side Minor Streams.

Delta Unimpaired Total Outflow

Estimates of unimpaired Net Delta Outflow in DWR 2007 were computed generally as Delta Unimpaired Total Inflow minus unimpaired net use in the Delta, including both lowlands and uplands. Delta Unimpaired Total Inflows was calculated as the sum of the Sacramento Valley and San Joaquin Valley Unimpaired Total Outflows as described above and the East Side Streams Unimpaired Total Outflow. The later consists of four sub-basins including San Joaquin Valley East Side Minor Streams, Cosumnes River at Michigan Bar, Mokelumne River at Pardee Reservoir, and Calaveras River at Jenny Lind. Generally the unimpaired net use in the Delta is an estimate of the consumptive use from riparian and native vegetation (replacing historical irrigated agriculture and urban areas), plus evaporation from water surfaces, minus precipitation, and assumes that existing Delta levees and island remain intact. Unimpaired flow graphs in this report use the unimpaired flow record from 1922 to 2003.

5. Flow Criteria

Two types of criteria are provided in this report: numeric flow criteria, and other, non-numeric, measures that should be considered to complement the numeric criteria. Numeric criteria are subdivided into two categories: category “A” criteria have more and better scientific information, with less uncertainty, to support specific numeric criteria than do Category “B” criteria. Summary numeric criteria are provided for Delta outflow, as well as Sacramento River and San Joaquin River inflows, and Hydrodynamics (Old and Middle River, Inflow-Export Ratios, and Jersey Point flows) in Tables 19 through 22.

In addition to new criteria for Delta outflows, inflows, and hydrodynamics, some of the objectives for the protection of fish and wildlife from the 2006 Bay-Delta Plan are advanced as criteria in this report. While the State Water Board did not specifically reevaluate the methodology and basis for the Bay-Delta Plan objectives, the State Water Board recognizes that these flows provide some level of existing protection for fish and wildlife and, in the absence of more specific information, merit inclusion in these criteria. At the time the Bay-Delta Plan objectives were adopted, they were supported by substantial evidence, including scientific information. While the purpose of this report is to develop flow criteria using best available scientific information, water quality objectives are established taking into account scientific and other factors pursuant to Water Code section 1241.

5.1 Delta Outflows

Following are Delta outflow criteria based on analysis of the species-specific flow criteria and other measures:

1) Net Delta Outflow: 75% of 14-day average unimpaired flow for January through June
2) Fall X2 for September through November
    - Wet years X2 less than 74 km (greater than approximately 12,400 cfs)
    - Above normal years X2 less than 81 km (greater than approximately 7,000 cfs)
3) 2006 Bay-Delta Plan Delta Outflow Objectives for July through December

Delta outflow criteria 1 is a Category A criterion because it is supported by more robust scientific information. Delta outflow criteria 2 and 3 are Category B criteria because there is less scientific information to support specific numeric criteria, but there is enough information to support the conceptual need for flows. Category A and B criteria are both equally important for protection of the public trust resource, but there is more uncertainty about the appropriate volume of flow required to implement Category B criteria. Following is discussion and rationale for these criteria.

The narrative objective of the flow criteria is to halt the population decline and increase populations of native species as well as species of commercial and recreational importance. The need to estimate the magnitude, duration, timing, and quality of Delta outflows necessary to support viable populations of these species is inherent to this objective. McElhany et al. (2000) proposed that four parameters are critical for evaluating population viability: abundance, population growth rate, population spatial structure, and diversity. Delta outflow may affect one, all, or some combination of these parameters for a number of resident and anadromous species. A species-specific analysis of flow needs for a suite of upper estuary species is included in section 4.2.4.

An analysis of generation to generation population abundance versus Delta outflows indicates that the "likelihood" of an increase in the longfin smelt FMWT abundance index in 50% of years corresponded with flow volumes of approximately 9.1 MAF (51,000 cfs) and 6.3 MAF (35,000 cfs) during January through March and March through May, respectively. (TBI/NRDC 2, pp. 17-19.) The provision of sufficient flows to achieve these flow volumes during January through March and March through May in approximately 45% and 47% of years, respectively, is intended to promote increased abundance and improved productivity for longfin smelt and other desirable estuarine species. Based on a comparison of the flows needs identified in section 4.2.4, it appears that winter-spring outflows designed to be protective of longfin smelt would benefit the other upper estuary species evaluated. The DFG recommended that spring outflows extend through June to fully protect a number of estuarine species. (DFG 1, pp. 2-5.) During June, sufficient outflow should be provided to maintain X2 in Suisun Bay (between 75 km and 64 km). (DFG closing comments, p. 7; DFG 2, p. 6.)

The State Water Board recognizes that the target flow volumes of 9.1 MAF (Jan-Mar, 51,000 cfs) and 6.3 MAF (Mar-May, 35,000 cfs) in greater than or equal to approximately 45% and 47% of years, respectively, and the positioning of X2 in Suisun Bay during the month of June are necessary in order to promote increased abundance and improved productivity for longfin smelt and other desirable estuarine species. An approach based on a percentage of unimpaired flows is intended as a means of distributing flows to meet the above-mentioned criteria in a manner that more closely resembles the natural hydrograph. Such an approach also recognizes the importance of preserving the general attributes of the flow regimes to which the native estuarine species are adapted.

Analyses of historic conditions (1921 to 2003), indicates that at 75% of unimpaired flows, average flows of 51,000 cfs occurred between January and March in approximately 35% of years, while average flows of 35,000 cfs happened between March and May in 70% of years. At 75% of unimpaired flow, X2 would be maintained west of Chipps Island more than 90% of the time between January and June (analyses not shown). Rather than advance multiple static flow criteria for the January through March, March through May, and June time periods, the State Water Board determines, as a Category A criterion, that 75% of 14-day average unimpaired flow is needed during the January through June time period to promote increased abundance and improved productivity for longfin smelt and other desirable estuarine species. It is important to note that this criterion is not a precise number; rather it reflects the general timing and magnitude of flows needed to protect public trust resources in the Delta ecosystem. However, this criterion could serve as the basis from which future analysis and adaptive management could proceed.

Given the extensive modifications to the system there may be a need to diverge from the natural hydrograph at certain times of the year to provide more flow than might have actually occurred to compensate for such changes. Fall outflow criteria, intended to improve conditions for Delta smelt by enhancing the quantity and quality of habitat in wet and above normal water years, represent such an instance. As a Category B criterion, the State Water Board determines that sufficient outflow is needed from September through November of wet and above normal water year types to position X2 at less than or equal to 74 km and 81 km, respectively (Fall X2 action). In addition, the Delta Outflow Objectives contained within the Bay-Delta Plan for July through December are advanced as a Category B criterion. The State Water Board does not recommend increasing fall flows beyond those stipulated in the Bay-Delta Plan and Fall X2 action at this time. The quantity and timing of fall outflows necessary to protect public trust resources warrants further evaluation.

Category A: Winter – Spring Net Delta Outflows

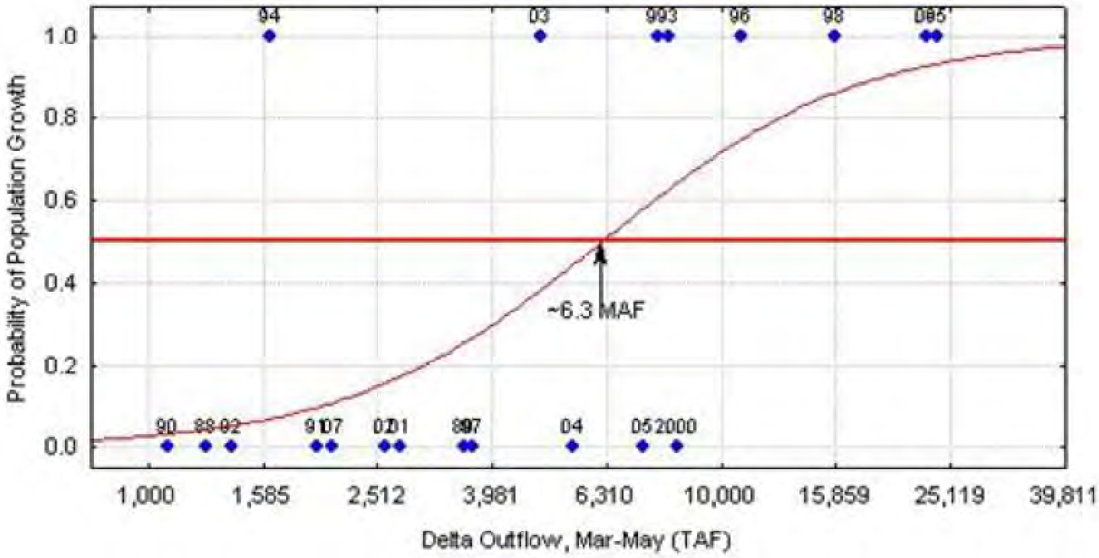
The flow regime is important in determining physical habitat in aquatic ecosystems, which is in turn a major factor in determining biotic composition. (DEFG 1.) Bunn and Arthington (2002) highlight four principles by which the natural flow regime influences aquatic biodiversity: 1) developing channel form, habitat complexity, and patch disturbance, 2) influencing life-history patterns such as fish spawning, recruitment, and migration, 3) maintaining floodplain and longitudinal connectivity, and 4) discouraging non-native species. Altering flow regimes affects aquatic biodiversity and the structure and function of aquatic ecosystems. The risk of ecological change increases with greater flow regime alteration. (Poff and Zimmerman 2010.)

A suite of native, and recreationally or commercially important species were evaluated in an effort to assess the timing, volume, and quality of water necessary to protect public trust resources. Flow criteria were developed for each of the species identified by DFG as those that are priority concern and will benefit the most as a result of improved flow conditions. (DFG closing comments, p. 3.) For Delta outflow, this included longfin smelt, delta smelt, starry flounder, American shad, bay shrimp (*Crangon* sp.), mysid shrimp, and *Eurytemora affinis*. Through this process, data or information pertaining to life history attributes (e.g., timing of migration, spawning, rearing), relationships of species abundance or habitat to Delta outflow, season or time period when flow characteristics are most important, factors influencing and/or limiting populations, and other characteristics were assessed and summarized in the individual species write-ups.

Statistically significant relationships between annual abundance and X2 (or outflow) have been demonstrated for a diverse assemblage of species within the estuary. (Stevens and Miller 1983; Jassby et al. 1995; Kimmerer 2002a; Rosenfield and Baxter 2007; Kimmerer *et al*. 2009.) The causal mechanisms underlying the variation in annual abundance indices of pelagic species in the estuary are poorly understood, but likely vary across species and life stages.

Longfin smelt have the strongest X2-abundance relationship of those species for which such a relationship has been demonstrated. (Kimmerer et al. 2009.) Abundance indices for this species are inversely related to X2 during its winter-spring spawning and early rearing periods. (Stevens and Miller 1983; Jassby et al. 1995; Kimmerer 2002a; Rosenfield and Baxter 2007; Kimmerer et al. 2009.) However, a four-fold decline in the relationship, with no significant change in slope, occurred after 1987, coincident with the introduction and spread of the introduced clam *Corbula amurensis.* (Kimmerer 2002a.) Reduced prey availability due to clam grazing has been identified as a likely mechanism for the decline in the X2-abundance relationship. (Kimmerer 2002a.)

One of the key biological goals of the informational proceeding was to identify the flows needed to increase abundance of native and other desirable species. Logit regression (StatSoft 2010, as cited in TBI/NRDC 2, p.17) was used to address the question: What outflow corresponded to positive longfin smelt population growth 50% of the time in the past? Logit regression is used to find a regression solution when the response variable is binary. For the purpose of this analysis, the generation-over-generation changes in abundance indices were converted to a binary variable (increase = 1 or decrease = 0). The analysis was conducted using FMWT abundance indices for the period extending from 1988 to 2007 (post-*Corbula*). Two periods of the winter-spring seasons (January to March and March to May) were evaluated, as different life stages of longfin smelt are present in the Delta during those periods (spawning adults and larvae/juveniles, respectively) and the mechanisms underlying the flow-abundance relationship may occur and/or vary in some or all of the months during these periods. (TBI/NRDC 2, p. 13.) The results were statistically significant ($p < 0.015$) and revealed that the "likelihood" of an increase in FMWT abundance index in 50% of years corresponded with flows of approximately 9.1 MAF and 6.3 MAF during January through March and March through May, respectively. (Figure 11, TBI/NRDC 2, pp. 17-19.)



Logit regression showing relationship between March through May Delta outflow and generation-over-generation change in abundance of longfin smelt (measured as the difference between annual FMWT abundance indices). Positive changes in the abundance index were scored at "1" and declines were scored as "0". Arrow indicates flows above which growth occurred in more than 50% of years. Point labels indicate year of the FMWT index. (Source: TBI 2, Figure 15.)

Figure 11. Logit Regression Showing Relationship Between March through May Delta Outflow and Generation-Over-Generation Change in Longfin Smelt Abundance

A similar analysis was conducted for bay shrimp (*Crangon* sp.), a species whose flow-abundance relationship did not experience a "step decline" following the invasion of *Corbula.* (Kimmerer 2002a.) Results of the logit analysis indicate that abundance indices for this species increased in about 50% of years when flows during March through May were approximately 5 MAF. (TBI/NRDC 1, p. 17.) Therefore, flows associated with positive changes in the longfin smelt abundance index are anticipated to improve the likelihood of increases in bay shrimp abundance as well.

An analysis of historical longfin smelt flow-abundance relationships that corresponded to recovery targets in the Recovery Plan for the Sacramento/San Joaquin Delta Native Fishes (USFWS 1996) was also conducted. During the periods of January through March and March through May, cumulative Delta outflows of greater than 9.5 MAF and greater than 6.3 MAF, respectively, historically corresponded to abundance indices equal to or exceeding the recovery targets. (TBI/NRDC 2, p. 14.) These results are based on the intersection of the 1967 to1987 flow-abundance relationship and the recovery target. Use of the 1988 to 2007 flow-abundance relationship predicts lower abundance indices per any given flow, as compared to the historical relationship. Use of the pre-*Corbula* flow-abundance relationship underscores the need to address other stressors that may be affecting longfin smelt abundance concurrently with improved flow conditions. (TBI/NRDC 2, p. 14.) Applying this method and the logit regression produces very similar results.

As noted above, the results of the logit analysis indicate that the “likelihood” of an increase in the longfin smelt FMWT abundance index in 50% of years corresponded with flows of approximately 9.1 MAF and 6.3 MAF during January through March and March through May, respectively. (TBI/NRDC 2, pp. 17-19.) Hereafter, these two flow volumes are reported in cubic feet per second, as 51,000 cfs and 35,000 cfs, respectively. Analyses indicate that under historic unimpaired conditions (1921 to 2003) average flows of 51,000 cfs occurred between January and March in approximately 50% of years (Figure 12a), while average flows of 35,000 cfs happened between March and May approximately 85% of the time (Figure 13a). The review of the historic record suggests that it is unrealistic to expect a 100% return frequency for the two magnitudes. A point of reference for determining a more realistic return frequency might be the actual (impaired) flows that occurred from 1956 to 1987. This was a time period when native fish were more abundant than today. Actual average flows between 1957 and 1987 of 51,000 cfs occurred between January and March in approximately 45% of years (Figure 12b). Similarly average flows of 35,000 cfs occurred between March and May 47% of the time (Figure 13b). However, since 2000, average flows of this magnitude only occurred about 27% and 33% of the time, respectively (Figures 12b and 13b). At 75% of unimpaired flow, average flows of 51,000 and 35,000 cfs would happen 35% and 70% of the time, respectively (Figure 12a and Figure 13a). Finally, the DFG has indicated that spring outflows should continue through June to fully protect a number of estuarine species (DFG 1, pp.2-5.)

A fixed 75% of unimpaired flow would extend the flow criteria to other years and distribute flows in a manner that more closely resembles the natural hydrograph. Expression of this criterion as a 14-day running average would better reflect the timing of actual flows (compared with a 30-day running average) while still allowing for a time-step to which reservoirs could be operated. The appropriateness of the 14 day averaging period warrants further evaluation. The unimpaired flows from which the 75% criterion is calculated are monthly values. Estimates of 14-day average unimpaired flows have not been published, but a cursory analysis indicates that they are likely to generate an exceedance curve similar to one generated with monthly values.

The State Water Board therefore determines that the Net Delta Outflow criterion be 75% of the 14-day average unimpaired flow between January and June (Figure 14a, Table

20). Consistent with the DFG recommendation (closing comments, p. 7) that X2 be maintained between 65 and 74 km (Chipps Island and Port Chicago) from January through June, a criterion of 75% of unimpaired flow, would maintain X2 west of Chipps Island more than 90% of the time, between January and June, based on monthly averages (analyses not shown). The return frequency for all months combined is about 98% of the time (Figure 14a). This compares with about a 90% percent return frequency between 2000 and 2009 (Figure 14b).

b)

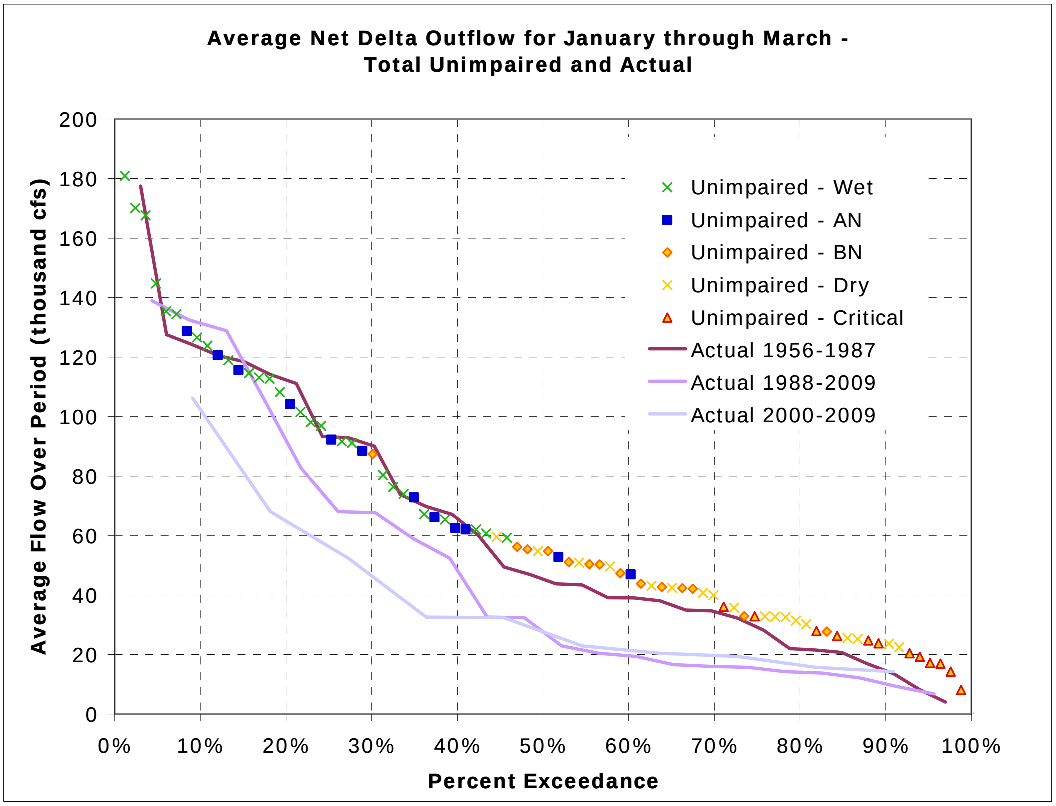

Figure 12. Net Delta Outflow Flow Exceedance Plot - January through March

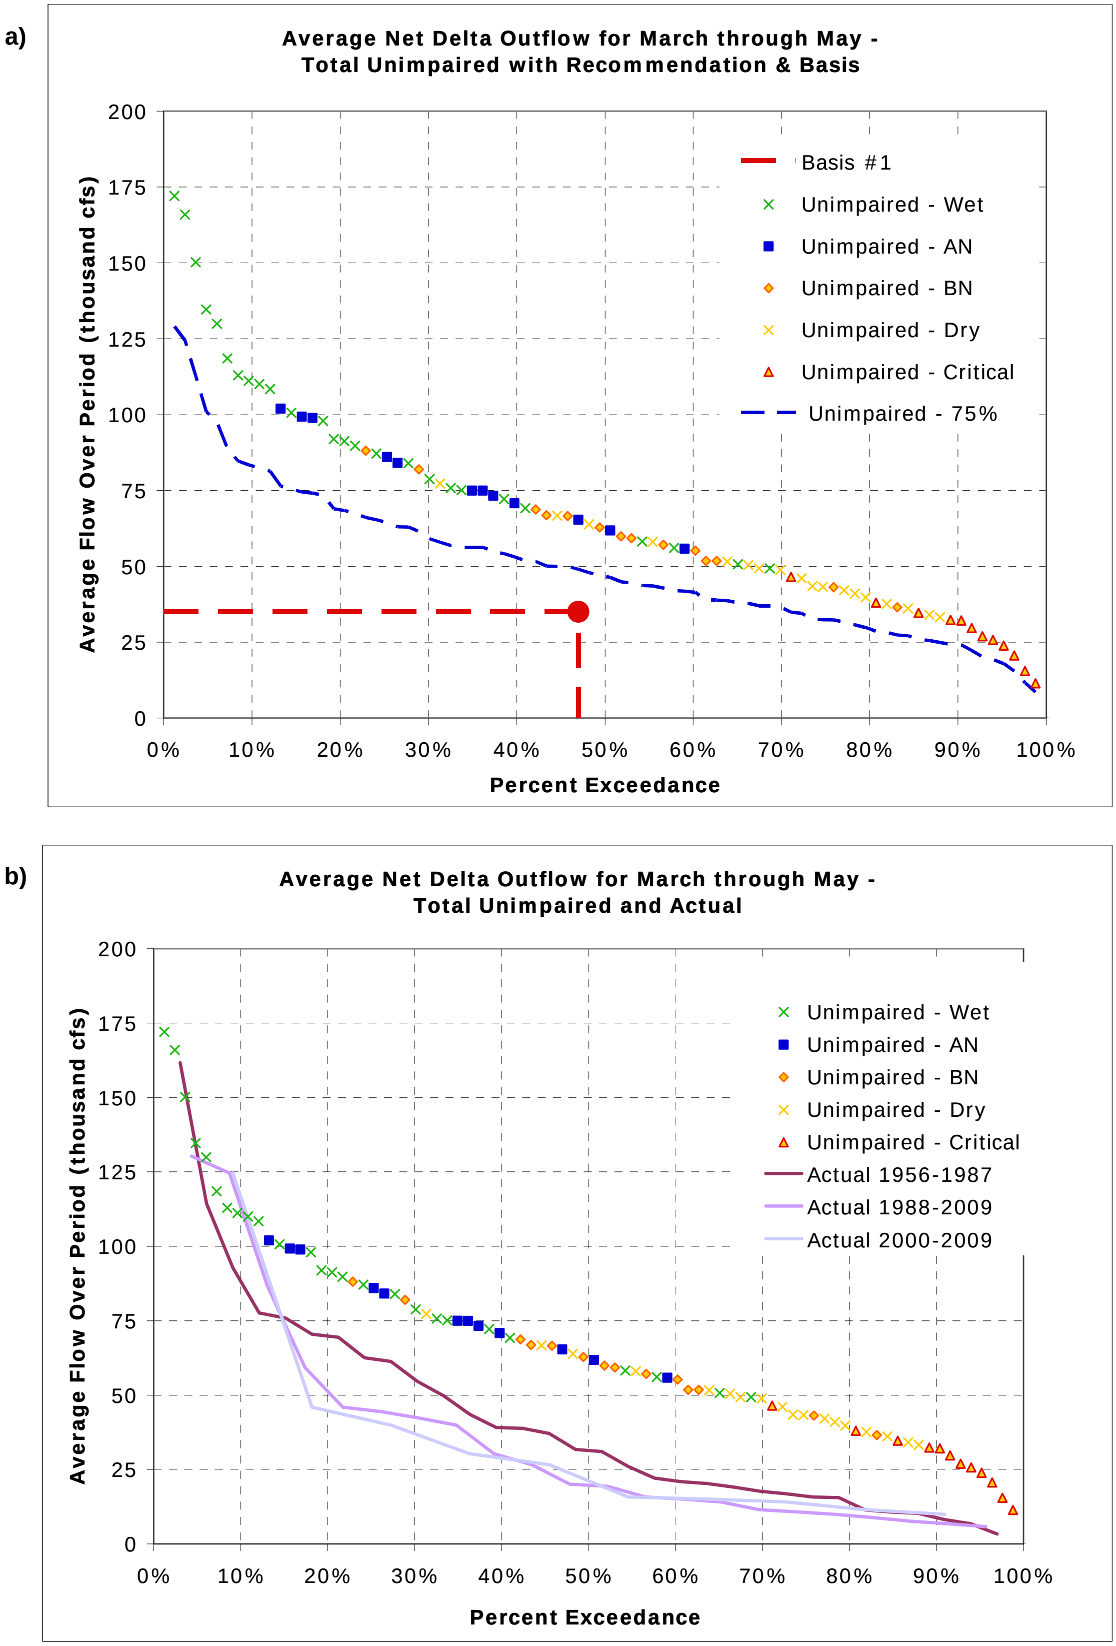

Figure 13. Net Delta Outflow Flow Exceedance Plot - March through May

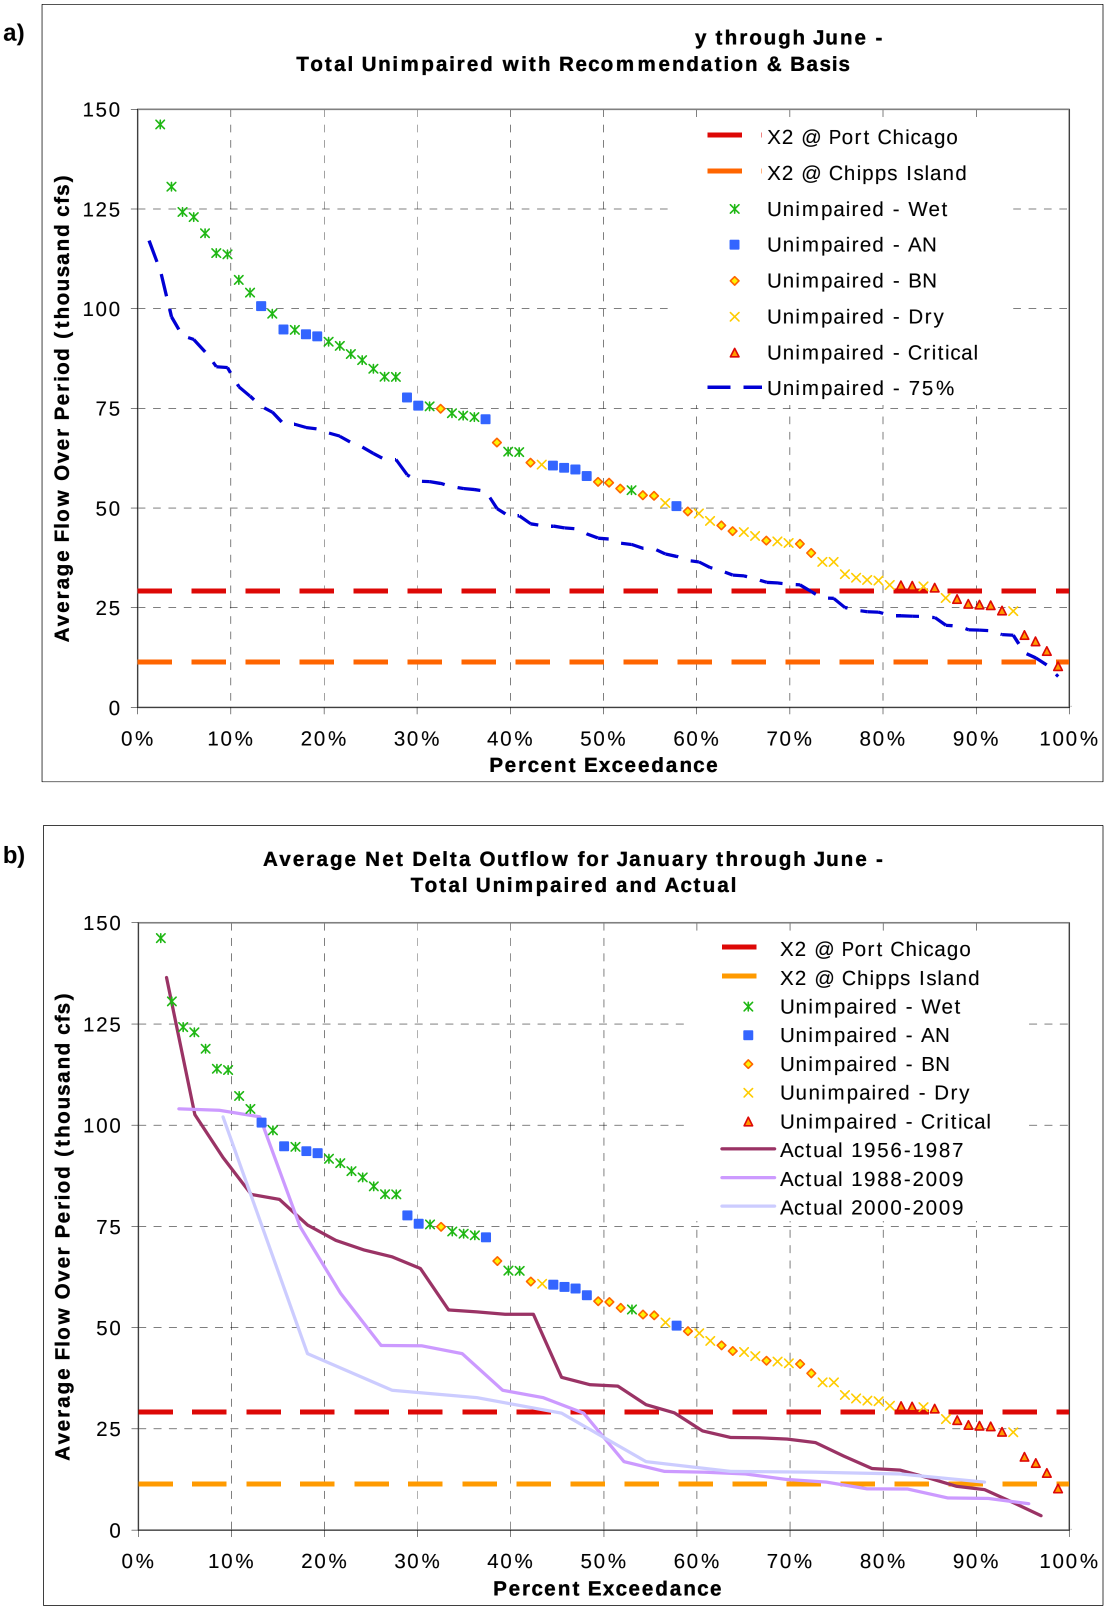

Figure 14. Net Delta Outflow Flow Exceedance Plot - January through June

The net Delta outflow criterion of 75% of unimpaired flows from January through June is anticipated to increase the likelihood of positive population growth for a number of other public trust species, notably those for which abundance-X2 relationships have been demonstrated, including American shad, striped bass, starry flounder, bay shrimp (*Crangon franciscorum*), and *Eurytemora affinis* (spring abundance). For example, the spring (March through May) abundance of *Eurytemora affinis* has been positively related to flow, following the invasion of *Corbula.* (Kimmerer 2002a.) This species represents an important prey item for most small fishes, particularly those with winter and early spring larvae, such as longfin smelt, delta smelt and striped bass. (Lott 1998, Nobriga 2002, Bryant and Arnold 2007, DFG unpublished.) Increases in the abundance of prey species, such as *E. affinis* and bay shrimp, has the potential to improve productivity of the estuarine food web and benefit a number of fishes, especially given that food limitation has been identified as a potential contributing factor in the POD. (Baxter *et al*. 2008.) Additional information concerning the relationship of population abundance to flow for these species is provided in the species life history section of this report.

Delta smelt abundance does not respond to freshwater outflow in a predictable manner similar to that of other numerous estuarine species. (Stevens and Miller 1983; Jassby et al. 1995; Kimmerer 2002a.) However, freshwater outflow during spring (March to June) does affect the distribution of delta smelt larvae by transporting them seaward toward the low salinity zone. (Dege and Brown 2004.) Ideal rearing habitat conditions for this species are believed to be shallow water areas most commonly found in Suisun Bay. (Bennett 2005.) Outflows that locate X2 in Suisun Bay (mean April through July location) produce the highest delta smelt abundance levels; however, low abundances have also been observed under the same conditions, which indicates several mechanisms must be operating. (Jassby et al. 1995; DFG 1, p. 15.) A criterion of 75% of unimpaired flow is expected to place X2 in Suisun Bay from March through June in nearly all years.

The DFG's current science-based conceptual model is that placement of X2 in Suisun Bay represents the best interaction of water quality and landscape for fisheries production given the current estuary geometry. (DFG 2, p. 6.) The DFG (closing comments, p. 7) provided recommended flow criteria for the Delta based on the placement of X2, for January through June (exact period varied by species), for longfin smelt, starry flounder, bay shrimp, zooplankton, and American shad. For each of these species, the DFG (*Id*.) recommends that sufficient outflow be provided to position X2 between 75 km and 64 km. These criteria are generally consistent with spring X2 requirements in the 2006 Bay-Delta Plan, which requires salinity at one compliance point (81 km) not to exceed 2 psu continuously, and at two other compliance points (64 km [Port Chicago] and 75 km [Chipps Island]) not to exceed 2 psu for a set number of days during February through June. Positioning X2 at 75 km and 64 km is equivalent to a 3-day running average Net Delta Outflow Index of 11,400 cfs and 29,200 cfs, respectively. Implementation of the 75% of unimpaired flow criteria would be largely consistent with the intent of the DFG's recommendations by placing X2 between Chipps Island and Port Chicago, or further to the west, in nearly all years during the January through June period.

The step-decline in the abundance-X2 relationship that occurred after 1987 for many of these species in combination with the lack of understanding concerning the causal mechanisms underlying those relationships leads to uncertainty regarding the future response of these species to elevated flows. In addition, a number of major changes to the Delta landscape, including levee failure and island flooding, are likely to occur over the next several decades. (Lund et al. 2007, 2008.) Flow regimes needed to maintain desired environmental conditions will change through time, in response to changes in the geometry of waterways, climate, and other factors. A number of "stressors" are currently being evaluated as potential contributors to the POD, including attributes of physical and chemical fish habitat. (Sommer et al. 2007; Baxter et al. 2008.) Increasing flows, without concurrent improvements to habitat and water quality, would decrease the extent of expected improvements in native species abundances and habitats. (DOI 1, p. 40.) However, the scientific information received during this proceeding supports the conclusion that flow, though not sufficient in and of itself, is necessary to protect public trust resources and that the current flow regime has harmed native species and benefited non-native species. Each of these issues adds further support to the need for a strong adaptive management program.

The specific flow criteria may need to be tempered by the need to maintain water in reservoirs to provide adequate cold water resources to support egg incubation, juvenile rearing, and holding in the Sacramento River, San Joaquin River, and associated tributary basins. It may not be possible to attain the outflow criteria and meet the thermal needs of the various runs of Chinook salmon and other sensitive species in certain years. Water supply modeling and temperature analyses should be conducted to identify conflicting requirements to achieve both outflow and cold water temperature goals.

Category B: Fall X2

Abiotic habitat parameters for delta smelt have been described for both the summer and fall seasons as combinations of salinity, temperature, and turbidity. (Nobriga et al. 2008; Feyrer et al. 2007; Feyrer et al. in review.) During fall, delta smelt typically occur in low salinity rearing habitats located around the confluence of the Sacramento and San Joaquin Rivers. Suitable abiotic habitat for delta smelt during fall has been defined as relatively turbid water (Secchi depths < 1.0 m) with a salinity of approximately 0.6-3.0 psu. (Feyrer et al. 2007.) Long-term trend analysis has shown that environmental quality, as defined by salinity and turbidity, has declined across a broad geographical range, most notably within the south-eastern and western regions of the Delta, leaving a relatively restricted area in the lower Sacramento River and around the confluence of the Sacramento and San Joaquin rivers with the least habitat alteration, compared to the rest of the upper estuary. (Feyrer et al. 2007, DOI 1, p.34.)

The amount of habitat available to delta smelt is controlled by freshwater flow and how that flow affects the position of X2, geographically, in the estuary (Figure 15). (Feyrer et al. in review.) Through the use of a 3D hydrodynamic model, Kimmerer et al. (2009) showed that the extent of delta smelt habitat, as defined by salinity, increases as X2 moves seaward. When X2 is located downstream of the confluence of the Sacramento and San Joaquin rivers, suitable abiotic habitat extends into Suisun and Grizzly bays, resulting in a large increase in the total area of suitable abiotic habitat. (Feyrer et al. in review.) The average position of X2 during fall has moved upstream, resulting in a corresponding reduction in the amount and location of suitable abiotic habitat. (Feyrer et al. 2007; Feyrer et al. in review.)

Average Net Delta Outflow for September, October, and November are presented in Figure 16, Figure 17, and Figure 18. Historically, unimpaired flows in fall were independent of water year type. Interestingly, actual outflow was greater than unimpaired flow between 1956 and 1987. However, fall outflows have fallen since then and since 2000 are almost always less than unimpaired flow. This is consistent with the observations of Feyrer et al. (2007) that fall X2 has moved upstream and this has reduced the amount of available habitat for smelt in fall.

Fall conditions may be very important for delta smelt, since this period of time coincides with the pre-spawning period for adult delta smelt. (Feyrer et al. 2007.) In general, reductions in habitat constrict the range of these fishes, which combined with an altered food web, may affect their health and survival. (Feyrer et al. 2007.) There is a statistically significant stock-recruitment relationship for delta smelt in which pre-adult abundance measured by the FMWT positively affects the abundance of juveniles the following year in the Summer Townet survey. (Bennett 2005; Feyrer et al. 2007, as cited in USFWS 2008.) Incorporating the combined effects of specific conductance and Secchi depth improved the stock-recruitment relationship. (Feyrer et al. 2007.)

Feyrer et al. (In Review) demonstrated that delta smelt are more abundant when a large amount of habitat is available. However, the relationship between habitat area and FMWT abundance is complex and not strong. (NAS 2010.) When the area of highly suitable habitat is low, either high or low FMWT indices can occur (Figure 15). Therefore, delta smelt can be successful in instances where habitat is limited. More important, however, is that the lowest abundances all occurred when the habitat-area index was less than 6,000 ha. (Feyrer et al. in review; NAS 2010.) This potentially suggests that while reduced habitat area may be an important factor associated with the worst population collapses, it is not likely the only cause of the collapse. (NAS 2010.)

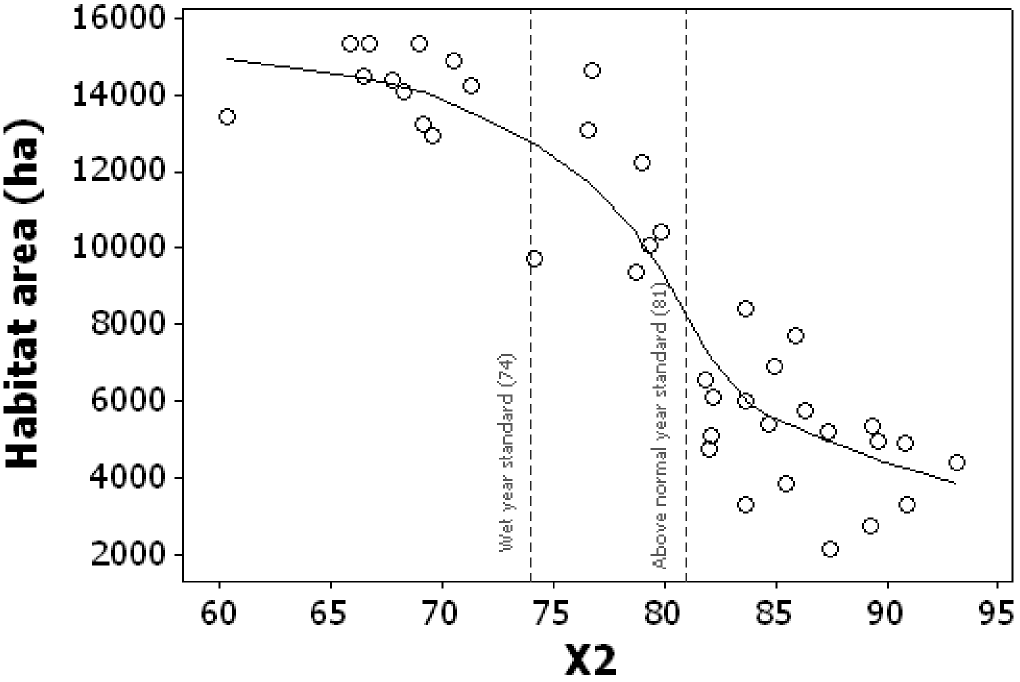
The fall X2 action described in the USFWS Opinion is focused on wet and above normal years because these are the years in which project operations have most significantly affected fall outflows. Actions in these years are more likely to benefit delta smelt. (USFWS 2008.) The action calls for maintaining X2 in the fall of wet years and above-normal years at 74 km and 81 km, respectively. (Figures 14, 15, and 16; USFWS 2008.) In addition to increasing the quality and quantity of habitat for delta smelt, moving X2 westward in the fall may also reduce the risk of entrainment by increasing the geographic and hydrologic distance of delta smelt from the influence of the Project export facilities. (DOI 1, p. 34.)

The NAS (2010) commented on this action in their review of the USFWS Opinion and concluded:

> “The X2 action is conceptually sound in that to the degree that habitat for smelt limits their abundance, the provision of more or better habitat would be helpful. However, the examination of uncertainty in the derivation of the details of this action lacks rigor. The action is based on a series of linked statistical analyses (e.g., the relationship of presence/absence data to environmental variables, the relationship of environmental variables to habitat, the relationship of habitat to X2, the relationship of X2 to smelt abundance), with each step being uncertain. The relationships are correlative with substantial variance being left unexplained at each step. The action also may have high water requirements and may adversely affect salmon and steelhead under some conditions (memorandum from USFWS and NMFS, January 15, 2010). As a result, how specific X2

> targets were chosen and their likely beneficial effects need further clarification."

The State Water Board determines that inclusion of the delta smelt fall X2 action as a Category B flow criterion, consistent with requirements stipulated in the USFWS Opinion will likely improve habitat conditions for delta smelt. However, in light of the uncertainty about specific X2 targets and the overall effectiveness of the fall X2 action, the State Water Board recommends this action be implemented within the context of an adaptive management program. The program should include studies designed to clarify the mechanisms underlying the effects of fall habitat on the delta smelt populations, the establishment and peer review of performance measures and performance evaluation related to the action, and a comprehensive review of the outcomes of the action and effectiveness of the adaptive management program. (USFWS 2008.) Absent study results demonstrating the importance of fall X2 to the survival of delta smelt, fall flows beyond those stipulated in the fall X2 action for the protection of delta smelt are not recommended at this time.



Relationship between X2 and habitat area for delta smelt during fall, with standard shown for wet and above normal years. (Source: USFWS 2008, Figure B17).

Figure 15. X2 Versus Habitat Area for Delta Smelt During Fall

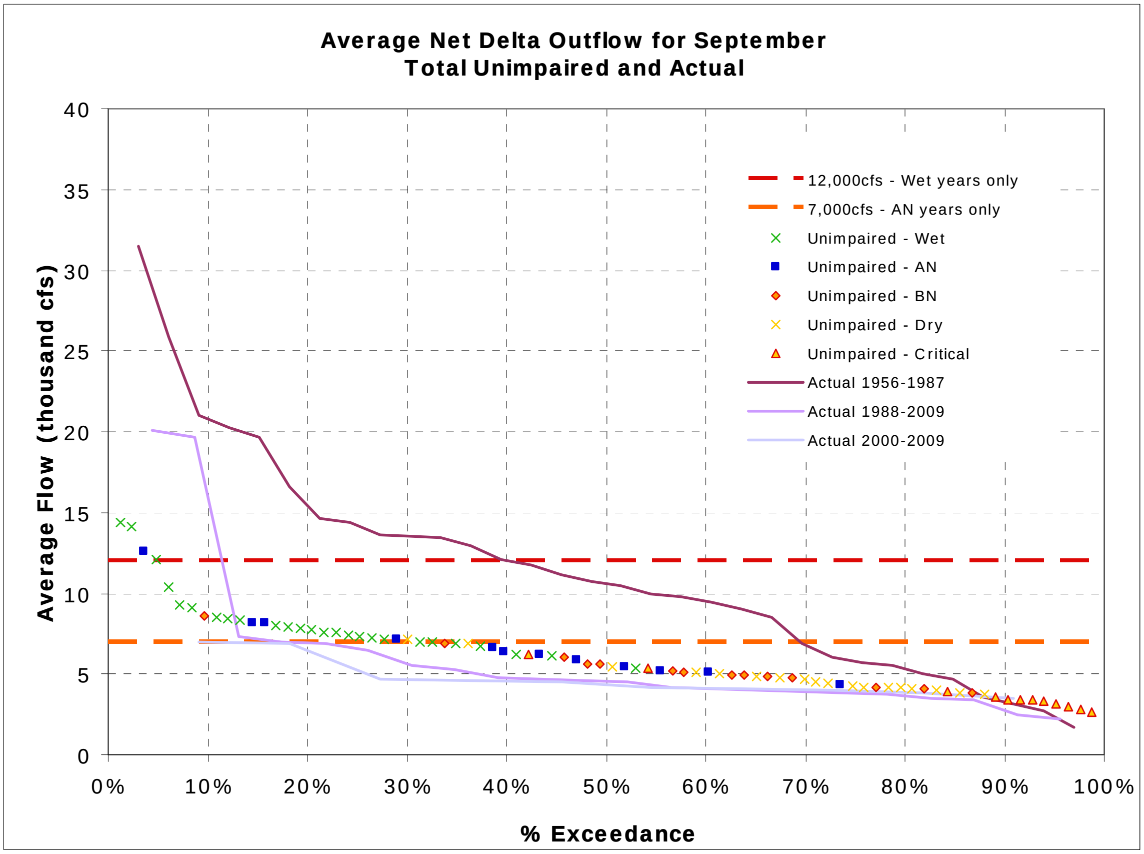


Figure 16. Net Delta Outflow Flow Exceedance Plot - September

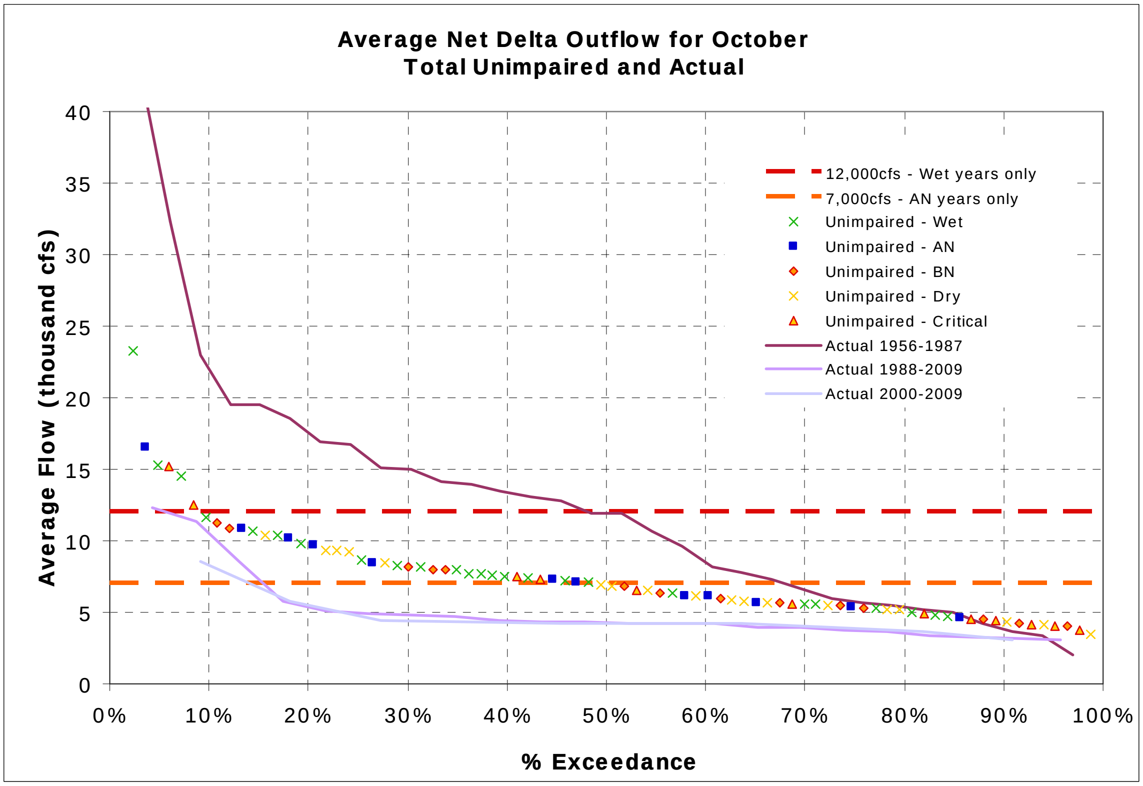

Figure 17. Net Delta Outflow Flow Exceedance Plot - October

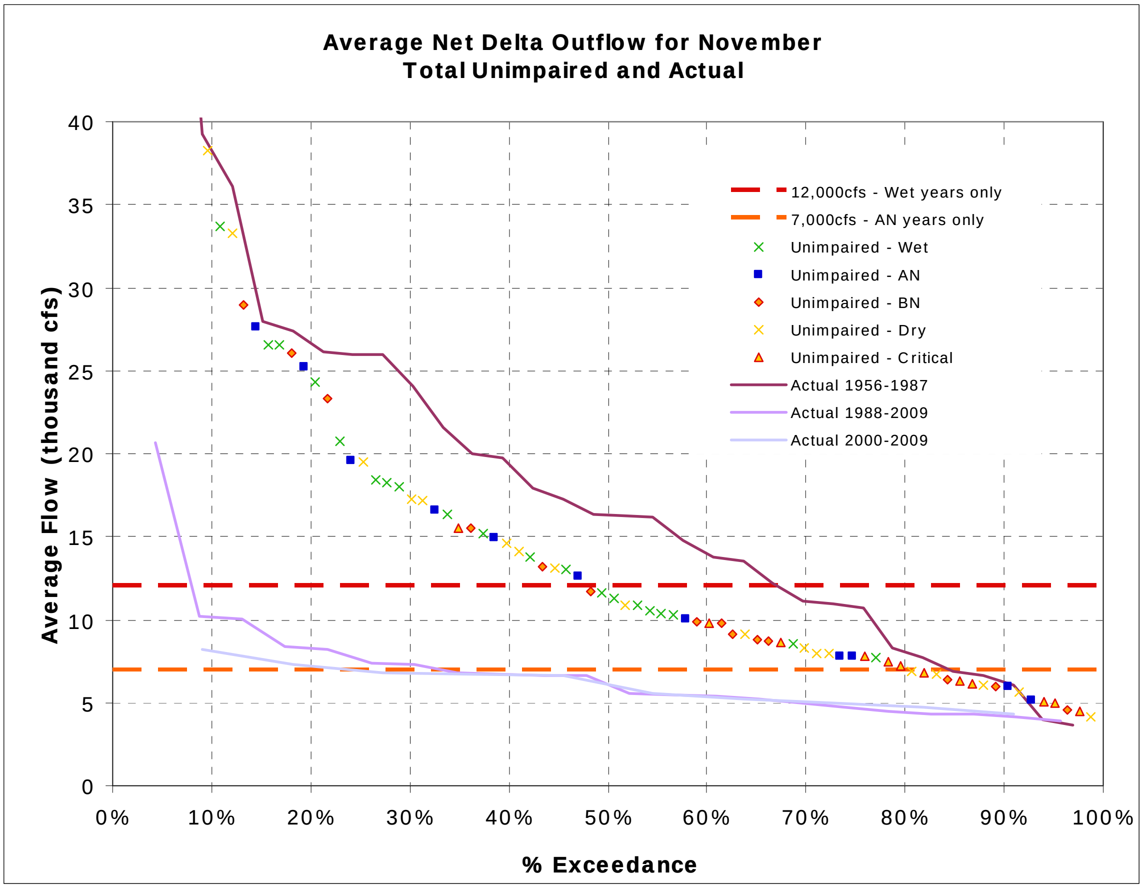

Figure 18. Net Delta Outflow Flow Exceedance Plot - November

The specific Delta outflow criteria may need to be tempered by the need to maintain water in reservoirs to provide adequate cold water and tributary specific flows on tributaries to the Delta. It may not be possible to attain both the flow criteria and meet the thermal and tributary specific flow needs of all of the sensitive species in the Delta Watershed. Water supply modeling and temperature analyses should be conducted to identify conflicting requirements to achieve both flow and cold water temperature goals.

<u>Category B: 2006 Bay-Delta Plan</u> <u>Summer – Fall Delta Outflow</u>
Resident estuarine species, such as delta smelt, require flows sufficient to provide adequate habitat throughout the year. Delta outflow criteria for January through June are discussed above. In addition to providing flows to support resident species, sufficient flows must also be provided in the fall to provide attraction cues and a homing mechanism for returning adult salmon. Criteria for fall salmon attraction flows on the Sacramento and San Joaquin rivers are discussed in Sections 5.2 and 5.3. The 2006 Bay-Delta Plan contains summer – fall Delta outflow water quality objectives for fish and wildlife beneficial uses, which are summarized below in Table 19.

Table 19. 2006 Bay-Delta Plan Delta Outflow Objectives for July through December

Water Year	**July**	**Aug**	**Sept**	**Oct**	**Nov**	**Dec**
Critical	4000	3000	3000	3000	3500	3500
Dry	5000	3500	3000	4000	4500	4500
Below Normal	6500	4000	3000	4000	4500	4500
Above Normal	8000	4000	3000	4000	4500	4500
Wet	8000	4000	3000	4000	4500	4500

Multiple participants submitted testimony concerning the need for additional flows in the fall to benefit delta smelt, striped bass, and other resident species (CSPA 1, p. 7; CWIN 2, p. 29; DOI 1, pp. 46-48; EDF 1, pp. 49-50; TBI/NRDC 2, pp. 27-37), and as a means to potentially control the spread of harmful invasive species (e.g., *Corbula* and toxic algae). (TBI/NRDC 2, pp. 27-37.) The recommendations were based largely on recent research conducted by Feyrer *et al*. (2007 and In Review) and the fall X2 action in the USFWS's Opinion. The Fall X2 action in the USFWS Opinion requires that sufficient outflow be provided in September through November of Above Normal and Wet water year types to position X2 at 81 km and 74 km, respectively. This action was restricted to Above Normal and Wet years because these are the years in which project operations have most significantly affected fall outflows and to limit potential conflicts with cold water pool storage. (USFWS 2008.)

Following its review of the USFWS Opinion, the NAS (2010) noted that:

> "[a]lthough there is evidence that the position of X2 affects the distribution of smelt, the weak statistical relationship between the location of X2 and the size of smelt populations makes the justification for this action difficult to understand… The X2 action is conceptually sound in that to the degree that the amount of habitat available for smelt limits their abundance, the provision of more or better habitat would be helpful… the committee concludes that how specific X2 targets were chosen and their likely beneficial effects need further clarification."

The USFWS Opinion also recognized uncertainty concerning the position of fall X2 and subsequent abundance of delta smelt and requires that the action be implemented with an adaptive management program to provide for learning and improvement of the action over time.

However, some participants provided flow recommendations that called for increased fall outflows during all water year types, as compared to the objectives in the 2006 Bay-Delta Plan, and in certain instances in excess of those required by the USFWS Opinion. Given the need for improved understanding concerning the fall X2 criterion, including the mechanisms underlying the effects of fall habitat on delta smelt populations, determination of specific X2 targets, potential conflicts with cold water pool storage, and the likely effectiveness of the action, the State Water Board is not advancing criteria for increased fall flows in Critical, Dry, and Below Normal water year types beyond those required in the 2006 Bay-Delta Plan and in Above Normal and Wet water year types beyond those stipulated in the fall X2 action (Category B). The quantity and timing of fall outflows necessary to protect public trust resources warrants further evaluation and underscores the need for a well-designed adaptive management program. The potential to use variability in flows during summer and fall months as a means of controlling the distribution and abundance of invasive species should also be evaluated.

5.2 Sacramento River

Following are the Sacramento River inflow criteria based on analysis of the species-specific flow criteria and other measures:

1) Sacramento River Flow at Rio Vista: 75 percent of 14-day average unimpaired flow from April through June to increases juvenile salmon outmigration survival for fall-run Chinook salmon
2) Sacramento River Flow at Rio Vista: 75 percent of 14-day average unimpaired flow from November through March to increases juvenile salmon outmigration survival for other runs of Chinook salmon
3) Sacramento River at Wilkins Slough: Provide pulse flows of 20,000 cfs for 7 days starting in November coincident with fall/early winter storm events; the timing, magnitude, duration, and number of pulses should be determined on an adaptive management basis informed by unimpaired flow conditions and monitoring of juvenile salmon migration to promote juvenile salmon emigration
4) Sacramento River Flow at Freeport: Provide flows of 13,000 to 17,000 cfs in the Sacramento River downstream of confluence with Georgiana Slough when salmon are migrating through the Delta from November through June to increase juvenile salmon outmigration survival by reducing straying into Georgiana Slough and the central Delta
5) Sacramento River at Rio Vista: 2006 Bay-Delta Plan flow objectives for September and October to provide Fall adult Chinook salmon attraction flows

The magnitude, duration, timing, and source of Sacramento River inflows are important to all runs of Chinook salmon migrating through the Bay-Delta and several different aspects of their life history. Inflows are needed to provide appropriate conditions to cue upstream adult migration to the Sacramento River and its tributaries, adult holding, egg incubation, juvenile rearing, emigration from the Sacramento River and its tributaries, and other functions. Sacramento River inflows are important throughout the year to support various life stages of the different Chinook salmon runs inhabiting the Sacramento River. However, given the focus of this proceeding on inflows to the Delta and the importance of the juvenile salmon emigration period, the Sacramento River inflow criteria included in this report focus primarily on flows needed to support emigrating juvenile Chinook salmon from natal streams through the Delta. Following is a brief summary of the Sacramento River inflow criteria that were developed based on the species-specific flow needs analyses for salmon included in section 4.2.3 followed by a detailed discussion.

Available scientific information indicates that average April through June flows of 20,000 to 30,000 cfs on the Sacramento River at Rio Vista represent a flow threshold at which survival of juveniles and subsequent adult abundance is substantially improved for fall-run Chinook salmon. Less information is available for the other runs of Chinook salmon on the Sacramento River. However, outmigration flows needed to protect other races are assumed to be generally the same since factors that affect fall-run survival are generally applicable to other runs with some exceptions. In addition, analyses indicate that providing pulse flows of 20,000 cfs at Wilkins Slough on the Sacramento River beginning in November and extending through the first of the year provides for earlier migration timing and increased survival of juvenile winter, spring, and late-fall run Chinook salmon. In addition, information indicates that flows of 13,000 cfs to 17,000 cfs may be needed on the Sacramento River at Freeport to prevent salmon from migrating through Georgiana Slough and the interior Delta where survival is substantially lower.

Continuity of flows from natal stream through the Delta and flow variability are also important so rather than static April through June threshold flows of 20,000 to 30,000 cfs, the State Water Board determines, as a Category A criterion, that 75% of unimpaired flow is needed to achieve a threshold flow of 25,000 cfs (average of 20,000 and 30,000 cfs) approximately 50% of the time. The same percentage of unimpaired flow for the November through March period is also advanced as a Category B criterion due to the lack of information upon which this criterion was based. In addition, as Category B criteria, the State Water Board determines that shorter pulse flows of 20,000 cfs for 7 days at Wilkins Slough are needed starting in November and extending through the first of the year and flows of 13,000 cfs to 17,000 cfs at Freeport are needed from November through June to provide additional protection for Sacramento River Chinook salmon. The State Water Board also advances the Sacramento River flow objectives from the Bay-Delta Plan during September and October to provide a minimal level of protection during these months pending development of additional information concerning flow needs during this period. All of the Sacramento River flow criteria are not precise; rather they reflect the general timing and magnitude of flows needed to protect public trust resources, but could serve as a reasonable basis from which future analysis and adaptive management could proceed. The criteria also do not consider other Sacramento River flow needs.

Sacramento River Inflow as a Percentage of Unimpaired Flows

It appears to be important to preserve the general attributes of the natural hydrograph to which the various salmon runs adapted over time. Information indicates that Chinook salmon respond to variations in flows and need some continuity of flow between natal streams and the Delta for transport and homing fidelity. As such, the historic practice of developing monthly flow criteria to be met from limited sources may be less than optimal for protecting Chinook salmon runs. At the same time, given the impediments to fish passage into historic spawning and rearing areas, there may also be a need to diverge from the natural hydrograph at certain times of year to provide more flow than might have naturally occurred or less flow such that those flows are available at other times of year to mitigate for passage and habitat issues (e.g. cold water pool management).

Based on the above, the State Water Board developed Sacramento River inflow criteria, intended to mimic the natural hydrograph during the peak emigration period, to protect emigrating juvenile Chinook salmon. While emigration of some runs may occur outside of this period, peak emigration is generally believed to occur between November through June. As such, the criteria are recommended to apply to this time period. To achieve the attributes of a natural hydrograph, the criteria are recommended as a percentage of unimpaired flow on a 14-day average, to be provided generally on a proportional basis from the tributaries to the Sacramento River. The 14-day average is intended to better capture the peaks of actual flows compared to a 30-day average time-step, while still allowing for a time-step at which facilities can be operated. The appropriateness of this time-step for protecting public trust resources should be further evaluated.

Spring Sacramento River Inflows at Rio Vista

The species-specific flow needs analyses for salmon in section 4.2.3 indicates that average April through June flows of 20,000 to 30,000 cfs on the Sacramento River at Rio Vista provide for improved survival and abundance of juvenile fall-run Chinook salmon on the Sacramento River.

Flow exceedance graphs were used to determine the percentage of flow needed to achieve various flows needed to protect Chinook salmon. Analysis of unimpaired flows at Freeport (Figure 19) shows that under historic unimpaired conditions, average April through June flows of 30,000 cfs or more would occur in approximately 60% of years. Flows of 25,000 cfs or more would occur is approximately 72% of years, and flows of 20,000 cfs or more would occur in roughly 85% of years. At 75% of unimpaired flows, average flows of 30,000 cfs would be achieved between April and June in roughly 37% of years, flows of 25,000 cfs would be achieved in roughly 50% of years, and flows of 20,000 cfs would be achieved in approximately 70% of years. At 50% of unimpaired flows, flows of 30,000 cfs would be achieved in approximately 15% of years, flows of 25,000 cfs in roughly 25% of years, and flows of 20,000 cfs in roughly 35% of years. Actual flows of 30,000, 25,000, and 20,000 cfs were met in 26, 32, and 39% of years, respectively between 1986 and 2005. It is important to note, however, that unimpaired flows between 1986 through 2005 are not necessarily representative of the longer term unimpaired flow record. Flow criteria equal to 75% of unimpaired flows during the April through June period, on average, would therefore provide favorable conditions for fall-run juvenile Chinook salmon in at least 50% of years (assuming 25,000 cfs flows). As a result, the State Water Board advances 75% of unimpaired flows on a 14-day average from April through June as a potential means to achieve the 20,000 to 30,000 cfs Sacramento River flow threshold discussed above while maintaining variability and the attributes of the natural hydrograph. This criterion is included as criterion 1) for Sacramento River flows and is a Category A criterion.

The unimpaired estimates from which the 75% criterion is calculated are monthly estimates. Estimates of 14-day unimpaired flow have not been published, but are expected to generate an exceedance curve similar to one generated with monthly estimates. This specific percent of unimpaired flow and the averaging period should be adaptively managed. More information and analyses should be conducted to determine if there are maximum flows above which no, or significantly diminishing, additional biological or geomorphological benefits are obtained. This criterion would allow for flows to vary over time coincident with precipitation events reflecting the natural hydrograph. Climate change, however, and its associated effect on flow patterns will likely change how effective such flows are in protecting Chinook salmon. As such, these flow criteria would need to be adaptively managed in the future to ensure the protection of Chinook salmon.

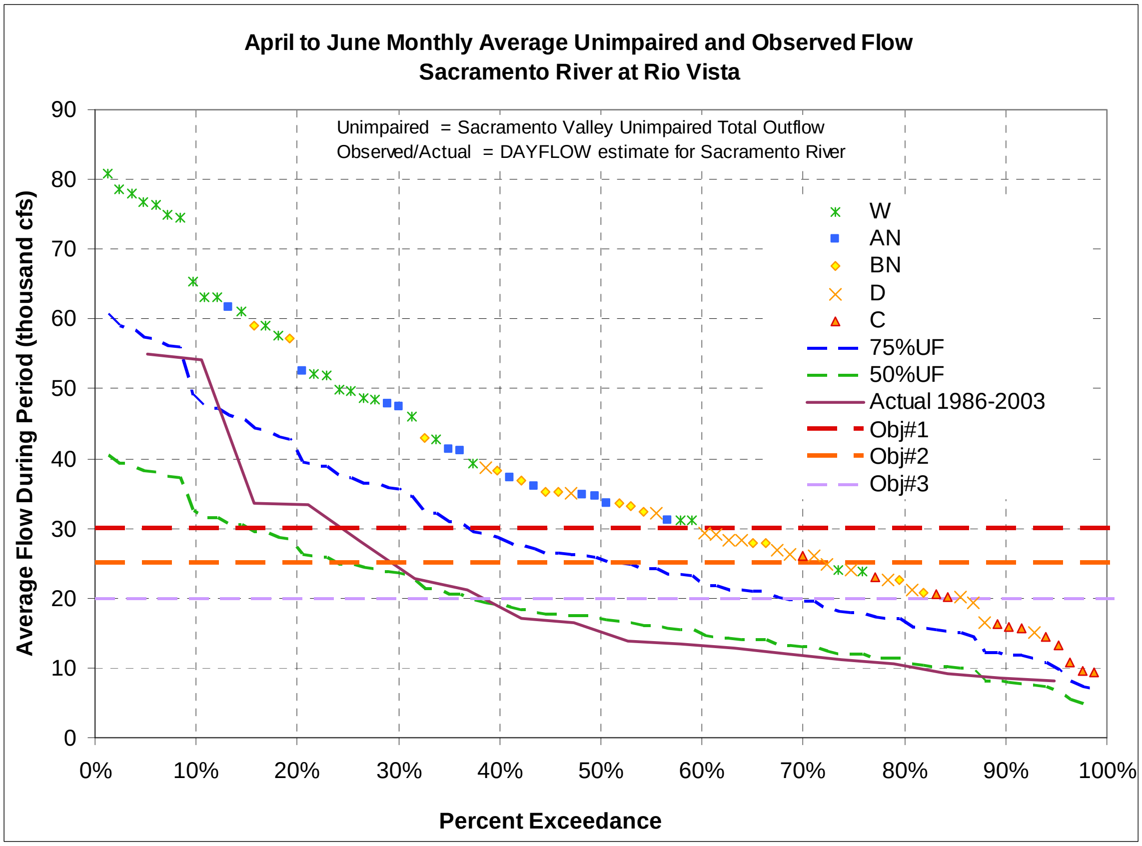

Figure 19. Sacramento River Flow Exceedance Plot - April through June

Fall and Winter Sacramento River Inflows at Rio Vista

Available data and analysis focus primarily on juvenile fall-run Chinook salmon outmigration. Outmigration flows to protect other races and life stages are assumed to be generally the same since factors that affect fall-run survival are generally applicable to other runs, with some exceptions including temperature, which may not be a concern in the winter months. (USFWS 1992, p. 8.) In the absence of sufficient data and analyses regarding flows needed for other Chinook salmon runs, however, the State Water Board advances 75% of unimpaired flows between November and March as an initial criterion from which future analysis and adaptive management could proceed. There is, however, no specific information that indicates that 75% is the correct percent of unimpaired flow. Additional quantitative analyses should be conducted to determine the specific flow needs of winter, spring, and late-fall run Chinook salmon.

Sacramento River Flow at Freeport

Analyses show that Chinook salmon survival is significantly lower for fish migrating through Georgiana Slough. Reverse flows in the vicinity of Georgiana Slough increase the occurrence of salmon migrating through Georgiana Slough. The available data show that flows of 13,000 to 17,000 cfs on the Sacramento River at Freeport provide adequate flow conditions to prevent reverse flows in Georgiana Slough. Flow criteria of 13,000 to 17,000 cfs on the Sacramento River at Freeport when salmon are migrating through the Delta during the November through June period is advanced as a Category B criterion. Additional analyses should be conducted to verify that flows of this magnitude are needed to achieve the desired outcome of significantly reducing straying of outmigrating juvenile Chinook salmon. These flows are also expected to benefit adult Chinook salmon returning to the Sacramento River basin to spawn during this period. However, additional analyses regarding the relationship of adult Chinook salmon and reverse flows in Georgiana Slough should also be conducted.

Sacramento River Flow at Wilkins Slough

Information discussed in the species-specific flow needs analyses for salmon in section 4.2.3 indicates that significant precipitation in the Sacramento River in the fall facilitates emigration of juvenile Chinook salmon. When this flow is delayed, emigration of salmon is also delayed resulting in reduced survival to the Delta. The available data show that juvenile salmon require flows of 15,000 cfs to 20,000 cfs at Wilkins Slough by November continuing through the first of the year to facilitate emigration. These flows are needed to provide ecological continuity from natal streams to the Delta. Information supports a range of pulse flows of 15,000 cfs to 20,000 cfs at Wilkins Slough to be provided coincident with fall and early winter storm events. This range should be adaptively managed and further evaluated. Absent additional information, flows of 20,000 cfs for seven days are advanced. Such an approach will retain the attributes of the natural hydrograph and provide for ecological continuity. The timing, magnitude, duration, and number of pulses should be determined through adaptive management, informed by unimpaired flow conditions and monitoring of juvenile salmon migration. Additional analyses should be conducted regarding this flow relationship to refine these criteria and inform adaptive management.

Sacramento River at Rio Vista: 2006 Bay-Delta Plan Objectives

The above criteria cover flows on the Sacramento River from the November through June time period. In addition, the Bay-Delta Plan provides minimum flows from September through December. Aside from what is discussed above, there was no new information submitted in the record for this proceeding on fall flows and the Sacramento River fall flow objectives were not specifically reviewed. In the absence of any new information, the State Water Board advances the 2006 Bay Delta Plan Sacramento River inflow objectives for September and October as a Category B criterion. Given that Chinook salmon may also be present in the Sacramento River during July and August, it is likely warranted that some minimal flows be provided during those months as well. However, adequate information on which to base such flows was not readily available for this proceeding. Further, adequate minimal flows during this time period may be provided by temperature and other requirements and reservoir releases for power production and export operations.

The specific Sacramento River flow criteria may need to be tempered by the need to maintain water in reservoirs to provide adequate cold water and tributary specific flows in the Sacramento River basin. It may not be possible to attain both the flow criteria and meet the thermal and tributary specific flow needs of the various runs of Chinook salmon and other sensitive species in the Sacramento River basin. Water supply modeling and temperature analyses should be conducted to identify conflicting requirements to achieve both flow and cold water temperature goals.

5.3 San Joaquin River

Following are the San Joaquin River inflow criteria based on analysis of the species-specific flow criteria and other measures:

1) San Joaquin River at Vernalis: 60%of 14-day average unimpaired flow from February through June
2) San Joaquin River at Vernalis: 10 day minimum pulse of 3,600 cfs in late October
3) San Joaquin River at Vernalis: 2006 Bay-Delta Plan flow objective for October

San Joaquin River inflow criterion 1 and 2 are Category A criteria because they are supported by sufficiently robust scientific information. The 2006 Bay-Delta Plan San Joaquin River inflow objective for October is included as a Category B criterion because it is not clear that eliminating this criterion in lieu of criteria 2 would provide adequate protection to migrating adult Chinook salmon. Following is discussion and rationale for these criteria. Category A and B criteria are both equally important for protection of the public trust resource, but there is more uncertainty about the appropriate volume of flow required to achieve the goals of the Category B criterion. Following is discussion and rationale for these criteria.

As discussed in the Sacramento River inflow section, the magnitude, duration, timing, and source of San Joaquin River inflows are important to Chinook salmon migrating through the Bay-Delta and several different aspects of their life history. Inflows are needed to provide appropriate conditions to cue upstream adult migration to the San Joaquin River and its tributaries, adult holding, egg incubation, juvenile rearing, emigration from the San Joaquin River and its tributaries, and other functions. San Joaquin River inflows are important for much of the year to support various life stages of San Joaquin basin fall-run Chinook salmon (and spring-run when they are reintroduced). However, given the focus of this proceeding on inflows to the Delta and the lack of information received concerning spring-run flow needs on the San Joaquin River, the San Joaquin River inflow criteria included in this report focus on flows needed to support migrating fall-run Chinook salmon from and to natal streams through the Delta. Following is a brief summary of the San Joaquin River inflow criteria that were developed based on the species-specific flow needs analyses for salmon included in section 4.2.3 followed by a detailed discussion.

Available scientific information indicates that average March through June flows of 5,000 cfs on the San Joaquin River at Vernalis represent a flow threshold at which survival of juveniles and subsequent adult abundance is substantially improved for fall-run Chinook salmon and that average flows of 10,000 cfs during this period may provide conditions necessary to achieve doubling of San Joaquin basin fall-run. Both the AFRP and DFG flow recommendations to achieve doubling also seem to support these general levels of flow, though the time periods are somewhat different (AFRP is for February through May and DFG is for March 15 through June 15). Available information also indicates that flows of 3,000 to 3,600 cfs for 10 to 14 days are needed during mid to late October to reduce straying, improve olfactory homing fidelity, and improve gamete viability for San Joaquin basin returning adult Chinook salmon.

Continuity of flows from natal stream through the Delta and flow variability are also important, so rather than advancing static flow criteria for the spring period to support emigration of juvenile San Joaquin basin fall-run Chinook salmon, the State Water Board determines, as a Category A criterion, that 60% of unimpaired flow from February through June is needed in order to achieve a threshold flow of 5,000 cfs or more in most years (over 85% of years) and flows of 10,000 cfs slightly less than half of the time (45% of years). Given that the focus of this proceeding is on protection of public trust resources, the State Water Board determines that the time period for these flows should be extended to cover all three periods supported by the DFG, AFRP, and TBI/NRDC analyses concerning flow needs. In addition, the State Water Board determines, as a Category A criterion, that flows of 3,600 cfs are needed for 10 days in late October. These flows could also be provided in a manner that better reflects the natural hydrograph to coincide with natural storm events. Until additional information is developed, maintaining the October pulse flow called for in the 2006 Bay-Delta Plan is also determined to be a Category B criterion to assure that the existing protection provided during this period is not diminished. All of the San Joaquin River flow criteria are not precise; rather they reflect the general timing and magnitude of flows needed to protect public trust resources, but could serve as a reasonable basis from which future analysis and adaptive management could proceed. The criteria also do not consider other San Joaquin River flow needs.

San Joaquin River Inflows as a Percentage of Unimpaired Flow During the Spring

As discussed in the Sacramento River inflow section, it is important to preserve the general attributes of the natural hydrograph to which the various salmon runs adapted to over time, including variations in flows and continuity of flows. Accordingly, as with the Sacramento River flow criteria, the State Water Board developed flow criteria for San Joaquin River inflows to protect emigrating juvenile Chinook salmon intended to mimic the natural hydrograph during the peak emigration period of February through June. This period may also cover a portion of the rearing period for juveniles as well. As with the Sacramento River flow criteria, to achieve the attributes of a natural hydrograph, the criteria are advanced as a percentage of unimpaired flow on a 14-day average, to be achieved on a proportional basis from the tributaries to the San Joaquin River. The unimpaired estimates from which the 60% criterion is calculated are monthly estimates. Estimates of 14-day unimpaired flow have not been published, but the exceedance curve is likely similar to one generated with monthly estimates. The appropriateness of this time-step and the percentage of unimpaired flows should be further evaluated.

To determine the percentage of unimpaired flow needed to protect Chinook salmon, the State Water Board reviewed flow exceedance information to determine what percentage of flow would be needed to achieve various flows. The analysis in section 4.2.3 indicates that increasing spring flows on the San Joaquin River and its tributaries is needed to protect Chinook salmon in the San Joaquin River basin. The TBI/NRDC analyses of temperatures and population growth indicate that there is a threshold response for fall-run Chinook salmon survival to flows above 5,000 cfs during the spring period and that average flows of 10,000 cfs during this same period may provide adequate flows to achieve doubling. Both the AFRP and DFG modeling analyses also seem to support these flows. However, the time periods for the AFRP recommended flows is from February through May and the time period for the DFG recommended flows is from March 15 through June 15. AFRP, DFG, and TBI/NRDC provide different recommendations for how to distribute flows during the spring period in different years, with increasing flows in increasingly wet years. All are generally consistent with an approach that mimics the natural flow regime to which these fish were adapted. Other analyses speak to the validity of this approach. (Propst and Gido, 2004 and Marchetti and Moyle, 2001, as cited in DOI 1, p. 25.) San Joaquin River flow criteria for the

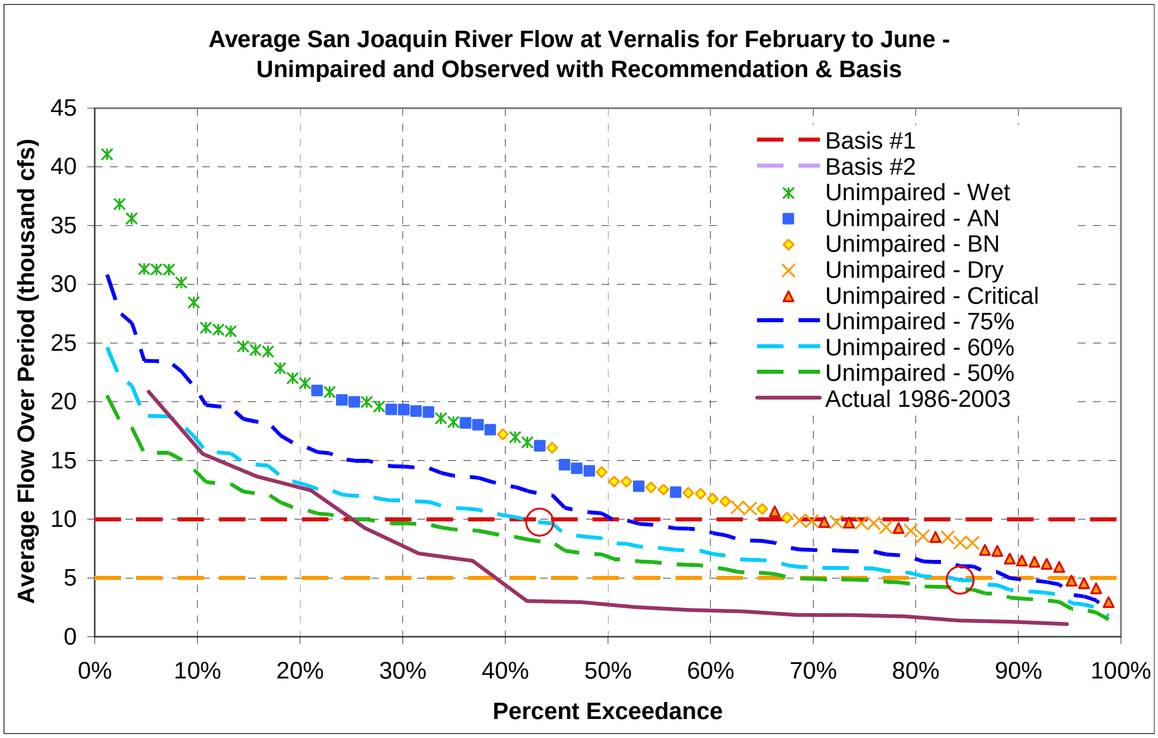
February through June period are determined to be 60% of unimpaired flows. Figure 20b shows that if 60% of unimpaired San Joaquin River flow at Vernalis were provided, average March through June flows would meet or exceed 5,000 cfs in over 85% of years (shown by red circle). An unimpaired flow of 60% during this period would also meet or exceed 10,000 cfs during the March through June time period in approximately 45% of years. The exceedance rates are not significantly different if applied to the February through June period as shown in Figure 20a. Additional information should be developed to determine whether these flows could be lower or higher and still meet the Chinook salmon doubling goal in the long term.

San Joaquin River Fall Flows

In addition to spring flows, fall pulse flows on the San Joaquin River are needed to provide adequate temperature and DO conditions for adult salmon upstream migration, to reduce straying, improve gamete viability, and improve olfactory homing fidelity for San Joaquin basin salmon. Analyses support a range of flows from 3,000 to 3,600 cfs for 10 to 14 days during mid to late October. Absent additional information, the State Water Board determines flow criteria for late fall to be 3,600 cfs for a minimum of 10 days in mid to late October. Providing these flows from the tributaries to the San Joaquin River that support fall-run Chinook salmon appears to be a critical factor to achieve homing fidelity and continuity of flows from the tributaries to the mainstem and Delta. Until additional information is developed regarding the need to maintain the 2006 Bay-Delta Plan October flow objective, these flows supplement and do not replace the 2006 Bay-Delta Plan October flow requirements such that flows do not drop below historic conditions during the remainder of October when the pulse flow criteria would not apply. Additional analyses should be conducted to determine the need to expand the pulse flow time period and modify the criteria to better mimic the natural hydrograph by coinciding pulse flows with natural storm events in order to potentially improve protection by mimicking the natural hydrograph.

Given that salmon and steelhead may be present in the San Joaquin River and its tributaries for all or most of the year (including spring-run in the future) and that the Bay-Delta plan does not currently include any flow requirements from July through September and November through January, additional flow criteria for the remainder of the year may be needed to protect Chinook salmon and their habitat. Specifically, additional criteria for spawning, egg incubation, rearing and riparian vegetation recruitment may be needed. However, adequate information is not available in the record for this proceeding upon which to base such criteria at this time. Additional information, building on the AFRP and other analyses, should be developed to determine needed flows for the remainder of the year.

a)



b)

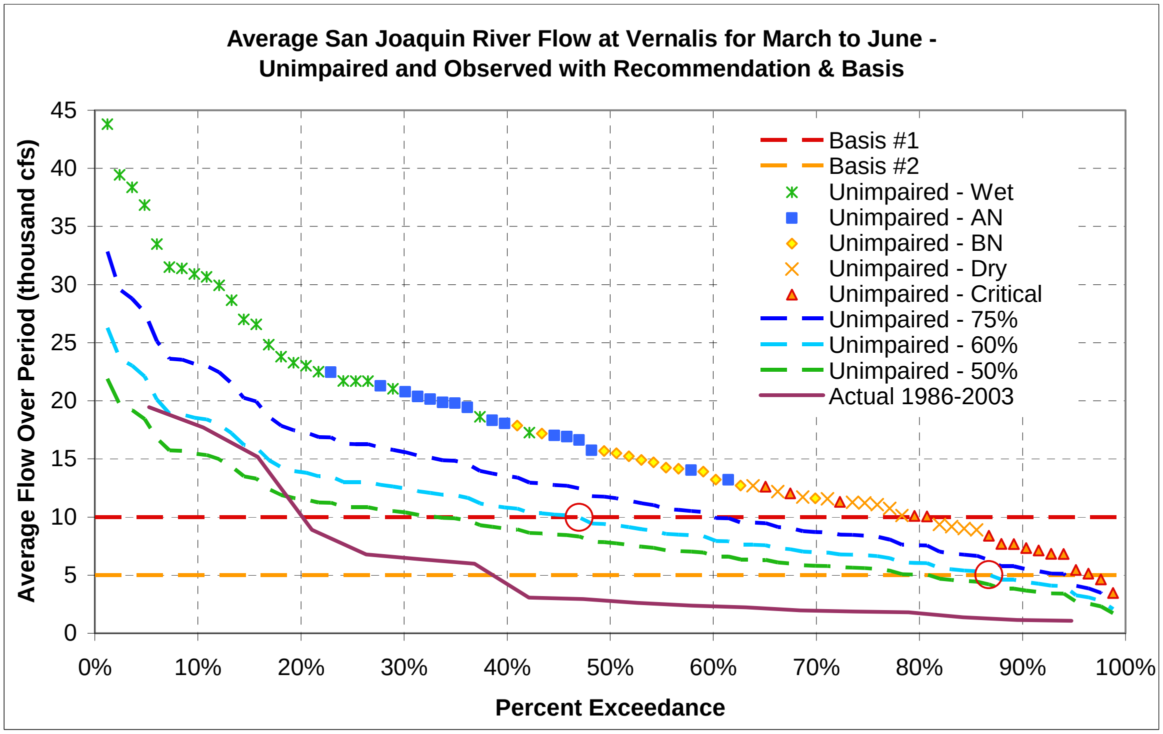


Figure 20. San Joaquin River Flow Exceedance Plot - February through June

The specific San Joaquin River flow criteria may need to be tempered by the need to maintain water in reservoirs to provide adequate cold water and tributary specific flows in the San Joaquin River basin. It may not be possible to attain both the flow criteria and meet the thermal and tributary specific flow needs of steelhead, fall-run Chinook salmon, and other sensitive species in the San Joaquin River basin. Water supply modeling and temperature analyses should be conducted to identify conflicting requirements to achieve both flow and cold water temperature goals.

5.4 Hydrodynamics

The following hydrodynamic related criteria have been developed based on analysis of the species-specific flow criteria and other measures discussed above:

1) San Joaquin River Flow to Export Ratio: Vernalis flows to exports great than .33 during the 10 day San Joaquin River pulse flow in October
2) Old and Middle River Flows: greater than -1,500 cfs in March and June of Critical and Dry water years
3) Old and Middle River Flows: greater than 0 or -1,500 cfs in April and May of Critical and Dry water years, when FMWT index for longfin smelt is less than 500, or greater than 500, respectively
4) Old and Middle River Flows: greater than -5,000 cfs from December through February in all water year types
5) Old and Middle River Flows: greater than -2,500 when salmon smolts are determined to be present in the Delta from November through June
6) San Joaquin River Flow to export Ratio: Vernalis flow to exports greater than 4.0 when juvenile San Joaquin River salmon are migrating in the mainstem San Joaquin River from March through June
7) San Joaquin River at Jersey Point Flows: Positive flows when salmon are present in the Delta from November through June
8) 2006 Bay-Delta Plan Exports to Delta Inflow Limits for the Entire Year

Hydrodynamic criteria 1 is a Category A criterion because it is supported by more robust scientific information. Hydrodynamic criteria 2-7 are Category B criteria because there is less scientific information, with more uncertainty, to support the specific numeric criteria. The 2006 Bay-Delta Plan exports to Delta inflow objective (criteria 8) is offered as a Category B criterion as a minimal level of protection when the other criteria above do not apply. However, the validity of the specific export restrictions included in the 2006 Bay-Delta Plan were not specifically reevaluated. Category A and B criteria are both equally important for protection of the public trust resource, but there is more uncertainty about the appropriate volume of flow required to achieve the goals of the Category B criteria. Following is discussion and rationale for these criteria.

Pelagic Species Criteria

Net OMR reverse flows have increased in both magnitude and frequency with the development of the California water projects (Figure 8) and are having a detrimental effect on biotic resources in the Delta. (Brown et al. 1996.) It is also clear that the negative impact of net OMR reverse flows increases as Sacramento River inflows and net Delta outflow decreases. (Grimaldo et al. 2009; Kimmerer 2008; USFWS 2008; NMFS, 2009.) Net OMR flow restrictions for the protection of longfin and Delta smelt are only recommended for dry and critically dry water years when less Delta outflow may be available (Table 23, criteria 2 and 3). No spring restrictions for the protection of longfin and delta smelt are proposed for other water year types if the higher net Delta outflow criteria are met. If higher outflows are not provided in wetter years, then restrictions on OMR may be needed in these years as well. The State Water Board determines that net OMR flow criteria of greater than -5,000 cfs, from December through February in all water year types, to protect upstream migrating adult smelt are needed. The -5,000 cfs criterion may need to be made more protective if a large portion of the smelt population moves into the central Delta. The additional restrictions would be recommended after consultation with the USFWS (2008) Smelt Working Group. Spring and winter net OMR flow criteria for the protection of longfin and Delta smelt are classified as Category B because, as noted by the NAS (2010),

> "… the data do not permit a confident identification of the threshold [OMR] values to use … and … do not permit a confident assessment of the benefits to the population… As a result, the implementation of this action needs to be accompanied by careful monitoring, adaptive management and additional analyses that permit regular review and adjustment of strategies as knowledge improves…"

Chinook Salmon Criteria

Salmon must migrate through the Delta past the effects of the south Delta export facilities and the associated inhospitable conditions in the central Delta, first as juveniles on their way to the ocean, and later as adults returning to spawn. Exports change the hydrodynamic patterns in the Delta, drawing water across the Delta rather than allowing water to flow out of the Delta in a natural pattern. Over the years, different criteria have been developed to attempt to protect migrating salmon from the adverse hydrodynamic conditions caused by the south Delta export facilities in order to preserve the functional flows needed for migration that could be used to protect public trust resources. Net OMR flows, Jersey Point flows, and Vernalis flow to export ratios are all criteria that can be used to protect migrating salmon. The State Water Board advances a combination of these criteria to protect migrating salmon from export effects.

Increasingly negative net OMR flows have been shown to increase particle entrainment, particularly beginning at flows between -2,500 and -3,500 cfs. While juvenile salmon do not necessarily behave like particles, the particle entrainment estimates are a useful guide until additional information can be developed using evolving acoustic tracking methods and other appropriate techniques. Reduced negative net OMR flows should also provide some level of protection from the indirect reverse flow effects related to fish entering the central Delta where predation and other sources of mortality are higher. Based on the above, the State Water Board determines criteria for net OMR flows should be for greater than -2,500 cfs when salmon are present in the Delta during the peak juvenile outmigration period of November through June, for the protection of Chinook salmon. This is a Category B criterion because there is limited information upon which to base a specific numeric criteria at this time. Such information should be developed to better understand the relationship between salmon survival and net OMR flows to determine more specific criteria that would protect against entrainment and other factors leading to indirect mortality.

Increased reverse flows at Jersey Point have also been shown to decrease survival of salmon smolts migrating through the lower San Joaquin River. However, the precise Jersey Point flow that is necessary to protect migrating salmon is unclear. In addition, it is unclear whether the same functions of such a flow could be better met using different criteria such as net OMR flows or San Joaquin River flow to export ratios. The State Water Board therefore advances positive Jersey Point flows when salmon are present in the Delta during the peak juvenile salmon outmigration period of November through June. Again, this is a Category B criterion because there is limited information upon which to base a specific numeric criteria at this time.

Increased San Joaquin River flow to export ratios appear to improve survival for San Joaquin River salmon, though the exact ratio that is needed to protect public trust resources is not well understood. A San Joaquin River flow to export ratio of greater than 4.0 is recommended as a Category B criterion when San Joaquin River juvenile salmon are outmigrating from the San Joaquin River from March through June. There is, however, sufficient information in the record to support a Category A criterion for exports to be kept to less than 300% of San Joaquin River flows (equal to a San Joaquin River flow to export ratio of more than 0.33) at the same time that the recommended San Joaquin River pulse flows are provided. Additional analyses should be conducted to determine if this time frame should be extended to capture more of the San Joaquin River adult Chinook salmon return period between October and January.

The NAS review concerning OMR restrictions for salmon concluded that:

> "…the strategy of limiting net tidal flows toward the pump facilities is sound, but the support for the specific flows targets is less certain. In the near-term telemetry-based smolt migration and survival studies (e.g, Perry and Skalski, 2009) should be used to improve our understanding of smolt responses to OMR flow levels." (NAS 2010, p. 44.)

Much additional work is needed to better understand the magnitude and timing of the recommended criteria and how net OMR flow criteria should be integrated with other criteria for San Joaquin River flows, San Joaquin River flows to export ratios, Sacramento River flows, and net OMR flow restrictions for the protection of pelagic species. For all of the OMR, Jersey Point, and Vernalis flows to export ratiocriteria, further analysis and consideration is needed to determine: 1) how salmon presence should be measured and the information used to temper the criteria; 2) an appropriate averaging period; and 3) how to adaptively manage to assure that flows are sufficiently, but not overly, protective.

The October San Joaquin River flow to export ratio criteria is a Category A criterion since the basis for this minimum criterion is sufficiently understood to develop a quantitative criteria. Additional analyses should still, however, be conducted to determine if this criteria could be refined to provide better protection for migrating adult San Joaquin River Chinook salmon. All of the other hydrodynamic criteria for the protection of Chinook salmon are Category B criteria.

The San Joaquin River flow to export criterion during the spring is also a Category B criterion due to a lack of certainty regarding the needed protection level. Regarding this issue, the NAS concluded that:

> "…the rationale for increasing San Joaquin River flows has a stronger foundation than the prescribed action of concurrently managing inflows and exports. We further conclude that the implementation of the 6-year steelhead smolt survival study (action IV.2.2) could provide useful insight

> as to the actual effectiveness of the proposed flow management actions as a long-term solution.” (NAS 2010, p. 45.)

In addition, based on similar uncertainty regarding needed protection levels and interaction between net OMR flows and San Joaquin River flows to export ratios, the San Joaquin River at Jersey Point criterion is also a Category B criterion. More work is needed to develop a suite of operational tools and an operational strategy for applying those tools to protect public trust resources in the Delta from the adverse hydrodynamic effects of water diversions, channel configurations, reduced flows, and other effects.

2006 Bay-Delta Plan Export Objectives
The 2006 Bay-Delta Plan includes export limitations for the entire year. From February through June exports are limited to 35-45% of Delta inflow. (State Water Board 2006a, pp. 184-187.) From July through January, exports are limited to 65% of Delta inflow. (*Id.)* The export to Delta inflow restrictions are intended to protect the habitat of estuarine-dependent species. (State Water Board 2006b, pp. 46-47.) These export restrictions provide a minimum level of protection for public trust uses and should be maintained to the extent that the other recommended criteria do not override them.

For all of the hydrodynamic criteria, biologically appropriate averaging periods need to be developed. Averaging periods may need to include a two-step approach whereby a shorter averaging period is included that allows for some divergence from the criteria and a longer averaging period is included that does not.

5.5 Other Inflows - Eastside Rivers and Streams

The Cosumnes and Mokelumne rivers, and smaller streams such as the Calaveras River, Bear Creek, Dry Creek, Stockton Diversion Channel, French Camp Slough, Marsh Creek, and Morrison Creek are all tributary to the Delta. Flows should generally be provided from tributaries in proportion to their contribution to unimpaired flow.

5.6 Other Measures

5.6.1 Variability, Flow Paths, and the Hydrograph

Criteria should reflect the frequency, duration, timing, and rate of change of flows, and not just volumes or magnitudes. Accordingly, whenever possible, the criteria specified herein are expressed as a percentage of the unimpaired flow rather than as a single number or range of numbers that vary by water year type. Additional efforts should focus on restoring habitat complexity. Inflows should generally be provided from tributaries to the Delta watershed in proportion to their contribution to unimpaired flow in order to assure connection between Delta flows and upstream tributaries, to the extent that such connections are beneficial to protecting public trust resources. Flows should be at levels that maintain flow paths and positive salinity gradients through the Delta. This concept is reflected in the specific determinations made above. More study is needed to determine to which tributaries such criteria should apply. For example, since the percent of unimpaired flow criteria determined to protect public trust uses for San Joaquin River inflows is at times lower than the criteria determined for Delta outflow, more study is needed to determine the appropriate source of such flows to protect public trust resources. All determined flow criteria must also be tempered by the need to protect health and safety. No flow criteria, for example, should be in excess of flows that would lead to flooding. For all of the flow criteria, there may be a need to reshape the specified flows to better protect public trust resources based on real-time considerations. All of the criteria should be implemented adaptively to allow for such appropriate reshaping to improve biological and geomorphological processes.

Moyle *et al* (2010) concluded, however, that there is a fundamental conflict between restoring variability and maintaining the current Delta:

> “restoring environmental variability in the Delta is fundamentally inconsistent with continuing to move large volumes of water through the Delta for export. The drinking and agricultural water quality requirements of through-Delta exports, and perhaps even some current in-Delta uses, are at odds with the water quality and variability needs of desirable Delta species.”

5.6.2 Floodplain Activation and Other Habitat Improvements

Activated floodplains stimulate food web activity and provide spawning and rearing habitat for floodplain adapted fish. The frequency of low-magnitude floods that occurred historically has been reduced, primarily by low water control levees. The record supports the conclusion that topography changes associated with future floodplain restoration will provide improved ecosystem function with less water. Studies and demonstration projects for, and implementation of, floodplain restoration projects should therefore proceed to allow for the possible reduction of flows required to protect public trust resources in the Delta.

<u>Floodplain Flow Determinations for Protection of Salmon and Splittail</u>:
Floodplain and off-channel inundation are required for splittail spawning and appear to be important in protecting Chinook salmon. At the same time, it is also important how and when such inundation occurs. Due to the effects of levees and dams, natural side channel and floodplain inundating flows have been substantially reduced. As a result, modification to weirs and other changes may be needed to substantially improve floodplain inundation conditions on the Sacramento and San Joaquin rivers. Based on the above, the State Water Board determines that an effort be made to provide appropriate additional seasonal floodplain habitat for salmon, splittail, and other species in the Central Valley. The various recommendations the State Water Board received for floodplain inundation are included in Appendix A.1. The State Water Board has no specific flow determinations for floodplain inundation. The State Water Board recommends that BDCP, the Council, and others continue to explore the various issues concerning flood protection, weir modifications, and property rights related to floodplain inundation.

Other future habitat improvements will likely change the response of native fishes to flow and allow flow criteria to be modified. Habitat restoration should proceed to allow for the possible reduction of flows required to protect public trust resources in the Delta. Other future habitat restoration that should be reviewed and implemented include:

- Development of slough networks with natural channel geometry and less diked and rip-rapped channel habitat
- Increased tidal marsh habitat, including shallow (one to two meters) subtidal areas in both fresh and brackish zones of the estuary (in Suisun Marsh, for example)

- Create large expanses of low salinity open water habitat in the Delta

5.6.3 Water Quality and Contaminants

Any set of flow criteria should include the capacity to readily adjust the flows to adapt to changing future conditions and improved understanding. (DEFG 1.) As our understanding of the effect of contaminants on primary production and species composition in the Sacramento River and Delta improves, flow criteria may need to be revisited.

The Central Valley and San Francisco Regional Water Boards should continue developing Total Maximum Daily Loads (TMDLs) for all listed pollutants and adopting programs to implement control actions. Specifically, the Central Valley Regional Board should require additional studies and incorporate discharge limits and other controls into permits, as appropriate, for the control of nutrients, including ammonia.

5.6.4 Coldwater Pool Resources and Instream Flow Needs on Tributaries

The flow criteria contained in this report should be tempered by the need to maintain cold water resources and meet tributary specific flow needs in the Delta watershed. It may not be possible to attain all of the identified flow criteria in all years and meet the tributary flow needs and thermal needs of the various runs of Chinook salmon, steelhead, and other sensitive species. Temperature and water supply modeling analyses should be conducted to identify conflicting requirements to achieve both flow and cold water temperature goals. In addition, these flow determinations do not consider the needs of other non-fish species and terrestrial species which should be considered before any implementation of these criteria.

5.6.5 Adaptive Management

The numeric criteria are all short term criteria that are only appropriate for the current physical system and climate. There is uncertainty in these criteria even for the current physical system and climate, and therefore for the short term. Long term numeric criteria, beyond five years, for example, and assuming a modified physical system, are highly speculative. Only the underlying principles for the proposed numeric criteria and the other measures are advanced as long term determinations.

The information received in this proceeding suggests that the relationships between hydrology, hydrodynamics, water quality, and the abundance of desirable species are often unclear. In preparing for the long term, resources should be directed toward better understanding these relationships. In particular, there is significant uncertainty associated with Category B numeric criteria advcanced in this report. Category B criteria should therefore be high priority candidates for grant funded research.

A strong science program and a flexible management regime are critical to improving flow criteria. The relationship between flow, habitat, and abundance is not well enough understood to recommend flows in the Delta ecosystem without some reliance on adaptive management to better manage these flows. The State Water Board intends to work with the Council, the Delta Science Program, IEP, and others to develop the framework for adaptive management that could be relied upon for the management and regulation of flows in the Delta. The State Water Board will consider supporting and incorporating into its regulations greater reliance upon adaptive management in its flow regulations.

5.7 Summary Determinations

Table 20 through Table 23 provide summary determinations for Delta outflows, Sacramento inflows, San Joaquin River inflows, and hydrodynamics, respectively. Each table shows various numbered criteria, applicable to the shaded range of months. Criteria fall into two categories. Category "A" criteria have more robust scientific information to support specific numeric criteria than do Category "B" criteria. Both categories of criteria are considered equally important for protection of public trust resources in the Delta ecosystem, and are supported by scientific information on function-based species or ecosystem needs. The basis and explanation for each criterion is provided. Each table is appended with the following notes to explain the limitations and constraints of how the criteria should be considered:

- All flows are subject to appropriate ramping rates to avoid ramping impacts to public trust resources
- These flow criteria should be tempered by tributary specific flow needs and the need to manage cold-water resources for the protection of public trust resources
- Criteria for percentages of unimpaired flows apply only up to a specified maximum cap; appropriate maximum flow caps still need to be determined based on public trust needs and to avoid flooding.
- Additional flows may be needed for the protection of public trust resources for periods of time for which no flow criteria have been determined or where Bay-Delta Plan flow objectives are advanced, but adequate information is not available at this time to determine such flows

These criteria are made specifically to achieve the stated goal of halting the population decline and increase populations of native species as well as species of commercial and recreational importance. Additionally, positive changes in the Delta ecosystem resulting from improved flow or flow patterns will benefit humans as well as fish and wildlife, especially when accompanied by large-scale habitat restoration and pollution reduction. (Moyle *et al*, 2010.)

In addition, Table 24 contains a summary of other issues and concepts that should be considered in conjunction with the numeric criteria. These other measures are also based on a synthesis of the best scientific information submitted by participants in the State Water Board's Informational Proceeding. These criteria and other measures, however, must be further qualified as to their limitations. The limitations of this and any other flow prescription are described at the end of the Fleenor *et al*. (2010) "flow prescriptions" report as a "further note of caution":

> "How much water do fish need?" has been a common refrain in Delta water management for many years… it is highly unlikely that any fixed or predetermined prescription will be a "silver bullet". The performance of native and desirable fish populations in the Delta requires much more than fresh water flows. Fish need enough water of appropriate quality over the temporal and spatial extent of habitats to which they adapted their life history strategies. Typically, this requires habitat having a particular range of physical characteristics, appropriate variability, adequate food supply and a diminished set of invasive species. While folks ask "How much water do fish need?" they might well also ask, "How much habitat of different types and locations, suitable water quality,

> improved food supply and fewer invasive species that is maintained by better governance institutions, competent implementation and directed research do fish need?" The answers to these questions are interdependent. We cannot know all of this now, perhaps ever, but we do know things that should help us move in a better direction, especially the urgency for being proactive. We do know that current policies have been disastrous for desirable fish. It took over a century to change the Delta's ecosystem to a less desirable state; it will take many decades to put it back together again with a different physical, biological, economic, and institutional environment."

The State Water Board concurs with this cautionary note and recommends the flow criteria and other conclusions advanced in this report be used to inform the planning efforts for the Delta Plan and BDCP and as a report that can be used to guide needed research by the Delta Science Program and other research institutions.

Table 20. Delta Outflow Summary Criteria

Delta Outflows

Category A

O	N	D	J	F	M	A	M	J	J	A	S	Criteria
			▨	▨	▨	▨	▨	▨				1) Net Delta Outflows: 75% of 14-day average unimpaired flow

Category B

O	N	D	J	F	M	A	M	J	J	A	S	Criteria
▨	▨										▨	2) Fall X2 a. Wet years: X2 less than 74 km (greater than approximately 12,400 cfs) b. Above normal years: X2 less than 81 km (greater than approximately 7,100 cfs)
▨	▨								▨	▨	▨	3) Net Delta Outflows: 2006 Bay-Delta Plan Delta Outflow Objectives - applies during critical, dry, and below normal years

Basis for Criteria and Explanation

1) Promote increased abundance and improved productivity (positive population growth) for longfin smelt and other desirable estuarine species
2) Increase quantity and quality of habitat for delta smelt; fall X2 requirement limited to above normal and wet years to reduce potential conflicts with cold water pool storage, while promoting variability with respect to fall flows and habitat conditions in above normal and wet water year types; expected to result in improved conditions for delta smelt, however, the statistical relationship between fall X2 and abundance is not strong; note 2) above regarding need for improved understanding concerning the fall X2 action also applies
3) Fish and wildlife beneficial use protection

Notes:

- These flow criteria do not consider any balancing of public trust resource protection with public interest needs for water.
- All flows are subject to appropriate ramping rates to avoid ramping impacts to public trust resources.
- These flow criteria should be tempered by tributary specific flow needs and the need to manage cold-water resources for the protection of public trust resources.
- Criteria for percentages of unimpaired flows apply only up to a specified maximum cap; appropriate maximum flow caps still need to be determined based on public trust needs and to avoid flooding.
- Additional flows may be needed for the protection of public trust resources for periods of time for which no flow criteria are recommended or where 2006 Bay-Delta Plan flow objectives are recommended, but adequate information is not available at this time to recommend such flows.

Table 21. Sacramento River Inflow Summary Criteria

Sacramento River Inflows

Category A

Water Year												**Criteria**
O	N	D	J	F	M	A	M	J	J	A	S	
						▨	▨	▨				1) Rio Vista: 75% of 14-day average unimpaired flow[1]

Category B

Water Year												**Criteria**
O	N	D	J	F	M	A	M	J	J	A	S	
	▨	▨	▨	▨	▨							2) Rio Vista: 75% of 14-day average unimpaired flow to support same functions as #1 for other runs of Chinook salmon
	▨	▨	▨									3) Wilkins Slough: Provide pulse flows of 20,000 cfs for 7 days starting in November coinciding with storm events producing unimpaired flows at Wilkins Slough above 20,000 cfs until monitoring indicates that majority of smolts have moved downstream[2]
	▨	▨	▨	▨	▨	▨	▨	▨				4) Freeport: Positive flows in Sacramento River downstream of confluence with Georgiana Slough while juvenile salmon are present (approximately 13,000 to 17,000 cfs)
▨											▨	5) Rio Vista: 2006 Bay-Delta Plan flow objectives

Basis for Criteria and Explanation, and Notes

1) Increase juvenile salmon outmigration survival and abundance for fall-run Chinook salmon
2) Promote juvenile salmon emigration for other runs of Chinook salmon
3) Increase juvenile salmon outmigration survival by reducing diversion into Georgiana Slough and the central Delta
4) Increases juvenile salmon outmigration survival
5) Fall adult Chinook salmon attraction flows

Notes:

- These flow criteria do not consider any balancing of public trust resource protection with public interest needs for water.
- All flows are subject to appropriate ramping rates to avoid ramping impacts to public trust resources.
- These flow critiera should be tempered by tributary specific flow needs and the need to manage cold-water resources for the protection of public trust resources.
- Criteria for percentages of unimpaired flows apply only up to a specified maximum cap; appropriate maximum flow caps still need to be determined based on public trust needs and to avoid flooding.
- Additional flows may be needed for the protection of public trust resources for periods of time for which no flow criteria are recommended or where 2006 Bay-Delta Plan flow objectives are recommended, but adequate information is not available at this time to recommend such flows.

[1] 75% of unimpaired flow at Freeport applied to Rio Vista

[2] Definition of storm, number of storms, and how to determine when the majority of juveniles have outmigrated needs to be determined.

Table 22. San Joaquin River Inflow Summary Criteria

San Joaquin River Inflows												
Category A												
Water Year												Criteria
O	N	D	J	F	M	A	M	J	J	A	S	
				▨	▨	▨	▨	▨				1) Vernalis: 60% of 14-day average unimpaired flow
▨												2) Vernalis: 10 day minimum pulse flow of 3,600 cfs in late October (e.g., October 15 to 26)
Category B												
Water Year												Criteria
O	N	D	J	F	M	A	M	J	J	A	S	
▨												3) Vernaisl: 2006 Bay-Delta Plan October flows
Basis for Criteria and Explanation, and Notes												

1) Increase juvenile Chinook salmon outmigration survival and abundance and provide conditions that will generally produce positive population growth in most years and achieve the doubling goal in more than half of years
2) Minimum adult Chinook salmon attraction flows to decrease straying, increase DO, reduce temperatures, and improve olfactory homing fidelity
3) Adult Chinook salmon attraction flows

Notes:

- These flow criteria do not consider any balancing of public trust resource protection with public interest needs for water.
- All flows are subject to appropriate ramping rates to avoid ramping impacts to public trust resources.
- These flow criteria should be tempered by tributary specific flow needs and the need to manage cold-water resources for the protection of public trust resources.
- Criteria for percentages of unimpaired flows apply only up to a specified maximum cap; appropriate maximum flow caps still need to be determined based on public trust needs and to avoid flooding.
- Additional flows may be needed for the protection of public trust resources for periods of time for which no flow criteria are recommended or where 2006 Bay-Delta Plan flow objectives are recommended, but adequate information is not available at this time to recommend such flows.

Table 23. Hydrodynamics Summary Criteria

Hydrodynamics: Net OMR, Inflow-Export Ratios, and Jersey Point

Category A

Water Year												Criteria
O	N	D	J	F	M	A	M	J	J	A	S	
▨												1) San Joaquin River Flow to Export Ratio: Vernalis flows to exports greater than 0.33 during fall pulse flow (e.g., October 15 – 26); complementary action to San Joaquin River inflow critieria #2

Category B

Water Year												Criteria
O	N	D	J	F	M	A	M	J	J	A	S	
					▨			▨				2) Net OMR Flows: greater than -1,500 cfs in Critical and Dry water years
						▨	▨					3) Net OMR Flows: greater than 0 or -1,500 cfs in Critical and Dry water years, when FMWT index for longfin smelt is less than 500, or greater than 500, respectively
		▨	▨	▨								4) Net OMR Flows: greater than -5,000 cfs in all water year types
	▨	▨	▨	▨	▨	▨	▨	▨				5) Net OMR Flows: greater than -2,500 cfs when salmon smolts are determined to be present in the Delta
					▨	▨	▨	▨				6) San Joaquin River Flow to Export Ratio: Vernalis flows to exports greater than 4.0 when juvenile San Joaquin River salmon are migrating in mainstem San Joaquin River
	▨	▨	▨	▨	▨	▨	▨	▨				7) Jersey Point: Positive flows when salmon present in the Delta
▨	▨	▨	▨	▨	▨	▨	▨	▨	▨	▨	▨	8) Exports to Delta Inflows: 2006 Bay-Delta Plan exports to inflows restrictions

Basis for Criteria and Explanation

1) Reduce straying and improve homing fidelity for San Joaquin basin adult salmon
2) Reduce entrainment of larval / juvenile delta smelt, longfin smelt, and provide benefits to other desirable species
3) Same as number 2), but if the previous FMWT index for longfin smelt is less than 500, then OMR must be greater than 0 (to reduce entrainment losses when abundance is low), or greater than -1,500 if the previous FMWT index for longfin smelt is greater than 500
4) Reduce entrainment of adult delta smelt, longfin smelt, and other species; less negative flows may be warranted during periods when significant portions of the adult smelt population migrate into the south or central Delta; thresholds for such flows need to be determined
5) Reduce risk of juvenile salmon entrainment and straying to central Delta at times when juveniles are present in the Delta; will also provide associated benefits for adult migration
6) Improve survival of San Joaquin River juvenile salmon emigrating down the San Joaquin River and improve subsequent escapement 2.5 years later
7) Increase survival of outmigrating smolts, decrease diversion of smolts into central Delta where survival is low, and provide attraction flows for adult returns
8) Protection of estuarine dependent species

(cont.)

Notes:

- These flow criteria do not consider any balancing of public trust resource protection with public interest needs for water.
- All flows are subject to appropriate ramping rates to avoid ramping impacts to public trust resources.
- These flow critieria should be tempered by tributary specific flow needs and the need to manage cold-water resources for the protection of public trust resources.
- Criteria for percentages of unimpaired flows apply only up to a specified maximum cap; appropriate maximum flow caps still need to be determined based on public trust needs and to avoid flooding.
- Additional flows may be needed for the protection of public trust resources for periods of time for which no flow criteria are recommended or where 2006 Bay-Delta Plan flow objectives are recommended, but adequate information is not available at this time to recommend such flows.

Table 24. Other Summary Determinations

Variability and the Natural Hydrograph:

- Criteria should reflect the frequency, duration, timing, and rate of change of flows, and not just volumes or magnitudes. Accordingly, whenever possible, the criteria specified above are expressed as a percentage of the unimpaired hydrograph.
- Inflows should generally be provided from tributaries to the Delta watershed in proportion to their contribution to unimpaired flow unless otherwise indicated. This concept is reflected in the specific criteria above.

Floodplain Activation and Other Habitat Improvements:

- Studies and demonstration projects for, and implementation of, floodplain restoration, improved connectivity and passage, and other habitat improvements should proceed to provide additional protection of public trust uses and potentially allow for the reduction of flows otherwise needed to protect public trust resources in the Delta.

Water Quality and Contaminants:

- The Central Valley and San Francisco Regional Water Boards should continue developing TMDLs for all listed pollutants and adopting programs to implement control actions.
- The Central Valley Regional Board should require additional studies and incorporate discharge limits and other controls into permits, as appropriate, for the control of nutrients and ammonia.

Coldwater Pool Resources and Instream Flow Needs on Tributaries:

- Temperature and water supply modeling and analyses should be conducted to identify conflicting requirements to achieve both flow and cold water temperature goals.

Adaptive Management:

- A strong science program and a flexible management regime are critical to improving flow criteria. The State Water Board should work with the Council, the Delta Science Program, IEP, and others to develop the framework for adaptive management that could be relied upon for the management and regulation of Delta flows.
- The numeric criteria in this report are all short term criteria that are only appropriate for the current physical system and climate; actual flows should be informed by adaptive management
- Only the underlying principles for the numeric criteria and these other measures are advanced as long termcriteria.

Appendix A, Table 7. Notes for Tables 1 through 6.

No.	Entity	Type	Notes (excerpts from source documents)
1	D1641	Outflow	All water year types - Increase to 6000 if the Dec 8RI is > than 800 TAF
2	D1641	Outflow	Habitat Protection Flows, minimum Delta outflow calculated from a series of rules that are described in Tables 3 and 4 of D1641
3	Draft D1630	Outflow	Striped Bass, Antioch spawning - Delta outflow index, Sac Riv at Chipps Island, average for the period not less than value shown (cfs).
4	Draft D1630	Outflow	Striped Bass, general - Delta outflow index, Sac River at Chipps Island - average for period not less than value shown (cfs), May period = May 6-31
5	Draft D1630	Outflow	Suisun Marsh - Delta outflow index at Sac River at Chipps Island - average of daily DOI for each month, not less than value shown (cfs)
6	Draft D1630	Outflow	Suisun Marsh - Delta outlflow index, Sac River at Chipps Island - minimum daily DOI for 60 consecutive days in the period
7	Draft D1630	Outflow	Suisun Marsh - Delta outflow index, Sac River at Chipps Island - average of daily DOI for each month, not less than value shown, in cfs: applies whenever storage is at or above minimum level in flood control reservation envelope at two of the following - Shasta Reservoir, Oroville Reservoir, and CVP storage on the American River
8	TBI et al	Outflow	Water year categories represent exceedance frequencies for the 8-river index, they are not equivalent to the DWR "water year types" (which account for storage and other conditions). TBI_Exhibit 2 (Outlfow). References for correlation btw winter-spring outlfow and abundance of numerous species on p.3. Winter-spring Delta outflow criteria approximate the frequence distribution of outflow levels, i.e., the relationship btw outflow and the 8 River Index, for the 1956-1987 period. Winter and spring outlfow recommendations to benefit public trust uses of pelagic species (as represented by abundance and productivity of longfin smelt, Crangon shrimp, and starry flounder and spatial distribution of longfin smelt) (see TBI Exhibit 2, pp 21-25). Two methods were used to develop outflow criteria: an analysis of historical flow-abundance relationships that corresponded to recovery targets for longfin smelt abundance (Native Fishes Recovery Plan, USFWS 1995), and an analysis of population growth response to outflows in order to identify outflows that produced population growth more than 50% of the time. Applying these
8 cont	TBI et al	Outflow	two methods produces very similar results regarding desirable outflow levels. Break in summary table at mid-Mar is artificial, original table included Mar under both Winter and Spring, so for simplicity, it was split at 15 Mar. Fall outflows (TBI Exhibit 2, p. 35, Table 1 and Fig 27) - analyzed emerging statistical evidence of relationship btw outlfow and abundance and distribution of delta smelt and striped bass (Feyrer et al 2007; Feyrer et al In Review; DSWG notes, Aug 21, 2006), in order to develop recommendations. Recommendations occassionaly exceed unimpaired outflow in limited cases (would require reservoir releases in fall independent of antecedent conditions).

Appendix A, Table 7. Notes for Tables 1 through 6.

No.	Entity	Type	Notes (excerpts from source documents)
9	CSPA / C-WIN	Outflow	Net Delta Outflow, as a 14-day running average - Source WRINT-DFG Exh 8 (1992). Feb-Mar - flows correspond to Table 8 (p.23), Alternative C (Estuarine species - target mean monthly flows based on data from DWR's 1995 Level of Development + 50% increase). Orig. recommendations by month, C-WIN/CSPA took average of Feb and Mar, and reported as such. Apr-July - flows correspond to Table 2 (p16), Alternative C (mean Delta outflows required to maintain populations of 1.7 million adult striped bass). Aug-Jan - based on Alt C (discussed above), in combination with flow recommendations developed by C-WIN for Jan. DFG identified flows for all months except Jan, C-WIN developed a method for Jan flows from DayFlow information (C-WIN extracted monthly average Delta outflows from DayFlow, sorted them, and then allocated them to water years based on unimpaired runoff data from the California Data Exchange Center. The medians of the water year types were then used as January flows in developing our optimal conditions recommendations for mean Delta outflows in the August 1 through January 31 period).
10	EDF / Stillwater	Outflow	Stillwater Focal Species Approach - Source - EDF closing comments (Table 1), Supporting Info - EDF Exhibit 1 (Winter [Dec-Feb] outflows - p.52-53). A primary objective was to provide enough Delta outflow to maintain X2 westward of 65 km, w/ variations to allow eastward excursion of X2 as far as 80 km in drier water year types. Proximate function is to increasethe westward extent of fresh water into Suisun and San Francisco bays to more closely approximate historical conditions. "This will serve to increase the availability of food resources to larval fish species in late winter as well as improve access to low salinity habitat in the shallows of Grizzly and Honker bays (Feyrer et al 2009)." Flows also designed to limit the eastward distribution and density of overbite clam. "...low salinity may inhibit spawning and subsequent adult recruitment, thereby reducing grazing pressures on phytoplankton and the pelagic food web. Improvements in food resources to the western Delta will serve to increase populations of Delta smelt, striped bass, and other pelagic species that are currently in decline."
11	EDF / Stillwater	Outflow	Stillwater Focal Species Approach - Source - EDF closing comments (Table 1), Supporting Info - EDF Exhibit 1 (Spring [Mar-May] Outlfows - p.55-56). Spring flows primarily based on delta outflows needed to maintain X2 in locations that are beneficial to delta pelagic fish populations as well as the provision of floodplain inundation in the Yolo Bypass during March Primary objective was to provide enough Delta outflow to maintain X2 westward of 65 km, w/ variations to allow eastward excursion of X2 as far as 70 km in drier water year types. References in justification: Feyrer et al. In Revision, Bennett et al 2005. Herbold 1994, Hobbs et al 2004, Bennett et al. 2008, and others). Secondary goal is to provide sufficient flows to maintain inundated season floodplain habitat in Yolo Bypass and lower SJ Riv for varying periods in March based on water year type. These floodplain inundation flows should be coordinated with flows in late winter to provide prolonged periods of inundation.
12	EDF / Stillwater	Outflow	Stillwater Focal Species Approach - Source - EDF closing comments (Table 1), Supporting Info - EDF Exhibit 1 (Fall [Sept-Nov] - pp.49-50; Summer - pp.57-58) Summer (Jun-Aug) and Fall flows based primarily on Delta outflows needed to maintain X2 in the shallow-water habitats of Suisun Bay. Secondary objective for Fall outflows from the Delta were to provide attraction flows for upstream-migrating salmonids and to maintain adequate DO concentrations for fall-run chinook salmon within the lower SJ River system. Summer and Fall - in some months and water year types, depending on water year type and month, the projected monthly outflows are higher than the unimpaired and/or current flow ranges. Thus some modification of upstream reservoir release schedules may be required to meet these flows. Fall - references in justification - Feyrer et al 2007; Feyrer et al In revision; Bennet et al 2002; Jassby et al 1995; and others

Appendix A, Table 7. Notes for Tables 1 through 6.

No.	Entity	Type	Notes (excerpts from source documents)
13	EDF / Stillwater	Outflow	EDF_Closing Comments (Table 1) - Peak flows required to provide floodplain inundation are assumed to be concurrent between the Sac and SJ River basins as well as the east side tributaries. However, the duration of the peak flows varies by water year (see notes 69-74)
14	EDF / Stillwater	Outflow	EDF_Closing Comments (Table 1) - Includes 14 days of floodplain inundation flow of 64000 cfs in the Sac River
15	EDF / Stillwater	Outflow	EDF_Closing Comments (Table 1) - Includes 7 days of floodplain inundation flow of 64000 cfs in the Sac River
16	EDF / Stillwater	Outflow	EDF_Closing Comments (Table 1) - Includes 21 days of floodplain inundation flow of 64000 cfs in the Sac River and 14 days of floodplain inundation flow of 14800 cfs in the SJ River
17	EDF / Stillwater	Outflow	EDF_Closing Comments (Table 1) - Includes 14 days of floodplain inundation flow of 64000 cfs in the Sac River and 7 days of floodplain inundation flow of 14800 cfs in the SJ River.
18	EDF / Stillwater	Outflow	EDF_Closing Comments (Table 1) - Includes 28 days of floodplain inundation flow of 64000 cfs in the Sac River and 21 days of floodplain inundation flow if 14800 cfs in the SJ River
19	EDF / Stillwater	Outflow	EDF_Closing Comments (Table 1) - Includes 21 days of floodplain inundation flow of 64000 cfs in the Sac River and 14 days of floodplain inundation flow of 14800 cfs in the SJ River
20	USFWS	Outflow	Delta smelt biological opinion (RPA concerning Fall X2 requirements [pp. 282-283] - improve fall habitat [quality and quantity] for DS) (references USFWS 2008, Feyrer et al 2007, Feyrer et al in revision) - Sept-Oct in years when the preceeding precipitation and runoff period was wet or above normal, as defined by the Sacramento Basin 40-30-30 Index, USBR and DWR shall provide sufficient Delta outflow to maintain monthly average X2 no greater than 74 km and 81 km in Wet and Above Normal yrs, respectively. During any November when the preceding water yr was W or AN, as defined by Sac Basin 40-30-30 index, all inflow into the CVP/SWP reservoirs in the Sac Basin shall be added to reservoir releases in Nov to provide additional increment of outflow from Delta to augment Delta outflow up to the fall X2 of 74 km and 81 km for W and AN water yrs, respectively. In the event there is an increase in storage during any Nov this action applies, the increase in reservoir storage shall be released in December to augment the Dec outflow requirements in SWRCB D-1641.
21	CDFG	Outflow	Outflow recommendations from closing comments. Originally provided as X2 recommendations - Source - DFG Exhibit 1 and Exhibit 2 - Consolidates recommendations for American Shad, Longfin Smelt, Starry Flounder, Bay Shrimp, Zooplankton (consistent with D1641 requirements to maintain X2 at one of two compliance points in Suisun Bay [64 km or 75 km] from Feb-June). Longfin smelt = Jan - June; Starry flounder, Bay shrimp, zooplankton = Feb - Jun; and American Shad = April - June.
22	DWR / SFWC	Outflow, SJ Riv Inflow, Sac Riv Inflow, OMR	DWR_closing comments, in response to request for a table identifing recommended flows, DWR submitted summary of D-1641 objectives.

Appendix A, Table 7. Notes for Tables 1 through 6.

No.	Entity	Type	Notes (excerpts from source documents)
23	UCDavis - Delta Solutions Group	Outflow	Functional Flow 5a - Delta Smelt flows, 48000 cfs, from March through May (5 out of 10 years, every other year). Maintain freshwater to low salinity habitat in the northeastern Delta to Napa River, facilitating a broad spatial and temporal range in spawning and rearing habitat (Bennett 2005, Hobbs et al 2005). Flow recommendation not based on water year type, but rather number of years out of 10. Based on exports through an alternative form of conveyance (e.g., peripheral canal or tunnel).
24	Draft D1630	Sac River Inflow	Function = Chinook salmon. Sac River at Freeport. Average flow at Freeport >18000 cfs for a 14-day continuous period corresponding to release of salmon smolts from Coleman Nat Fish Hatchery. Anticipate to occur in late April or early May. If no fish are released from the hatchery, the Executive Director shall determine the appropriate timing of this pulse flow with advice from CDFG.
25	Draft D1630	Sac River Inflow	Function = striped bass, general; Sac River at Freeport - 14-day running average at Freeport >13000 cfs for a 42-day continuous period, with minimum mean daily flow >9000 cfs. Requirement initiated when real-time monitoring indicates the presence of striped bass eggs and larvae in Sac River below Colusa. This period should begin in late April or early May in most years.
26	Draft D1630	Sac River Inflow	Function = chinook salmon. Sac River at Rio Vista - 14-day running average of minimum daily flow.
27	CDFG	Sac River Inflow	Chinook salmon, smolt outmigration. (1) Feb - Oct base flows. Source - DFG Exhibit 14 (WRINT-DFG-8, p.11). (2) Apr - Jun pulse flows. Source - DFG Exhibit 1, page 1, 6, and USFWS Exhibit 31 (Kjelson).
28	CSPA	Sac River Inflow	CSPA Closing Comments. Source - CDFG_1992_WRINT-DFG-Exhibit #8, p.11. Minimum base flow, measured at Rio Vista. 14-day average flow.
29	CSPA / C-WIN	Sac River Inflow	Sacramento River from Freeport to Chipps Island - Pulse flows - flows needed to sustain viable migration corridor for optimal smolt passage and survival. Source - USFWS Exhibit 31 (Kjelson)
30	PCFFA	Sac River Inflow	Function = salmonid juvenile outmigration. PCFFA closing comments, Source - USFWS Exhibit 31 (Kjelson). Kjelson and Brandes research - found that flows of 20000 to 30000 cfs yield the greatest survival of juvenile salmon during out-migration from Sac River to San Francisco Bay (PCFFA recommends splitting the difference and setting standard at 25000 cfs). Set from Hood to Chipps Island.
31	USFWS	Sac River Inflow	USFWS testimony concerning scientific information used to determine flow criteria. Source: U.S. Department Of the Interior - Comments Regarding the California State Water Resources Control Board's Notice of Public Informational Proceeding to Develop Delta Flow Criteria for the Delta Ecosystem Necessary to Protect Public Trust Resources, Sections II and III, pages 25, 54, and 57. "The catch of juvenile salmon at Chipps Island between April and June is correlated to flow at Rio Vista (USFWS, 1987; Brandes and McLain, 2001; Brandes et al., 2006). The highest abundance leaving the Delta has been observed when flows at Rio Vista between April and June averaged above 20,000 cfs which is also the level where we have observed maximum survival in the past (USFWS, 1987)" (p.25).

Appendix A, Table 7. Notes for Tables 1 through 6.

No.	Entity	Type	Notes (excerpts from source documents)
32	AR / NHI	Sac River Inflow	AR_NHI_Exh1 (testimony of Cain, Opperman, and Tompkins) and AR_NHI_closing comments. Purpose - interconnect side channels with main channel, contribute to foodweb productivity and rearing habitat for salmon. Inundated off-channel habitat such as high flow channels can also provide rearing habitat for salmon (Peterson and Reid 1984), but regulated spring flows are generally insufficient to inundate these habitats for prolonged periods (30-60 days), A recent study of these habitats in the Sac River determined that a large proportion of secondary channels between Red Bluff and Colusa become fully connected to the river at flows above 12000 cfs (Kondolf 2007). (from AR_NHI_Exh1 p.28)
33	AR / NHI	Sac River Inflow	AR_NHI_Exh1 (Testimony of Cain, Opperman, and Tompkins) and AR_NHI_closing comments - aid migration of winter-run chinook, in later months aid migration of spring and fall-run. Recent analyses indicate that the onset of emigration of winter-run fish to the Delta at Knights Landing is triggered by flow pulses of 15000 cfs at Wilkins Slough, and emigration from the Sac River to Chipps Island follows pulse flows of 20000 cfs at Freeport (del Rosario 2009). Previous studies found that smolt survival increased with increasing Sac River flow at Rio Vista, with maximum survival observed at or above about 20000 and 30000 cfs (USFWS 1987, Exhibit 31). Despite uncertainty about the exact magnitude of flow necessary to initiate substantial bank erosion, there is growing evidence that flows between 20000 and 25000 cfs will erode some banks while flows above 50000 to 60000 cfs are likely to cause widespread bank erosion (Stillwater 2007).
34	TBI / NRDC / AR / NHI	Sac River Inflow	TBI_Exh3 (Inflows - Table 3), TBI_closing comments (Table 3), AR/NHI_Exh1 (Testimony of Cain, Opperman, and Tompkins), AR/NHI closing comments - Table 3. Flows recommended for floodplain inundation (Sutter and Yolo Bypasses) - salmonid rearing, splittail spawning and early rearing. Flows measured at Verona. Flow magnitudes assume structural modifications to the weir to allow inundation at lower flow rates than is currently possible. Reservoir releases should be timed to coincide with and extend duration of high flows that occur naturally on less regulated rivers and creeks. The duration target is fixed for each year type, but actual timing of inundation should vary across the optimal window depending on hydrology and to maintain life history diversity.
35	NMFS	Sac River Inflow	NMFS_Exh9 (from ARFP 1995), Sturgeon (Grn and Wht) - adult migration to spawning and downstream larval transport
36	NMFS	Sac River Inflow	Public Draft Recovery Plan for Central Valley Salmon and Steelhead (October 2009). NMFS_Exhibit_5. Section 6.1.1 Recovery Action Narrative, Action 1.5.9, p.158.
37	EDF / Stillwater	Sac River Inflow	Source: EDF_Exh1 (Stillwater Sciences - Focal Species Approach). Spring flows - Establishing base flows of at least 10000 cfs in the Sac Riv in spring would improve transport of eggs and larval striped bass and other young anadromous fish and to reduce egg settling and mortality at low flows (USFWS 2001, EDF_Exh1, p.53). Proximate function of Delta inflows is to maintain net transport of passively swimming fishes (juv salmonids, larval delta smelt, and striped bass) and nutrients towards Suisun and San Francisco bays (USFWS 2008). Goal of winter and spring floodplain activation flows (managed pulse flows of approx 64000 cfs at Verona) is to maintain inundated seasonal floodplain habitat conditions in much of Yolo Bypass during January and April for a minimum of 21, 35, and 49 days in Below Normal, Above Normal, and Wet water year types, respectively. The NMFS (2009) draft recovery plan for Sac winter-run chinook, CV spring-run chinook, and CV steelhead ESUs calls for an annual spring flow of 8000 cfs (approx 64000 cfs at Verona) above the initial spill level "to fully activate the Yolo Bypass floodplain." For the

Appendix A, Table 7. Notes for Tables 1 through 6.

No.	Entity	Type	Notes (excerpts from source documents)
37 cont	EDF / Stillwater	Sac River Inflow	purposes of this assessment, Stillwater allocated the Delta inflows for floodplain inundation to February and March. Summer Delta inflows to be determined by Delta outflows. Fall Inflows - Maintenance of D1641 flow standards in necessary to provide attraction flows for Chinook salmon, although these levels would potentially need to be increased to provide adequate Delta outflows. Winter Inflows - Winter flows primarily designed to provide upstream migration passage for salmonids and striped bass during Dec and Jan, as well as to inundate floodplains such as Yolo Bypass for benefit of rearing juv salmonids and other floodplain associated species (p.50-51). See Spring for discussion of goal of combined winter-spring floodplain activation flows.
38	EDF / Stillwater	Sac Riv Inflow / SJ Riv Inflow	Inflows determined based on Delta outflows (EDF_Exh1 - Stillwater Focal Species)
39	EDF / Stillwater	Sac River Inflow	These levels may need to be increased to provide adequate Delta outflows (EDF_Exh1 - Stillwater Focal Species)
40	UCDavis - Delta Solutions Group	Sac River Inflow	Functional Flow 2a - Sac River adult salmon - 10000 cfs to to occur from Oct - June during 6 out of 10 years (references Newman and Rice 2002, Williams 2006, Harrell et al. 2009, USFWS Exhibit 31 1987, Kjelson and Brandes 1989). Functional Flow 2b - Sac River juvenile salmon migration - 25000 cfs from Mar - June during 6 out of 10 years (references Newman and Rice 2002, Williams 2006, Harrell et al. 2009, USFWS Exhibit 31 1987, Kjelson and Brandes 1989). Flows not based on water year type, but rather number of years out of ten.
41	UCDavis - Delta Solutions Group	Sac River Inflow	Functional Flow 2c - Sacr River adult sturgeon flows - 70000 cfs to occur between Jan and May during 1 out of 10 years (flows for salmon -2a, 2b, and 1a,1b) (Kohlhorst et al 1991 [flow rate], Harrell and Sommer 2003 [passage problems at Fremont Weir]). Flows not based on water year type, but rather number of years out of ten.
42	UCDavis - Delta Solutions Group	Sac River Inflow	Functional Flow 1a - yolo bypass inundation - salmon and splittail (area inundated based on recommended flows BDCP draft rpt 2008) (other references related to flow and corresponding extent of habitat in Yolo Bypass Moyle et al. 2004, Sommer et al. 2004, Harrell and Sommer 2003, Harrell et al. 2009). Functional Flow 1b - yolo bypass pulse - salmon and splittail (area inundated based on recommended flows BDCP draft rpt 2008) (other references related to flow and corresponding extent of habitat in Yolo Bypass Moyle et al. 2004, Sommer et al. 2004, Harrell and Sommer 2003, Harrell et al. 2009). Functional Flows 1a and 1b require flows at Freeport of approx. 45750 and 50150 cfs, respectively, based on regressions of historical data.
43	D1641	SJ River Inflow	Base Vernalis minimum monthly average flow rate in cfs (the 7-day running average shall not be less than 20% below the objective). Take the higher objective if X2 is required to be west of Chipps Island
44	D1641	SJ River Inflow	Pulse Vernalis minimum monthly average flow rate in cfs. Take the higher objective if X2 is required to be west of Chipps Island
45	D1641	SJ River Inflow	Pulse - up to an additional 28 TAF pulse/attraction flow to bring flows up to a monthly average of 2000 cfs except for a critical year following a critical year. Time period based on real-time monitoring and determined by CalFed Op's group

Appendix A, Table 7. Notes for Tables 1 through 6.

No.	Entity	Type	Notes (excerpts from source documents)
46	Draft D1630	SJ River Inflow	SJ River at Vernalis. Function = chinook salmon. Minimum daily flow, in cfs, for 21-day continuous period. Start date depends on beginning of chinook salmon smolt out-migration from SJ basin. During this time, water right holders on Mokelumne and Calaveras rivers shall bypass all inflows for 5 consecutive days. Daily mean combined pumping at Tracy, Banks, and Contra Costa pumping plants shall be ≤1500 cfs. All pumping restrictions are to be split equally between CVP and SWP. Total annual maximum of 150 TAF for the two salmon flows (these and fall attraction flows) from the SJ Basin reservoirs
47	Draft D1630	SJ River Inflow	SJ River at Vernalis. Function = chinook salmon. Minimum daily flow, for 14-day continuous period. Start date depends upon beginning of chinook salmon adult spawning migration. Attraction flow shall be provided only if water is avaiable from the 150 TAF alloted for the two salmon flows. During this time, water right holders on Mokelumne and Calaveras rivers shall bypass all inflows for 5 consecutive days.
48	CDFG	SJ River Inflow	Source: SJR Salmon Model V.1.6 (CDFG 2009), DFG Exhibit 3 (Flows needed in the Delta to restore anadromous salmonid passage from the SJ River at Vernalis to Chipps Island) - Table 10 - South Delta (Vernalis) flows needed to double smolt production at Chipps Island (by water year type), and CDFG closing comments. Flows to support smolt outmigration.
49	CSPA / C-WIN	SJ River Inflow	CSPA and C-WIN Closing Comments - CSPA Table 2. Based on WRINT-DFG Exhibit 8 (1992) and C. Mesick 2010 (C-Win Exh 19). Pulse flows in all years to attract adult spawning salmonids, Oct 20-29, SJR at Vernalis. To the tributary flows (each measured at their confluence with SJ Riv mainstem (see Mesick 2010), C-WIN / CSPA added in a flow of the SJ Riv below Millerton Lake reflecting that river's fair share unimpaired flow, as well as accretions and other inflows. Combined valley flows at Vernalis assumes tributaries (Mer, Stan, Tuol) are 67.06% of total SJ River flow at Vernalis. Spring - pulse flows for temperature regulation, migration cues, habitat inundation. Oct - pulse flows to attract adult salmonids.
50	TBI / NRDC	SJ River Inflow	TBI Exhibit 3 - Delta Inflows (Table 1, p.28), TBI / NRDC closing comments (Table 3b). Flows >5000 cfs to maintain minimum temperature (≤ 65F) for migrating salmonids in April and May. Flows >20000 to trigger floodplain inundation. Year-round flows should exceed 2000 cfs to alleviate potential for DO problems in DWSC.
51	AR / NHI	SJ River Inflow	AR_NHI_Exh1 (testimony of Cain, Opperman, and Tompkins) and AR_NHI_closing comments (Table 2). SJ River flows to benefit salmon rearing habitat and smolt out-migration (increase flow velocities and turbidity), with focus on temperature (maintain temp at or below 65F) and floodplain inundation. Criteria recommended to be in addition to those stipulated in D1641.
52	EDF / Stillwater	SJ River Inflow	EDF / Stillwater Exh 1 (focal species approach, pp.47-49). Based upon investigations for the SJ River DO TMDL, minimum instream flows at the Stockton DWSC should be maintained in excess of 1,800 cfs during Sept and Oct of each year. Low DO in the lower SJ River has been found to impede upstream salmon migration (NMFS 2009, p.74). Studies by Hallock (1970) indicate that low DO at Stockton delay upmigration and straying rates.
53	EDF / Stillwater	SJ River Inflow	EDF / Stillwater Exh 1 (focal species approach, pp.47-49). Flows during November should correspond to current minimum Federal Energy Regulatory Commission (FERC) spawning flow requirements from the Stanislaus, Tuolumne, Merced, and upper San Joaquin rivers.

Appendix A, Table 7. Notes for Tables 1 through 6.

No.	Entity	Type	Notes (excerpts from source documents)
54	EDF / Stillwater	SJ River Inflow	EDF / Stillwater Exh 1 (focal species approach, pp.47-49). Salmonid spawning attraction flows in excess if 3500 cfs at Vernalis should be provided for 10-14 days during October, using coordinated releases from the SJ River and tributaries. For remainder of fall, Delta inflows would be determined by the minimum instream flow requirements of the SJ River basin and east side tributaries. Upstream flow levels would likely be increased to meet the Delta outflow recommendations.
55	EDF / Stillwater	SJ River Inflow	EDF / Stillwater Exh 1 (focal species approach, pp.54). "Although USFWS (1995) previously recommended spring Delta inflows ranging from 4,050 cfs to 15,750 cfs at Vernalis based upon of regression models of Chinook salmon smolt survival. The current D-1641 flow minimums range from 3,110 cfs to 8,620 cfs (Table 1-5), depending upon water year type, have never been fully implemented. In addition to baseline flows, for the benefit of rearing Chinook salmon and other native fishes, floodplain activation flows should be provided..."
56	EDF / Stillwater	SJ River Inflow	EDF / Stillwater Exh 1 (focal species approach, pp.51-52). Winter Inflows - Minimum flows at Vernalis and the eastside tributaries should be coordinated to maintain net seaward flows at Jersey Point of 1000 cfs in Critical and Dry years, 2000 cfs in Below and Above Normal years, and 3000 cfs in Wet years (USFWS 1995 3-Xe-19). Net seaward flows for benefit of outmigrating juvenile salmon.
57	EDF / Stillwater	SJ River Inflow	EDF / Stillwater Exh 1 (focal species approach, pp.54-55). For the benefit of rearing chinook salmon and other native fishes, floodplain activation flows should be provided of 14800 cfs in the lower SJ River in Above Normal and Wet water year types. A series of pulse flows instead of a single extended high flow event might also be used to achieve the desired target of continuous days of inundated floodplain. Goal for combined winter and spring floodplain activation flows is to maintain inundated seasonal floodplain habitat conditions (or the potential for such conditions in sites where floodplain restoration actions may be undertaken in the future) in the lower SJ River during Jan through Apr for a minimum of 21 and 35 consecutive days in Above Normal and Wet water year types, respectively. For the purposes of this assessment, Stillwater allocated the Delta inflows for floodplain inundation to February and March. Also discusses inundation of Cosumnes River floodplain.
58	USFWS	SJ River Inflow	USFWS testimony concerning scientific information used to determine flow criteria. Source: U.S. Department Of the Interior - Comments Regarding the California State Water Resources Control Board's Notice of Public Informational Proceeding to Develop Delta Flow Criteria for the Delta Ecosystem Necessary to Protect Public Trust Resources, Sections II and III, pages 56-57 and 25. Quote in table from p.56-57. "The Anadromous Fish Restoration Program has developed estimates of flow levels needed at Vernalis to achieve a 53% increase (page 9) and a doubling (page 10) in predicted Chinook salmon production for the basin (USFWS, 2005). These Vernalis flow criteria vary by water year type and by month between February and May. We recommend these flows as starting point for establishing minimum and maximum volume of flow for increasing juvenile salmon and steelhead survival in the San Joaquin basin." (p.25).
59	AFRP	SJ River Inflow	Anadromous Fish Restoration Program (ARFP). Recommended streamflow schedules to meet the AFRP Doubling Goal in the San Joaquin River Basin (USFWS, 27 Sept 2005). Salmon doubling - total average flow (Stanislaus, Tuolumne, Merced) that would be expected to double the total predicted Chinook salmon production for the basin.

Appendix A, Table 7. Notes for Tables 1 through 6.

No.	Entity	Type	Notes (excerpts from source documents)
60	AFRP	SJ River Inflow	Anadromous Fish Restoration Program (ARFP) - Recommended streamflow schedules to meet the AFRP Doubling Goal in the San Joaquin River Basin (USFWS, 27 Sept 2005). Total average flow (Stanislaus, Tuolumne, Merced) that would be expected to achieve a 53% increase in total predicted Chinook salmon production for the basin.
61	NMFS	SJ River Inflow	NMFS OCAP Bio Opinion, Action IV.2.1 (pp.641-644) San Joaquin River Inflow to Export Ratio - both interim (2010-2011) and long-term (beginning in 2012) requirements are stipulated. Interim flows are based on maintaining a minimum status quo for SJ River basin salmonid populations. Long term flow schedules for the SJ River are expected to result from SWRCB proceedings on SJ River flows. Export limitations and flows are also described on pp. 642-644
62	NMFS	SJ River Inflow	NMFS_Exh9 (from AFRP 1995) - Sturgeon (Green and White), mean monthly flows - ensure suitable conditions for sturgeon to migrate and spawn and for progeny to survive.
63	UCDavis - Delta Solutions Group	SJ River Inflow	Functional Flows 3a - transport juvenile salmon (references USFWS Exhibit 31, 1987; Newman and Rice 2002; Williams 2006) - wet years - 20000 cfs, Apr-Jun (2 out of 10 years); AN years - 15000 cfs, April - Jun 15 (4 out of 10 years); BN years - 10000 cfs, Apr-May (6 out of 10 years); Dry years - 7000 cfs, Apr-May 15 (8 out of 10 years); and Critical years - 5000 cfs, Apr (10 out of 10 years). Functional Flows 3c - adult salmon recruitment (reference USFWS Exhibit 31, 1987) - 2000 cfs year round (10 out of 10 years) (flows were not experienced in unimpaired conditions, but likely result from the disturbed conditions). Functional Flows 3b - Improve DO conditions in DWSC (2000 cfs, July-Oct, all years) (Lehman et al 2004, Jassby and VanNieuwenhuyse 2005).
64	D1641	OMR	Export/Inflow ratio - the maximum percent Delta inflow diverted for Feb may vary depending on the Jan 8RI (see D1641)
65	D1641	OMR	SWP/CVP Export Limit - All water year types, Apr 15 - May 15, the greater of 1500 cfs or 100% of 3-day avg. Vernalis flow. Maximum 3-day average of combined export rate (cfs), which includes Tracy Pumping Plant and Clifton Court Forebay Inflow less Byron-Bethany pumping. The time period may need to be adjusted to coincide with fish migration. Maximum export rate may be varied by CalFed Ops Group.
66	Draft D1630	OMR	Reverse flow restrictions for all year types are relaxed when combined CVP and SWP exports are < 2000 cfs. Export pumping restriction is relaxed for all year types when Delta outflow > 50000 cfs, except for the export pumping restriction during the SJ River pulse period. July 1 - Jan 31 - 14-day running average flow (as calculated in DAYFLOW), these restrictions do not apply whenever the EC at the Mallard Slough monitoring station is < 3 mmhos/cm. QWEST standards in 1630 discussed in DOI submittal, p.53, section concerning reverse flows.
67	CSPA / C-WIN	OMR	CSPA closing comments, C-WIN closing comments, CSPA_Exh1_Jennings. Combined export rates would be 0 cfs in all years from March 16 through June 30. Prevent entrainment and keep migration corridors open to maximize salmon juvenile and smolt survival. Facilitate SJ River salmonid migration down Old River.
68	CSPA / C-WIN	OMR	CSPA and C-WIN closing comments - flow direction, entrainment protection and provision of migration corridors

Appendix A, Table 7. Notes for Tables 1 through 6.

No.	Entity	Type	Notes (excerpts from source documents)
69	CSPA / C-WIN	OMR	SJ River at Jersey Point flow recommendations (positive 14-day mean flows). Source: CSPA_exh1_Jennings_test; CDFG_1992_WRINT-DFG-Exhibit #8, Alt C (p.11, flows at Jersey Pt from Apr 1 through June 30, salmon); AFRP Working Paper, 1995, p. 3-Xe-19 (salmon). Function maintain positive flow for salmonid smolt outmigration and protect Delta smelt, originally two separate recommendations. DS - Feb 1 - Jun 30, Salmon - Oct 1 - Jun 30, only difference between flow recommendations where overlap occurred was DS in AN years = 2500 cfs, salmon in AN years = 2000. For this table, recommendations merged and 2500 cfs used for AN years (+DFG Exh 8 recommends 2500 cfs in AN years)
70	TBI / NRDC	OMR	TBI/NRDC closing comments (Table 4). The hydrodynamic recommendations expressed as Vernalis flow and/or export to inflow ratios in TBI/NRDC Exh4 (Delta Hydrodynamics, p.30) were converted to OMR flows, using the San Joaquin flow recommendations as described in TBI/NRDC Exh 3 (Delta Inflows), for inclusion in Table 4. Note: recommended OMR flows assume SJ River flows recommended in TBI Exhibit 3 are also implemented. (*) - when the previous longin smelt FMWT index <500, OMR flows in Jan-Mar are >0. This corrects a typographical error in the table on p.30 of TBI Exhibit 4
71	AFRP	OMR	Anadromous Fish Restoration Program (ARFP) (Working Paper on Restoration Needs, Habitat Restoration Actions to Double Natural Production of Anadromous Fish in the Central Valley of California, Volume 3, 1995, p. 3-Xe-19). Action 3 - Maintain positive QWEST flows, or an equivalent measure of net seaward flows at Jersey Point, of 1000 cfs in Critical and Dry years, 2000 cfs in below- and above normal years, and 3000 cfs in wet years from Oct 1 through June 30. Objective - Increase survival of smolts migrating down the mainstem rivers, decrease the number of smolts diverted into the central Delta, increase the survival of smolts diverted into the central Delta, and provide attraction flows for San Joaquin Basin adults (Oct - Dec).
72	NMFS	OMR	NMFS OCAP Bio Opinion, Action IV.2.3 - Old and Middle River Flow Management (pp. 648-652). See action triggers on pp. 648-650. Actions will be taken in coordination with USFWS RPA for Delta Smelt and State-listed longfin smelt 2081 incidental take permit. During the Jan 1 - Jun 15 period, the most restrictive export reduction shall be implemented.
73	USFWS	OMR	USFWS testimony concerning scientific information used to determine flow criteria. Source: U.S. Department Of the Interior - Comments Regarding the California State Water Resources Control Board's Notice of Public Informational Proceeding to Develop Delta Flow Criteria for the Delta Ecosystem Necessary to Protect Public Trust Resources, Sections II and III, pages 50, 53, and 24-25 (references USFWS 1992; AFRP Working Paper p.3-Xe-19, USFWS 2005, Restoration Action #3; D-1630, pp44-47). "Based on the scientific information we reviewed, the Board should develop reverse flow criteria that would maintain the Old and Middle river flow positive during key months (January through June) of the year to protect important public trust resources in the Delta" (p.53).

Appendix A, Table 7. Notes for Tables 1 through 6.

74	USFWS	OMR	USFWS testimony concerning scientific information used to determine flow criteria. Source: U.S. Department Of the Interior - Comments Regarding the California State Water Resources Control Board's Notice of Public Informational Proceeding to Develop Delta Flow Criteria for the Delta Ecosystem Necessary to Protect Public Trust Resources, Sections II and III, pages 24,25, and 53. "In a previous Board exhibit (USFWS, 1992), we showed a positive relationship between temperature corrected juvenile survival indices and flow at Jersey Point for marked fish released at Jersey Point (QWEST) (USFWS, 1992, p.21). In addition, the AFRP Working Paper (USFWS, 1995) Restoration Action #3 calls for maintaining positive QWEST flows, or an equivalent measure of net seaward flows at Jersey Point, of 1000 cfs in critical and dry years, 2000 cfs in below- and above-normal years, and 3000 cfs in wet years from Oct 1 through June 30. Higher flow at Jersey Point has been provided during the VAMP period (mid-April to mid-May) with the adoption of VAMP flows and exports. We encourage the Board to retain or expand this
74 cont	USFWS	OMR	type of action to assure the contribution of downstream flow from the San Joaquin Basin to Delta outflow for the protection of juvenile and adult salmonids migrating from the San Joaquin basin."
75	USFWS	OMR	USFWS OCAP Bio Opinion - RPA re: OMR flows. Component 1 - Adults (Dec - Mar) - Action 1 (protect upmigrating delta smelt) - once turbidity or salvage trigger has been met, -2000 cfs OMR for 14 days to reduce flows towards the pumps. Action 2 (protect delta smelt after migration prior to spawning) - OMR range between -1250 and -5000 cfs determined using adaptive process until spawning detected. pp.280-282
76	USFWS	OMR	USFWS OCAP Bio Opinion - RPA re: OMR flows. Component 2 - Larvae/Juveniles - action starts once temperatures hit 12 degrees C at three delta monitoring stations or when spent female is caught. OMR range between -1250 and -5000 cfs determined using adaptive process. OMR flows continue until June 30 or when Delta water temperatures reach 25 degrees C, whichever comes first. pp. 280-282
77	CDFG	OMR	Longfin Smelt Incidental Take Permit (2009), p. 9-10, Condition 5.1. This Condition is not likely to occur in many years. To protect adult longfin smelt migration and spawning during December through February period, the Smelt Working Group (SWG) or DFG SWG personnel staff shall provide OMR flow advice to the Water Operations Management Team (WOMT) and to Director of DFG weekly. The SWG will provide the advice when either: 1) the cumulative salvage index (defined as the total longfin smelt salvage at the CVP and SWP in the December through February period divided by the immediately previous FMWT longfin smelt annual abundance index) exceeds five (5); or 2) when a review of all abundance and distribution survey data and other pertinent biological factors that influence the entrainment risk of adult longfin smelt indicate OMR flow advise is warranted. Permittee shall ensure the OMR flow requirement is met by maintaining the OMR flow 14-day running average is no more negative than -5000 cfs and the initial 5-day running average is not more negative than -6250 cfs. During any time OMR flow restrictions for
77 cont	CDFG	OMR	the FWS's 2008 Biological Opinion for delta smelt are being implemented, this condition (5.1) shall not result in additional OMR flow requirements for protection of adult longfin smelt. Once spawning has been detected in the system, this Condition terminates and 5.2 begins. Condition 5.1 is not required or would cease if previously required when river flows are 1) > 55000 cfs in the Sac River at Rio Vista; or 2) > 8000 cfs in the SJ River at Vernalis. If flows go below 40000 cfs in the Sac River at Rio Vista or 5000 cfs in the SJ River at Vernalis, the OMR flow in Condition 5.1 shall resume if triggered previously. Review of survey data and other pertinent biological factors that influence the entrainment risk of adult longfin smelt may result in a recommendation to relax or cease an OMR flow requirement.

Appendix A, Table 7. Notes for Tables 1 through 6.

No.	Entity	Type	Notes (excerpts from source documents)
78	CDFG	OMR	Longfin Smelt Incidental Take Permit (2009), p. 10-11, Condition 5.2. To protect larval and juvenile longfin smelt during Jan-June period, the SWG or DFG SWG personnel shall provide OMR flow advice to the WOMT and the DFG Director weekly. The OMR flow advice shall be an OMR flow between -1250 and -5000 cfs and be based on review of survey data, including all of the distributional and abundance data, and other pertinent biological factors that influence the entrainment risk of larval and juvenile longfin smelt. When a single Smelt Larval Survey (SLS) or 20 mm Survey sampling period results in: 1) longfin smelt larvae or juveniles found in 8 or more of the 12 SLS or 20mm stations in the central and south Delta (Stations 809, 812, 901, 910, 912, 918, 919) or, 2) catch per tow exceeds 15 longfin smelt larvae or juveniles in 4 or more of the 12 survey stations listed above, OMR flow advice shall be warranted. Permittee shall ensure the OMR flow requirement is met by maintaining the OMR flow 14-day running average no more negative than the required OMR flow and the 5-day running average is within 25% of the
78 cont	CDFG	OMR	required OMR. This Conditions OMR flow requirement is likely to vary throughout Jan through June. Based on prior analysis, DFG has identified three likely scenarios that illustrate the typical entrainment risk level and protective measures for larval smelt over the period: High Entrainment Risk Period: Jan - Mar OMR range from -1250 to -5000 cfs; Medium Entrainment Risk Period: April and May OMR range from -2000 to -5000 cfs, and Low Entrainment Risk Period: June OMR -5000 cfs. When river flows are: 1) greater than 55000 cfs in the Sac River at Rio Vista; or 2) greater than 8000 cfs in the SJ River at Vernalis, the Condition would not trigger or would be relaxed if triggered previously. Should flows go below 40000 cfs in Sac River at Rio Vista or 5000 cfs in the SJ River at Vernalis, the Condition shall resume if triggered previously. In addition to river flows, the SWG or DFG SWG personnel review of all abundance and distribution survey data and other pertinent biological factors that influence the entrainment risk of longfin smelt may result in a recommendation by DFG to WOMT to relax or cease an OMR flow requirement.

87	EDF / Stillwater	Ouflow	EDF_Closing Comments (Table 1) - Mean Historical Delta Outflow Volumes (TAF) for 1956-2003 by month and water year type. Historical and unimpaired flow values are based on Water Years 1956-2003 using California Central Valley Unimpaired Flow Data, 4th ed. (CDWR 2007). In instances where there was a difference between Dry and Critically Dry years, the value for Critically Dry years was selected. Originally reported as volume (TAF). Conversion calculated as follows: (TAF/month)(1000 AF/TAF)(43560 ft3/AF)(month/X days)(day/86400 sec)

Appendix B: Enacting Legislation

California Water Code, Division 35 (Sacramento-San Joaquin Delta Reform Act of 2009), Part 2 (Early Actions), Section 85086

(a) The board shall establish an effective system of Delta watershed diversion data collection and public reporting by December 31, 2010.

(b) It is the intent of the Legislature to establish an accelerated process to determine instream flow needs of the Delta for the purposes of facilitating the planning decisions that are required to achieve the objectives of the Delta Plan.

(c)

> (1) For the purpose of informing planning decisions for the Delta Plan and the Bay Delta Conservation Plan, the board shall, pursuant to its public trust obligations, develop new flow criteria for the Delta ecosystem necessary to protect public trust resources. In carrying out this section, the board shall review existing water quality objectives and use the best available scientific information. The flow criteria for the Delta ecosystem shall include the volume, quality, and timing of water necessary for the Delta ecosystem under different conditions. The flow criteria shall be developed in a public process by the board within nine months of the enactment of this division. The public process shall be in the form of an informational proceeding conducted pursuant to Article 3 (commencing with Section 649) of Chapter 1.5 of Division 3 of Title 23 of the California Code of Regulations, and shall provide an opportunity for all interested persons to participate. The flow criteria shall not be considered predecisional with regard to any subsequent board consideration of a permit, including any permit in connection with a final BDCP.
>
> (2) Any order approving a change in the point of diversion of the State Water Project or the federal Central Valley Project from the southern Delta to a point on the Sacramento River shall include appropriate Delta flow criteria and shall be informed by the analysis conducted pursuant to this section. The flow criteria shall be subject to modification over time based on a science-based adaptive management program that integrates scientific and monitoring results, including the contribution of habitat and other conservation measures, into ongoing Delta water management.
>
> (3) Nothing in this section amends or otherwise affects the application of the board's authority under Part 2 (commencing with Section 1200) of Division 2 to include terms and conditions in permits that in its judgment will best develop, conserve, and utilize in the public interest the water sought to be appropriated.

(d) The board shall enter into an agreement with the State Water Project contractors and the federal Central Valley Project contractors, who rely on water exported from the Sacramento River watershed, or a joint powers authority comprised of those contractors, for reimbursement of the costs of the analysis conducted pursuant to this section.

(e) The board shall submit its flow criteria determinations pursuant to this section to the council for its information within 30 days of completing the determinations.

Going with the flow: the distribution, biomass and grazing rate of *Potamocorbula* and *Corbicula* with varying freshwater flow (May and October 2009-2011).

J. Thompson[1], K. Gehrts[2], F. Parchaso[1], H. Fuller[2]

[1] U.S. Geological Survey, Menlo Park, CA; [2] Division of Environmental Services, Department of Water Resources , West Sacramento, CA

Summary of findings:

Spatially intensive benthic samples from >200 stations were analyzed for bivalve biomass, filtration rate, grazing rate, and water column turnover rate for three Octobers (2009-2011) to determine if the increased freshwater flow in fall 2011 would decrease the bivalve grazing in the low salinity zone in fall. Relative to the previous two dry years, the biomass of bivalves was decreased in the shallow portions of Grizzly and Honker Bays and in Western Suisun Marsh (including Montezuma and Suisun Slough) in 2011. The reduction in biomass was sufficient to limit the potential for bivalves to control phytoplankton biomass accumulation in fall. It is likely they could decrease the phytoplankton biomass by their feeding, but they did not have a sufficient grazing rate to exceed the phytoplankton growth rate during fall 2011, if the phytoplankton growth rate is assumed to be similar to that observed by Kimmerer et al. (2012) in 2006-2007.

Introduction

The POD conceptual model recognizes that food limitation may be contributing to the decline of Delta Smelt (Baxter et al. 2008). The questions of how food has changed during the POD years and the factors responsible for those changes have not been resolved. We know that the variability in salinity decreased in late summer and fall during the POD and that Delta Smelt are mostly in the low salinity zone (LSZ) during this period. There are several components of the LSZ food web that might be affected by this change in salinity. We discuss here the response of the benthic bivalves and how their change in biomass in space and time might reduce phytoplankton, copepods, bacteria, and possibly microzooplankton.

The distributions of *Potamocorbula amurensis* (*Potamocorbula* hereafter) and *Corbicula fluminea* (*Corbicula* hereafter) are dependent on the salinity distribution at the time their larvae are available for settlement, the number of adults present in the area of settlement, and the environmental stresses on the population after settlement. Field data shows that these bivalves overlap within the LSZ region which is consistent with laboratory studies on the juvenile/larval salinity tolerances for both species (Nicolini and Penry 2000, McMahon 1999). Based on data collected for the Environmental Monitoring Program Benthic Program we know that *Potamocorbula* is more persistent and is a larger presence in the LSZ than is *Corbicula*. We have also observed that the pattern is reversed upriver of the LSZ where the freshwater clam, *Corbicula*, becomes the dominant form. It is important to understand the dynamics of both clams as previous field (Thompson et al 2008, Lopez et al. 2006) and modeling (Lucas et al 2002, Lucas et al 2009) work has shown that both bivalves can limit phytoplankton biomass in the bay and delta. In addition, experimental work has shown zooplankton nauplii and ciliates can be filtered out of the water column by *Potamocorbula* in the bay (Kimmerer et al 1994, Greene et al 2011). *Corbicula* can filter fast-moving ciliates (Scherwass et al 2001) and glochidia (Scherwass et al 2005) but there have been no experiments on their ability to filter copepod nauplii. Thus, *Potamocorbula* may limit food supplies in the LSZ and both *Potamocorbula* and *Corbicula* may consume phytoplankton and zooplankton as it is transported towards the LSZ although *Corbicula* are likely to dominate in this upstream habitat in most years.

Because Delta Smelt feed on zooplankton (mostly calanoid copepods, Nobriga 2002) throughout their lives, any direct reduction in zooplankton through filtration by bivalves or indirect reduction in zooplankton due to food limitation needs to be examined. Thus, this project concentrated on the magnitude of bivalve grazing within the LSZ, within the tidal dispersion zone of the LSZ, and upstream of the LSZ during the fall periods.

Bivalve conceptual models

The distribution and dynamics of *Potamocorbula* and *Corbicula* are based on their physiological salinity limits and their life history characteristics. As explained below, *Potamocorbula* is the dominant grazer within the LSZ and *Corbicula* is the dominant grazer upstream of X2. As X2 and the LSZ moves up- and down-bay, the overlapping region of *Corbicula* and *Potamocorbula* moves with it so we will always have to consider both species when we examine foodweb dynamics in the LSZ. In addition, declines in phytoplankton biomass can not be assumed to be due to local grazing due to the tidal dispersion of pelagic particles and thus grazing must be assessed in regions within the tidal dispersion sphere of influence. The major difference in *Potamocorbula* and *Corbicula* other than their salinity tolerance is their method and season of reproduction that determines their distribution within their salinity range and their response to the fall increase in salinity intrusion.

Potamocorbula

Potamocorbula is a dioecious (sexes are separate), fecund (45,000-220,000 oocytes), broadcast spawning bivalve with external fertilization, a short lived non swimming trochophore larvae and a motile suspension feeding veliger larvae. Both larval stages have a broad salinity tolerance (2-30). The larvae settle at day 17-19 and thus can be moved by the currents for substantial distances before settling.

Potamocorbula recruitment usually occurs in the western Delta in fall and in the northern estuary in early spring through fall (Parchaso and Thompson 2002). Thus larvae have been available to respond to the recent fall periods of increasing salinity. We observed an increase in the biomass and abundance of *Potamocorbula* at Chipps Island in late 1999 and early 2000 (USGS unpublished data). We hypothesize that the increasing salinity in fall that began in 1999 allows fall larvae to settle further upstream. The high salinity may also allow *Potamocorbula* that settles in previously marginal salinity zones to persist, because individuals have grown sufficiently large in fall to become more tolerant of environmental stresses during the following winter.

The antidote to this fall incursion of bivalves is a large outflow event such as was seen in spring 2006. The mass mortality in spring 2006, observed as a drop in abundance and biomass of *Potamocorbula* to near zero at a Chipps Island station (USGS unpublished data), was short lived. The recruitment and subsequent biomass was very high in the fall of 2006 at that location because there were no adults to interfere with the larvae, and the salinity was high enough for a long enough period to allow the recruits to grow and persist. The elevated fall 2006 biomass then carried into the spring of the following year when Delta outflow was again low. We hypothesize that the effect of the recent increases in fall salinity was an increase in recruitment of *Potamocorbula* in traditionally lower salinity areas. The corollary to this hypothesis is that if these animals are given sufficient time to grow they become more resistant to osmotic and physical stresses during the winter peaks in Delta outflow which results in higher grazing rates in the following spring than we might expect with normal fall salinity distributions.

Corbicula

Corbicula is a simultaneous hermaphrodite (Kraemer and Galloway 1986) thereby making it possible for one individual to establish a population. Adults hold unfertilized eggs until there is sufficient food at which time they produce sperm and the eggs are fertilized. The larvae (pediveligers) develop in 3-5 days, are brooded in the gills of the adult before release, cannot swim but are found in the plankton for their first 48 hours, and are limited to salinities ≤2. They depend on their small size (200 µm) and mass (0.1 mg dry weight) to allow currents to re-suspend and transport them after settling (Aldridge and McMahon 1978). As a freshwater bivalve, this strategy is good for moving larvae downstream with the currents but may be less effective at widening their distribution throughout the system. It is not surprising that *Corbicula*, as a freshwater bivalve, would have an opposite reproductive seasonality to that of *Potamocorbula*. Eng (1979) and Heinsohn (1958) found a large spawning peak in the spring followed by a smaller fall peak in the Delta. If this reproductive seasonality persists today then *Corbicula* is most likely to expand down river and down-bay in the spring but its expansion into new down bay areas is likely to be limited in fall by the increasing salinity.

Methods

The DWR EMP program sampled 175 benthic stations (single sample at each location with a $0.05m^2$ bottom grab) throughout the Delta and northern bay in one week in May and October from 2007-2011 (Figure 1). The sampling design (generalized random tessellated stratified design) allows for a random selection of stations in various strata which DWR defined as habitat type (lake, large river, river, slough, bay, large bay). The station locations changed each year for all but 50 stations (the annual panal) which were sampled throughout the program. Twenty two additional stations were added beginning in October 2009 to establish channel-shoal pairings at some locations to determine if shallow locations had significantly different bivalve populations than their adjacent channel stations. In order to focus on the low salinity zone and it’s nearby habitat, we further parsed the strata into the following regions (Figure 2): Grizzly/Honker Bays (≤4m), Shallow Suisun Bay (not in channel and <7m), Channel Suisun Bay, Lake (Big Break and Sherman Lake with adjoining sloughs), Western Suisun Marsh (Suisun Slough, Montezuma Slough west of Nurse Slough), Eastern Suisun Marsh (Montezuma Slough east of Nurse Slough), and Confluence (Sacramento River up to Browns Island, San Joaquin River to False River out of Franks Tract).

Samples were sieved through 0.5mm screens, preserved in 10% formalin in the field, and changed to 70% alcohol at 1-2 weeks. Samples of live bivalves were collected at annual panel stations to estimate weight as a function of length; clams were measured, dried, weighed, ashed, and reweighed to determine ash-free dry weight (AFDW). Samples were sorted by a contractor (Hydrozoology) and returned to DWR. Bivalves from all samples were measured using an image analyzer or hand calipers and length of each animal in each sample was converted to AFDW using the live animal length to weight conversions calculated at the annual panel stations. Biomass at a station was estimated by summing these values.

Consumption rate was estimated two ways. The first rate, the filtration rate, is the highest consumption rate that we would expect. Filtration rate is the product of bivalve biomass and species specific pumping rates (PR's) which were adjusted for temperature. *Potamocorbula* pumping rates have been estimated at two temperatures to be ≈400 L $(gAFDW)^{-1}d^{-1}$ at temperatures ≥15°C and 270 L $(gAFDW)^{-1}d^{-1}$ at temperatures <15°C (Cole et al. 1992). *Corbicula* pumping rate was determined at four temperatures by Foe and Knight 1986) and data were fitted to an exponential model which was then used to determine temperature specific pumping rates. Filtration rates assume no depletion boundary layer (the local reduction in food concentration when vertical mixing rate is too low to compensate for the loss due to consumption at the bed) and that animals filter all of the time. The second rate, the grazing rate, incorporates a concentration boundary layer and is smaller than the filtration rate when there are large populations. Filtration rates were converted to grazing rates by reducing the pumping rates to adjust for the presence of a concentration boundary layer. This adjustment was based on O'Riordan's (1995, Figure 7b) refiltration relationship, $n_{max} = F_c/(s/d_o)$, where $n_{\max}$ is the maximum refiltration proportion (ie the proportion of water previously filtered), F_c is a species specific refiltration factor determined in the laboratory for *Potamocorbula* (2.5) and *Venerupis* (3.0, similar to *Corbicula* in size and habit), s is the distance between siphon pairs, and d_0 is the diameter of the excurrent siphon. The diameter of the excurrent siphon was changed throughout each year to reflect the change in average size of animals as the year progressed, and the distance between siphon pairs was based on density of animals observed in our benthic sampling assuming equidistant spacing within the 0.05 m^2 grab. The use of maximum refiltration proportion maximizes the effect of the concentration boundary layer resulting in a conservative grazing rate estimate. The combined use of filtration rate and grazing rate should give a reasonable range of possible consumption rates. We assumed all bivalves grazed continuously.

Data and Approach

Biomass, filtration rate, grazing rate and grazing rate water column turnover rate have been calculated for each region and are summarized in Tables 1-4. Water column turnover rate is a method of normalizing grazing and filtration rates by depth of the water column. The resulting number is more intuitive of the bivalves effect on pelagic particles (biologic and refractory) than grazing rate because it reflects the number of times in a day that a population could filter the overlying water column if the water was stationary. With this value, the importance of water depth becomes apparent; if it is assumed that the same population lived on the bottom of a 1m vs a 10m water column, the bivalves would filter the 1 m water column ten times the rate at which they filter the deeper water column.

The data are not normally distributed and regions have unequal number of samples so non-parametric measures of statistical significance (Kruskal-Wallis) have been used to compare regions and time periods. As with most benthic data, the median value is shown in plots because it is the best way to eliminate the influence of one very high or very low value in a region.

Findings

General Distribution Patterns

When the entire sampling domain with the data from all three years is combined, there are several observations that can be made about persistent patterns that don't seem to be affected by water year type (Figures 3 and 4a). First *Potamocorbula* has a larger presence, and thus larger filtration rate in fall than spring, and the opposite is true of *Corbicula*. Second, *Potamocorbula* have very low filtration rates in the spring in the shallows of Grizzly and Honker Bays for all three years. Third, filtration rates for both bivalves in the lower reaches of Sacramento and San Joaquin Rivers (just upstream of confluence) are consistently lower than the surrounding areas and there appears to be less seasonality in this region than in the rest of the system.

These persistent distribution patterns become even more apparent when we narrow the focus to the LSZ (Figure 4b). We can also see that the area where the two bivalve species overlaps can be described as within and just upstream of the confluence and on the eastern end of Montezuma Slough (east of Nurse Slough). When the distributions are plotted separately for each year (Figure 5a) and compared for May and October we see that the zone of overlap in May is within the range of X2 over the previous 6 months with a few exceptions in 2009-2010. In 2011 *Potamocorbula* were consistently upstream of the maximum X2 in the previous 6 months. This pattern persists into fall 2011 with *Potamocorbula* being observed upstream of the X2 maximum in all years (Figure 5b). Unlike May 2011, the October 2011 distribution showed some *Corbicula* within the X2 range.

Differences between years in regions (Fall 2009-2011)

When the filtration rates, grazing rates, and water column turnover rates are compared between years within the regions, only the values in the Grizzly/Honker Bay shallows and the Western Suisun Marsh showed a statistically significant difference between years (Kruskal-Wallis, $p<0.05$). Grizzly/Honker bay biomass, filtration, grazing, and turnover rates were all similar in 2009 and 2010 but were significantly less in 2011 than in 2010 (Figure 6a, 6b). The western Suisun Slough rates were similar in 2009 and 2010 but the 2011 rates were different from both the 2009 and 2010 rates (Figure 7a, 7b). The location of these decreased grazing rates is important as we might expect pelagic primary producers to do best in the shallows of Grizzly and Honker Bays and we might expect that marsh production would have a better chance of reaching other consumers when the bivalve grazers were greatly reduced as seen in 2011.

Differences between areas in years (Fall 2009-2011)

Because we are most interested in the effect that the bivalve grazers have on the system, we will show grazing turnover rates in this section (data for other parameters are in tables 1-4). The pattern and values for grazing turnover rate were similar in 2009 and 2010 with the shallow regions, Grizzly/Honker Bay, Suisun Bay Shallow, and West Suisun Marsh, having much higher values than the remaining areas that are mostly upstream or deeper than these stations (Figures 8 and 9). The bimodal distribution of values highlights the significant differences in these groups. The Confluence region had significantly lower turnover rates than those observed in Grizzly/Honker Bay and in the West Suisun Marsh in both 2009 and 2010. The West Suisun Marsh also had significantly higher rates than were observed in Suisun Channel in 2009 and 2010. In addition the Confluence rates were significantly lower than the Grizzly/Honker Bay rates and the West Suisun Marsh rates were significantly higher than the rates in the Lakes region in 2010 Figure 9).

Grazing turnover rates in 2011were lower and the bimodal distribution of values was less pronounced. There were no significant differences between the regions with the median values fell between 0.1 and 0.5 d^{-1} (Figure 10).

Time Series in Grizzly/Honker Bay Shallows

Figures 11 and 12 show the full time series (May 2009-October 2011) for all parameters for the Grizzly/Honker Bay region. Because the shallow areas are the presumed source of locally grown phytoplankton, grazing in this region is the most likely to have an effect on net phytoplankton growth.

Biomass, filtration rate, grazing rate, and grazing rate turnover rate all show the same strong seasonal pattern which is expected since all values are derived from biomass. In this region, where the bivalves are almost all *Potamocorbula*, filtration rate is derived from biomass with one conversion factor. It should be noted that in other regions, where *Corbicula* and *Potamocorbula* occur together the conversions are less linearly related to biomass.

Spring filtration rates (medians of 0.2-0.3 m d^{-1}) are about an order of magnitude less than fall filtration rates (2, 4, and 1 m d^{-1}). Grazing rates showed a similar pattern with spring rates (0.2, 0.3, and 0.1 m d^{-1}) an order of magnitude less than fall rates (2, 3, 1 m d^{-1}). Grazing water column turnover rate was very low with populations needing 10-20 days to totally turnover the water column in spring (0.1, 0.1, 0.05 d^{-1}). Fall grazing turnover rates were much higher with populations turning over the water column every 1-2 days (0.6, 1, 0.4 d^{-1}). If we assume a spring phytoplankton growth rate of 0.5-0.6 d^{-1} (Kimmerer et al in press) we can state that the bivalves were unlikely to be a controlling factor on spring phytoplankton biomass accumulation in any year. Fall phytoplankton growth rates have not been recently measured but summer rates (0.7-1.0 d^{-1}) would be about equivalent to the loss rates by bivalves in 2009-2010 but not in 2011 when bivalve turnover rates (0.4 d^{-1}) were unlikely to limit a bloom from developing in the shallow water.

Significance of Findings

We saw a decline in bivalve biomass and therefore grazing rate during and following the increased freshwater flow in spring and fall 2011. In examining the shallow Grizzly and Honker Bay data we found that bivalve grazing was unlikely to have an impact on net phytoplankton growth in spring during any of the years examined (2009-2011). We also found that the fall grazing rates were sufficient to potentially limit phytoplankton biomass accumulation in 2009-2010 but not in 2011.

The reduction in bivalve biomass and therefore grazing in 2011 could be due to recruitment losses in spring or fall and our ongoing work with the monitoring station samples should help delineate the cause. We were surprised by the persistence of *Potamocorbula* in the confluence area in 2011 despite the down bay position of X2. Our present working hypothesis is that it is the salinity gradient and therefore change in salinity over short periods of time that is important in determining the distribution of both species rather than the absolute salinity at a location. If true, this hypothesis would support the presence of *Potamocorbula* upstream of X2 in spring 2011.

Next Steps

Fall Study: We will measure bivalves and calculate biomass, filtration rate and grazing rate of the bivalves in the May and October 2012 GRTS samples when the samples have been sorted. We are presently measuring bivalves in the monitoring stations to better determine the seasonality of recruitment of both species and to determine if there are interannual and spatial differences in recruitment. Recruitment patterns are a critical component in our understanding of why bivalves have limited success in some areas and during some periods. We are submitting abstracts for two posters for the Bay-Delta conference that will highlight what we learn about recruitment for each species.

HSG Study: We are finishing the analyses of the May 2011 data and when that is complete we will repeat the analysis done here on the samples from throughout the study domain. The values reported will include biomass, grazing and filtration rates, and recruit abundance and the analysis will include the effect of depth on these rates for each species.

The combination of analyses in both studies will give us an opportunity to examine if and when populations that settle in the fall are still present in spring and if these "carry-over" populations are adding a new dimension to the bivalve community seasonal patterns.

Delta Chinook Final Report

Curry Cunningham, Noble Hendrix, Eva Dusek-Jennings, Robert Lessard and Ray Hilborn

EXECUTIVE SUMMARY

This project developed a stage-structured life history model of summer, spring and winter run Chinook salmon, fitted this model to available data on salmon stock abundance and environmental conditions, and estimated the impact of the environmental conditions on survival of the different stocks of Chinook salmon. This model was then used to forecast how differences in future climate change, marine conditions or productivity, and water exports would affect the survival of the different stocks of Chinook salmon.

We used several statistical techniques to evaluate the relative importance of environmental variables on the survival including both information theoretic approaches and Bayesian approaches. Due to the large number of potential explanatory covariates (59) and the inability to fit all combinations of these covariates, we used Akaike Information Criterion for small sample size (AICc) and a novel method for exploring the model space. The approach used a forward stepwise model building with AICc as the selection criteria. The steps were: 1) fit a null model without any covariate effects to the available data; 2) construct a proposal model by selecting a covariate at random from amongst the set of 59 possible covariates; 3) fit the proposed model to the data; 4) compare the proposal model to the null model; 5) keep proposal model if reduction in AICc value is greater than 2 units; 6) repeat sampling covariates without replacement, fitting the model to data, and evaluating AICc i.e. until all covariates have been tested.

Using the information theoretic approaches we found support for environmental impacts of 14 variables including flow, temperature, sediment concentration, export inflow ratios, exports, ocean upwelling, curl and PDO. The top three environmental drivers affecting fall run were export to inflow ratio, spring upwelling south of the Farallon Islands, and the delta gross channel depletion. The top three drivers affecting spring run were size at Chipps Island, export levels, and sediment concentration at Freemont. The three main factors affecting winter-run were minimum flow during fry rearing, temperatures during egg incubation, and spring upwelling south of the Farallon Islands. We then conducted a Bayesian analysis using these 14 variables to calculate the posterior distribution of the impact of these variables on survival.

We conducted forward simulations under four different export regimes to understand how management of exports would affect each of the races. Furthermore, we evaluated export management under two different climate scenarios and two ocean productivity scenarios to understand how climate variability and ocean productivity may act in concert with management of exports to affect the three Chinook runs. We developed a harvest model that reflected current management of the Central Valley Chinook stocks in which low levels of winter run escapement can reduce fall run harvest.

We found that both climate and exports affected projected survival and the potential recruits per spawner for wild populations. Under current export levels all stocks of spring run would increase across all climate scenarios tested. Winter run would increase except under the most pessimistic of the four climate conditions we evaluated. Mainstem Fall run would have recruits per spawner greater than 1 under the two optimistic climate scenarios and less than 1 under the two pessimistic climate scenarios although the future trend in mainstem fall chinook could be heavily influenced by straying from hatcheries and thus hard to predict. A 30% increase in exports decreased spring and fall stock survival to the point where they would all decline regardless of the climate scenario. A 30% decrease in exports improved survival and recruits per spawner for all stocks.

We found spring Chinook stocks to be most sensitive to exports and less sensitive to climate conditions, whereas winter Chinook were more sensitive to climate conditions than exports.

We did not evaluate alternative ocean harvest scenarios, although reduction or elimination of ocean harvest would increase survival to spawning and thus contribute to rebuilding in the same way as better climate or reduced exports.

INTRODUCTION

Salmon populations in the Sacramento River are far below historical numbers. Fisheries closures have been implemented to protect spring-run Chinook (SRC), winter-run Chinook (WRC), and even fall-run Chinook (FRC), which until 2005, had been considered a healthy stock. The FRC was the staple of the California salmon fishery, has been closed in several years. The FRC have been the most heavily subsidized with hatchery fish. The impact on commercial and recreational fisheries has been dramatic. A variety of reasons in both freshwater and marine environments have been cited as causes of the decline, but it appears that salmon have been subjected to something of a “perfect storm” of deleterious effects, both natural and anthropogenic in origin.

Historically both WRC and SRC used the upstream, higher altitude tributaries of the Sacramento River, but the current extent of accessible freshwater habitat differs greatly and their lower abundances have led to concern and listing by both state and federal agencies (Yoshiyama et al. 1998, 2000, Lindley et al. 2004). WRC and SRC were separated both temporally and geographically in their spawning habitat. Winter-run historically used the headwater springs, spawned in the early summer, emerged from the gravel in late summer, emigrated over the winter, and entered the ocean the following spring (Lindley et al. 2004). Development of eggs was dependent on relatively constant flow and cool temperatures of the spring fed streams. Currently, WRC are confined to spawning in the Sacramento River. SRC used the high spring flows to reach the upper tributaries of the Sacramento in summer and waited out the summer in high elevation pools. Spawning commenced in the fall and juveniles emerged the following spring. Stream residency varied and could last over a year. Out-migration occurred in both spring and fall depending upon time of residency. There are currently several extant subpopulations of SRC. Lindley et al. (2004) suggest that there are four principle groupings that might form the basis of a meta-population structure: 1. Winter-run, 2. Butte Creek spring-run, 3.

Deer and Mill Creek spring-run, 4. Fall-run, late fall-run and Feather/Yuba spring-run. Since several of these runs overlap in their usage of stream and mainstem habitat, it is reasonable to consider that they may compete for resources and therefore a modeling approach that accounts for these overlaps could improve the precision of population predictions. Additionally, variation in survival of one population can provide additional statistical ability to the estimation of environmental effects that influence both populations.

Over the past several decades, substantial resources have been devoted to the management of water resources, fisheries, and habitat in the San Francisco Bay-Sacramento River Delta (Bay-Delta) ecosystem in general, with particular attention being given to resident Chinook salmon runs. There has been increasing concern for species in decline, with the listing of WRC and SRC in the Central Valley (CV) under both federal (Endangered Species Act, ESA) and state laws. The exceedingly low return of FRC in 2008 led to a complete closure of salmon fisheries. Many studies have been conducted in an attempt to explain sources of mortality in freshwater and in the ocean. Tagging studies have shown extremely low survival in freshwater. Wells et al. (2007) showed strong associations between survival and ocean climate indices, providing evidence for a linkage between survival and primary productivity during the marine portion of the life cycle.

Fish interact with natural and anthropogenic aspects of their environment and there can be significant variation in such externalities. Decisions regarding fisheries management, water management and research direction should account for all significant and predictable sources of variation in those externalities where they have a measurable effect on survival. What is lacking is an integrative model that can provide a level of detail in water resource management and fishery management that accounts for interactions between salmon populations, both in the wild as well implicitly captured in the mechanics of fisheries policy.

Although mathematical models of salmon species have been developed both at the individual (e.g., Kimmerer 2001, Jager and Rose 2003) and the population (e.g., Botsford and Brittnacher 1998) level, management and research direction have been based primarily on qualitative compilations of what is known about individual salmon runs. Management would benefit from models that more closely link environmental conditions to biological response. Lessard et al. (*submitted manuscript*) built upon the general principle that survival could be broken down into life history stages so that the relevant environmental factors in each stage could be factored into the estimation of the productivity and capacity parameters that predict density dependence in survival rates. A series of competing models were compared using a statistical modeling and population dynamics platform (OBAN), each reconstructing population dynamics and estimating the relative effects of environmental conditions in freshwater and ocean stages. The study found that temperature, flow and exports explained most of the variation in freshwater. Historically, gate positions of bypasses and cross channels have explained some of the variation in survival, however, water management agencies have responded to biological needs and have in recent years adjusted the timing and magnitude of water redirection activities to mitigate negative effects on salmon. Wind stress curl, a primary productivity surrogate (Wells et al. 2008), was the leading factor explaining variation in ocean survival, although indices such as the Pacific Decadal Oscillation (Mantua et al. 1997) and sea surface temperature also explained variation in ocean survival, although not throughout enough of the timeframe of the study to be statistically competitive in model selection.

For the population dynamics portion of the project, we developed a multi-stock model of the three Central Valley Chinook salmon species-at-risk (WRC, SRC and FRC) that incorporates mortality in all phases of salmon life history, and includes the effects of uncertainty in assessing population status. The approach involves several categories of models: (1) the population dynamics models, (2) the parameter estimation model, (3) the growth model, and (4) the fisheries management model that calibrates fishing effort to the predicted runs of the individual populations.

PART I FITTING A STATISTICAL MODEL

METHODS; MODEL DESCRIPTION

The goal of this project was evaluate the environmental drivers of survival for Chinook salmon populations spawning in the Sacramento River, CA watershed, in a statistically rigorous manner. More generally, our purpose was to test a range of hypotheses describing the putative factors facilitating or limiting survival, factors both natural and anthropogenic in origin and describing both biotic and abiotic processes. To achieve this goal we have created a stage-structured population dynamics model, which estimates the direction and magnitude of influence that a range of these factors, or environmental covariates, have on survival through specific portions of the Chinook life cycle, when fit to available juvenile and adult spawning abundance data. The population dynamics model is currently used to explore the environmental drivers of survival for four fall-run populations including: 1) Mainstem Sacramento wild-spawning Chinook, 2) Battle Creek Coleman National Fish Hatchery produced Chinook, 3) Feather River Hatchery produced Chinook, and 4) American River Nimbus Hatchery produced Chinook, as well as three spring-run populations including: 1) Deer Creek, 2) Mill Creek, and 3) Butte Creek, wild-spawning Chinook.

The stage-structured population dynamics model described in this document compliments and expands upon previous analyses of interactions between environmental factors and survival of Chinook salmon populations of the Sacramento River watershed in several ways. First, while many previous analyses have modeled the survival or productivity of single components of the Sacramento River Chinook stock complex (i.e. (Newman and Rice 2002, Lindley and Mohr 2003, Newman and Brandes 2010, Zeug et al. 2012), fall-run (Newman and Rice 2002), late-fall-run (Newman and Brandes 2010), winter-run (Lindley and Mohr 2003, Zeug et al. 2012)) in isolation, the current population dynamics model is applied to multiple populations of both spring-run and fall-run Chinook and evaluates interactions between these populations at points in the life cycle where co-rearing and co-migration occurs. Second, the current population dynamics model approximates both wild and hatchery type life histories, utilizing historical records of hatchery releases from the Coleman National Fish Hatchery on Battle Creek, the Feather River Hatchery, and the Nimbus Fish Hatchery on the American River compiled by Huber and Carlson (in review). Third, we have utilized estimates of stray rates between hatcheries and wild populations of fall-run Chinook available from the proportional coded wire tagging program (Kormos et al. 2012, Palmer-Zwahlen and Kormos 2013), to reconstruct spawning abundance data in the presence of straying, prior to fitting the estimation model. Fourth, while previous analyses have primarily evaluated survival variation in either the freshwater or marine portions of the Chinook life cycle, we have created a population dynamics model with both marine and freshwater stages, permitting the testing of competing hypotheses for putative survival influences in all habitats utilized by Sacramento River Chinook. Fifth, while previous stage-structured population dynamics models used to evaluate the interaction between environmental factors and the survival of Sacramento Chinook including Zeug et al. (2012) have defined these interactions based upon a priori information or findings from other systems or laboratory experimentation, the population dynamics model we have created is statistical in nature, estimating the effect of the hypothesized environmental drivers of survival based upon historical variation observed in adult and juvenile abundance. The result is a flexible multi-stock, stage-structured, statistical, population dynamics model that estimates the influence of natural and anthropogenic environmental factors on survival of Chinook salmon throughout their life cycle, using both Bayesian and Maximum Likelihood methods.

The Data

In order to estimate the effect of various environmental covariates as well as basal productivity and capacity for the seven populations in specific life stages, the estimation model is conditioned on different types of data available for the Sacramento River system. The first type of data that are required by the estimation model are time-series of explanatory environmental covariates. For each environmental covariate being evaluated for its influence on Chinook survival, it is necessary to provide, a historical record of its value over time as a model input. Covariate data are z-standardized (Zar 2010) based upon the mean and standard deviation of the time-series (Eq. I.1).

(I.1) $$X_{t,i} = \frac{x_{t,i} - \sum_{t=1}^{Nt} x_{t,i} / Nt}{\sigma_i}$$

In this way, the ith covariate at time t ($x_{t,i}$) is transformed into units of standard deviations from the time-series mean, rather than untransformed values that span many orders of magnitude among covariates. By transforming covariate data into the same units, the magnitude of subsequently estimated coefficients describing the influence of individual covariates are more readily comparable and estimable.

Potential covariates were chosen for evaluation within the estimation model based upon first principals and a valid biological rationale for why each might be expected to influence either survival rate or stage-specific capacity. Covariates were developed came from a wide range of sources, including a review of the pertinent literature and expert opinion, and were created using data from the period of time throughout the year over which they were expected to exhibit the greatest influence (Table I.1).

TABLE I.1. Environmental covariates

Hypothesis Number	Covariate	Covariate Description	Location	Populations
1	fall.sac.mainstem - sacAirTemp.summer	Sacramento air temperature during summer (July - September) of the brood year	Sacramento, CA	Fall Sacramento Mainstem Wild

The second type of data required are time-series of abundance data for the populations included in the multi-stock population dynamics model. Estimates of the number of adult Chinook returning to natural spawning grounds and hatcheries are available from the GrandTab database (CDF&W 2014) for all seven populations evaluated as part of this study. However, since the Central Valley Constant Fractional Marking Program (CFM) was initiated in 2007, it has been possible to estimate the contribution of hatchery-origin Chinook to the spawning abundance observed on wild spawning grounds and the contribution of wild-origin Chinook production to observed returns to regional hatcheries (Kormos et al. 2012). Historical abundances for the seven Chinook populations were reconstructed to account for straying between hatcheries and natural spawning grounds, using the average of the estimated proportion of observed adult Chinook straying in 2010 (Kormos et al. 2012) and 2011 (Palmer-Zwahlen and Kormos 2013). Average (2010-2011) proportions of observed adult abundance that were comprised of hatchery and wild individuals in each population (Table I.2), were used to reconstruct historical abundances for the fall-run spawning populations.

Location	Origin	Recovery	2010	2011	Average
Upper Sacramento	Hatchery	Wild	20%	27%	**24%**
Battle Creek	Hatchery	Wild			
	Wild	Hatchery	11%	11%	**11%**
Feather River	Hatchery	Wild	78%	90%	**84%**
	Wild	Hatchery	5%	4%	**5%**
American River	Hatchery	Wild	32%	66%	**49%**
	Wild	Hatchery	21%	23%	**22%**

Table I.2. Proportion of observed adult abundance by location estimated from CWT recoveries to be of wild or hatchery origin in 2010 and 2011, and the average used to reconstruct historical abundances.

For example, in order to reconstruct the fall-run wild Sacramento mainstem population spawning abundance, each year 24% of the observed spawning abundance was remove and reallocated to the Coleman National Fish Hatchery (Battle Creek) adult abundance, while 11% of the observed Battle Creek hatchery (CNFH) abundance was removed as wild migrants into the hatchery (Fig. I.1).

	wild	wild	hatchery	wild	hatchery	wild	hatchery

Figure I.1. Empirical schematic showing how the historical abundance of the 1967 population for the four fall-run Chinook populations were reconstructed through additional or removal of the abundance of other stocks.

Adult abundances for the four fall-run Chinook populations were reconstructed using the methods detailed above for years 1967 – 2010 (Fig. I.2). Existing adult abundance estimates reported by CDF&W (2014) for the spring-run populations included in our analyses (i.e. Deer, Mill, and Butte Creeks) were assumed to be minimally impacted by hatchery straying and therefore unaltered (Fig. I.2).

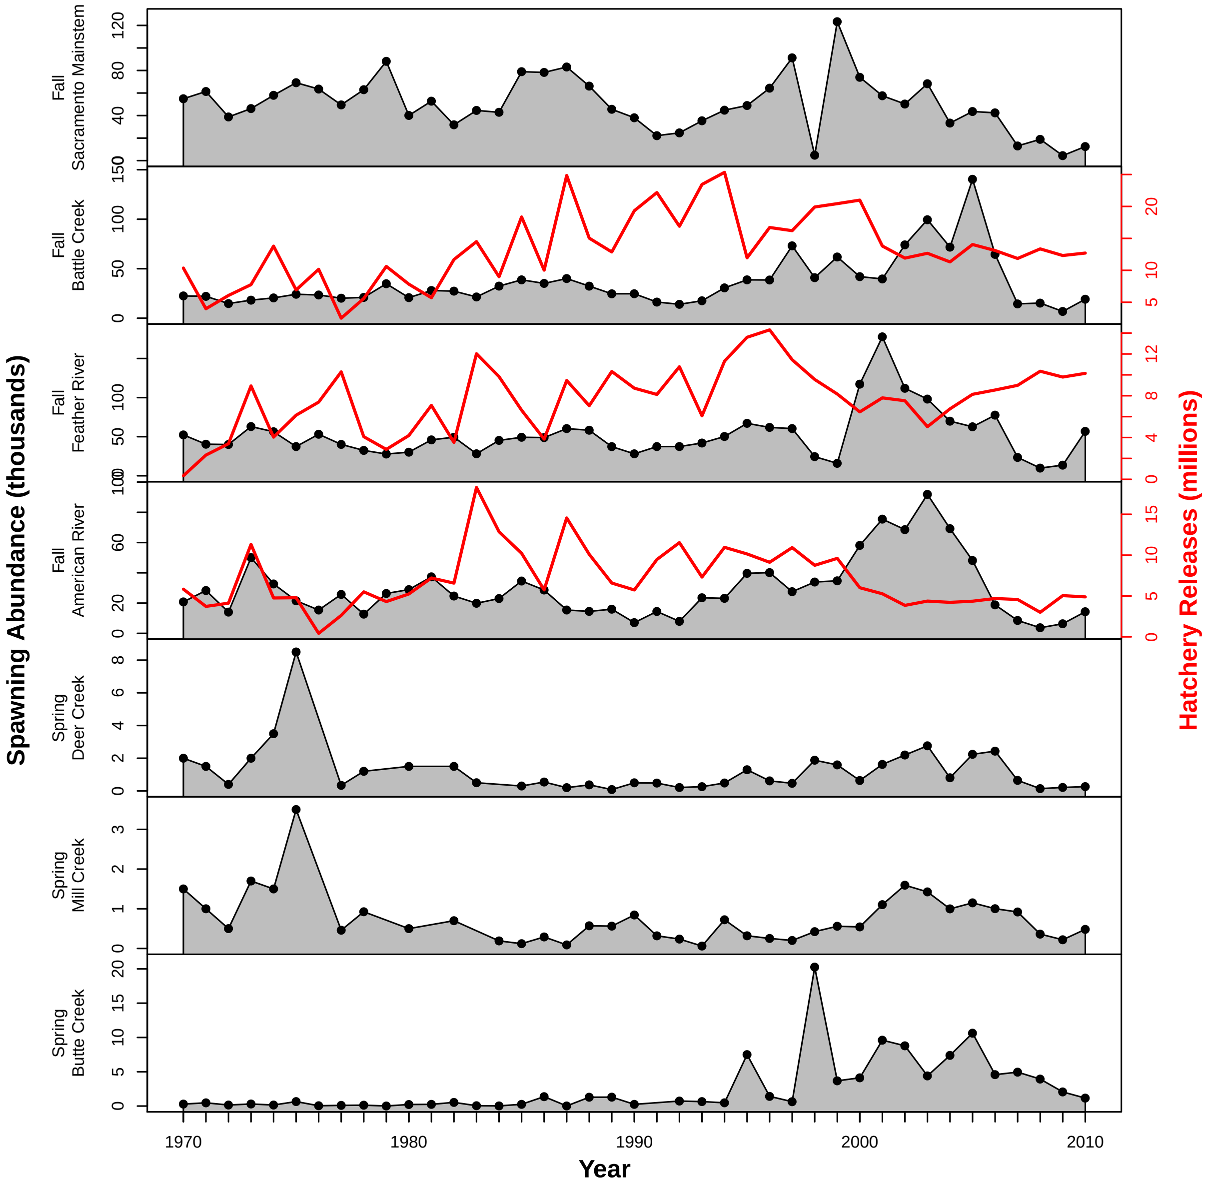

Figure I.2. Adult abundance (grey area plot) and hatchery release (red line) data for Sacramento River Chinook. Fall-run abundances are reconstructed based upon hatchery-wild stray rate estimates, while spring-run abundances are as reported in GrandTab 2014.

Estimates of juvenile Chinook abundance in Sacramento River system were also used to inform estimates of model parameters. The inclusion of additional abundance indices to which the estimation model is fit, confers a greater ability to partition mortality between life stages and more precise estimation of the strength and magnitude of influence from environmental covariates. Poytress et al. (2014) have used available trap efficiency information to calculate absolute abundance indices for juvenile Chinook passing Red Bluff Diversion Dam, partitioned by race. Fall-run juvenile Chinook abundance estimates from 2002 forward were assumed to be comprised predominantly of two populations, the wild Sacramento Mainstem population and the Battle Creek (CNFH) Hatchery population. Therefore, model estimates of the combined abundance of these two populations were compared to the estimates provided by Poytress et al. (2014) in likelihood calculations.

The third type of data required by the estimation model are historical hatchery releases. As constructed, the estimation model allows for specification of the wild or hatchery life-history type for each population. Three of the seven populations currently in included in our analysis are of hatchery origin, therefore annual hatchery release numbers were required for the Battle Creek (CNFH) Hatchery, Feather River Hatchery, and American River (Nimbus) Hatchery populations. Huber and Carlson (in review) have expended significant time and effort to digitize and render historical hatchery reports in an easily accessible and usable format. For the three hatchery population included in our analysis, we have used these hatchery release data to in place of the functional relationship between spawning abundance and fecundity assumed for the wild spawning populations. Figure I.2 shows hatchery release numbers from Huber and Carlson (in review) for each of the three fall-run hatchery populations.

Hatchery release practices have historically differed amongst facilities and over time, with on-sight releases, releases in the Sacramento-San Joaquin delta, releases in San Francisco Bay, and many locations in between (Huber and Carlson in review). At this time, hatchery release location was not specifically considered. However, for populations whose release strategies allow fish to bypass the mortality incurred in the upriver stage, this should manifest as a reduction in the estimated influence of covariates linked to the upriver stage. In this way, although we do not specifically adjust the model stage pathway depending on hatchery release location in each year, this should not be expected to introduce any significant bias in our estimates of coefficients describing the influence of environmental covariates.

The fourth type of data required for these analyses were annual estimates of harvest rate by population. Harvest rate estimates are available from the U.S. Fish and Wildlife Chinookprod database. For each population of interest, this database uses both the abundance estimates from the Grandtab (CDF&W 2014) database and ocean harvest numbers from the Pacific Fishery Management Council (PFMC) to calculate harvest rates in the marine and in-river regions. For our purposes, we have calculated the total harvest rate by stock and year as the sum of ocean ($C_{t,p}^{ocean}$) and in-river catch ($C_{t,p}^{in-river}$), divided by the total abundance including observed escapement ($E_{t,p}$) and catches for that population (p) in that year (t) (Eq. I.2).

(I.2) $$hr_{t,p} = \frac{C_{t,p}^{ocean} + C_{t,p}^{in-river}}{E_{t,p} + C_{t,p}^{ocean} + C_{t,p}^{in-river}}$$

Estimation model structure

The purpose of our analysis is to test the various hypotheses regarding what natural and anthropogenic factors have influenced Sacramento River Chinook salmon survival historically, during both the freshwater and marine portions of the Chinook life cycle. Furthermore, we wish to use estimates of the drivers of Chinook survival to generate robust predictions for future abundance under a range of alternative climate change, oceanographic, and water management scenarios. In order to achieve this objective we have created a population dynamics model that estimates the influence of environmental covariates as well as population-specific basal productivity (maximum survival) rates and rearing capacities for different stages in the life cycle.

The statistical population dynamics model is stage-structured, simulating the entire Chinook life cycle from egg to spawning adult, and partitioning mortality events between those separate spatio-temporal stages. For the freshwater portion of the life cycle, these stages are defined by the migration pathways exhibited by the various Chinook populations and the availability of two data types. First, freshwater life stages are defined in accordance with the availability of environmental covariate data, so as to accurately reflect the point in time and location within Sacramento River network where the Chinook have the most substantial exposure to the environmental covariates. Second, model stages are structured to correspond with juvenile indices of abundance at Red Bluff, CA (Poytress et al. 2014). The estimation model contains six stages, three associated with juvenile rearing in freshwater and nearshore regions, and three associated with the marine component of the life cycle (Fig. I.3). The first stage represents rearing of juveniles in tributaries and upper reaches of the Sacramento River mainstem. The second model stage represents the area within the Sacramento River watershed including the Sacramento-San Joaquin Delta through Chipps Island. The third stage represents juvenile rearing in the nearshore region from San Francisco Bay and the Gulf of Farallones. Stages 4-6 represent the years spent in the marine environment, with associated probability of maturation and potential for ocean harvest.

Figure I.3. Map of estimation model stage structure.

The population dynamics model tracks cohorts of Chinook from specific brood years forward in time across sequential model stages. Chinook abundance is represented by $N_{y,s,p}$ or the number of individuals from brood year y, surviving to stage s, of population p. The abundance of Chinook of brood year y and population p, surviving to the end of the current stage (s) is dependent upon the year, stage, and population specific survival rate $SR_{y,s,p}$ in Equation I.3.

(I.3) $$N_{y,s,p} = N_{y,s-1,p} * SR_{y,s,p}$$

Survival though the spatio-temporally explicit life stages is described by a Beverton-Holt transition function (Moussalli and Hilborn 1986). The Beverton-Holt equation, while traditionally used in the evaluation of spawner-recruit data (Beverton and Holt 1957), provides a useful approximation for survival of individuals from one model stage to the next, as influenced by two factors: 1) the productivity rate $p_{y,s,p}$, and 2) the rearing capacity $K_{y,s,p}$ of each stage (Eq. I.4).

(I.4) $$SR_{y,s,p} = \frac{p_{y,s,p}}{1 + \frac{p_{y,s,p} * \sum_{i=1}^{Npop} \alpha_{p,i,s} * N_{y,s-1,i}}{K_{y,s,p}}}$$

In this formulation (Eq. I.4) the year, stage, and population-specific productivity ($p_{y,s,p}$) represents the maximum survival rate in the absence of density-dependent compensation.

Conversely, the year, stage, and population-specific capacity ($K_{y,s,p}$) describes the total number of individuals that can potential survive through the model stage. However, given that we are evaluating multiple co-migrating and co-rearing populations, equation I.4 also includes an interaction effect ($\alpha_{p,i,s}$) which describes how many individuals of the focal population p are displaced with respect to the stage capacity ($K_{y,s,p}$) for each individual of population i. In this way no interaction effect for a stage may be specified with a zero value for all elements of $\alpha_{p,i,s}$ except $\alpha_{p,i=p,s}$. Positive, non-zero values indicate that the abundance of other populations (i) results in a reduction in overall rearing capacity for the focal population (p), and therefore reduced survival at high abundance levels which approach the stage-specific capacity ($K_{y,s,p}$). Specifying $\alpha_{p,i,s}$ elements equal to one create a situation where capacity is shared across populations with symmetric impacts on capacity.

In our current analysis we have identified the Sacramento-San Joaquin Delta stage (2nd) and nearshore stage (3rd) as points of possible competition and therefore capacity interactions within the model. Fall-run and spring-run juvenile Chinook are assumed to compete with members of their own race within these two stages of the life cycle and therefore shared capacities are assumed, with symmetric interactions (i.e. $\alpha_{p,i,s}$ elements equal to 1).

The productivity ($p_{y,s,p}$) capacity ($K_{y,s,p}$) parameters in the population dynamics model are time varying and assumed to change in response to inter-annual variation in the environmental covariates under evaluation. The productivity parameter for population p, of brood year y, in stage s is a function of the basal productivity $\beta_{s,p,0}$, or the average survival for members of that population in the current stage, as well as the sum of environmental covariate c values at time t ($X_{t,c}$) multiplied by their respective coefficients ($\beta_{s,p,c}$) which describe the influence of each covariate on stage and population-specific productivity $p_{y,s,p}$ (Eq. I.5).

$$p_{y,s,p} = \frac{1}{1 + \exp\left(-\beta_{s,p,0} - \sum_{c=1}^{Nc_{s,p}} \beta_{s,p,c} * X_{t,c}\right)} \qquad \text{(I.5)}$$

$$t = y + \delta_c$$

δ_c is the covariate-specific temporal reference which is the difference between the brood year y and the year in which the cohort will interact with that covariate, and is used as a pointer to ensure that the covariate value for the correct year is used when tracking each cohort forward in time, and $Nc_{s,p}$ is the number of productivity covariates linked to each population in each stage. The overall productivity parameter value ($p_{y,s,p}$) is a logit transformation of the additive effects of the basal productivity rate and covariate effects, which ensures that its value is smoothly scaled between 0 and 1 (Eq. I.5).

The capacity parameter for each population's brood year specific cohort in each stage ($K_{y,s,p}$) is likewise a function of a basal, or average, stage and population specific capacity across years ($\gamma_{s,p.0}$) and the additive effects of capacity-related covariates ($Y_{t,k}$) and the population-specific coefficients ($\gamma_{s,p.k}$) describing the magnitude and direction of influence each holds (Eq. I.6).

(I.6)
$$K_{y,s,p} = \exp\left(\gamma_{s,p,0} + \sum_{k=1}^{Nk_{s,p}} \gamma_{s,p,k} * Y_{t,k}\right)$$
$$t = y + \delta_k$$

The capacity parameter ($K_{y,s,p}$) is described in natural log space for ease of estimation and to ensure it is bounded within the set of positive values, where k is the covariate reference number and δ_k is the temporal reference for the offset from the brood year for each covariate, indicating when the population interacts with each specific covariate in the life cycle.

However, for populations of Chinook occupying the same habitats and subject to the same environmental covariates, it may be reasonable to assume that a common response in survival to a particular covariate is exhibited. For this reason we have further allowed for a coefficient describing the effect of a particular covariate to be shared across populations. In this way several productivity ($\beta_{s,c}$) capacity ($\gamma_{s.k}$) coefficients may be common across a subset of populations. This reduces model complexity, increases parsimony, and improves the ability to estimate of coefficient values for which a common survival response is biologically defensible.

The basal capacity parameters for a population ($\gamma_{s,p.0}$, see Eq. I.6), or group of interacting populations for which $\alpha_{p,i,s} > 0$ (see Eq. I.4), represent the maximum rearing capacity for that population in that stage over time in the absence of influence from environmental covariates. For populations that are currently well below historical abundance levels, or for populations without subsequent juvenile abundance estimates, it is often difficult to estimate these basal stage capacity values. However, auxiliary information may be used to inform these stage-specific capacities. Recent work by Noble Hendrix, in collaboration with researchers at NOAA, has resulted in monthly juvenile Chinook salmon capacity estimates for the Sacramento River mainstem and the Sacramento-San Joaquin Delta (Hendrix et al. 2014). In place of estimating stage capacities for: 1) Sacramento River mainstem-spawning wild fall-run Chinook in the upstream stage (1st), 2) mainstem-spawning wild, Battle Creek (CNFH) hatchery, Feather River Hatchery, and American River (Nimbus) Hatchery, populations in the Sacramento-San Joaquin Delta stage (2nd), and 3) Deer, Mill, and Butte Creek populations in the Sacramento-San Joaquin Delta stage (2nd), we have used capacity estimates available from NOAA in-stream Chinook capacity modelling (see Appendix A - Delta Submodel). The average of estimated monthly capacities in the Sacramento Mainstem for the period between January and April in each year, was used for as the input capacity for mainstem-spawning wild fall-run population. The average of estimated monthly Sacramento – San Joaquin Delta rearing capacities for the March – May and February – April periods, were used as the input capacities for the fall-run and spring-run populations in that stage, respectively.

Capacity estimates for the Sacramento-San Joaquin Delta from NOAA in-stream Chinook habitat capacity modelling were only available after 1980 (Hendrix et al. 2014). Given that our population dynamics model begins in year 1967, it was necessary to assume a fixed capacity for the period prior to 1980. NOAA Delta capacity estimates correlate most directly with water year type, therefore the average of estimated capacities for the fall-run and spring-run populations by water year type were calculated and used in place of actual capacity estimates prior to 1980. These average capacities by water year type and Chinook run type were used in years prior to 1980 based on the reported water year.

Survival for cohorts of Chinook is tracked forward in time across spatio-temporal model stages in the same manner (Eq. I.4, I.5, I.6) independent of whether the stage is in the freshwater or marine portion of the life cycle and independent of the ontogenetic status of individuals. However, for the final three model stages representing the 1st, 2nd, and 3rd year in the ocean, it is necessary to account for both the maturation process and marine harvest when tracking the number of individuals entering the next stage. Harvest mortality is assumed to occur after the annual mortality event, but prior to maturation. Catch by year, population, and stage ($C_{t,p,s}$) is the number of surviving individuals multiplied by the population specific harvest rate observed in each year ($hr_{t,p}$), scaled by the stage (i.e. ocean age) specific catchability coefficient (ε_s) (Eq. I.7).

(I.7)
$$\begin{gathered} C_{t,p,s} = N_{y,s,p} * SR_{y,s,p} * \left(hr_{t,p} / \varepsilon_s \right) \\ t = y + \rho_s \\ \varepsilon_s = \{0, 0, 0, 0, 1.54, 1.0\} \end{gathered}$$

In equation I.7, ρ_s is the temporal offset for model stages that indicates the difference between the brood year and the calendar year, so that the proper annual harvest rate may be referenced. Annual harvest rate estimates were obtained from the Pacific Fishery Management Council (PFMC).

For the three ocean life-stages, the number of individuals of a cohort moving to the next stage is governed by the survival rate ($SR_{y,s,p}$), annual catch estimate ($C_{t,p,s}$), and the maturation probability (ϕ_s) (Eq. I.8).

(I.8)
$$\begin{gathered} N_{y,s+1,p} = \left(N_{y,s,p} * SR_{y,s,p} - C_{t,p,s} \right) * \left(1 - \phi_s \right) \\ \phi_s = \{0, 0, 0, 0.1, 0.942, 1\} \\ t = y + \rho_s \end{gathered}$$

While the cohort specific survival rate varies over time, the maturation probability (ϕ_s) is assumed to be temporally invariant. So then, the number of individuals of a cohort advancing to the next ocean stage is the number in the previous stage ($N_{y,s,p}$) that have survived, less the proportion that matures and begins homeward migration (Eq. I.8). The return abundance ($R_{y,s,p}$) is the number of individuals from a cohort that survived marine and harvest mortality, and have initiated the maturation process and return to freshwater to spawn (Eq. I.9).

(I.9)
$$R_{y,s,p} = \left(N_{y,s,p} * SR_{y,s,p} - C_{t,p,s} \right) * \phi_s$$

The predicted number of spawning adults of each population in each year ($\hat{A}_{t,p}$) is the sum of returning individuals ($R_{y,s,p}$) across stages or equivalently ocean age classes (Eq. I.10).

(I.10) $$\hat{A}_{t,p} = \sum_{s=1}^{Nstage} R_{y,s,p}$$
$$t = y + \rho_s$$

Depending on whether a wild-type or hatchery-type life history is assumed for each population the next cohort ($N_{y,s=1,p}$) will be created either based on the predicted number of spawning adults and an assumed fecundity value of 2000 eggs/individuals (Eq. I.11) or based upon recorded releases from hatchery facilities (Eq. I.12).

(I.11) $$N_{y,s=1,p} = \hat{A}_{t=y,p} * fec$$

(I.12) $$N_{y,s=1,p} = RH_{t=y,p}$$

In order to estimate the value for model parameters including basal productivities ($\beta_{s,p,0}$) and capacities ($\gamma_{s,p.0}$) for each population in each stage, and coefficients describing the direction and magnitude of influence each environmental covariate has on either productivity ($\beta_{s,p,c}$) or capacity ($\gamma_{s,p.k}$) for individual populations or shared amongst populations ($\beta_{s,c}$ and $\gamma_{s,k}$), the model must be fit to available abundance data. We employ a maximum likelihood approach to compare abundance predictions with available data and estimate model parameter values (Hilborn and Mangel 1997). Predicted adult spawning abundances are calculated (Eq. I.10) as part of the population dynamics model. Absolute abundance estimates for juveniles are available for Chinook passing Red Bluff Diversion Dam (Poytress et al. 2014), and we assume that the mainstem Sacramento wild population and Battle Creek hatchery (CNFH) population comprise the majority of the juvenile fall-run Chinook sampled at this location, so the juvenile abundance estimate is calculated as the sum of these two populations (Eq. I.13)

(I.13) $$\hat{J}_t = \sum_{p=1}^{2} N_{y,s=1,p}$$
$$t = y + \rho_{s=1}$$

Model predicted adult spawning abundances are compared to empirical data, and model parameters are estimated by minimizing the negative log-likelihood of the model given the observed data (Eq. I.14).

(I.14) $$L_A\left(\Theta \mid A_{t,p}\right) = \prod_{t=1}^{n} \frac{1}{\hat{\sigma}_p\sqrt{2\pi}} \exp\left[-\frac{\left(\ln(A_{t,p}) - \ln(\hat{A}_{t,p})\right)^2}{2\hat{\sigma}_p^2}\right]$$

The likelihood of the model parameters, given the spawning abundance data, assume a that observation error in log transformed abundances are normally distributed, with the standard deviation of the observation error distribution ($\hat{\sigma}_p$) equal to the maximum likelihood estimate (Eq. I.15).

(I.15) $$\hat{\sigma}_p = \sqrt{\sum_{t=1}^{n} \frac{\left(\ln(A_{t,p}) - \ln(\hat{A}_{t,p})\right)^2}{n}}$$

Under the same assumptions the observation error likelihood of the model parameters given juvenile abundance data (Eq. I.13) was calculated (Eq. I.16)

(I.16) $$L_J\left(\Theta \mid J_t\right) = \prod_{t=1}^{n} \frac{1}{\hat{\sigma}_J \sqrt{2\pi}} \exp\left[-\frac{\left(\ln(J_t) - \ln(\hat{J}_t)\right)^2}{2\hat{\sigma}_J^2}\right]$$

using the maximum likelihood estimate for the standard deviation of the normal observation error distribution from the juvenile data (Eq. I.17).

(I.17) $$\hat{\sigma}_J = \sqrt{\sum_{t=1}^{n} \frac{\left(\ln(J_t) - \ln(\hat{J}_t)\right)^2}{n}}$$

The total data likelihood (Eq. I.18) is the sum of the negative log of the likelihood from the juvenile and adult abundance data.

(I.18) $$LL_T = -\ln\left(L_A\right) - \ln\left(L_J\right)$$

Model parameter values that minimized the total negative log likelihood (LL_T) were found using AD Model Builder (Fournier et al. 2012). AD Model Builder (ADMB) is a software platform allowing complex non-linear minimizations for models containing a large number of parameters while also permitting profile likelihoods or posterior distributions for parameters of interest to be estimated. ADMB was selected as the software design platform for this project because of its flexibility, computational efficiency and ability to reliably sample a complex multivariate likelihood surface. In addition to its benefits as a fast and stable optimization tool for fitting statistical models to data, ADMB also estimates uncertainty in and correlations between model parameters based on their derivative structure.

When fit to available abundance data the ADMB stage-structured population dynamics model provides estimates of model parameters, uncertainty in those parameter estimates, and the hessian matrix for model parameters from which the parameter covariance matrix may be derived. However, with 37 separate environmental covariates to be tested as competing hypotheses it was necessary to define metrics for model fit and parsimony. We use the Akaike Information Criterion corrected for small sample sizes (AICc) (Burnham and Anderson 2002) as a metric for model parsimony (Eq. I.19).

(I.19) $$AICc = 2LL_T + 2p + \frac{2p\left(p+1\right)}{n-p-1}$$

AICc balances the degree to which a model is able to explain the variability in data (LL_T) against the number of parameters estimated (p) and number of data used in estimation (n), and provides a basis for model selection. The second statistic used to evaluate model fit is the mean absolute percent error in model predictions (Eq. I.20).

$$\text{(I.20)} \quad MAPE_p = \frac{\sum_{t=1}^{n} \left| \frac{\hat{A}_{t,p} - A_{t,p}}{A_{t,p}} \right|}{n}$$

The method we have employed in the Sacramento for modelling the anadromous salmonid life cycle as a series of sequential, spatially-explicit, stage-specific Beverton-Holt transition functions that relate density-dependent survival to habitat covariates is similar to those successfully used to address conservation questions regarding other Chinook salmon populations along the West Coast. The Shiraz model developed by Scheuerell et al. (2006), employed to evaluate anthropogenic and habitat effects on production of Chinook in the Snohomish River basin of Puget Sound, Washington, was one of the first to specify interactions between habitat variables and the productivity and capacity parameters of the Beverton-Holt functions describing survival though life stages. Subsequently, Battin et al. (2007) and Honea et al. (2009) employed stage-structured models governed by linked Beverton-Holt transition functions to evaluate the influence of climate change, hydrologic variability, and habitat restoration on populations of Chinook salmon in the Columbia River basin. All three of these analyses used a Shiraz-type approach by linking habitat and climate covariates to stage-specific survival.

However, the model we have designed for evaluating the environmental drivers of survival for Chinook salmon in the Sacramento River differs from the Shiraz-type models described above (Scheuerell et al. 2006, Battin et al. 2007, Honea et al. 2009) in several fundamental ways. First, the model used in these analyses is statistical in nature. Whereas Scheuerell et al. (2006), Honea et al. (2009), and Battin et al. (2007), all specify the relationships between environmental covariates and the productivity and capacity parameters of the Beverton-Holt function for each stage, based upon *in situ* observations, laboratory experiments, or expert opinion, the estimation framework we have created for the analysis of the drivers of Sacramento River Chinook survival estimates these relationships directly from the abundance data. Second, estimation of the relationships between environmental covariates and the Beverton-Holt productivity and capacity parameters, will not only provide point estimates of the effect of each covariate, but also estimates of uncertainty. By estimating both the value for coefficients describing covariate effects, as well as their uncertainty, we are not only be able to discern which covariates have the largest influence, but also which covariates have had a consistent influence historically. Finally, by estimating the value of coefficients describing the magnitude and direction of influence each environmental covariate has on stage-specific productivity or capacity, our method allows for the propagation of estimation uncertainty in those relationships forward when those model parameters are used to predict future abundance trends under alternative climate, marine productivity, or water use scenarios.

METHODS UNCERTAINTY – AICC SELECTIONS AND MCMC METHODS

In order to test a range of hypotheses regarding which environmental covariates influence the survival of seven populations of Sacramento River Chinook, we constructed a stage-structured statistical population dynamics model. When fit to available adult and juvenile abundance data, this model estimates the magnitude and direction of influence that a set of environmental covariates has on two components of Chinook survival, namely life-stage specific productivity (maximum survival) rates and capacities. In the process of fitting population dynamics models to data as part of our analysis, there were two sources of uncertainty that we considered directly. The first was structural uncertainty, or uncertainty in the subset of environmental covariates that best represent the processes driving changes in abundance over time. The second is estimation uncertainty, or uncertainty in our ability to identify the true direction and magnitude of the effect each environmental covariate imposes on Chinook survival. To address structural uncertainty in our analysis, we used a process of forward stepwise model building, based upon an AICc criteria, with replication to ensure complete evaluation of model space, or the range of potential models that may be used to describe trends in abundance over time. This process allowed us to define the “best” model or subset of potential environmental covariates (hypotheses) for describing observed population dynamics. To address the second type of uncertainty in our analysis, estimation uncertainty, we employed Markov Chain Monte-Carlo estimation methods to quantify the probability distributions for the coefficients describing the effect of each environmental covariate on survival.

Stepwise AICc Model Selection

In total 37 separate environmental covariates were identified by the study team as potential drivers of interannual variation in Sacramento Chinook survival. Describing the effects of these 37 environmental covariates on separate populations in the form of either population-specific effects or common influences on groups of populations, resulted in a total 59 covariate-by-population effects, whose influence on survival may be estimated based on their ability to explain observed Chinook abundance data. Each of these 59 covariate-by-population effects represents an alternative hypothesis to be tested in our analysis.

Hypotheses for covariate-by-population effects on Chinook survival may be compared to a “null” model that attempts to explain variation in the time-series’ of observed juvenile and adult abundance data based on only observed ocean harvest rates, hatchery release numbers, estimated productivities (maximum survival rates) for populations in the first life-stage, and annual capacities specified by the juvenile capacity modelling (Hendrix et al. 2014). The null model represents the base case, without any influence from environmental covariates. However, in order to define the model with the best potential to provide accurate predictions for population responses to future environmental, climate, and water management scenarios it was necessary to find the most parsimonious model, or subset of explanatory covariates. Model parsimony is defined by the balance between the ability to accurately explain variation in observed data, while estimating the fewest parameters possible. The Akaike information criterion, corrected for small sample sizes (AICc, Eq. I.19), quantifies model parsimony and provides a metric for selecting amongst competing models (Burnham and Anderson 2002). Competing models incorporating alternative combinations of covariate effects were compared based on their AICc values in order to define a “best-fit” model for generating predictions for future abundance trends.

With a total of 59 independent covariate-by-population effects to be tested for their ability to explain variation in historical Sacramento Chinook survival, the number of possible combinations of these effects, or potential models, is quite large. It becomes unrealistic to fit every possible model permutation to the available data and compare AICc values. Therefore we used a method for exploring the model space, or the range of potential models incorporating different combinations of these effects, which involved a forward stepwise model building with AICc as the selection criteria. Forward stepwise model building begins first by fitting the null model, without any covariate effects, to the available data. Second, a covariate is selected at random from amongst the set of 59 possible covariate-by-population effects and included in the model, and this model is subsequently fit to the data. Third, the AICc value for this new model is compared to that of the null model. If a reduction in AICc value for the model including the additional covariate of greater than 2 units is observed ($\Delta\text{AICc} \leq 2$), when the old model is compared to the model incorporating the new covariate, that covariate is kept, otherwise it is removed from the model. Moving forward, this process of randomly sampling covariates without replacement, fitting the model to data, and evaluating $\Delta AICc$, (i.e. steps two and three) are repeated until all covariates have been tested for their ability to improve model parsimony (see Fig. I.4).

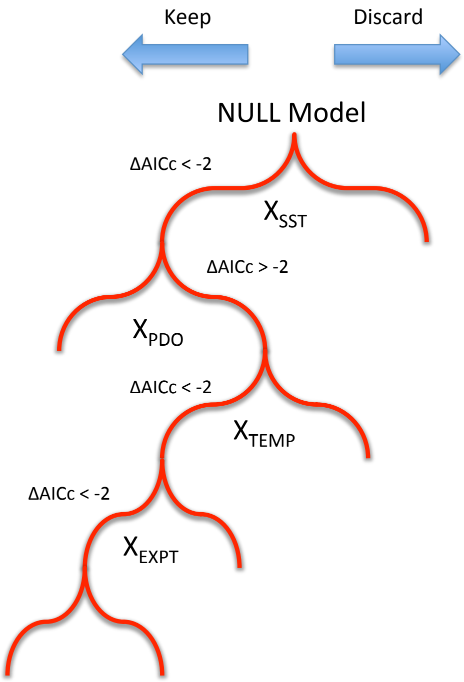

Figure I.4. Diagram of forward stepwise AICc model building process. Starting from the null model, covariates (X_{TEMP}, X_{PDO} etc.) are sampled at random without replacement from the set of 59 possible hypotheses and included in the statistical model. The model is then fit to abundance data and the difference in AICc values between the old and new models dictates whether that covariate is kept or discarded, and the next iteration begins.

The result of one round of forward stepwise AICc model building, or fitting the null model and 59 alternative models sequentially, is one realization of a best-fit model based upon the AICc criteria. However, experience indicates that given even small correlations among some environmental covariates, the order in which covariates are introduced has a subtle influence on the resulting model. Therefore, in order to more fully explore the uncertainty in model selection, we repeated the forward stepwise AICc process 1,000 times. By evaluating the frequency with which specific covariates appear in best-fit models across these 1,000 realizations, it is possible to determine which covariates are most important in explaining historical variation in Chinook survival. Furthermore, by repeating the stepwise AICc process 1,000 times, we are thoroughly exploring the model space and among these independently built models can determine the single model that has the lowest AICc among the candidate best-fit models.

Markov Chain Monte-Carlo Estimation Methods

The second critical piece of uncertainty in our analysis is estimation uncertainty. Estimation uncertainty describes variation in the estimated value of model parameters, and is a function of how well model parameters are informed by the available data. In order to quantify the level of estimation uncertainty in our analyses, particularly as it pertains to estimates of the coefficients describing the influence of environmental covariates on Chinook survival, we employed Bayesian estimation methods in addition to the maximum likelihood approach described above. Bayes' Theorem (Eq. I.21) describes the probability of a hypothesis θ, in our case a set of parameter values, given the data, which in our case are both adult spawning abundance ($A_{t,p}$) and juvenile abundance (J_t) observations.

(I.21) $$P(\theta \mid data) = \frac{P(data \mid \theta) P(\theta)}{\int P(data \mid \theta) P(\theta)}$$

The prior probability on logit transformed coefficients was normal with a mean of zero and standard deviation equal to 2.5, as per recommendations by King et al. (2010). Bounded uniform priors were assumed for all other estimated model parameters. Estimated initial (log) abundances 1967-1969 were bounded on the (0, 100) interval, basal stage productivities ($\beta_{s,p,0}$) were bounded on the (-25, 25) interval, and basal stage capacities ($\gamma_{s,p.0}$) bounded on the (-100, 100) interval. Bayesian estimation methods allow the posterior probability distribution for derived and estimated parameters to be calculated, and from it the full range of parameter uncertainty. The posterior probability distribution for model parameter i (θ_i) describes the probability that the true value of that parameter is equal to a specific value. Based upon the posterior probability distributions for model parameters, we are able to calculate the expected values for model parameters as well the uncertainty in those parameter estimates.

Markov Chain Monte-Carlo (MCMC) methods are commonly used numerical algorithms employed to draw samples from the posterior distributions for parameters in Bayesian models (Gelman et al. 2004). We employed the Random Walk Metropolis-Hastings (RW-MH) MCMC algorithm implemented in AD Model Builder (Fournier et al. 2012) to draw samples from posterior distributions of parameters in population dynamics model. The RW-MH MCMC algorithm is a widely applicable MCMC algorithm that accounts for correlations among model parameters. As implemented in ADMB, the RW-MH MCMC algorithm begins by finding the parameter values that maximize the complete data likelihood, or posterior modes, and then uses the estimated covariance matrix for model parameters to create a multivariate proposal distribution. Based upon this multivariate proposal distribution randomly drawn parameter sets, or MCMC jumps, are proposed and either accepted or rejected based upon comparison of the ratio of the proposed posterior density to that of the current state, with a random uniform (0,1) deviate. In this way, the RW-MH MCMC algorithm in ADMB begins as the posterior mode and samples the joint posterior.

MCMC chains were run for 5,000,000 iterations with a thinning rate of 1/1,000 to reduce posterior correlation. The first 30% of the chain was removed as a burn-in period, during which the chain approached the stationary distribution for model parameters. To ensure MCMC results converged to their stationary distribution, three independent chains were run simultaneously. Model convergence was tested in three separate ways. First, traceplots of MCMC samples were evaluated for the presence of discernable trends that would indicate a lack of convergence to the true stationary distribution. Second, posterior correlations at differing lags were calculated, wherein significant correlation would indicating a lack of convergence. Finally, Gelman and Rubin’s convergence diagnostic (Gelman and Rubin 1992, Brooks and Gelman 1998) was used to compare within and among chain variance to determine if all three chains had indeed converged to the same stationary distribution.

RESULTS MODEL FITS

Model Selection Results

In order to define the set of environmental covariates that best explains historical patterns in abundance for the seven populations of Sacramento Chinook, we employed a process of iterative forward stepwise AICc model selection. This process was meant to test the full range of alternative hypotheses for drivers of Sacramento Chinook survival, and define the most coherent set of covariates with the greatest explanatory power and predictive potential. Each iteration of model selection results in a candidate best-fit model, however it in order to fully explore model space it was necessary to repeat this process many times with a randomized order of covariate proposal in each iteration. By comparing the percent of times any particular covariate appeared across the 1,000 candidate best-fit models, we are able to determine which covariates or hypotheses have the greatest support from the data. Table I.3, describes the percentage of candidate best-fit models that incorporated each specific covariate.

Hypothesis	Covariate	Sum	Percent
58	spring.butte - sacAirTemp.spring	998	100%

Table I.3. **Model selection results. Percent inclusion rate for environmental covariate effects across 1,000 candidate best-fit models, each resulting from one round of forward stepwise-AICc model building. Note the covariate name includes the single population name, or the numbers for multiple populations upon whose survival the effect of the environmental covariate is shared. For reference population numbers are: 1) fall-run mainstem Sacramento wild-run Chinook, 2) fall-run Battle Creek Coleman National Fish Hatchery produced Chinook, 3) fall-run Feather River Hatchery produced Chinook, 4) fall-run American River Nimbus Hatchery produced Chinook, 5) spring-run Deer Creek wild Chinook, 6) spring-run Mill Creek wild Chinook, and 7) spring-run Butte Creek wild Chinook.**

Results of the iterative forward stepwise-AICc model selection (Table I.3) indicate that the set of environmental covariates (hypotheses) which best describe historical variation in Sacramento Chinook abundance encompass a wide range of locations within the life cycle, populations, and ecological processes. A higher inclusion rate across best-fit models for a specific covariate by population(s) effect may be interpreted as greater weight of evidence from the data that this covariate explains variation in survival and therefore may be of ecological importance (Table I.3). Foremost, it should be noted that the influence of spring air temperature at the city of Sacramento on survival of the Butte Creek population (spring.butte – sacAirTemp.spring) was included as an AICc-selected covariate in 998 of 1,000 best-fit models. This covariate represents air temperature during juvenile rearing (January – March) at the city of Sacramento, and is included as a surrogate for Butte Creek stream temperature. Additional covariates which were represented in 60% or greater of iteratively built models include: 1) the combined influence of the size of out-migrating spring-run juveniles on the survival of Deer, Mill and Butte Creek spring-run populations (.5.6.7-spring.size.chipps), 2) the combined influence of near-shore upwelling during the period of ocean entry (April – June) upon the survival of the four fall-run populations (.1.2.3.4-upwelling.south.early), and 3) the combined influence of the Pacific Decadal Oscillation during winter (January – May average) of the first year of marine residence (.1.2.3.4.5.6.7-pdo.early) on the survival of all four fall-run and three spring-run populations. The 5th most frequently included covariate was the effect of summer (July – September) air temperature at Sacramento during the brood year, on survival of Butte Creek spring-run Chinook (spring.butte-sacAirTemp.summer). This covariate was included to test hypothesis that high over-summer water temperatures may have a negative impact on the survival and successful spawning of adult spring-run Chinook holding in tributaries.

With respect to the representation of anthropogenic drivers of Chinook survival across the 1,000 forward-AICc built models, covariates describing the influence of water exports on spring and fall-run survival were the 6th, 7th, and 8th most often included. The combined effect of average water exports from the Sacramento – San Joaquin Delta between February and April quantified by the Dayflow QEXPORTS metric on survival of spring-run Chinook (.5.6.7-spring.dayflow.export), appeared in 54% of forward stepwise-AICc built models. Similarly, the covariate representing the combined effect of March – May average Sacramento – San Joaquin water exports on the survival of the four fall-run Chinook populations (.1.2.3.4-fall.dayflow.export) was included in 48% of stepwise-AICc built models, with the ratio of water exports to total Delta water inflow (Dayflow: EXPIN) during this same period (.1.2.3.4-fall.dayflow.expin) following closely with a 37% inclusion rate. Other covariates highlighting the influence of water routing and supply in the Sacramento – San Joaquin Delta were included in a smaller subset of stepwise-AICc built models. The influence of average net channel depletion (Dayflow: QCD) between February and April on the grouped spring-run Chinook populations (.5.6.7-spring.dayflow.cd) was included in 22% of the 1,000 stepwise-AICc built models. In addition, the combined influence of the average flow into Georgiana Slough and the Delta Cross Channel (Dayflow: QXGEO) February – April on the spring-run populations (.5.6.7-spring.dayflow.geo) was included in 19% of candidate best-fit models.

While the inclusion rate of specific covariate-by-population effects across the 1,000 stepwise-AICc built models provides an indication of the relative weight of evidence from the data, that each covariate holds some ability to explain historical patterns in survival, we consider the model with the lowest AICc value to have the best predictive ability. The single model with the lowest AICc value represents the most parsimonious fit to the data, explaining the greatest amount of observed variation in adult and juvenile abundance, while estimating the fewest parameters. This lowest AICc or "final" model provides the best basis for predicting future trends in abundance under alternative climate, marine production, and water management scenarios. The final model included 14 covariate-by-population effects, spanning both the freshwater and marine portions of the life cycle (Table I.4). In addition, the effects incorporated in the final model include both single-population effects as well as shared effects of environmental covariates across multiple populations. In total five of the covariates included in the final (lowest AICc) model were related to survival in the 1st (upriver) stage, six were related to the 2nd stage representing environmental effects on survival through the Sacramento – San Joaquin Delta, two were related to the 3rd stage influencing survival in the nearshore environment, and only one covariate was related to survival during subsequent years of marine residence.

Hypothesis Number	Covariate	Covariate Description	Model Stage	Populations
3	fall.sac.mainstem - keswick.discharge	Average January - March water discharge (cfs) at Keswick Dam	Upstream	Fall Sacramento Mainstem Wild
24	fall.battle.creek - sacAirTemp.spring	Sacramento air temperature during spring (January - March) emergence year	Upstream	Fall Battle Creek (CNFH) Hatchery
46	spring.deer - deer.discharge	Average October - December water discharge (cfs) at Deer Creek	Upstream	SpringDeer Creek
57	spring.butte - sacAirTemp.summer	Sacramento air temperature during summer (July - September) of the brood year	Upstream	Spring Butte Creek
58	spring.butte - sacAirTemp.spring	Sacramento air temperature during spring (January - March) emergence year	Upstream	Spring Butte Creek
40	.5.6.7-freeport.sed.conc	Average February - April monthly sediment concentration (mg/L)	Sacramento - San Joaquin Delta	Spring Deer Creek Spring Mill Creek Spring Butte Creek

51	.5.6.7-spring.size.chipps	Average size of spring-run Chinook at ocean entry from Chipps Island Trawl	Sacramento - San Joaquin Delta	Spring Deer Creek Spring Mill Creek Spring Butte Creek
6	.1.2.3.4-freeport.sed.conc	Average February - April monthly sediment concentration (mg/L)	Sacramento - San Joaquin Delta	Fall Sacramento Mainstem Wild Fall Battle Creek (CNFH) Hatchery Fall Feather River Hatchery Fall American River (Nimbus) Hatchery
10	.1.2.3.4-fall.dayflow.expin	Dayflow: Export/Inflow Ratio (EXPIN). March - May average	Sacramento - San Joaquin Delta	Fall Sacramento Mainstem Wild Fall Battle Creek (CNFH) Hatchery Fall Feather River Hatchery Fall American River (Nimbus) Hatchery
11	.1.2.3.4-fall.dayflow.cd	Dayflow: Net Channel Depletion (QCD). March - May average	Sacramento - San Joaquin Delta	Fall Sacramento Mainstem Wild Fall Battle Creek (CNFH) Hatchery Fall Feather River Hatchery Fall American River (Nimbus) Hatchery
17	.1.2.3.4-upwelling.south.early	NOAA Index for upwelling at Southern Location (36 N, 122 W), average of SPRING months (April - June)	Nearshore Region	Fall Sacramento Mainstem Wild Fall Battle Creek (CNFH) Hatchery Fall Feather River Hatchery Fall American River (Nimbus) Hatchery
20	.1.2.3.4.5.6.7-curl.late	NOAA Wind Stress Curl for upwelling at Northern Location (39 N, 125 W), average of FALL months (July - December)	Nearshore Region	Fall Sacramento Mainstem Wild Fall Battle Creek (CNFH) Hatchery Fall Feather River Hatchery Fall American River (Nimbus) Hatchery Spring Deer Creek Spring Mill Creek Spring Butte Creek
21	.1.2.3.4.5.6.7-pdo.early	Pacific Decadal Oscillation (PDO), average of January - May monthly indices during first year of mearine residence	1st Ocean Year	Fall Sacramento Mainstem Wild Fall Battle Creek (CNFH) Hatchery Fall Feather River Hatchery Fall American River (Nimbus) Hatchery Spring Deer Creek Spring Mill Creek Spring Butte Creek

Table I.4. Fourteen covariate-by-population effects included in the final AICc-selected model.

Of the covariate-by-population effects on upstream survival incorporated in the final model three were related to atmospheric temperature, used as a proxy for tributary-specific water temperatures, and two were related to water flow conditions. The three temperature-related covariate-by-population effects were all based on air temperature at Sacramento, CA and included: 1) the effect of average spring air temperature (January - March) on survival of the fall-run Battle Creek population in the year of emergence (fall.battle.creek - sacAirTemp.spring), 2) the effect of average summer air temperature (July – September) during the brood year on offspring production and oocyte through juvenile survival for the Butte Creek spring-run population (spring.butte - sacAirTemp.summer), and 3) the effect of average spring air temperature (January – March) in the year of emergence on survival of Butte Creek spring-run Chinook (spring.butte - sacAirTemp.spring). The two upstream covariate effects related to water flow conditions included, the influence of average water discharge rates (cfs^{-1}) at Keswick Dam during the period between January and March on the survival of Sacramento mainstem spawning wild fall-run Chinook (fall.sac.mainstem - keswick.discharge), and the effect of average water discharge in Deer Creek between October and December on the brood year survival of spring-run Chinook spawning in that tributary (spring.deer - deer.discharge).

The range of covariates which best describe historical patterns in juvenile Chinook survival through the Sacramento – San Joaquin Delta stage included factors both anthropogenic and natural in origin. Interestingly, the winter (February-April) concentration of sediment (mg/L) measured at Freeport, CA was selected based upon the AICc criteria as an important explanatory covariate for both grouped fall-run (.1.2.3.4-freeport.sed.conc) and spring-run (.5.6.7-freeport.sed.conc) populations. Two other covariate effects on the combined survival of fall-run Chinook populations which relate to water flow and management in the Sacramento – San Joaquin Delta were also identified in the final model, including average March – May Dayflow metrics for: 1) QCD or net channel depletion for in-delta consumptive use (.1.2.3.4-fall.dayflow.cd), and 2) EXPIN or the ratio of total delta exports to freshwater inflows (.1.2.3.4-fall.dayflow.expin) (CDWR 2014). In addition to sediment concentration, two other covariate effects on the combined survival of the Deer, Mill, and Butte Creek spring-run populations in the Sacramento – San Joaquin Delta were present in the AICc-selected final model. These included the influence of average monthly water exports and diversions from the delta (February – April) as quantified by the Dayflow metric QEXPORTS (CDWR 2014), which represents the sum of Central Valley Project exports, State Water Project exports, Contra Costa Water District diversions, and North Bay Aqueduct exports (.5.6.7-spring.dayflow.export), and the average size of juvenile spring-run Chinook caught in the Chipps Island Trawl (.5.6.7-spring.size.chipps).

Based on the AICc criteria and thorough exploration of model space using replicate stepwise model building, the final model identified three covariates able to explain some of variance in Chinook survival in the nearshore region following ocean entry and survival during subsequent years of marine residency. Survival for the four fall-run Chinook populations in the nearshore region was explained in part by upwelling patterns during the spring months (April – June) at the southern NOAA/PFEL monitoring site located at 36°N latitude and 122°W longitude (.1.2.3.4-upwelling.south.early). Additionally, the effect of average wind stress curl during July – December of the year of ocean entry on the survival of all seven combined spring and fall-run populations was included in the final model (.1.2.3.4.5.6.7-curl.late). The last covariate present in the final model linked to broad-scale marine climate patterns was the effect of the average Pacific Decadal Oscillation Index during the winter of the first year at sea (January – May) on the combined survival of all seven populations (.1.2.3.4.5.6.7-pdo.early).

These fourteen population-by-covariate effects, spanning freshwater and marine portions of the Chinook life cycle and all seven analyzed Chinook populations, represent the most parsimonious explanation for historical patterns in Chinook survival and observed juvenile and adult abundance. This final model was used as the basis for the subsequent Bayesian analysis of the effect of each of these covariates and their realized survival influence, and used for predicting future trends in abundance under alternative water management scenarios, predictions for future climate change, and marine production patterns.

Estimation Results

In order to estimate the direction and magnitude of the 14 covariate effects identified by AICc selection criteria across 1,000 stepwise-AICc built models (Table I.4), we have employed Bayesian methods with a MCMC sampler. Separate stage-structured models were used to represent each of the seven populations, however common effects across populations for specific covariates were estimated, and shared capacity constraints in the Sacramento – San Joaquin Delta were assumed for the four fall-run and three spring-run populations separately. Estimation of model parameters was informed by juvenile and adult abundance data, reconstructed to account for observed stray rates between hatchery and wild populations. Figure I.6 displays observed adult abundance data for the four fall-run Chinook populations and three spring-run populations as well as the posterior predictive distribution from the Bayesian population dynamics model. The posterior predictive distribution represented by the red line and shaded regions, describe the median, 50% and 95% credible intervals for the predicted adult spawning abundance or hatchery returns for each population in each year.

Results indicate that the model predicts the pattern for Deer and Mill Creek spring-run populations which exhibit higher adult abundances, relative to the time series, through 1984 followed by a period of lower adult abundance through the mid-1990s, followed by higher relative abundances through 2006 (Fig. I.5). Similarly for the Butte Creek spring-run population, the model captures the period of lower spawning abundance prior 1985 followed by a pronounced increase in abundance, ending with a relative plateau in the early 2000's (Fig. I.5). Model predictions for Sacramento Mainstem spawning wild fall-run Chinook and Feather River hatchery fall Chinook both fail to capture the low returns in 1998 – 1999, but capture the reduction in abundance observed in 2007 – 2008. In general for all seven populations of spring and fall-run Chinook included in the analysis, model predictions do not explicitly capture interannual variation, but explain much of the general trend in abundance across the time series (Fig. I.5).

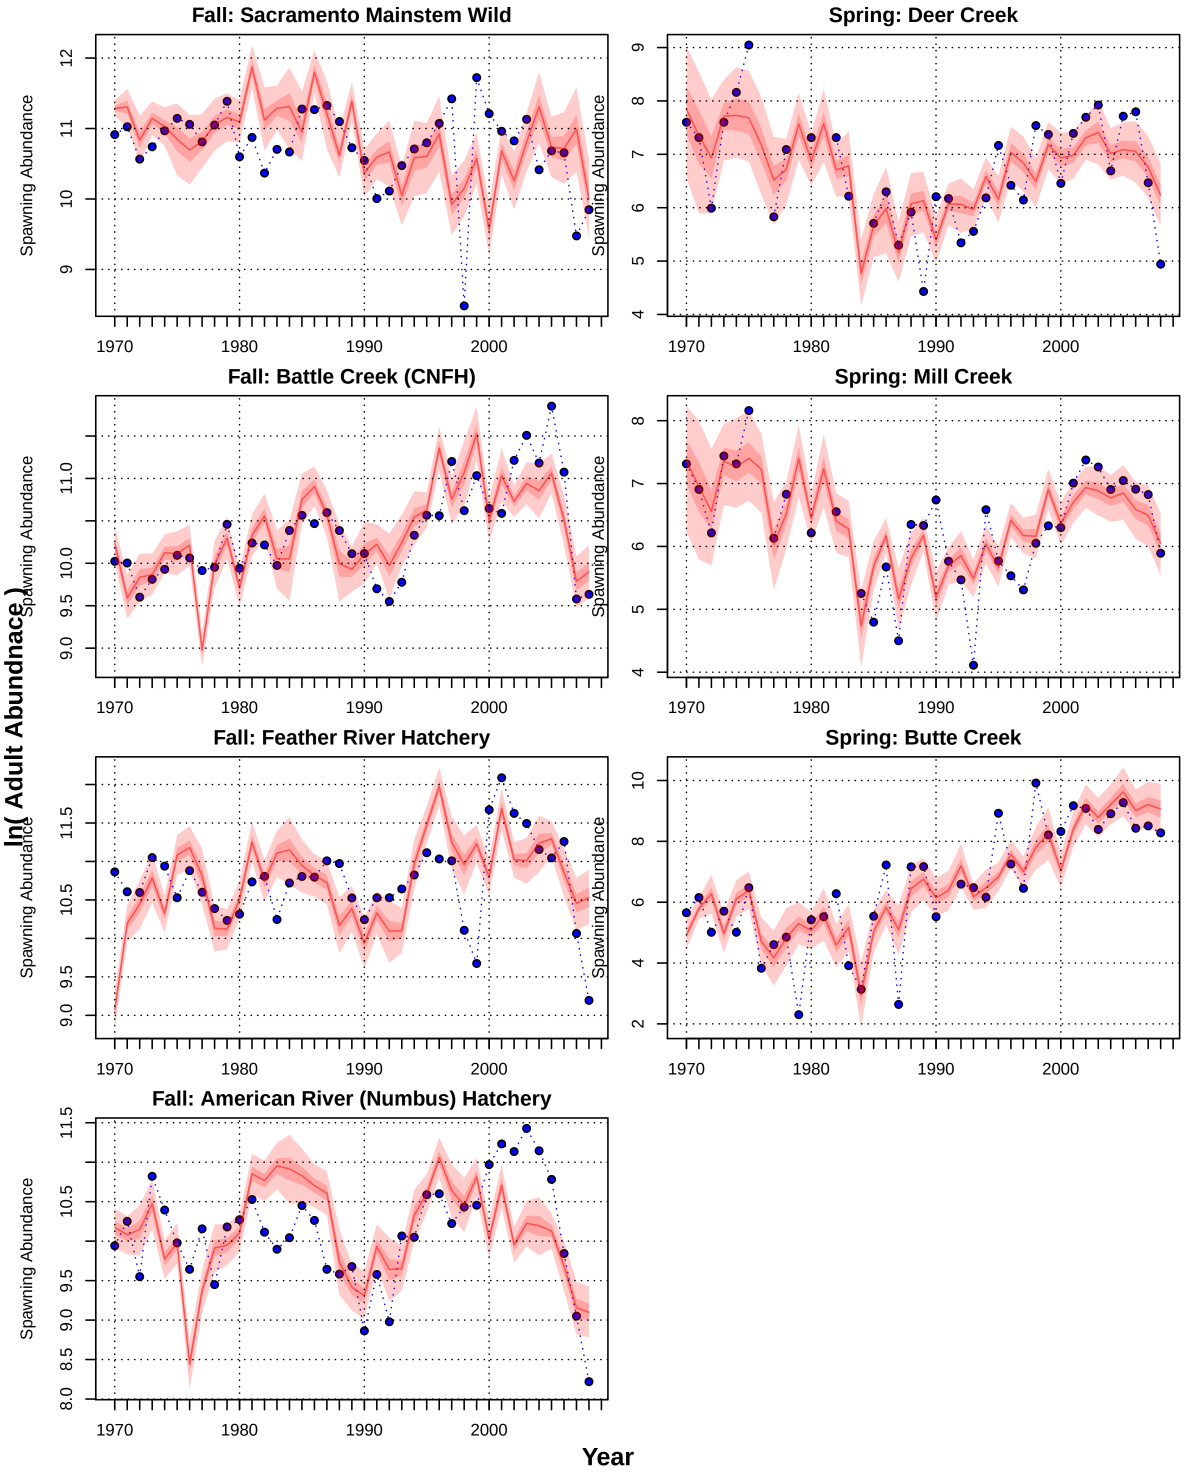

Figure I.5. **Bayesian population dynamics model fit to adult abundance data. Blue points and dashed lines indicate the observed adult abundance in each year on the spawning grounds or at the hatchery, reconstructed to account for average stray rates observed from coded wire tagging data (Kormos et al. 2012, Palmer-Zwahlen and Kormos 2013). Red shaded regions are the 95% and 50% credible intervals for the model predicted abundance in each year, and the red line describes the median of the posterior predictions for abundance in each year. Observed and predicted abundances are presented in natural log space.**

Posterior distributions for coefficients describing the direction and magnitude of influence each environmental covariate has on a specific population or group of populations were sampled, along with those for other model parameters including survival rate during the first (upstream) life-stage. Bayesian posterior distributions describe the estimated probability that a particular estimated or derived model parameter has a specific value. Figure I.6 displays posterior distributions for coefficients describing the influence of environmental covariates on survival, as well as those for parameters describing the base survival rate to Sacramento – San Joaquin Delta entry. In this figure, samples from posterior distributions arising from the three separate MCMC chains are drawn in different colors. Each parameter estimate is illustrated as a caterpillar plot whose median is described by a point, 50% credible interval by a thick line, and 95% credible interval by a thin line. The concordance of the parameter medians and credible intervals across the three MCMC chains, along with Gelman-Rubin test statistic values for all parameters ≤ 1.05, provide evidence that all three chains have converged to the same stationary distribution.

The bottom panel of figure I.6 displays model predictions for the value of the basal productivity parameter ($\beta_{s,p,0}$) in the upstream stage (Eq. I.5), or maximum survival rate to Sacramento – San Joaquin Delta entry. It should be noted that for the four wild-spawning populations (i.e. Mainstem Sacramento fall-run, and Deer, Mill, and Butte Creek spring runs), this parameter represents the maximum survival rate from egg to Delta entry, while for the three hatchery produced populations (Battle Creek (CNFH), Feather River, and American River (Nimbus) fall-run) this parameter represents the maximum survival rate from hatchery release to Delta entry. Parameter values in logit space are listed on the x-axis below the lower panel, while back transformed maximum survival rate values appear above the lower panel. Several things are clear from this figure I.6. First, the similarity in posterior distributions from each of the three chains again indicates that all three have converged to the same stationary distribution despite differing random walk trajectories through parameter space. Second, basal productivity or maximum survival rate for the upstream stage is both significantly higher and more variable for the three hatchery-reared populations. Higher maximum survival rates for these populations are to be expected given that they only represent mortality incurred after release, not mortality from fertilization to the date of release. However, the greater variance in maximum survival rate for the hatchery populations is easily discernable.

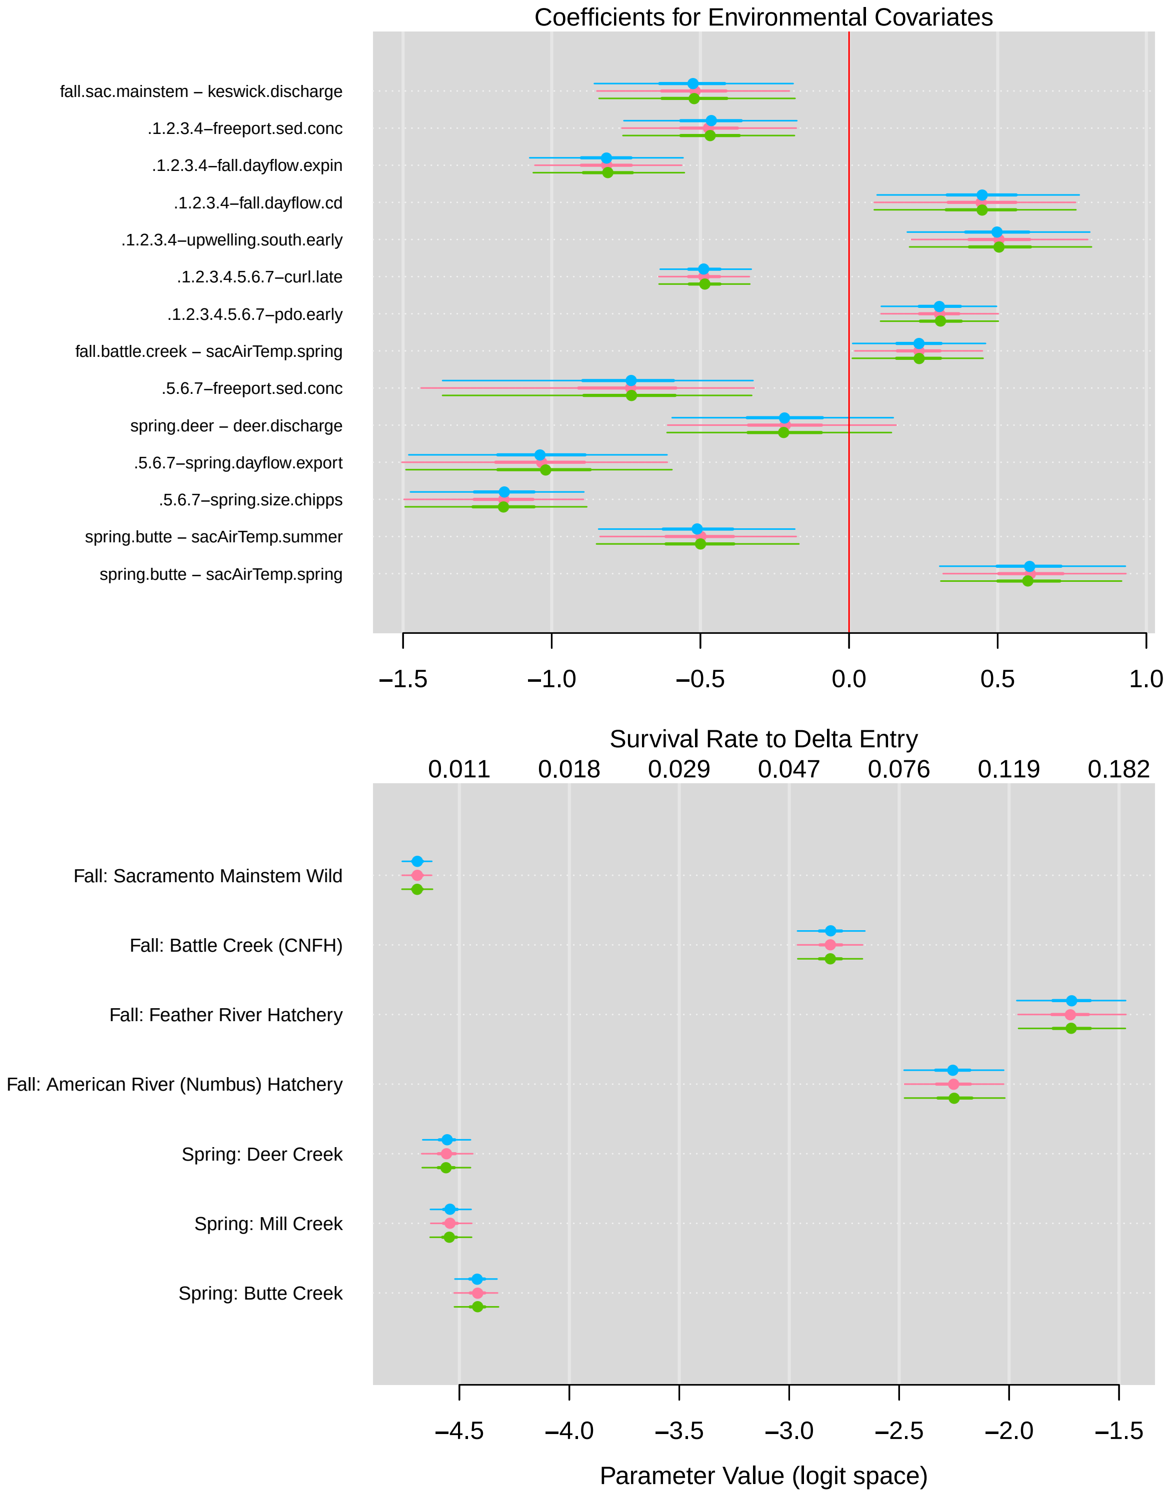

Figure I.6. Posterior probability distributions for coefficients describing the influence of environmental covariates on survival (top) and the maximum survival rate from egg (or hatchery release) to Sacramento – San Joaquin Delta entry. Caterpillar plots describe the median (dot), 50% credible interval (thick line), and 95% credible interval (thin line) of each posterior. Posteriors from each of the independent MCMC chains are depicted with different colours.

Posterior estimates for the value of the coefficients ($\beta_{s,p,c}$) describing the influence of each environmental covariate on a specified population, or group of populations, provide an indication of whether each covariate has a positive or negative influence on survival (Fig. 6, top panel). Table I.5 shows the estimated value for each of the coefficients along with their variance, and quantile range for each posterior distribution. These results indicate that of the 14 covariates included in the final model, 8 covariates were estimated to have a negative impact on stage-specific productivity (maximum survival rate), 5 were estimated to have a positive influence, and 1 was estimated to have a negative influence on average but with a 95% credible interval range overlapping zero. The covariates whose survival impact is estimated to be negative include the effect of: 1) water discharge (cfs-1) from Keswick Dam on Mainstem Sacramento spawning fall-run Chinook (fall.sac.mainstem - keswick.discharge), 2) sediment concentration at Freeport, CA (mg/L) on the combined survival of the four fall-run populations (.1.2.3.4-freeport.sed.conc), 3) the export to inflow ratio in the Sacramento – San Joaquin Delta on combine survival of the fall-run populations (.1.2.3.4-fall.dayflow.expin), 4) wind stress curl on the combined survival of all seven populations of spring and fall-run Chinook (.1.2.3.4.5.6.7-curl.late), 5) spring Freeport, CA sediment concentrations on the combined survival of the three spring-run Chinook populations (.5.6.7-freeport.sed.conc), 6) water exports from the Sacramento – San Joaquin Delta on the combined survival of the three spring-run populations (.5.6.7-spring.dayflow.export), 7) the average size of juvenile spring-run Chinook on combined spring-run survival (.5.6.7-spring.size.chipps), and 8) Sacramento air temperature during summer months of the brood year on survival of Butte Creek spring-run Chinook (spring.butte - sacAirTemp.summer).

Table I.5. Values for the posterior probability distributions for coefficients describing the influence of environmental covariates ($\beta_{s,p,c}$) on productivity (maximum survival rate).

Five of the coefficient values were estimated to be positive (Table I.5), indicating that an increase in the value of those covariates leads to an increase in the maximum survival rate for the associated population or group of populations. These covariates which are estimated to positively influence survival include the effect of: 1) upwelling in the nearshore region during spring of the ocean entry year on the combined survival of the fall-run Chinook populations (.1.2.3.4-upwelling.south.early), 2) spring air temperature at Sacramento, CA on the survival of fall-run Battle Creek (CNFH) Chinook (fall.battle.creek - sacAirTemp.spring), 3) spring air temperature at Sacramento, CA on the survival of Butte Creek spring-run Chinook (spring.butte - sacAirTemp.spring), 4) net channel depletion in the Sacramento – San Joaquin Delta resulting from within-delta consumptive use as quantified by the Dayflow metric QCD on the combined survival of the four fall-run Chinook populations (.1.2.3.4-fall.dayflow.cd), and 5) the magnitude of the Pacific Decadal Oscillation during winter (January – May) of the first year at in the ocean on the combined survival of all seven spring and fall-run Chinook populations (.1.2.3.4.5.6.7-pdo.early). For the 13 covariates classified above as having either a distinct positive or negative effect on survival, the posterior distribution describing the probability of the true value for each coefficient had a 95% credible interval that was completely above or below zero. Although the estimated median value for the coefficient describing the effect of Deer Creek discharge (cfs^{-1}) on Deer Creek spring-run Chinook survival (spring.deer - deer.discharge) is less than zero (i.e. -0.22, Table I.5) indicating an negative influence on survival, the 95% credible interval overlaps with zero indicating a significant probability (p=0.121) of the covariate having either no influence or a positive influence on survival.

While posterior probability distributions for coefficients representing the influence of each environmental covariate on stage and population-specific productivity ($\beta_{s,p,c}$) describe the model estimate for how much an increase or decrease in the value of that covariate is expected to change stage-specific productivity parameter of the Beverton-Holt equation (Eq. I.4), it is difficult to directly compare these estimated coefficient values for several reasons. First, the basal productivity rate ($\beta_{s,p,0}$) for each stage is population-specific, meaning that the magnitude of estimated coefficients ($\beta_{s,p,c}$) is always relative to the to the basal productivity rate for the population of interest. Second, coefficient values and basal productivity rates are estimated in logit space to ensure the resultant productivity value is smoothly scaled between 0 and 1 (Eq. I.5), and comparing coefficients and basal productivity rates in logit space may be difficult to interpret. Therefore, we have endeavored to translate the magnitude of the estimated environmental covariate effects into more easily interpretable changes in survival.

In order to translate the value of estimated coefficients describing the influence of environmental covariates into predictions for realized changes in survival, we calculated the survival rate for the seven populations from egg, or hatchery release, through adults returning to freshwater under a range of scenarios. Survival rates for each population were calculated by tracking a set number of individuals forward in time across life-stages, assuming no harvest mortality, and using parameter values sampled from the joint posterior for the estimation model. One thousand independent sets of model parameter values were sampled from their joint posterior in order to preserve posterior correlation, and used to quantify the variation in predictions for the influence of each environmental covariate on survival, arising from estimation uncertainty. Survival rate was calculated as the sum of spawning adults across return years, divided by the number of eggs or hatchery releases. The spawning abundance, used as the basis for calculating survival rates, was the 1970 – 2010 average for the wild-spawning populations (i.e. mainstem Sacramento fall-run, as well as Deer, Mill, and Butte Creek spring-run) and the average release numbers for the most recent 10 years for the Battle Creek (CNFH), Feather River, and American River (Nimbus) hatchery populations. Likewise, the most recent 10-year average was used for capacity of wild juvenile fall-run Chinook in the Sacramento mainstem and for the total capacity for spring-run and fall-run Chinook rearing in the Sacramento – San Joaquin Delta.

The distribution of survival rate predictions for each population (p), across the 1,000 independent sets of parameter values (i), was first calculated for a base case ($Sbase_{p,i}$). Under the base case the value for all environmental covariates was set at zero, which for z-standardized covariates is equal to the long-term average. Subsequently the covariate-specific survival ($Scov_{p,i,c}$) of each population across the 1,000 parameter sets was determined, as each covariate (c) was sequentially changed to have a value of 1. Covariate-specific survival ($Scov_{p,i,c}$) thus represents the population (p) and sample (i) specific survival rate when covariate c is increased in value to 1 standard deviation above the long-term mean. From this, the percentage difference in survival for each population resulting from an increase in the value of an environmental covariate was calculated as: $\%\ difference\ in\ Survival_{p,i,c} = \frac{(Scov_{p,i,c} - Sbase_{p,i})}{Sbase_{p,i}} * 100$. Table I.6 displays the mean and standard deviation for the expected percentage change in survival for each population across the sampled parameter sets, when each covariate is increased in value by 1 SD from the mean.

Table I.6. Percentage change in egg (or hatchery release) to adult survival resulting from covariate variation. Values in the table are the mean (sd) differences in survival between the base case and a scenario where the value of a specific covariate (row) is increased by 1 standard deviation from the long-term mean.

Figure I.7 displays the effect of each environmental covariate on each Chinook population, as the distribution of percentage change in egg (or hatchery release) to adult survival, expected when the value of a specific covariate is 1 SD above the long-term mean. Each panel in figure I.7 describes the influence of a single covariate, while each row within a panel is the survival change expected for a specific population. Within each panel the seven population-specific caterpillar plots describe the distribution of expected survival difference, with the point demarking the median, and the thick and thin lines defining the 50% and 95% credible intervals for the prediction. Two aspects of this analysis are important to consider. First, the figure describes the difference in survival between the base case (all covariates at the mean) and that when a single covariate value is changed, and although the survival differences may be the same across populations, this should not be not be taken as evidence that population-specific survival rates are also estimated to be the same. Second, an estimated survival difference at or near zero does not imply there is no survival effect, only that this interaction was not included in the final AICc-selected model. Any small, but non-zero survival effects are the result of changes in the survival of another population in response to the covariate, with which the focal population shares a capacity constraint at some point in the life cycle.

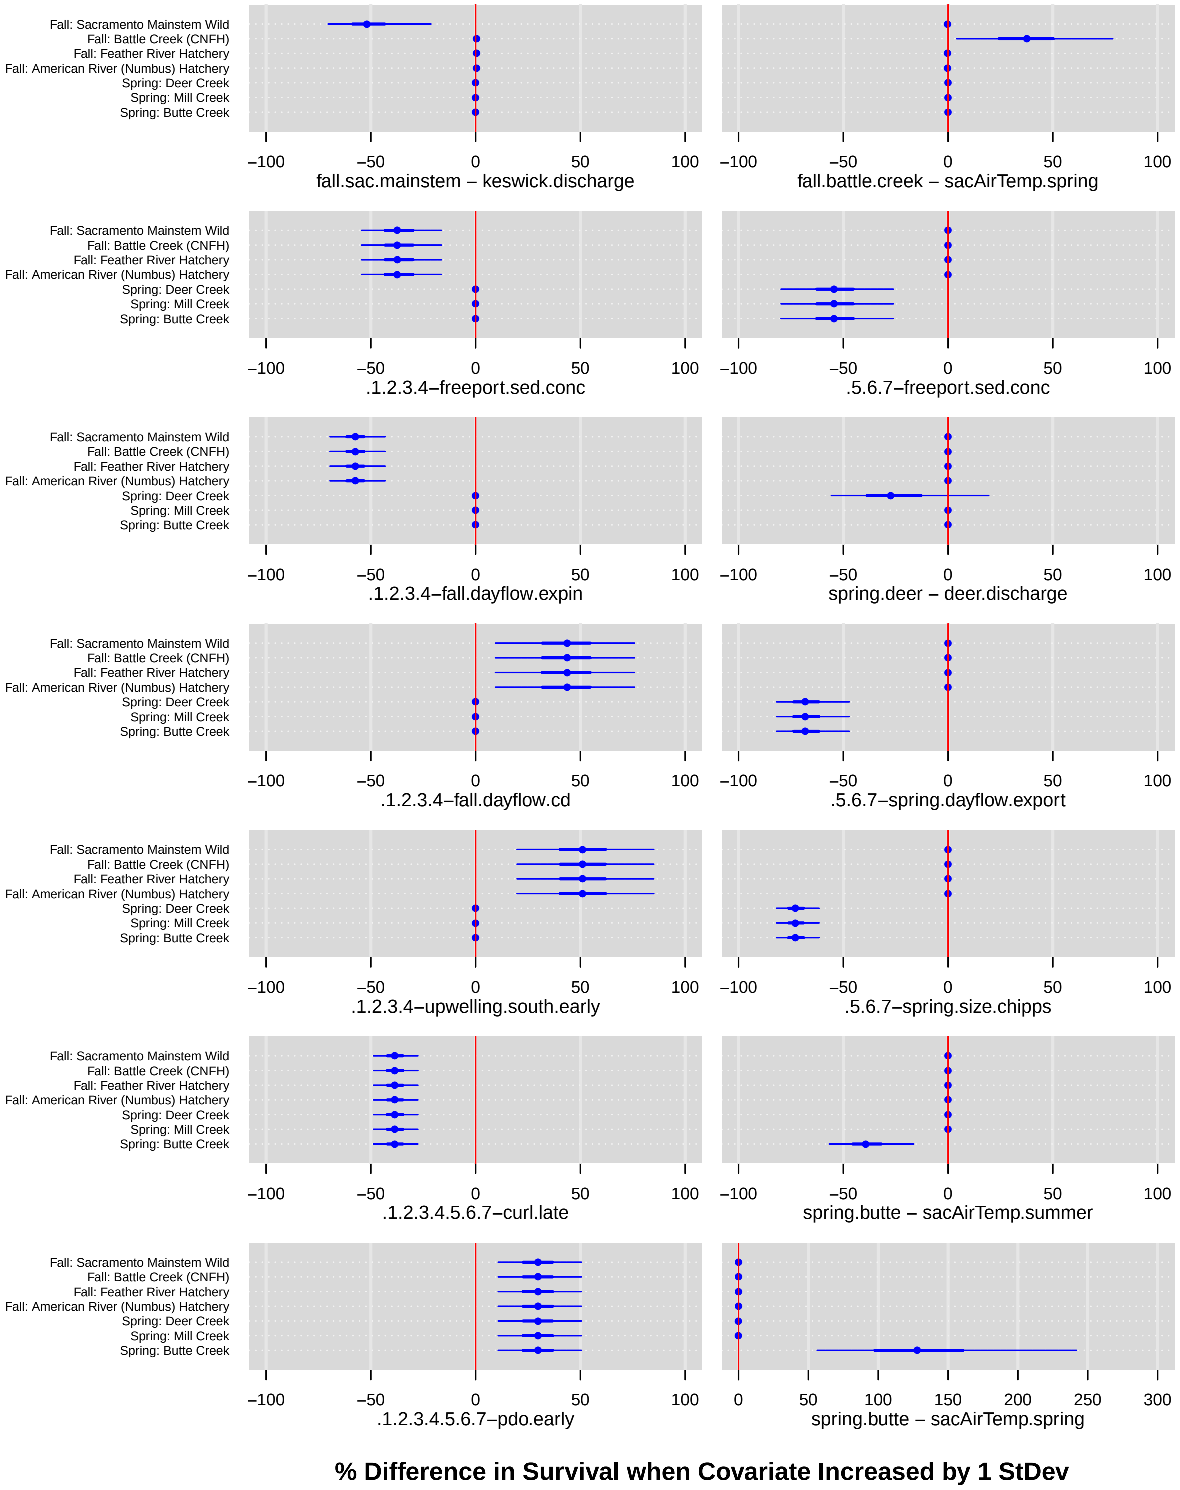

Figure I.7. Percentage change in egg (or hatchery release) to adult survival resulting from a 1 standard deviation increase in covariate values. Each panel represents the outcome of increasing the value of a specific covariate (listed below the x-axis), with each caterpillar plot describing the effect on each population (y-axis). Plotted values are the difference in survival between a scenario where the covariate value is increased and a base case where all covariates are equal to their long-term mean. Caterpillar plots describe the median (dot), 50% interval (thick line), and 95% interval (thin line) for each survival difference accounting for estimation uncertainty.

Results of this analysis of the environmental drivers of survival for Sacramento River fall and spring-run Chinook salmon indicate that several factors have the potential to significantly influence survival in the upstream portion of juvenile migration. Keswick Dam discharge is predicted to reduce egg to adult survival by 52.2%, for each increase in discharge rate of 1 SD. Increased air temperatures in the spring months following emergence are expected to increase the survival of Battle Creek (CNFH) fall-run Chinook by 37.5%, although the 95% credible interval for this predictions ranges from a moderate a modest 4.4% increase to a 79.8% increase indicating significant uncertainty in this prediction. Spring time air temperatures are expected to influence the early juvenile survival of Butte Creek spring-run Chinook in a similar direction but to a much greater extent with a predicted 124.7% increase. Conversely, increased summertime air temperatures during the period of adult upstream holding and egg development are expected to reduce survival by 39.4%, indicating that summertime temperatures may be reaching lethal levels or affecting adult fertility. The final environmental variable linked to the upstream stage and early juvenile survival is water discharge in Deer Creek, which is expected to reduce survival for Deer Creek spring-run Chinook by a modest 26.2%. However, it is important to note that there is significant uncertainty in this prediction with an increase in Deer Creek discharge by 1 SD predicted to have result in anywhere between a 59.4% reduction in survival and a 27% increase in survival 95% of the time.

Later in the life cycle for Sacramento River Chinook, several factors are expected to significantly influence juvenile survival in the Sacramento – San Joaquin Delta. A 1 SD increase in the concentration of sediment (mg/L) at Freeport, CA is expected to result in a 37.1% reduction in the survival of the four fall-run Chinook populations. Sediment concentration is predicted to have a slightly larger influence on survival of the three spring-run populations, with a 54.3% reduction in egg to adult survival. Water exports from the Sacramento – San Joaquin Delta, although quantified through different metrics, are expected to reduce survival of both spring and fall-run juvenile Chinook. An increase in total exports of 1 SD from the 1967-2010 average is predicted to result in a 68.1% reduction in the survival of Deer, Mill, and Butte Creek spring-run Chinook. Similarly, an increase in the ratio of Delta water exports to Delta inflow of 1 SD is expected to reduce survival of the four fall-run populations by 57.8%. Interestingly however, net channel depletion or the quantity of water removed from Delta channels to meet consumptive needs (Dayflow: QCD) is predicted to increase the survival of fall-run Chinook by 43.7%. The final covariate linked to survival of spring-run Chinook in the Sacramento – San Joaquin Delta is the average size of spring-run Chinook in the Chipps Island Trawl survey. Each increase in the average size of juvenile Chinook by 1 SD from the mean (1967-2010) is predicted to reduce survival by 72.9%.

Environmental conditions in the nearshore and marine portions of the Chinook life cycle were also found to have a significant impact on survival to adulthood. An increase in average nearshore upwelling during late spring (April – June) in the region south of San Francisco Bay of 1 SD above the mean, is expected to increase survival to adulthood by 51.2% for the four wild and hatchery-reared fall-run Chinook populations. Also related to marine patterns of nutrient transport and productivity, an increase average wind stress curl during the fall (July – December) of the first year of marine residency was estimated to reduce survival for the seven populations of spring and fall-run Chinook by 39%. The final covariate linked to Chinook survival in the marine environment was the Pacific Decadal Oscillation index during winter (January – May) of the first year of marine residence. An increase in PDO value of 1 SD above the 1967 – 2010 mean is predicted to increase survival of the seven populations of spring and fall-run Chinook by 30%, however there exists significant uncertainty in this prediction with the 95% credible interval ranging from 10.1 - 51% increase in egg or hatchery release to adult survival.

PART I DISCUSSION

This evaluation of the putative environmental drivers of survival for seven populations of spring and fall-run Chinook spawning within the Sacramento River watershed was comprised of two essential components. The first component was model selection or the process of determining the weight of evidence from the data for which subset of the 59 hypothesized covariate-by-population effects were able to best explain historical variation in Chinook salmon survival, and are therefore informative for predicting future trends in abundance. One thousand potential best-fit models were built using forward stepwise based upon AICc as the selection criteria. The percentage of the 1,000 best-fit models resulting from stepwise-AICc building which included a specific covariate provide a good indication of the relative amount of support each of these competing hypotheses had from the adult and juvenile abundance data (Table I.3). The fact that a range of covariates influencing both grouped and single Chinook populations at all points in the life cycle were present amongst those with a high inclusion rate provide evidence that there not exist a single population bottleneck within the life cycle. This indicates that variation in environmental factors a multiple points within the life cycle play a role in determining interannual survival to adulthood. Of further importance is the observation that both natural covariates, including temperature, water flow, and marine productivity patters, as well as those of anthropogenic origin (i.e. water exports, export/inflow ratio, and water routing) appear amongst the set with the highest inclusion rate. This finding indicates that variation in survival of Sacramento River Chinook population in not driven by natural or anthropogenic processes in isolation. The final model (Table I.4), chosen based on having the lowest AICc value amongst the 1,000 candidate best-fit models, likewise includes a range of covariates throughout the life cycle representing both natural and anthropogenic processes are statistically important predictors of survival.

The influence of striped bass (*Morone saxatilis*) on survival of spring-run Chinook was of particular interest given findings by Lindley and Mohr (2003), which indicated that higher future abundances of striped bass were likely to lead to greater extinction potential for winter-run Chinook. While the effect of striped bass on survival on spring-run Chinook was included in 36% candidate best-fit models, it did not appear in the final (lowest AICc) model. When included alongside other covariates in the final model, the estimated effect of striped bass abundance was centered near zero, indicating an inability to estimate a distinctly negative impact on grouped survival of spring-run Chinook. This result indicates that while striped bass abundance does explain some of the variation in spring-run Chinook survival, other explanatory covariates provide a better alternative explanation for historical abundance observations.

The estimated effect that water exports from the Sacramento – San Joaquin Delta on juvenile Chinook survival through this region was also of importance. While the effect of average water export levels on spring-run Chinook survival and the influence of export/inflow ratio on fall-run Chinook survival both appear in the final model, these two covariate effects have a 54% and 37% inclusion rates across the 1,000 candidate best-fit models. The fact that these export-related covariate effects do not appear at the top of the list of most often included covariates, indicates that while they have substantial potential to explain historical patterns in spring and fall-run Chinook survival, as indicated by distinctly negative survival effects whose 95% credible intervals do not overlap zero (Figure I.7 and Table I.6), there are other environmental covariate which explain a greater proportion of variation in historical abundance.

The second component of this evaluation was to estimate the direction and magnitude of change in survival rates resulting from variation in each of the covariates in the final model using Bayesian methods. When evaluating population dynamics model estimates for the effect of environmental covariates on survival, it is important to place each result in the proper biological context and determine if there exists a rational mechanistic explanation. The effect of Sacramento air temperatures on several populations appeared as AICc-selected explanatory covariates for several populations. Sacramento air temperature was employed as a proxy for water temperatures in upstream regions of the Sacramento River watershed for two reasons. First, significant and often linear relationships exist for between stream temperatures and air temperatures in most regions. Second, stream temperature data were not available continuously for the requisite time series (1967 – 2010) for all locations, resulting in the necessity for interpolation based on the relationship with air temperature. Therefore, for consistency in the covariate time-series and to reduce the risk of introducing additional uncertainty into the estimation process, we elected to use air temperatures as covariates in place of interpolated water temperatures. Results indicate a positive influence of increased spring (January - March) air temperatures on the survival of Battle Creek (CNFH) fall-run Chinook and Butte Creek spring-run Chinook. This temperature metric coincides with the period prior to and during which juvenile Chinook are rearing. The estimated positive influence of spring temperatures on Chinook survival could result indirectly from the increase in primary production fostered by increased water temperatures and subsequent effects on food availability. In this way growth potential for juvenile Chinook in freshwater depends indirectly on temperature in the rearing environment through food availability, and directly through effects on metabolism as warmer conditions allow juveniles to approach their bioenergetic optimum. Finally, there is some evidence that acclimation to higher temperatures early in life my facilitate higher thermal tolerance later in life, although research in this area has primarily focused on Great Lakes rainbow trout and has not been explicitly evaluated in Chinook (Myrick and Chech 1998). While spring time temperatures were estimated to have a positive influence at this point in the lifecycle, it is important to note that higher temperatures experienced later in the lifecycle during summer months may approach upper tolerance limits, resulting in negative survival impacts. However, the effect of increased summertime temperatures on juvenile survival was not evaluated as part of this analysis.

Contrary to the estimated positive effect of spring temperatures, air temperature during the summer months (July - September) of the brood year were found to have a negative impact on the survival of Butte Creek spring-run Chinook (Table I.6). For Butte Creek spring-run Chinook this time period coincides with the point in the life-cycle when adults are holding in freshwater prior to spawning. Prior to the creation of impassable barriers to upstream migration, the life history of spring-run Chinook was adapted to make use of high spring runoff events from snowmelt to migrate upstream into high elevation streams with tolerable temperature regimes where they could successfully mature during the summer months and await spawning when waters cooled to below 14 – 15^{0}C (Williams 2006). However, in Butte Creek mortality rates during the holding period were observed to exceed 20-30% in 2002 and 65% in 2003 during high temperature events (Ward et al. 2003). This is likely the result of the increased metabolic demands for adult spring-run Chinook while holding in freshwater during high temperature events, and the increased rate of disease onset and parasite load observed in other members of the *Oncorhynchus* genus exposed to high temperatures (Kocan et al. 2009).

Water flow conditions during juvenile rearing were also found to be important predictors of Chinook survival. Water discharge rates at Keswick Dam were found to negatively influence survival of mainstem spawning wild fall-run Chinook, and water discharge in Deer Creek was found to reduce survival of the Deer Creek spring-run population although to a lesser extent (Table I.6). While it is reasonable to assume that higher discharge rates could lead to greater access to valuable off-channel rearing habitat, water flow conditions additionally have the potential to influence foraging ability by juveniles through the availability of drifting food sources (Neuswanger et al. 2014). None the less the finding that fall-run Chinook survival was negatively influenced by increased water flow contradicts findings by Stevens and Miller (1983) and Newman and Rice (2002). With respect to the influence of water discharge on the survival of Deer Creek spring-run Chinook, this tributary is prone to concentrated high flow events due to flood control levees and a lack of riparian vegetation in its lower reaches (Tompkins 2006). For Deer Creek this may indicate that high water flow rates reduce foraging opportunities for juvenile Chinook, rather than enhancing them, as would be the case in a system with greater floodplain connectivity.

Findings related to the influence of environmental covariates on survival of fall and spring-run Chinook in the Sacramento – San Joaquin Delta are of particular interest in this study. First, the effect of sediment concentration in waters at Freeport, California appeared in the final AICc-selected model, and increases in sediment concentration were estimated to have a substantial negative influence on the survival of both spring and fall-run populations. This finding is contrary to a priori expectations that increased sediment concentrations might provide a survival benefit, if they limit the efficacy of visual predators such as striped bass. We remain limited in our ability to explain the estimated negative effect of sediment concentrations save for the fact that increased sediment influx might be linked to production potential for phytoplankton and the benthic periphyton which form the basis for the aquatic food web. Similarly, the estimated negative influence of average juvenile spring-run Chinook size on the common survival of the three spring-run populations appears contrary to a priori expectations. In the review of size selective mortality in teleost fishes Sogard (1997) found general support for the "bigger is better" hypothesis across taxa. Claiborne et al. (2011) also found that juvenile to adult survival of yearling Chinook from the Willamette River Hatchery increased with size at ocean entry. However, in an evaluation of the effect of size on survival from analysis of scale samples from Chinook returning to the same hatchery, Ewing and Ewing (2002) found either no significant size difference between juveniles at the hatchery and those at ocean entry, or in the case of the 1989 – 1990 brood years evidence for greater survival of smaller individuals. It is important to note that spring-run juvenile size data was unavailable until 1976. As a result we were forced to assume the long-term average for this covariate prior that year which may have influenced results related to this particular covariate.

Results of this analysis related to the influence of water exports from the Sacramento – San Joaquin Delta indicate a negative influence of the export/inflow ratio on the combined survival of the four fall-run Chinook populations and a negative influence increased total Delta exports on the combined survival of spring-run Chinook populations (Table I.6). These findings indicate that higher export rates lead to reduced survival for Sacramento River Chinook on average, however a mechanistic explanation remains elusive. Direct entrainment mortality seems an unlikely mechanism given the success of reclamation and transport procedures, even given increased predation potential at the release site. Changes to water routing may provide a more reasonable explanation for the estimated survival influence of Delta water exports. Higher exports, or export/inflow ratio, result in greater water diversion into the interior delta where survival has been observed to be substantially lower than that in the Sacramento River mainstem (Perry et al. 2010), potentially resulting from an increased encounter rate with predators or prolonged residence in areas with suboptimal feeding opportunities or dissolved oxygen concentrations.

In conjunction with freshwater drivers of survival for spring and fall-run Chinook populations of the Sacramento River watershed, results of this analysis indicate that several attributes of the marine environment have a significant influence on survival. Two covariates related to nearshore and offshore ocean current patterns and resultant nutrient movement within the water column were included as part of the final AICc-selected model. These covariates were the strength of nearshore upwelling and wind stress curl. Nearshore upwelling results in deep, cooler, and nutrient rich waters moving toward limnetic zone, with onshore transport and convergence fostering higher nearshore productivity during spring and summer. Conversely, wind stress curl is associated with offshore divergent transport (Wells et al. 2008). Our results indicate that increased nearshore upwelling during April – June of the year of ocean entry results in an increase in the combined survival of the four fall-run Chinook populations. Four alternative covariates quantifying upwelling patterns were evaluated as competing hypotheses for fall-run Chinook survival at different locations and quantifying time periods. Covariates were constructed using information from PFEL/NOAA monitoring sites both north and south of San Francisco Bay and for both the spring (April – June) and fall (July – December) periods. The AICc-selected covariate that appeared in the final model used the upwelling index data for spring time-period and at the southern location. Interestingly, although the effect of upwelling at the southern location in the spring months on the combined survival of spring-run Chinook appeared in 22% of candidate best-fit models, it did not appear in the final (lowest AICc) model, indicating that while upwelling may also be an important predictor of spring-run Chinook survival it appears to explain more variation in fall-run Chinook survival.

Wind stress curl was found to have a negative influence on the combined survival of all seven spring and fall-run Chinook populations. These results are not unexpected given findings by Wells et al. (2007) that indicate greater Chinook growth in the first year of life with increased nearshore upwelling and decreased wind stress curl. Wells et al. (2008) likewise found that reductions in wind stress curl were linked to increased production of rockfish species although they note this may be more related to dispersal of juvenile rockfish. The estimated reduction in survival for Chinook associated with greater wind stress curl is likely explained by trophic interactions, with findings by Macias et al. (2012) indicating that biomass concentrations for phytoplankton and zooplankton are likely to be substantially higher with coastal upwelling as opposed to wind stress curl driven upwelling offshore.

The Pacific Decadal Oscillation (PDO) describes a persisting periodicity in sea surface temperature, mixed layer depth, and strength and direction of ocean currents (Mantua and Hare 2002). Estimates for the influence of the PDO during January – May of the first year at sea indicating for the seven spring and fall-run Chinook populations, indicate increased survival is likely to be observed in during positive PDO events. This result is contrary to findings by Hare et al. (1999) which indicate positive PDO conditions favor production in Alaskan salmon stocks and disfavor the productivity of West Coast stocks, as well as findings by Wells et al. (2006) which highlight the negative covariation between size of Columbia River Chinook size and PDO values.

PART II SIMULATION OF FUTURE ABUNDANCE UNDER ALTERNATIVE CLIMATE, OCEANOGRAPHIC, AND WATER USE SCENARIOS

INTRODUCTION

The purpose of conducting forward population projections was to simulate future survival for Sacramento River Chinook under alternative climate, oceanographic, and water management scenarios. Simulating the four populations of fall-run and three populations of spring-run Chinook forward in time, provides a means for weighing differences in future survival under alternative water export levels, relative to the uncertainty in future climate change and ocean productivity. In order to generate predictions for future survival, we integrated results from the Bayesian estimation model with expectations for future environmental conditions under two alternative future ocean production trends, two predictions for future climate change, and at four potential levels of future water exports (see Appendix B). In addition to differences in future Chinook survival arising from natural and anthropogenic environmental factors, we have also propagated both estimation and process uncertainty forward in our predictions for future abundance and realized survival rates.

Future climate scenarios were based upon the U.S. Bureau of Reclamation's (USBR) Operations and Criteria Plan (OCAP) Study (USBR 2008). Two alternative scenarios for overland climate change were evaluated, the OCAP Study 9.2 and 9.5. The OCAP Study 9.2 (referenced as: **cc92**) describes a wetter and cooler prediction for future climate change, with a mean increase in temperature of 0.42° C and an increase in precipitation of 12.5%. Conversely, the OCAP Study 9.5 (referenced as: **cc95**) describes a dryer and warmer outlook for future climate change in the Central Valley, with a mean increase in temperature of 1.56° C and a decrease in precipitation of 12%. In addition to differing scenarios regarding climate change, two alternative predictions for future ocean conditions were explored. These two scenarios, one representing traditional perceptions of positive growth conditions for Chinook (referenced as **oceanUP**) and the other representing negative growth conditions (referenced as **oceanDOWN**), describe alternative patterns in nearshore upwelling and temperature, and future trends in broad-scale ocean currents.

Paired with these alternative scenarios for future climate change and ocean production, were four scenarios related to the magnitude of future water exports from the Sacramento-San Joaquin Delta. The four future scenarios for total water exports included: 1. **expAVG** (future exports equal to the 1967 – 2010 average), 2. **expZERO** (zero future water exports), 3. **expUP30** (an increase in future exports to 30% above the historical average), and 4. **expDOWN30** (a decrease in future exports to 30% below the historical average). While it is clear that some of these water export scenarios are economically infeasible (i.e. expZERO) they were included as part of the population projections to bound the range of potential biological outcomes from management actions. All export scenarios are based upon the historical export values calculated as the average of March – May Dayflow (QEXPORT) values for fall-run Chinook, and the average of February – April values for spring-run Chinook.

In total, these 2 onshore climate change scenarios, 2 ocean production scenarios, and 4 water export scenarios, resulted in 16 different realizations of the future environment for Chinook populations of the Sacramento River watershed. These sixteen environmental scenarios were subsequently translated into future covariate values (see Appendix B), for use as inputs in projecting the populations forward in time and determining realized future survival rates.

SIMULATION METHODS

Realized future survival rates were simulated by projecting all seven populations of Sacramento River Chinook forward in time for 50 years (2007 – 2057). The structure of the population dynamics model utilized to estimate stage-specific survival rates and the direction and magnitude of response by populations (or groups of populations) to environmental covariates, formed the basis for these forward population projections. Population and brood year specific cohorts of Chinook were tracked forward in time through the same six spatio-temporal life-stages (i.e. upstream/tributaries, Sacramento-San Joaquin Delta, nearshore, and the 1st, 2nd, and 3rd years in the ocean). In the same way as the estimation model, both the wild-spawning and hatchery production life cycles were represented in population projections, with wild-spawning populations linked to future cohort production through a fixed fecundity per individual, and hatchery production fixed at the population-specific average of releases from the most recent 10-year period. Stage-specific capacities for Sacramento mainstem-spawning fall-run Chinook in the upstream stage, and the grouped spring-run and fall-run populations in the Sacramento-San Joaquin Delta, were fixed at the average of estimates from Hendrix et al. (2014) for the most recent 10-year period. Estimated values for population dynamics model parameters including stage and population-specific productivity rates, and coefficients describing the direction and magnitude of influence that environmental covariates have on stage-specific productivity (maximum survival) rates, were used when simulating future trends in abundance.

When simulating future trends in Chinook abundance in order to evaluate differences in realized survival, it was necessary to account the two major sources of uncertainty in our analysis and propagate this uncertainty forward into predictions under alternative environmental and export scenarios. The first source of uncertainty in generating robust predictions for future abundance is uncertainty in the estimates of population dynamics model parameters. This includes uncertainty in the estimated value of life-stage and population specific basal productivity rates, as well as coefficients describing the influence of environmental covariates on survival. Estimation uncertainty arises when estimated values for model parameters are poorly informed by the available data, leading to broad posterior probability distributions indicating a broad range of parameter values with similar probabilities of being correct given the data. To account for estimation uncertainty in model parameters, we drew 1,000 independent sets of model parameter values from the joint posterior sampled by the Bayesian estimation model. By drawing parameter sets from the joint posterior, and repeating the 50-year forward projection of the seven populations using each of the independent parameter sets, we are able to capture the influence of both the true uncertainty in parameter values and posterior correlations between estimated parameters.

The second source of uncertainty that was integrated into forward projects was process uncertainty, or temporal variation in the state of future population dynamics. For each of the 1,000 replicate forward simulations, a random process deviate was introduced in the calculation for initial abundance in the first model stage (Eq. II.2, II.3).

(II.2)

$$N_{y,s=1,p,e,i} = A_{t=y,p,a,e,i} * fec * \exp\left(\varepsilon_{y,p,i} - \frac{\sigma_p^2}{2}\right)$$

$$\varepsilon_{y,p,i} \sim N\left(0, \sigma_p\right)$$

Equation II.2 describes how process uncertainty is introduced into the wild-spawning life cycle used to represent the Sacramento mainstem fall-run, and Deer, Mill, and Butte Creek spring-run Chinook populations. The number of individuals entering the upstream (1st) model stage ($N_{y,s=1,p,e,i}$), of brood year y, population p, in simulation i of environmental scenario e, is a function of the number of spawning adults returning in calendar year t = y of population p ($A_{t=y,p,e,i}$), the fixed fecundity rate of 2,000 eggs/individual ($fec = 2{,}000$), and the exponentiated brood year y, population p, and simulation i specific process deviate ($\varepsilon_{y,p,i}$). Conversely, equation II.3 describes how initial abundance in the first model stage was calculated with process errors for the three populations of hatchery-produced fall-run Chinook, where RH_p is the fixed level of hatchery releases for each population.

(II.3)

$$N_{y,s=1,p,e,i} = RH_p * \exp\left(\varepsilon_{y,p,i} - \frac{\sigma_p^2}{2}\right)$$

$$\varepsilon_{y,p,i} \sim N\left(0, \sigma_p\right)$$

Process deviates ($\varepsilon_{y,p,i}$) for each brood year y, population p, and replicate simulation i, were generated as random draws from a normal distribution with mean equal to 0, and population-specific standard deviations (σ_p). The standard deviations for the process error distributions (σ_p) were the maximum likelihood estimates for the residual observation uncertainty from fitting the original population dynamics model to historical abundance data. In total 1,000 randomly drawn process deviates, corresponding to the replicate simulations using parameter sets drawn from the joint posterior, were generated for each population in each of the 50 years of the forward simulation. To ensure comparability, the same set sets of brood year and population specific process deviates were used across environmental scenarios.

When simulating future trends in Sacramento Chinook abundance and evaluating realized survival rates, it was necessary to incorporate the likely impact of future fishery removals. Fishing mortality was simulated based upon the current Reasonable and Prudent Alternative (RPA) management scheme for Central Valley Chinook (see “Simulation of Harvest Rates” below). Annual allowable harvest rates for fall-run Chinook are established based upon the Sacramento Index (SI), however maximum harvest rates are further contingent upon minimum abundance requirements for ESA listed winter-run Chinook. When projecting populations forward in time, it was necessary to simultaneously model the future dynamics of winter-run Chinook in response to the 16 environmental scenarios under evaluation. Results from the evaluation of Sacramento River winter-run Chinook using the OBAN model (see Appendix D) which was run in parallel with the spring and fall run model, were used to simulate the future abundance of Sacramento River winter-run Chinook across the same 50-year time-series in response to differences in future climate change, marine production, and water exports across scenarios. Moving forward in time, future harvest rates depended on the model-predicted abundance of fall-run Chinook and winter-run Chinook (see “Simulation of Harvest Rates”). Spring-run harvest rates were scaled at 95% of fall-run harvest rates.

SIMULATION OF FUTURE HARVEST RATES

Background

The Pacific Fisheries Management Council (Council) manages the harvest of salmon on the coasts of California, Oregon, and Washington. The ocean salmon fishery targets Chinook, coho, and pink salmon species, which include Sacramento River Chinook salmon. The Sacramento River Chinook stocks overlap with Klamath River Chinook salmon in a mixed stock fishery. Furthermore, the Sacramento River fall Chinook (SRFC) is an indicator stock for the Central Valley Fall complex and Klamath River fall Chinook (KRFC) is an indicator stock for the Oregon/Northern California Chinook complex. As indicator stocks, the Council calculates both acceptable biological catches (ABC) and annual catch limits (ACL) for the SRFC and KRFC.

Both Sacramento River and Klamath River Chinook are composed of stocks supported by hatchery production and stocks that are listed as a conservation concern under the Endangered Species Act (ESA). In the Sacramento River and Klamath River mixed fishery, the Sacramento winter-run (federally listed as threatened in 1990 and as endangered in 1994 under ESA), Central Valley spring-run (listed as threatened under ESA in 1999) and the California coastal (listed in 1999) may limit harvest rates. Target harvest rates for the Sacramento fall run are determined annually via a forecast of abundance indexes of Chinook salmon to both rivers. Management of the fishery occurs through a series of spatially explicit openings and closures to structure the harvest effort in such a manner to ensure conservation of portions of the stocks that may be at low abundances while allowing harvest of those stocks that are healthy. There are a series of Council meetings to review the forecasted abundance and possible management alternatives.

NMFS developed a Biological Opinion in 2010 (2010 Opinion) to evaluate the effects of the ocean salmon fishery on winter run stock (Biological Opinion on the Authorization of Ocean Salmon Fisheries Pursuant to the Pacific Coast Salmon Fishery Management Plan and Additional Protective Measures as it affects the Sacramento River Winter Chinook Salmon (winter-run) Evolutionary Significant Unit (NMFS 2010)). In the 2010 Opinion, NMFS identified that winter-run cohorts could be reduced (i.e., decrease in the number of spawners relative to the number of spawners in the absence of the fishery) by 10 to 25% due to the ocean salmon harvest with an average rate of 20%. Most of the impacts occur south of Point Arena, CA from contacts with the recreational fishery (O’Farrell 2012).

To avoid a jeopardy conclusion on the operation of the ocean salmon fishery, NMFS developed a Reasonable and Prudent Alternative (RPA) to allow explicit control of the management process to reduce impacts when extinction risk of winter run increases (e.g., due to low stock size or periods of decline). After the issuance of the 2010 Opinion, the Council was given options to either increase size limits or enact seasonal closures to reduce the fishery impacts on winter-run in 2010 and 2011.

In 2012, NMFS performed a Management Strategy Evaluation (MSE) for different control rules based on the abundance of winter-run Chinook for setting the allowable harvest rate on the mixed stock fishery (Winship et al. 2012). The control rules set allowable impacts of age-3 winter-run south of point Arena as: 1) 0 impact (a closed fishery south of Point Arena); 2) 25% impact, which is the historical estimate of impact rate; 3) 20% impact, which is the current rate; and four alternatives (4-7) that reduce impact rates at certain winter-run thresholds. These MSE compared the impact rate under each of the control rules relative to the potential for increasing extinction risk of winter-run Chinook.

Management of Sacramento River Chinook

Fall-run

The fishery impact rate for SRFC is set by evaluating the Sacramento Index (SI) in each year. The SI is calculated as the sum of a) harvest south of Cape Falcon, OR; b) SRFC impacts due to non-retention in ocean fisheries; c) harvest in the recreational fishery in the Sacramento River basin; and d) SRFC spawner escapement. The SI is forecasted each year using a regression model with an autocorrelated error term that uses the number of SRFC jacks from the previous year as the dependent variable.

The estimates of the SI are subsequently used to determine the status of the fishery as overfished, approaching overfished, rebuilding, or rebuilt. The important metrics for determining the status are the minimum stock size threshold (MSST) (91,500 for SRFC) and the stock size at maximum sustainable yield (122,000). Given the status of the fishery, the allowable biological catch, annual catch limit, and the overfished limit can then be calculated.

The determination of the fishing rate is described as follows (PFMC 2014). The discrete fishing rate (F) at the overfishing limit, F_{OFL}, is defined as being equal to F_{MSY} (or the maximum fishery mortality threshold) and the spawner size (S) at the overfishing limit, $S_{OFL} = N \text{ x } (1 - F_{MSY})$. Because, SRFC is a Tier-2 fishery, the fishing rate consistent with the allowable biological catch $F_{ABC} = F_{MSY} \times 0.90$ and $S_{ABC} = N \text{ x } (1 - F_{ABC})$, where N is the spawner equivalent units. Finally, the fishing rate consistent with the allowable catch limits, F_{ACL}, is equivalent to F_{ABC} and $S_{ACL} = N \text{ x } (1-F_{ACL})$, which results in $S_{ACL} = S_{ABC.}$. The impact rate is determined by the SRFC control rule as a function of the potential spawner abundance (in this case the spawner abundance is the Sacramento Index = SI) (Figure II.1).

Winter-run

The current RPA (NMFS 2012) uses a fishery control rule with a reduction in fishery impact as a function of 3-year geometric average of winter-run escapement. The escapement is defined as the total male and female, natural-origin and hatchery-origin escapement as estimated by an annual carcass survey (USFWS 2011). The fishery control rule has the following threshold definitions (Figure II.1): A) from escapement of 0 to 500, the allowable impact rate south of Point Arena is 0; B) from escapement of 501 to 4000, the impact rate is linearly increasing from 0.1 to 0.2; C) from escapement of 4000 to 5000, the impact rate is 0.2. The impact rate for escapement > 5000 is undefined. For purposes of the MSE, NMFS assumed that the impact rate would be 0.2 for any 3-year geometric mean of escapement > 4000 as described on pg. 57 of Winship et al. (2012). We assumed the same upper bound of 0.2 for age-3 impact when the 3-year geometric average escapement was > 5000.

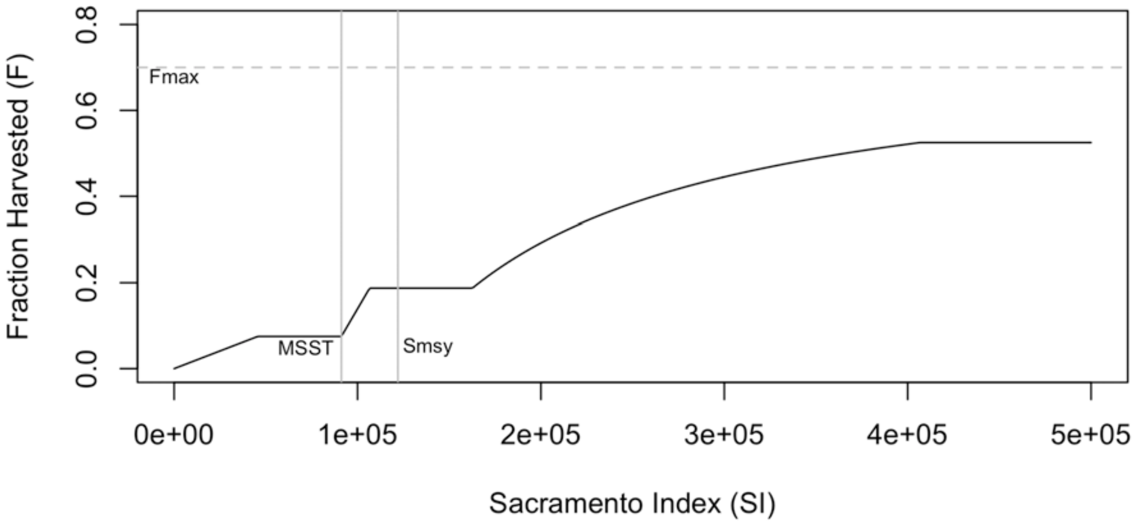

Figure II.1. Fishery control rule as a function of the potential spawner abundance (Sacramento Index) used for setting impact rates for Sacramento River fall-run Chinook.

The fishery control rule defines the impact rates south of Point Arena, which largely encompasses the winter-run marine distribution. Fall-run Chinook are found north of Point Arena, and the fishery control rule for those areas is dependent upon the abundance index for fall run.

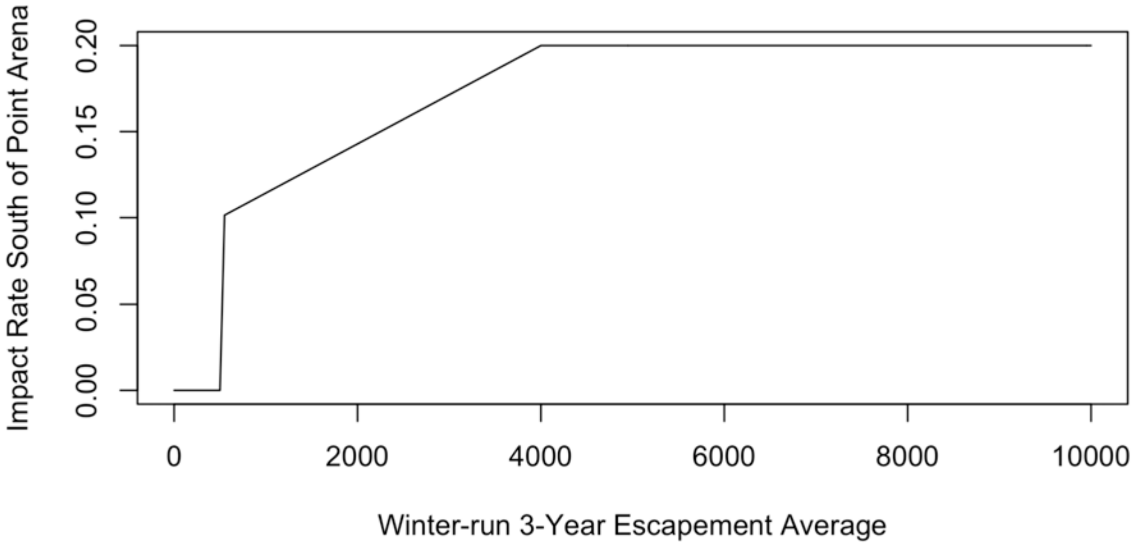

Figure II.2. Fishery control rule as a function of the trailing 3-year geometric average of winter-run abundance.

For example, the SI forecast in 2014 was 634,650 (PFMC 2014). The spawner escapement associated with overfishing in 2014 is 139,623, which is calculated as a function of F_{MSY} (0.78) and the SI abundance forecast of 634,650. The SRFC is a Tier 2 stock, so the $F_{ABC} = F_{MSY} * 0.90 = 0.70$, and the spawner escapement associated the allowable biological catch was forecasted to be $S_{ABC} = N\ (1\text{-}F_{ABC}) = 190{,}395$.

In 2014, the 3-year geometric mean of winter-run abundance was 2,380, which resulted in a maximum forecasted impact rate on age-3 winter-run of 15.4% (in comparison it was 13.7% in 2012 and 12.9% in 2013).

Reducing the maximum impact rate on age-3 winter-run may have important consequences for the actual harvest rates on SRFC. Recently, Satterthwaite et al. (2013) compared the ocean distribution of fall-run, winter-run, and spring-run during the summer and fall, which provides some understanding of the spatial differences in the relative contacts per unit effort of the fishery, which is a proxy for the spatial distribution of each run. Sacramento River fall-run have relative contacts per unit effort of approximately 0.2 for management areas located south Latitude 42 N at the CA OR border, and 0.1 north of Latitude 42 N and Cape Falcon at the OR WA border. These results suggest that the closing of fishing south of Point Arena, as would be required for winter-run 3-year average escapement of less than 500, can have potential consequences for the total fall-run impact rate. For more information, please see PFMC (2014).

Spring Run

There are no explicit fishery management rules for spring run, though it has been noted in past NMFS Biological Opinions (e.g., NMFS 2010) that protections for winter run are likely to be beneficial for spring run. Comparisons of ocean and river impact rates of spring-run relative to SRFC by US Fish and Wildlife Service for the purposes of meeting the goals of the Central Valley Project Improvement Act (CVPIA) indicated equivalent ocean fishery rates were assumed for sprint-run and fall-run, whereas river impact rates were consistently lower for spring-run (Chinookprod_032011.xlsx obtained from http://www.fws.gov/stockton/afrp/). Overall, total fishing impact rates for spring-run were approximately 0.95 of fall-run.

Harvest Model

The management of SRFC requires annual management rules to optimize the fishery due to changing abundances of winter-run and Klamath River stock sizes in addition to the status of other stocks (e.g., PFMC 2014). The management process can be simplified by making several assumptions about the fishery management dynamics:

- Klamath River Fall Chinook do not limit the values of F_{ABC} calculated annually for SRFC.
- The Klamath River fall age 4 harvest rate limits, intended to protect California Coastal Chinook, do not limit the values of F_{ABC} calculated annually for SRFC.
- Abundance of age-3 SRFC and winter-run are obtained from the spring-run & fall-run life cycle model and the winter-run models, respectively. In the actual management of SRFC, estimates of an adult (age 3-5) abundance index in year *t* are calculated from regressions to age-2 abundances in year *t*-1.

- The fishery acts without error; thus, management overfishing (i.e., total annual exploitation rate exceeds the maximum fishing mortality threshold of 0.78) cannot occur.

The following steps were developed for calculating the annual impact rate for SRFC (F_{FR}), and Sacramento winter-run Chinook (F_{WR}).

1. Calculate an estimate of the Sacramento Index as the sum of the four components identified previously.
2. Determine the fall-run impact rate F_{FR} based on the fishery control rule for SRFC (Figure II.1). The control rule specifies that even if the stock is approaching an overfished condition (the SRFC stock has a 3 year geometric average (t-2, t-1, current year) that is below the threshold of 91,500), a *de minimis* fishery will occur at the rate defined by the fisheries control rule.
3. Calculate the trailing 3-year geometric average of winter-run abundance.
4. Depending upon the 3-year geometric value, set the fishery impact rate for winter-run (Figure II.2). If the winter-run impact rate is 0, reduce F_{FR} by 25% to account for lost fishing opportunities south of Point Arena.
5. Set the impact rate for spring-run $F_{SR} = 0.95F_{FR}$ to reflect reduced river impact rates.

RESULTS

Future trends in abundance for seven populations of fall and spring-run Chinook spawning in tributaries of the Sacramento River watershed were simulated under different scenarios for future climate change and ocean productivity, and alternative levels of water export from the Sacramento-San Joaquin Delta. Results from a Bayesian multi-stock population dynamics model, fit to historical abundance data, were used to parameterize forward simulations. In addition, future trends in abundance for Sacramento winter-run Chinook were also simulated to allow for implementation of the current fishery management process. All eight populations were simulated forward in time for 50 years in response to the 16 alternative environmental scenarios (combinations of future climate, ocean productivity, and water exports), subject to capacity interactions arising from juvenile competition, and accounting for estimation uncertainty and process error in future predictions. The forward simulation for each environmental scenario was replicated 1,000 times with randomly drawn process deviates and model parameter values.

Differences in future outcomes for these populations in response to the 16 scenarios are best quantified through comparison of realized survival rates within populations and across scenarios. Realized survival rate was calculated in two ways depending on the life history of the individual populations. First, for wild-spawning Chinook stocks (mainstem Sacramento fall-run, and Deer, Mill and Butte Creek spring-run), realized survival was calculated as the as the survival rate from egg to spawning adult, or the sum of spawning adults from a brood year across return years, divided by the spawning abundance producing that cohort multiplied by the assumed fecundity (Eq. II.4).

(II.4)
$$RS_{y,p,e,i} = \frac{\sum_{a=1}^{Nages} A_{t,p,a,e,i}}{E_{y,p,e,i}}$$
$$t = y + \tau_a$$

In equation II.4, realized survival ($RS_{y,p,e,i}$) from brood year y, of population p, for environmental scenario e, and simulation i, is a function of the adult abundance surviving both natural and fishing mortality and returning to spawn ($A_{t,p,a,e,i}$) in calendar year t, of population p and age a, resulting from simulation i of environmental scenario e, and the number of eggs ($E_{y,p,e,i}$) resulting from brood year y for that population, scenario and simulation. τ_a represents the difference between brood year y and the calendar year of return t, for individuals returning at each age a.

Realized survival for the hatchery-produced populations (Battle Creek (CNFH), Feather River, and American River (Nimbus) fall-run) is determined by the ratio of returning adult spawners ($A_{t,p,a,e,i}$) to the number of hatchery for that population (RH_p), which is assumed constant in the future (Eq. II.5)

(II.5)
$$RS_{y,p,e,i} = \frac{\sum_{a=1}^{Nages} A_{t,p,a,e,i}}{RH_p}$$
$$t = y + \tau_a$$

Predictions for future realized survival rates for the three spring-run (Fig. II.3) and four fall-run (Fig. II.4) populations across years and replicate scenarios, accounting for future fishing mortality, across environmental and export scenarios show some consistent patterns. As expected, survival rates for the hatchery-produced Chinook populations were much higher than those predicted for the wild-spawning populations, given that realized survival was measured as survival from release to spawning adult, as opposed to egg to adult survival (Table II.1). For the fall-run Chinook populations, the final model estimated a net positive impact of nearshore upwelling on survival, as a result these four populations show higher average survival rates for scenarios which included a 10% increase in upwelling (oceanUP) across both future climate change and water export scenarios. Across fall-run populations, simulated positive upwelling conditions in the future resulted in an average increase in realized survival of between 12% and 67% (mean: + 44%) across export scenarios, when compared with those scenarios incorporating a 20% reduction in nearshore upwelling (oceanDOWN, Table II.1). With respect to the spring-run Chinook populations, substantially smaller differences in realized survival rates in response to the oceanUP scenarios were observed, with 5 – 17% decreases in average realized egg to adult survival (Fig. II.3). Winter-run Chinook on the other hand, were predicted to exhibit higher survival in response to the increased upwelling under the oceanUP scenario, with 7 – 36% higher survival (Table II.1)

Predictions for differences in realized survival rate across water export scenarios indicated similar general trends across both populations and potential differences in future climate change. For all populations realized survival rates were predicted to be highest under the zero export scenario, followed by scenarios simulating a 30% reduction in exports, average exports, and a 30% increase in water exports (Fig. II.3, II.4). When compared to scenarios simulating future survival in response to water export levels at the 1967 – 2010 average, spring-run Chinook populations are expected to exhibit a higher average realized survival in response to a 30% reduction in export volumes, with survival 27 – 48% higher for Deer Creek, 29 – 51% higher for Mill Creek, and 19 – 38% higher for Butte Creek Chinook, across environmental scenarios. Fall-run Chinook populations are predicted to exhibit somewhat smaller increases in survival under a 30% export reduction (expDOWN30) relative to average water exports in the future (expAVG), with realized survival higher by 12 – 26% for Sacramento mainstem wild-spawning Chinook, and between 14% and 27% for the three hatchery-produced fall-run Chinook populations across environmental scenarios (Table II.2). Winter-run Chinook are predicted to respond to a 30% reduction in future water exports, with only a 3 – 9% increase in survival relative to the average export scenario (Table II.2).

When future dynamics of Sacramento Chinook populations were simulated with a 30% increase in water exports (expUP30), compared to the average export scenario the mainstem Sacramento wild-spawning Chinook were predicted to experience 16 – 28% lower median realized survival rates from egg to spawning adult, while the three hatchery-produced populations were predicted to exhibit a 14 – 25% reduction in future survival from release to adulthood, depending on the climate change and ocean production scenario (Fig II.4, Table II.2). Simulation of future Deer, Mill, and Butte Creek survival indicated that, relative to the average water export scenario, average realized egg to adult survival was predicted to be 39 – 53% lower in the presence of a 30% increase in future water exports (Fig. II.3, Table II.2). The simulation results again indicate that the response by winter-run Chinook to altered export levels is minimal, with a 0 – 3% reduction in average realized egg to adult survival, across environmental scenarios.

Predictions for realized survival under the zero future export scenario (expZERO) were higher for all populations, however the magnitude of the difference in survival between this and the average export scenario (expAVG) was largely contingent upon the climate change scenario and population of interest. The Deer and Mill Creek spring-run populations exhibited the largest difference in realized survival between the zero and average export scenarios, under the OCAP 9.2 climate change prediction and positive ocean conditions (cc92.oceanUP) (Fig. II.3). Predicted survival in the absence of exports was 79% higher for Deer Creek, 85% higher for Mill Creek, and 59% higher for Butte Creek Chinook, compared to average exports (Table II.2). Interestingly, the Butte Creek spring-run Chinook population also showed one of the smallest responses to the zero export scenario across populations, with only 27% higher survival compared to the average export scenarios under the OCAP 9.5 climate change and lower ocean production environmental scenario (cc95.oceanDOWN). This increase in predicted survival is quite minimal when compared to the 62 – 83% higher survival predicted for the fall-run Chinook populations with zero exports, under the same environmental scenario (Table II.2). In general however, average realized survival for fall-run Chinook under the zero export scenario is expected to be 28 – 62% higher for the mainstem Sacramento wild-spawning population and 44 – 83% higher for the hatchery-produced populations, when compared to expectations under the average export scenario. While results indicated that realized winter-run Chinook survival would be minimally influenced by a 30% increase or reduction in future exports, the zero export scenario is predicted to increase survival by 28 – 91%, most appreciably when combined with a cooler and wetter future climate change scenario and positive future marine conditions (cc92.oceanUP).

In addition to higher median realized survival rates, the zero export scenario is also predict to also produce more variable survival in the future. While most pronounced for the spring-run Chinook populations, when the variability in realized survival is compared across export scenarios it is consistently higher for the zero export case, across all populations (Fig. II.3, Fig. II.4). The Butte Creek population exhibits the greatest variation in future survival, specifically under the zero export scenario, and for the OCAP 9.2 climate change pathway across export scenarios (Fig. II.3).

While these forward simulation results suggest that higher and more variable realized survival can be expected under the zero export scenario, across populations, climate change trajectories, and ocean productivity patterns, it is also evident that a 30% reduction in water exports (expDOWN30) is likely to achieve an increase in realized survival of a substantial magnitude in many cases. For example, on average across environmental scenarios the Butte Creek population is expected to exhibit a 41% increase in average realized survival under the zero export scenario, and a similarly large increase of 27%, with a 30% reduction in spring export volumes (Fig. II.3, Table II.2). This amounts to a difference of only a 14 percentage points in the predicted survival rate increase; between the zero export and 30% export reduction scenarios. Results are similar for the other spring-run populations, with a difference of 25 percentage points for Mill and Deer Creek spring-run Chinook. Improvements in survival under the zero export scenario, relative to the 30% export reduction scenario (expDOWN30), are on average greater for the hatchery-produced fall-run Chinook populations, but likewise suggest that on average across environmental scenarios, a difference in survival of only 26 – 43 percentage points is likely to be observed (Table II.2).

The percentage difference in realized survival increase, for the zero export and 30% reduction scenarios, relative to the average export scenario, is most variable for the winter-run Chinook population. The percentage increase in survival difference between expZERO and expDOWN30 is smallest under cc95.oceanDOWN scenario at 25, and greatest under the cc92.oceanUP scenario. This indicates that under a cooler and wetter future climate with greater upwelling (cc92.oceanUP), the ceasing all exports (expZERO) is likely to have a substantially higher survival benefit relative to reducing exports by 30% (expDOWN30). While, in the face of a hotter and drier future climate with reduced nearshore upwelling (cc95.oceanDOWN) where survival is severely limited by natural processes, both before and after the delta, the benefits of a 30% reduction and zero exports are more similar (Table II.2). This same pattern is predicted for the spring-run Chinook populations, but not the fall-run populations.

With respect to the influence of climate change on predictions for future realized survival, differences in outcomes amongst climate change scenarios differed across populations and were smaller on average when compared differences resulting from alternative export scenarios. The Butte Creek spring-run Chinook population is predicted to have consistently higher realized survival under the OCAP 9.2 climate change forecast, which represents a slightly slower rate of warming paired with increased precipitation (Fig. II.3). Conversely, both the spring-run Deer Creek and fall-run Sacramento mainstem wild-spawning populations show slightly, but consistently, higher survival under the OCAP 9.2 climate change trajectory which describes a greater increase in temperature paired with lower levels of future precipitation (Table II.1).

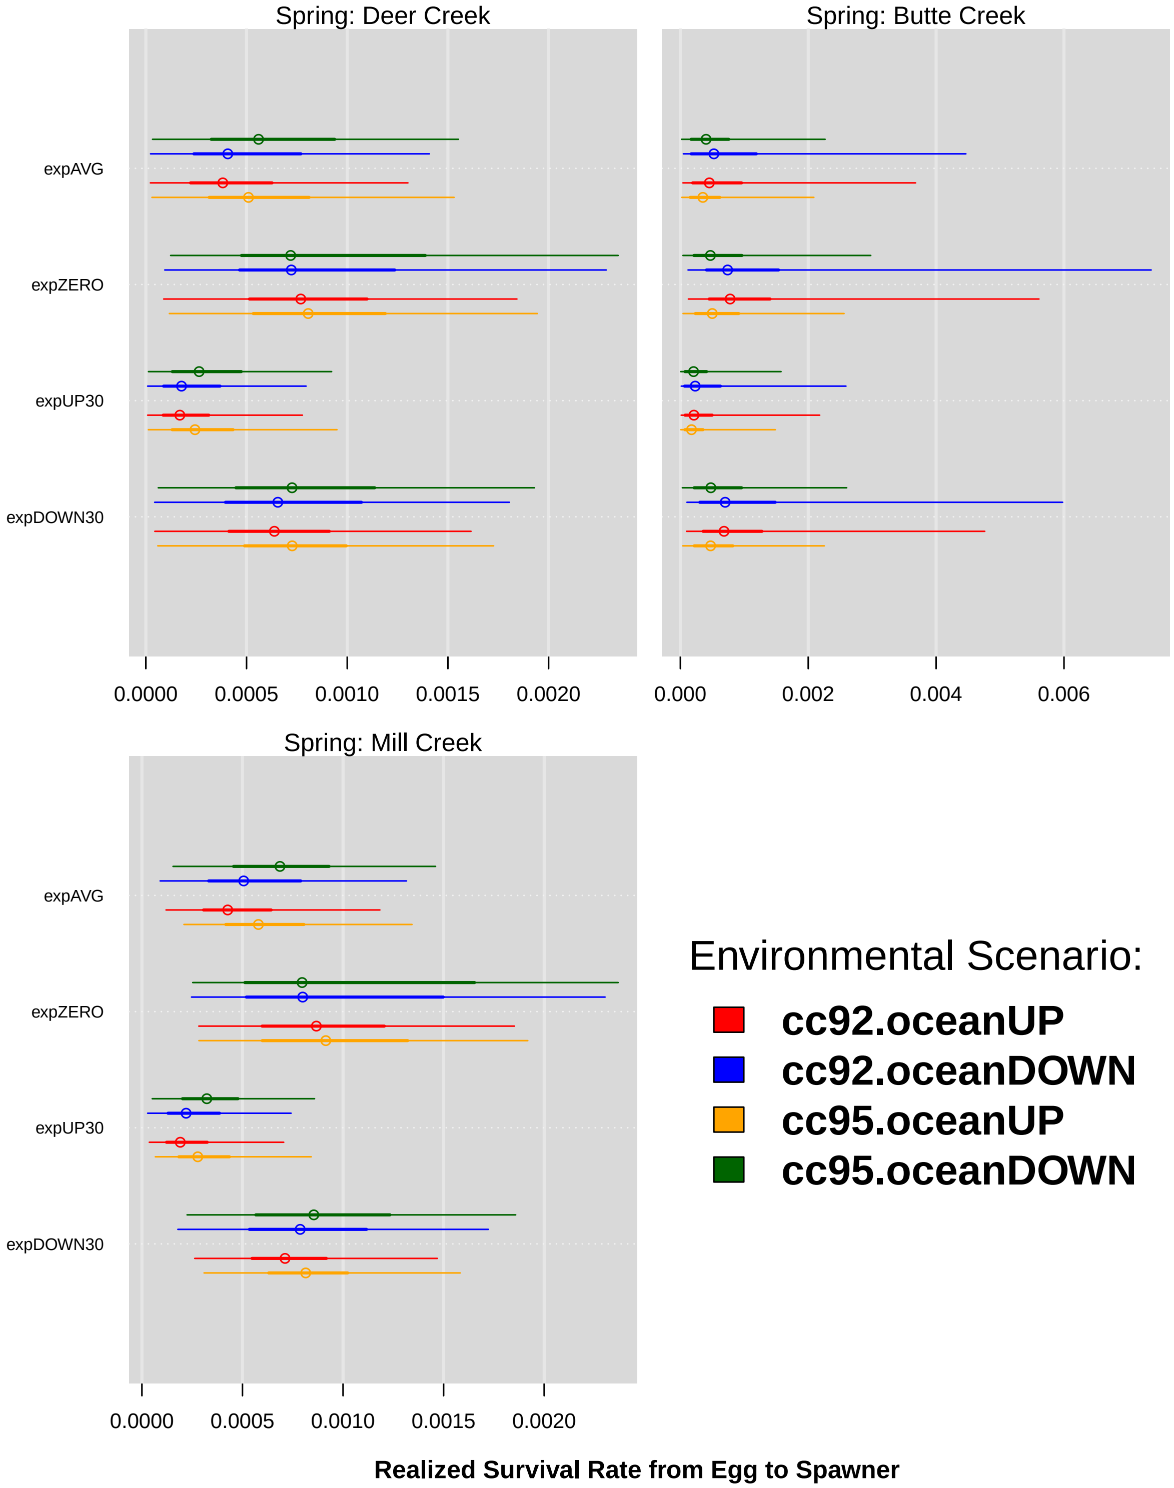

Figure II.3. Caterpillar plots describing the predicted distribution of realized survival to return, across years and simulations, for spring-run Chinook populations. The circle, thick line, and thin line describe the median, 50% credible interval and 95% credible interval for the predictions.

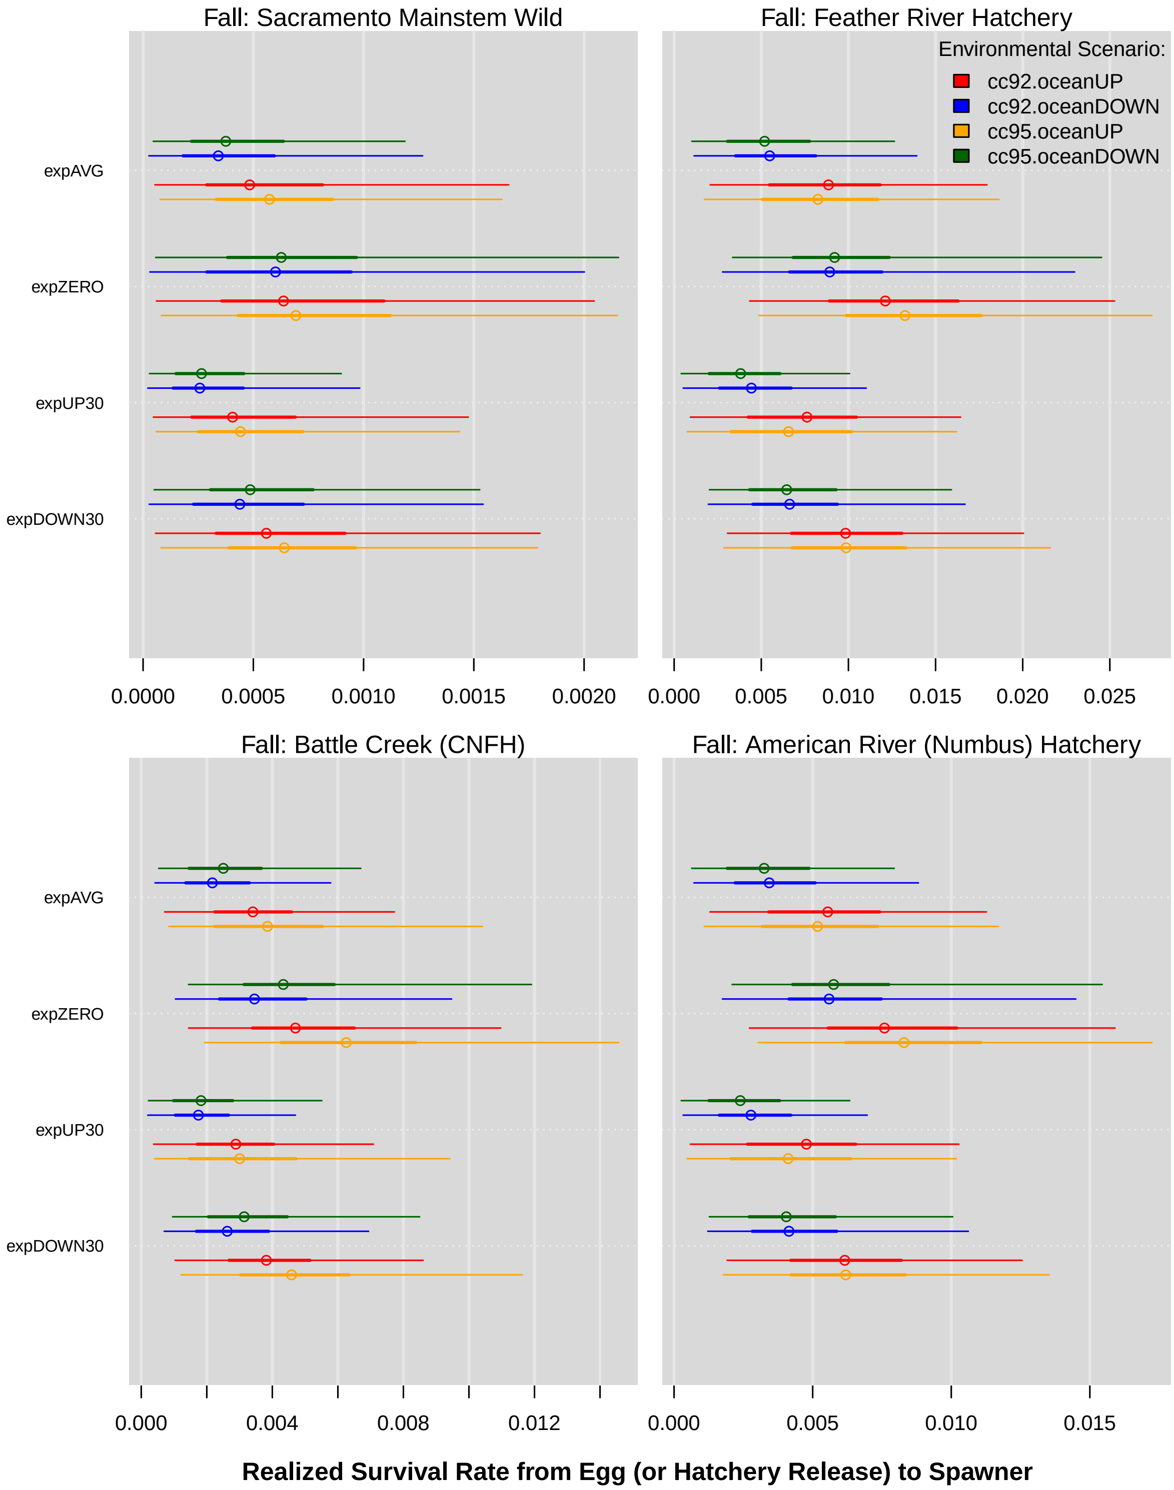

Figure II.4. Caterpillar plots describing the predicted distribution of realized survival to return, across years and simulations, for four fall-run Chinook populations. The circle, thick line, and thin line describe the median, 50% credible interval and 95% credible interval for the predictions.

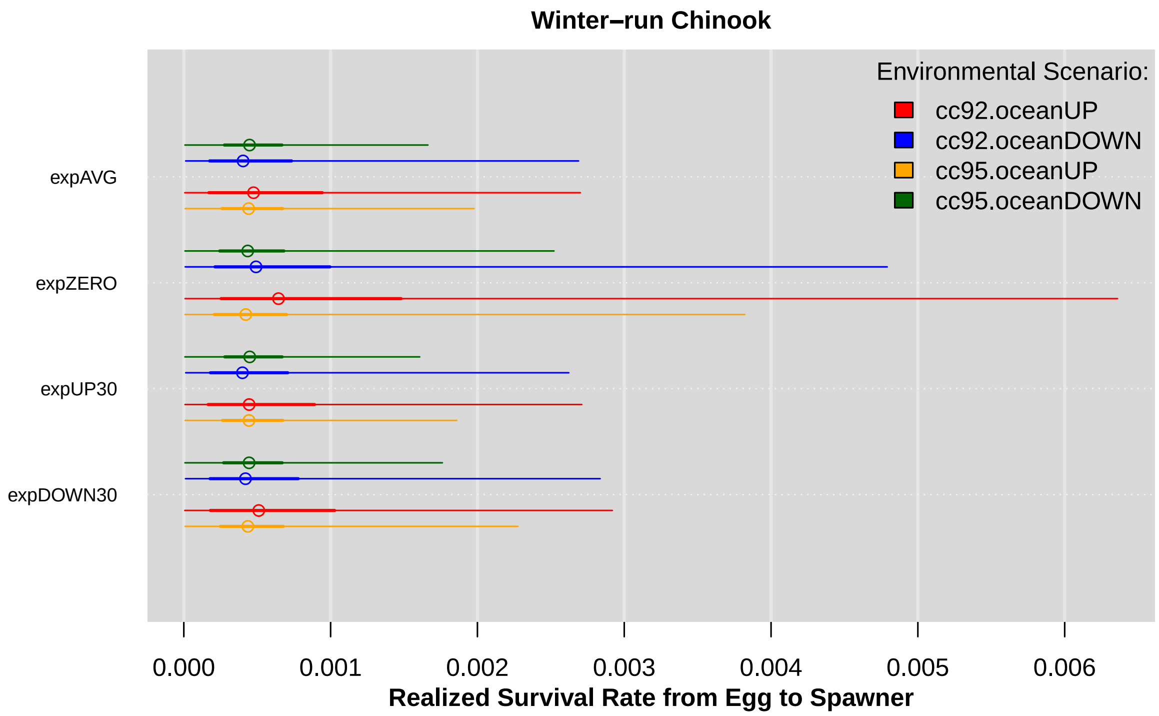

Figure II.5. Caterpillar plots describing the predicted distribution of realized survival to return, across years and simulations, for winter run Chinook populations. The circle, thick line, and thin line describe the median, 50% credible interval and 95% credible interval for the predictions.

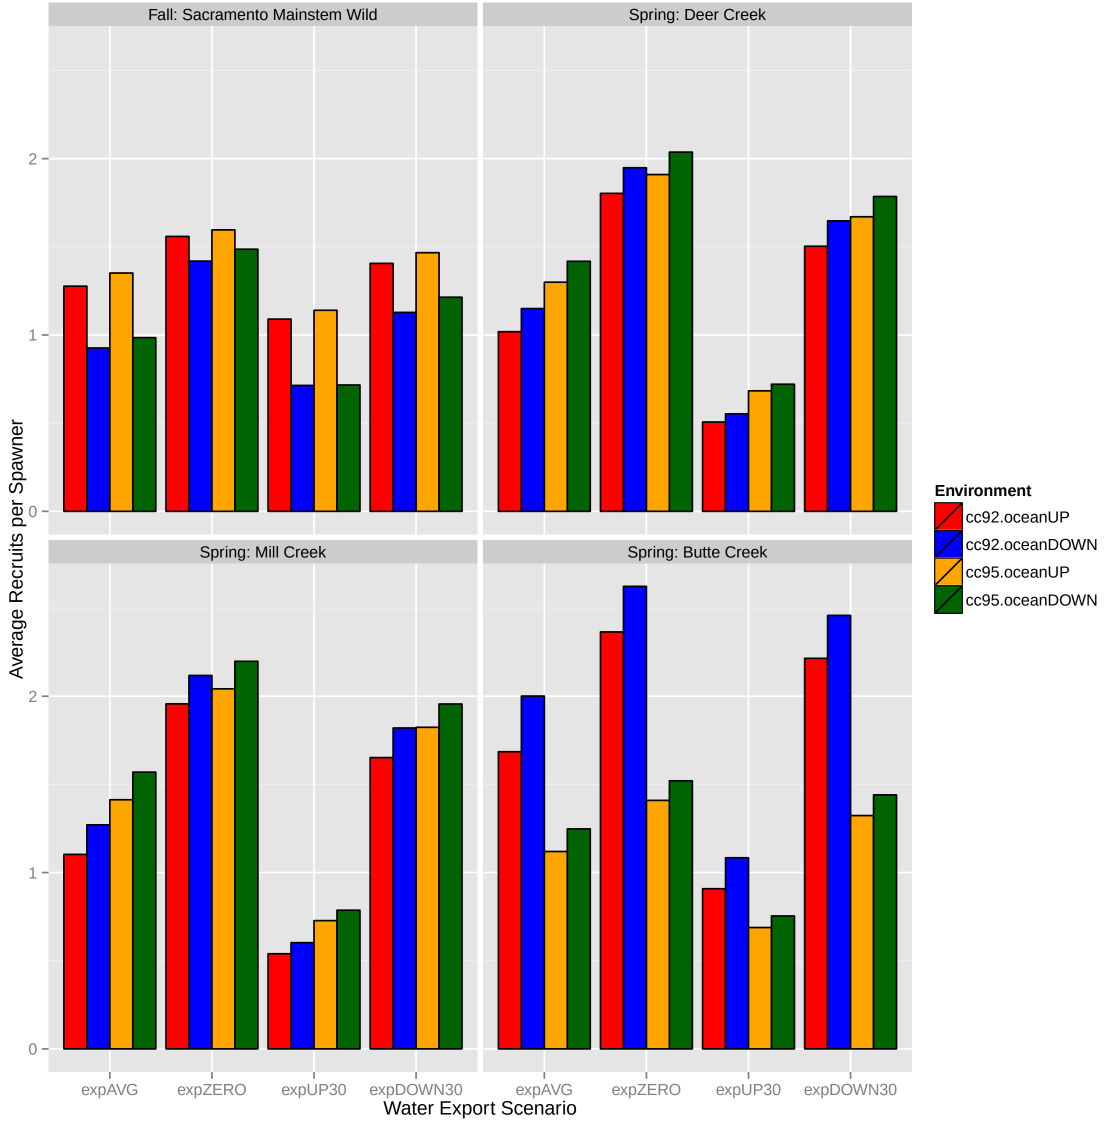
Table II.2. Percent difference in median realized survival from average export (expAVG) scenario, across environmental scenarios. Values shaded from red (low) to green (high) for ease of interpretation.

In addition to estimates for future realized survival rates, for wild-spawning populations the average productivity of populations across years and replicate scenarios was also evaluated. Figure II.6, displays the average number of recruits per spawner for the Sacramento mainstem wild-spawning fall-run Chinook population, and the Deer, Mill, and Butte Creek spring-run populations and winter run, under alternative water export scenarios and environmental conditions. Scenarios that predict average productivity of less than 1 recruit-per-spawner, indicate that those populations are unlikely to remain viable in the future and will tend toward extinction in the presence of environmental stochasticity. Forward simulation results for the mainstem Sacramento fall-run Chinook population indicate that under the average (expAVG) and 30% increase (expUP30) water export scenarios, average productivity in the face unfavorable ocean conditions producing a 20% reduction in future upwelling (oceanDOWN) is expected to be less than one recruit-per-spawner (Fig. II.6). However, under both of these future export scenarios average recruits-per-spawner is expected to expected to exceed one under favorable future ocean conditions (oceanUP).

Predicted future realized productivity (recruits-per-spawner) for the Deer, Mill, and Butte Creek spring-run populations is predicted to be significantly lower under the scenario representing a 30% increase in future exports (expUP30). For both the Deer Creek and Mill Creek populations, average realized productivity (recruits-per-spawner) is predicted to be less than one with a 30% increase in water exports (expUP30), across all four combinations of future climate change and marine conditions (Fig. II.6). Predictions for future productivity of the Butte Creek population indicate that with the more gradual climate warming and greater future precipitation under the OCAP 9.2 scenario indicate that even with a 30% increase in water exports (expUP30) the population may be expected to produce at or near 1 recruit-per-spawner, and therefore remain viable.

Average future productivity (recruits-per-spawner) is expected to be highest across environmental scenarios under the zero export (expZERO) and 30% reduction in future exports (expDOWN30). However, realized productivity is predicted to vary across populations in response to future climate change and ocean production scenarios. For the mainstem Sacramento wild-spawning fall-run population, future productivity in the face of positive ocean conditions and specifically increased nearshore upwelling (oceanUP) is predicted to be highest and exceed one recruit-per-spawner, independent of the climate change or export scenario. The form of future climate change is predicted to have the greatest impact on the Butte Creek spring-run Chinook population, with higher productivity, in terms of recruits-per-spawner, under the OCAP 9.2 scenario (Fig. II.6). This results from the fact that this population was found to be particularly sensitive to summertime temperatures, which are predicted to increase more precipitously under the OCAP 9.5 climate change scenario leading to reduced over-summer survival of adults holding prior to spawning. Spring run stocks are much more sensitive to exports than fall and winter run, but both fall and winter do see slight improvement under export restrictions.



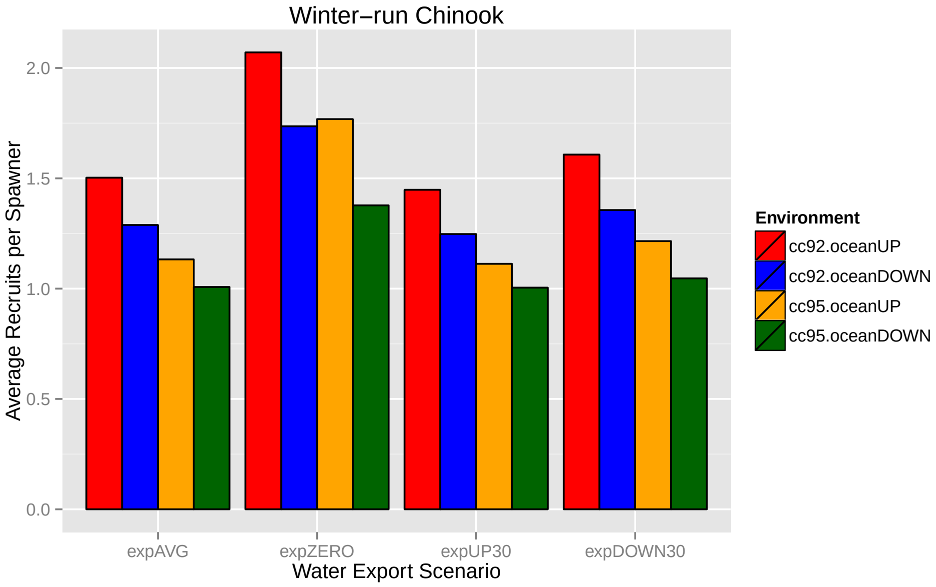


Figure II.6. Average number of realized recruits per spawner, across populations, environmental and export scenarios

PART II DISCUSSION

Results from a Bayesian population dynamics model estimating the stage and population specific maximum survival rates and changes in survival in response to natural and anthropogenic environmental covariates were used to parameterize simulations for future trends in population-specific abundance under alternative water export, climate change, and ocean production scenarios. Both estimation and process uncertainty were incorporated into future predictions by, first sampling model parameter values from the joint posterior, and second incorporating stochastic process deviations into the first modeled life-stage. One thousand replicate simulations of the 50-year future time series were used to fully quantify the influence of these two sources of uncertainty. The likely impact from future ocean harvest of Chinook was incorporated by simultaneously modeling the future trends in abundance for winter-run Chinook in the Sacramento system and replicating the current fishery management decision rules. We did not explore the impacts of modifying the harvest regime, but obviously any change in the fraction of fish harvested would have an analogous impact to increasing survival via changing exports or other environmental factors.

Results from these forward simulations in the form of estimates for future realized survival rates from egg, or hatchery release, to spawning adult, and estimates for realized productivity (recruits-per-spawner) indicate that while all populations are sensitive to differences in future water exports from the Sacramento-San Joaquin Delta, differences in the future environment are likely to have substantial population-specific impacts. The observation that predicted realized survival and productivity are generally higher for the fall-run populations and equal or lower for the spring-run populations under the oceanUP scenario results from several characteristics of the forward simulation model. The oceanUP scenario represents a 10% increase in future nearshore upwelling, paired with a smaller increase in future water temperatures at the Farallon Islands. While nearshore upwelling was found by the estimation model to significantly increase survival in the nearshore region for fall-run Chinook populations, this covariate was not AICc-selected for the spring-run populations. As a result, predictions for future realized survival for the fall-run Chinook populations show as consistently higher survival and productivity patterns in response to the oceanUP scenario. This prediction for higher realized survival for fall-run Chinook populations agrees with insights by Lindley et al. (2009) pointing to unusually low nearshore upwelling patterns as one of the proximate causes of the failure of the 2004 – 2005 fall-run brood years. In addition, the grouped survival of all seven Chinook populations was found to have a positive relationship with the Pacific Decadal Oscillation. The oceanUP scenario described an initial negative PDO phase, followed by a positive PDO phase, resulting in lower marine survival initially followed by higher marine survival in later years for the populations. The opposite pattern in marine survival was observed for the seven Chinook populations under the oceanDOWN scenario in response to the PDO pattern simulated in the opposite direction.

Future climate change scenarios had mixed impacts across populations as a result of the estimated response by populations to the environmental covariates impacted by the OCAP 9.2 and 9.5 predictions. The cooler and wetter OCAP 9.2 scenario had a particularly strong influence on the Butte Creek population, because a strong negative influence of high summertime temperatures was predicted for this population. However, the increase in water flow associated with the OCAP 9.2 scenario resulted in increased sediment concentration at Freeport, CA. Given the negative relationship between sediment concentration at this location and survival for both fall and spring-run Chinook, this aspect of the OCAP 9.2 scenario did result in some reduction in survival for all populations, although in some cases this effect was outweighed by the interaction with temperature.

Across all combinations of future export and environmental scenarios predictions for both realized survival and productivity (recruits-per-spawner) were highly variable. While we have focused on predicted differences in median survival and average productivity, the 95% credible intervals for these predictions overlap in almost all cases. This indicates that the combination of both estimation and process uncertainty introduced in the forward simulation process leads to significant variability in future abundance and our quantified metrics. This is particularly pronounced in future predictions of realized survival for the Butte Creek population, which are extremely right skewed (Fig. II.3).

Quantifying results of forward simulations for wild-spawning Chinook populations in terms of average productivity (recruits-per-spawner) provided an efficient means for determining under what water export scenarios and environmental conditions specific populations are expected to persist (recruits-per-spawner > 1), or decline toward extinction (Fig. II.5). For several of the populations under the 30% increase in future water export scenario (expUP30), and for the fall-run mainstem Sacramento wild-spawning population under the average export scenario paired with decreased future upwelling (oceanDOWN), average productivity was predicted at less than one. While this result suggests that under those conditions specific populations may be expected to decline in abundance, it is important to fully understand the assumptions involved in this prediction. First, the forward simulations assume that future fishing mortality rates will vary in accordance with current management practices, as influenced by the Sacramento Index and harvest limitations based upon the abundance of winter-run Chinook. A reduction in future fishing mortality rate may be sufficient to increase the productivity of these populations above 1 recruit-per-spawner and facilitate persistence. Second, predictions for future productivity do not account for the stray rates amongst hatchery and wild populations leading to source-sink dynamics (Johnson et al. 2012). These effects may be most important for the Sacramento mainstem wild-spawning fall-run Chinook population, which was found in 2010 and 2011 to have 20 – 27% of its observed spawning abundance resulting from hatchery-reared strays (Kormos et al. 2012, Palmer-Zwahlen and Kormos 2013). Whether the contribution of straying individuals may be enough to facilitate persistence of populations under environmental and export scenarios that are predicted by these analysis to lead to decline (recruits-per-spawner < 1), remains unknown.

APPENDIX A LINKAGES TO THE CENTRAL VALLEY LIFE CYCLE MODEL

BACKGROUND

The National Marine Fisheries Service (NMFS) Southwest Fisheries Science Center (SWFSC) initiated a project to develop life-cycle models of salmon populations in the Central Valley. The project objective is to build a framework to quantitatively evaluate how the management and operation of the Federal Central Valley Project (CVP) and California State Water Project (SWP) affect Central Valley salmon populations. The modeling framework will evaluate the current operations of the CVP and SWP, i.e., Operational Plan and Criteria (OCAP), and evaluate future water conveyance structures as proposed in the Bay Delta Conservation Plan (BDCP). The NMFS Central Valley Life Cycle Model (CVCLCM) targeted winter-run as the first race of Chinook for model development (Hendrix et al. 2014).

The CVCLCM framework is a stage-structured model. Stages in the model were based on developmental state as well as geographic location (e.g., smolts in the delta, smolts in the mainstem river, or smolts in a floodplain). State transitions among life-history stages are defined by a modified Beverton-Holt (Beverton 1957) that allows individuals exceeding the capacity of a habitat to move to a different geographic location rather than die in that habitat (Greene and Beechie 2004). The Beverton-Holt with movement function is defined by a survival rate, capacity, and movement rate (Figure A.1). Each of these parameters can be modeled as a function of environmental or anthropogenic factors that may be influenced by management (e.g., spatial extent of floodplain habitat as it affects capacity) and operational actions (e.g., flow as it affects movement or water temperature as it affects survival).

Capacity estimates for the river and delta habitats from the CVCLCM were used in the current fall-run and spring-run model. In addition, there are several products from the current model that will be useful to the CVCLCM, which is developing fall-run and spring-run life cycle models.

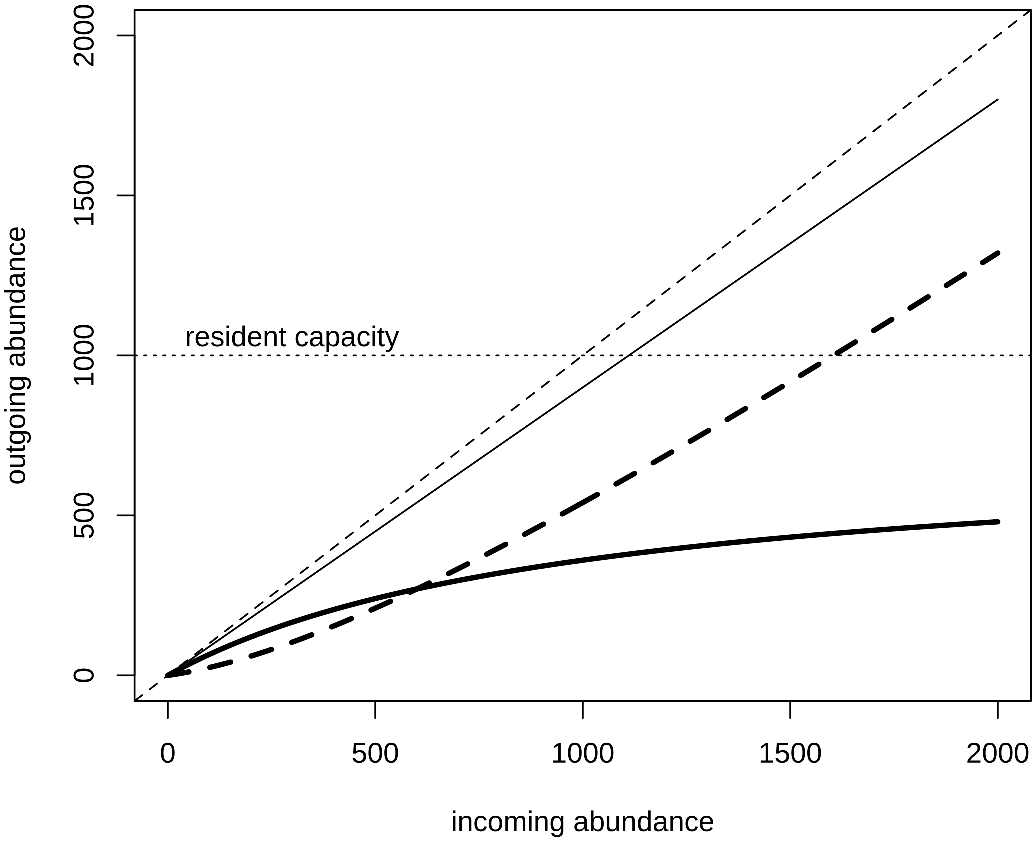

Figure A.1. Beverton-Holt with movement transition function. Outgoing abundance (thin solid line) is composed of migrants (thick dashed line) and residents (thick solid line), which are affected by the resident capacity (dotted horizontal line). Those fish that are not residents leave as migrants. The 1:1 line (thin dashed) is also plotted for reference.

PRODUCTS FROM THE CVCLCM USED IN THE FALL-RUN AND SPRING-RUN MODEL

Capacities

The CVCLCM developed estimates of monthly capacities for use in the Beverton-Holt transition function. The capacities were estimated in four habitats/geographic areas: 1) Sacramento River from headwaters to the city of Sacramento (river), 2) Yolo bypass (floodplain), 3) delta (city of Sacramento to Chipps Island) and 4) Chipps Island to the Golden Gate Bridge (bay). Two of these areas were used in the current fall-run and spring-run life-cycle model. The Sacramento River monthly capacity estimates were used for the Sacramento River mainstem spawning fall-run population in Stage 1 and the delta capacity estimates were used in fall-run (average delta capacity March to May) and spring-run (average delta capacity February to April) capacities for Stage 2.

Capacities for the river, floodplain, delta, and bay habitats were calculated in the CVCLCM as a function of habitat-specific capacity models (Hendrix et al. 2014). We provide details on the river and delta calculations and habitat capacity estimates, because they were included in the fall-run and spring-run model. In particular, the calculation of River capacity was modified since the publishing of the methods in Hendrix et al. (2014). Although the initial model development in the CVCLCM was focused on winter-run, the estimates of capacity are applicable to all races of Chinook in the Central Valley.

River Capacities

The River capacities were defined as a function of velocity and depth. For each variable preferred versus not-preferred categories were defined (Table A.1). The possible combinations of the 2 levels of 2 variables provided 4 categories of habitat quality for rearing Chinook salmon. The Central Valley is primarily a hatchery-dominated system with fish released at smolt size for rapid migration to the ocean, and natural stocks are at historically low levels; therefore, current estimates of fish density from the Central Valley may not be indicative of densities at capacity. As a result, densities from the Skagit River, WA were used to inform the maximum density estimates for each category (Greene et al. 2005). Two densities were used to calculate capacities: the 90th percentile and the 95th percentile of the distribution of densities by habitat category in the Skagit River.

Table A.1. Habitat variables used to define the River capacity.

Variable	Preferred or Not-preferred	Range
Velocity	Preferred	$\leq$ 0.15 m/s
	Not preferred	> 0.15 m/s
Depth	Preferred	> 0.2 m and $\leq$ 1m
	Not preferred	$\leq$ 0.2m or > 1m

Areas of habitat under each of the 4 categories were calculated by running the HEC-RAS model on a series of Sacramento River cross-sections that define cells. Each cell in the cross-section has a depth and velocity, and altering the flow changes the depth and velocity of a particular cell. The area of each cell that corresponded to a specific combination of velocity and depth category was tabulated for each monthly flow associated with a cross-section. The appropriate density of Chinook salmon for each of the 4 categories was applied to arrive at a density estimate for the Sacramento River in each month (Figure A.2).

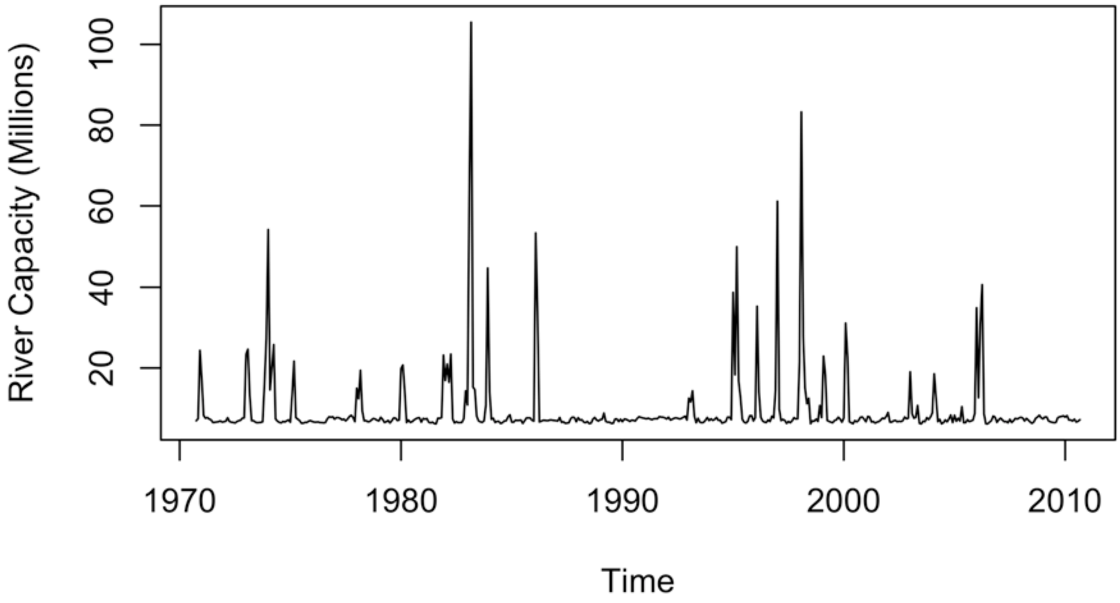

Figure A.2. Monthly capacity of Chinook salmon in the Sacramento River using a 90th percentile estimate of fish density.

Delta Capacities

The monthly capacities in the delta were defined as a function of several habitat attributes including: channel type, cover, shoreline type, blind channel area, salinity and vegetated cover along riverbanks. Analysis was conducted by using Geographic Information System (GIS) data layers. Habitat quality was determined by defining binary High/Low ranges for each axis of habitat quality, similar to the Preferred and Not-preferred approach used in the river habitat. In the delta, 8 categories of habitat quality were defined, each with an associated maximum density. Because not all habitats are accessible by rearing Chinook, a subsequent analysis was conducted to restrict habitat areas based on connectivity. Using beach seine data collected by US Fish and Wildlife Service (Speegle et al. 2013), a generalized linear model was used to estimate the probability of juvenile habitat use by seining location. This model was subsequently used to restrict habitat use by juvenile salmonids throughout the delta. Monthly estimates of capacity in the delta reflected the restricted access to particular areas of the delta and the seasonal absence of juvenile salmonids during the summer months (Figure A.3). Additional details on the capacity calculations can be found in Hendrix et al. (2014).

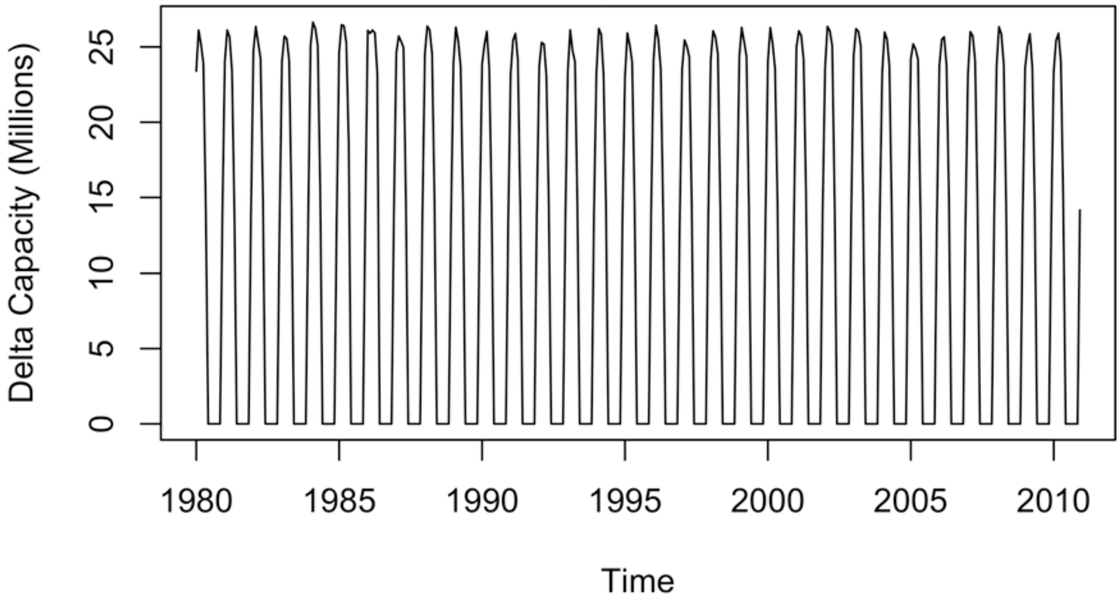

Figure A.3. Monthly capacities of Chinook salmon in the delta using a 90th percentile estimate of fish density.

PRODUCTS FROM THE FALL-RUN AND SPRING-RUN MODEL THAT COULD BENEFIT THE CVCLCM

In the current project, we are using a model for fall and spring-run that incorporates competition through density dependence via a Beverton-Holt transition. This interaction effectively removes some capacity for each of the interacting races. Initial model evaluations indicated that an external capacity value improves the ability to estimate an interaction effect e.g., between fall-run and spring-run or between hatchery and natural. Although the Beverton-Holt function in the CVCLCM incorporates a movement component, understanding the importance of both of these interactions is important in the context of the CVCLCM models for fall-run and spring-run Chinook.

The NMFS scientists developing the fall-run and spring-run CVCLCM models will benefit from interacting with the current fall-run and spring-run model. The current model uses the CVCLCM capacities for certain stages, but these can also be modeled as functions of covariates to allow further hypothesis evaluation. In addition, the time series of observations is greater for the current model than the CVCLCM, which is restricted to 1980 to 2010. Thus earlier escapement data can be used to help parameterize the CVCLCM. Finally, the speed with which alternative hypotheses can be developed and fit to the fall-run and spring-run escapement data provides a useful tool for model construction in the CVCLCM. Hypotheses can be developed and tested on the order of minutes to hours, whereas running the full CVCLCM under a new set of environmental drivers can take on the order of days.

APPENDIX B CLIMATE CHANGE SCENARIO PROJECTIONS

Climate change scenario projections were used to explore the level of impact that California's Central Valley Project (CVP) and State Water Project (SWP) operations can have on spring, fall and winter run Chinook under favorable and unfavorable climate forecasts. Model covariates were divided into three categories: overland covariates (river flows, river temperatures, air temperatures), nearshore ocean covariates (upwelling, PDO, wind stress curl, Farallon ocean temperatures), and anthropogenic water use covariates (exports, export/inflow ratios). Overland model covariates reflected two climate change scenarios: a warmer/drier scenario, and a cooler/wetter scenario. Nearshore ocean covariates explored two situations: favorable nearshore conditions for Chinook at ocean entry (increases in upwelling, PDO in negative phase, less warming of nearshore oceans), and unfavorable conditions (decreases in upwelling, PDO in positive phase, greater warming of nearshore oceans). Anthropogenic water use levels were modified with regard to exports to create four options: 1. future exports=mean historical exports; 2. future exports=mean historical exports +30%; 3. future exports=mean historical exports – 30%, and 4. future exports=0. A total of 16 climate change scenarios were generated using all combinations of overland covariates, nearshore ocean covariates and anthropogenic water use covariates (Table B.1).

METHODS

As the basis for our climate change scenarios, we used the United States Bureau of Reclamation's (USBR) Operations Criteria and Plan (OCAP) Study 9.2 and 9.5 (USBR 2008). OCAP Study 9.2 reflects a mean increase in temperature of 0.75° F (=0.42° C) and an increase of 12.5% in precipitation. OCAP Study 9.5 reflects a mean increase in temperature of 2.8° F (=1.56° C) and a decrease in precipitation of 12%. These temperature and precipitation changes represent a mean 30-year change between 1971-2000 and projected 2011-2040 levels. Study 9.2 and 9.5 are the extreme corners of a bounding box that captures the 10th and 90th percentiles for temperature increase and precipitation change that were predicted by 112 climate projections from a variety of climate models and greenhouse gas emission levels (USBR 2008). USBR used the following methodology to generate OCAP Study 9.2 and 9.5:

1. Plot temperature change (ΔT) vs. precipitation change (ΔP) over central California for each of 112 archived Downscaled CMIP3 Climate Projections (Downscaled CMIP3 Climate Projections Archive website).
2. Determine the 10th and 90th percentiles for predicted temperature and precipitation change.
3. Identify the levels of ΔT and ΔP associated with the 10th and 90th percentiles in the climate projections. The intersection of the 10th and 90th percentiles for ΔT with the 10th and 90th percentiles for ΔP form a bounding box with four corners.
4. Choose climate projections that most closely reflect the four corners of the bounding box. OCAP Study 9.2 reflects the mildest climate change conditions over central California (less warming/ wetter), while OCAP Study 9.5 reflects the most dramatic climate change conditions over central California (more warming/ drier).
5. Modify CalSim-II hydrology inputs and Sacramento River Water Quality Model (SRWQM) inputs based on temperature and precipitation values generated by the climate projections.

6. Run CalSim-II and SRWQM models using historical data that has been modified to reflect climate change, but is still run retrospectively.

We used CalSim-II and SRWQM outputs for OCAP Study 9.2 and 9.5 (USBR 2008 Appendix R zipped data), but projected the hindcast covariate values from 1946-2002 onto years 2007-2063 to obtain a forward projection, while retaining year-to-year variability in covariate values and the covariance structures present in the natural system. OCAP Study 9.2 and 9.5 provided two types of scenario outputs:

1. Streamflows and controlled discharges from dams and weirs: The CalSim-II model predicts mean monthly streamflows and discharges at various points throughout the Sacramento River system and the Delta, including the following covariates from the spring, fall and winter run Chinook models:
    a. **Keswick Dam discharge** (fall run): CalSim-II channel flows at C5 from OCAP Study 9.2 and 9.5 were used for years 1946-2002, averaged over January-March. Averaged values were then projected forward to become scenario values for 2007-2063 (Fig. B.1, Table B.2D).
    b. **Deer Creek discharge** (spring run): CalSim-II channel flows for Deer Creek were not available in OCAP Study 9.2 and 9.5. Instead, CalSim-II channel flows at C11305 (just past the confluence of Mill Creek, Deer Creek, Antelope Creek and discharge point D11305) from OCAP Study 9.2 and 9.5 were used for years 1946-2002, averaged over October-December. Deer Creek was separated from the other constituents of C11305 using the following methodology:
        i. CalSim-II channel flows at C11309 (Deer Creek), C11305 and D11305 were obtained from OCAP scenario NAA_Existing (no action alternative) for years 1946-2002, averaged over October-December. Deer Creek flow C11309 was divided by the sum of D11305 and C11305 to determine which proportion of Deer + Mill + Antelope Creek flows should be attributed to Deer Creek.
        ii. CalSim-II values C11305 + D11305 from OCAP Study 9.2 and 9.5 were multiplied by the vector of proportions for Deer Creek, one for each year (mean over all years=0.42, sd=0.05). These values were then projected forward to become scenario values for 2007-2063 (Fig. B.2, Table B.2D).
    c. **Exports / Inflow Ratio** (fall run): CalSim-II delta inflows (INFLOW-DELTA parameter) from OCAP Study 9.2 and 9.5 for 1946-2002, averaged over March-May, were used as the denominator in the Exports/Inflow ratio, while the four export scenarios (see *8. CVP and SWP Dayflow Exports*; and *8b. Mean Daily Exports March-May*, below) formed the numerator (Fig. B.3, Table B.2E).
    d. **Bend Bridge minimum monthly flow** (winter run): CalSim-II channel flows at C109 from OCAP Study 9.2 and 9.5 were used over years 1946-2002, selecting the minimum monthly flow between August-November. Minimum flow values were then projected forward to become scenario values for 2007-2063 (Fig. B.4, Table B.3A).
    e. **Freeport sediment concentration as a function of Freeport flow** (spring and fall run): Sediment concentrations at Freeport, averaged annually over February-April, were modelled as a linear function of Freeport flows (also averaged annually over February-April) from CalSim-II scenario

NAA_Existing at C169. The linear model equation, with intercept set to zero, is:

Freeport sediment conc. = CalSim-II flow at Freeport * 0.0022487

The R-squared value for the regression is 0.834 (Fig. B.5). Freeport flows from OCAP Study 9.2 and 9.5 for years 1946-2002, averaged over February-April, were then used in conjunction with the linear model to generate sediment concentrations. These were projected forward to years 2007-2063 (Fig. B.6, Table B.2D).

2. River temperatures: SRWQM generates mean monthly river temperatures at various nodes along major rivers in the Sacramento River system (USBR 2008 Appendix R zipped data)
   a. **Sacramento River temperature at Bend Bridge** (winter run): SRWQM outputs for OCAP Study 9.2 and 9.5 were extracted along the Sacramento River at Bend Bridge for 1946-2002. Model predictions were averaged for months July-September and projected onto years 2007-2063 (Fig. B.7, Table B.3B).

In addition to the OCAP Study 9.2 and 9.5 scenario outputs, we also used several other sources of data to generate scenario covariates:

3. Nearshore ocean upwelling estimates: Upwelling indices were obtained from NOAA’s Pacific Fisheries Environmental Laboratory (PFEL Upwelling website). We increased and decreased historic values (1946-2002) of upwelling by +10% and -20% to account for a range of changes to upwelling that might occur under climate change (N. Mantua pers. comm., 12/8/14). These altered historic values were then projected onto years 2007-2063.
   a. **Upwelling at 36° N, 122° W** (spring and winter run): NOAA upwelling index values at 36° N, 122° W (southwest of Monterey, CA) were averaged over April-June for years 1946-2002, and adjusted up or down before being projected onto 2007-2063 (Fig. B.8, Tables B.2B & B.3A).
4. Pacific Decadal Oscillation (PDO) index: PDO indices were obtained from the Joint Institute for the Study of the Atmosphere and Oceans (Mantua and Hare). Over the last century, the PDO has displayed a 20-30 year autocorrelation pattern (Mantua et al. 1997). To capture the future impact of positive (warm) and negative (cold) PDO cycles on Chinook populations, we used two ranges of historic PDO data and projected them forward to years 2007-2063: one was a sequence that began with a positive PDO phase before flipping to a negative PDO phase, while the other began with a negative PDO phase and then flipped to a positive PDO phase. Pacific Northwest and West coast salmon production is enhanced during the negative phase of the PDO, and tends to decline during positive phases of the PDO (Mantua et al. 1997, Hare et al. 1999).
   a. **PDO** (spring and fall run): PDO values between 1900 and 2013 were averaged annually over January-May, and two sequences with opposite patterns were selected for future scenarios (Fig. B.9). The sequence of years between 1922-1978 began with a positive PDO phase, flipping to a negative phase around 1947. The sequence of years between 1946-2002 began with a negative PDO phase, flipping to a positive phase around 1977 (Fig. B.10, Table B.2B).

5. Wind Stress Curl Index: Calculated values for NOAA wind stress curl index for upwelling at Northern Location (39° N, 125° W) were obtained from NOAA's Pacific Fisheries Environmental Laboratory (PFEL Derived Winds website).
    a. **Curl Index** (spring and fall run): Historic curl index values from 1946-2002 averaged over July-December were increased or decreased by 20% and plotted as forward projections for 2007-2063 (Fig. B.11). Curl trajectories from 1967-2063 suggested a long-term autocorrelation pattern (Fig. B.11). Because we did not have compelling reasons to believe that future curl values would follow the same pattern as historic values, we set the future scenario curl index equal to mean curl from 1967-2010 (standardized curl index = 0) (Table B.2B).
6. Farallon Islands ocean temperature: Water temperature data at the Farallon Islands (37° 41.8' N, 122° 59.9' W) were not available for all years between 1946 and 2002, so the methodology of projecting covariate values from 1946-2002 under climate change onto years 2007-2063 could not be used. Instead, we calculated the mean water temperature over February-April for 1967-2012, and increased it by 0.42° C (=0.75° F) to correspond with OCAP Study 9.2, and by 1.56° C (=2.8° F) to correspond with OCAP Study 9.5.
    a. **Farallon Islands ocean temperature** (winter run): Mean water temperature from February-April during years 1967-2012 was 11.8° C. This was increased to 12.3° C and 13.4° C to match with OCAP Study 9.2 and 9.5, respectively (Fig. B.12, Table B.3B).
7. Sacramento air temperatures: Sacramento air temperature projections for 2007-2063 were obtained from the Downscaled CMIP3 Climate Projections archive (Downscaled CMIP3 Climate Projections Archive website) for the same climate projections that were used to generate OCAP Study 9.2 and 9.5. Air temperatures were obtained for the modelled grid cell containing Sacramento's latitude/ longitude (38.5556° N, 121.4689° W). OCAP Study 9.2 was based on climate model mri cgcm2.3.2a with A2 emissions, simulation #5, and OCAP Study 9.5 was based on climate model ukmo hadcm3 with A2 emissions, simulation #1.
    a. **Sacramento air temperature - spring** (spring and fall run): Climate projections for the modelled cell over Sacramento were averaged annually over January-March and adjusted up by 4.55 °F to spatially downscale climate projections to match with historic Sacramento air temperature data. The adjustment factor was obtained for each climate projection by subtracting mean projected air temperature between 1960-2010 (averaged over January-March) from mean historical Sacramento air temperature over the same period. Resulting differences were averaged for the two scenarios to obtain an adjusting value of 4.55 °F (Fig. B.13, Table B.2A).
    b. **Sacramento air temperature - summer** (fall run): Climate projections for the modelled cell over Sacramento for July-September were adjusted up by 8.82° F to spatially downscale climate projections to match with historic Sacramento air temperature data. Methodology for obtaining the adjustment factor was the same as for spring Sacramento air temperatures (see above) (Fig. B.13, Table B.2A).
8. CVP and SWP Dayflow Exports: Dayflow data for exports from the Delta were obtained from California's Department of Water Resources (CA DWR Dayflow website). Average daily exports were calculated for 1967-2010 and modified to generate four future export scenarios: 1. future exports = mean historical exports; 2.

future exports = mean historical exports +30%; 3. future exports = mean historical exports – 30%; and 4. future exports = 0.

   a. **Mean daily exports February-April** (spring run): Dayflow exports were averaged annually over February-April for years 1967-2010 to form the historical export level, which was then modified for scenarios (Fig. B.14, Table B.2C).
   b. **Mean daily exports March-May, for Export/Inflow ratio** (fall run): Dayflow exports were averaged annually over March-May for years 1967-2010 to form the historical export level for the Export/Inflow ratio (see Fig. B.3 and Table B.2E for the Export/Inflow ratio).
   c. **Total daily exports December-June** (winter run): Dayflow exports were summed over all days between December and June, then averaged over 1967-2007 to form the mean historical export level, which was then modified for scenarios (Fig. B.15, Table B.3A).

9. Daily stream flows: Streamflow data are collected daily at select locations by USGS (USGS National Water Information System website). In order to generate future predictions for OCAP Study 9.2 and 9.5, the daily stream flow data had to be correlated to an appropriate CalSim-II output using linear models.
   a. **Number of days Sacramento River flow at Verona > 56,000 cfs** (winter run): A linear model was generated to relate CalSim-II monthly flows at Verona (C160 from OCAP scenario NAA_Existing) for 1967-2003 averaged over December-March, to the total number of days between December and March that Sacramento River flow at Verona exceeded 56,000 cfs (data from USGS National Water Information System website). The linear model is:

      # Days flow > 56,000 = -25.19 + CalSim-II flow at Verona * 0.001646

      with R-squared = 0.9285. This relationship was used in conjunction with CalSim-II flows at Verona (C160) for December 1946-March 2003, averaged over December-March, to generate future scenario values (projected onto 2007-2063) for number of days that Sacramento River flow at Verona exceeds 56,000 cfs (Fig. B.16, Table B.3B)

10. Water management operations: Discharges from dams, weirs and gates are managed in California to optimize diverse interests, including efforts to increase winter run Chinook populations.
    a. **Proportion of time Delta Cross Channel gate is open, December-March** (winter run): The current operations plan is to close the Delta Cross Channel (DCC) gate while winter run Chinook are out-migrating. As a result, future scenarios assume that the proportion of time that the DCC gate is open between December and March is zero (Table B.3B).

11. Parameters for which no future conditions could be generated:
    a. **Channel Depletion** (fall run): The net channel depletion is the quantity of water removed from the Delta channels to meet consumptive use, averaged over March-May. Since future population growth may be countered by water-saving technologies and measures, we set the future value of channel depletion equal to the mean value over 1967-2010 (or a standardized value of 0) (Table B.2A).
    b. **Smolt Size at Chipps Island** (spring run): For this parameter, we assumed that size of out-migrating smolt caught at Chipps Island will not change over

future years, so smolt size for the scenario projections was set equal to mean size over 1967-2010 (standardized value of 0) (Table B.2A).

ACKNOWLEDGEMENTS

We would like to thank Nate Mantua (NMFS – SWFSC) for advice on climate change impacts to physical characteristics of oceans, and Andrew Pike (NMFS – SWFSC) for his assistance with understanding and obtaining CalSim-II and SRWQM OCAP model outputs. For climate projection outputs that were used for scenario covariates, we acknowledge the modeling groups, the Program for Climate Model Diagnosis and Intercomparison (PCMDI) and the WCRP's Working Group on Coupled Modelling (WGCM) for their roles in making available the WCRP CMIP3 multi-model dataset. Support of the CMIP3 dataset is provided by the Office of Science, U.S. Department of Energy. Lastly, we thank Nate Mantua and Steve Hare for access to their historic PDO index values.

FIGURES

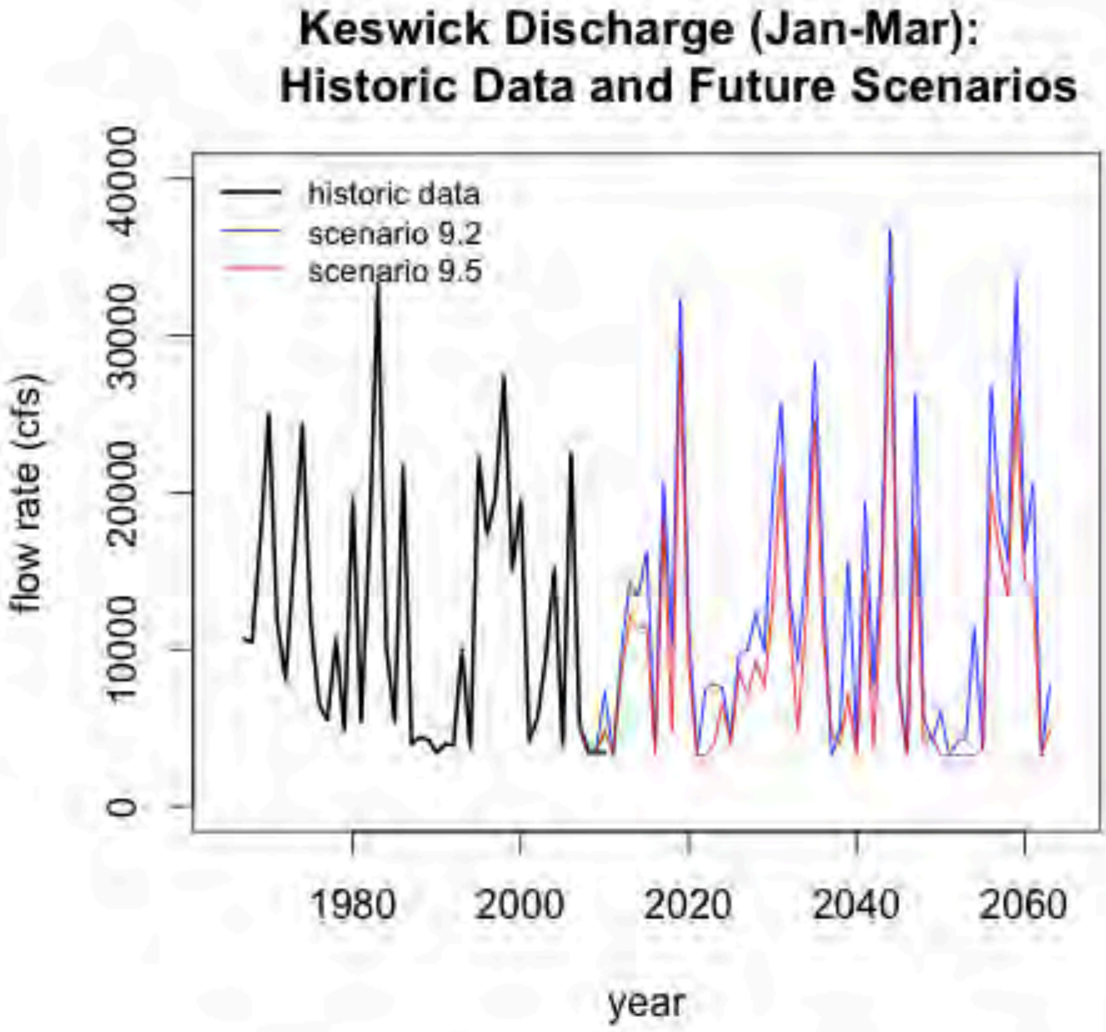

Figure B.1. Mean annual discharge (cubic feet per second, cfs) from Keswick Dam for January-March: historic data from 1967-2010 and climate change scenarios 9.2 and 9.5. Climate change scenarios were based on CalSim-II OCAP Study 9.2 and 9.5 values from 1946-2002, which were projected forward to 2007-2063.

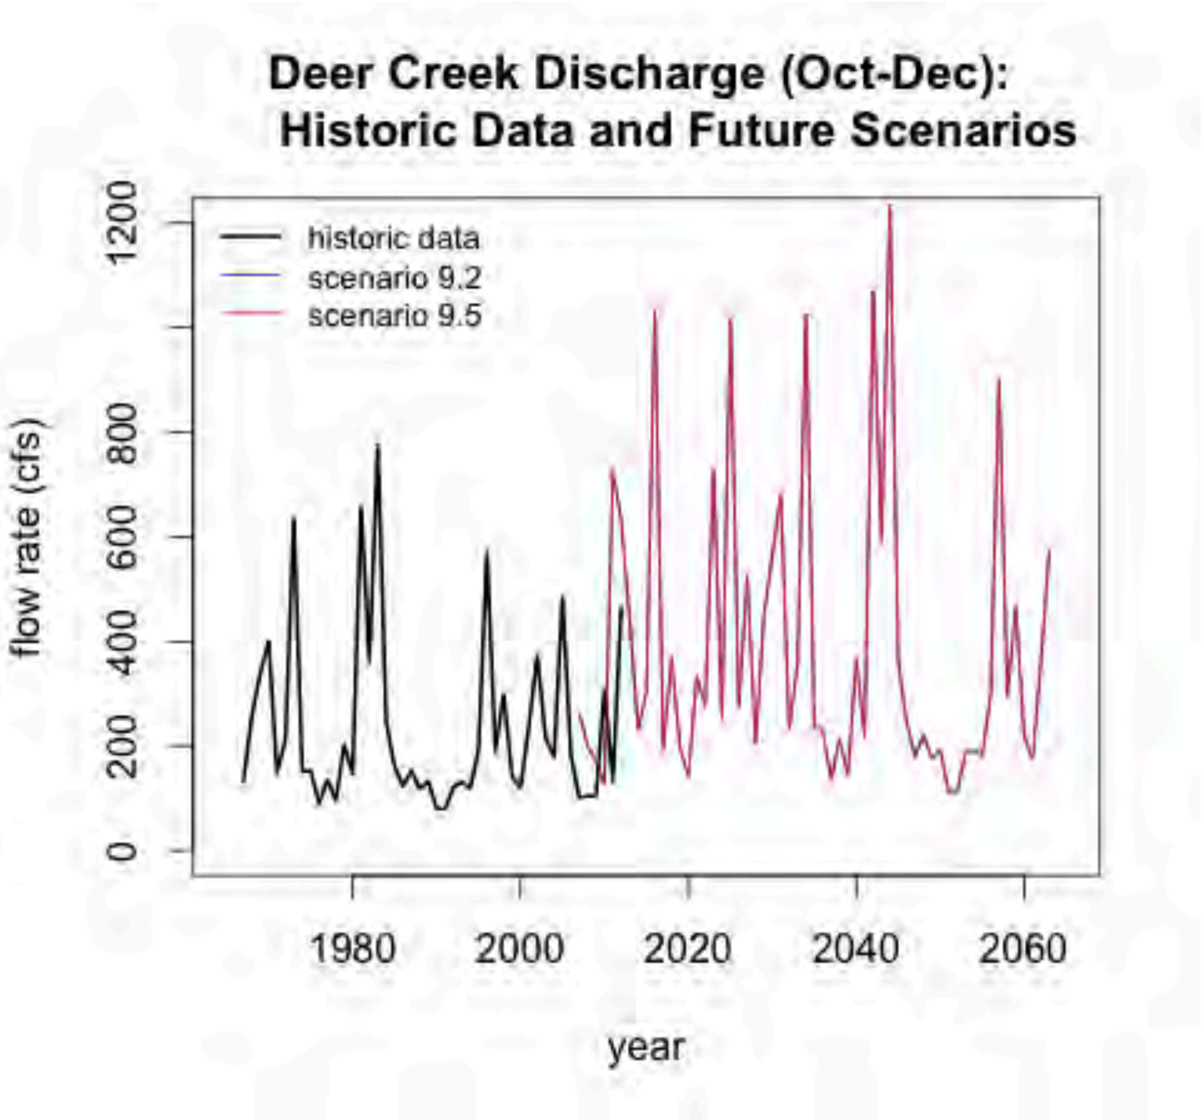

Figure B.2. Mean annual discharge (cfs) from Deer Creek for October-December: historic data from 1967-2012 and climate change scenarios 9.2 and 9.5. Climate change scenarios were based on CalSim-II OCAP Study 9.2 and 9.5 values from 1946-2002, which were projected forward to 2007-2063. Note that there is no difference in projection values between scenarios 9.2 and 9.5.

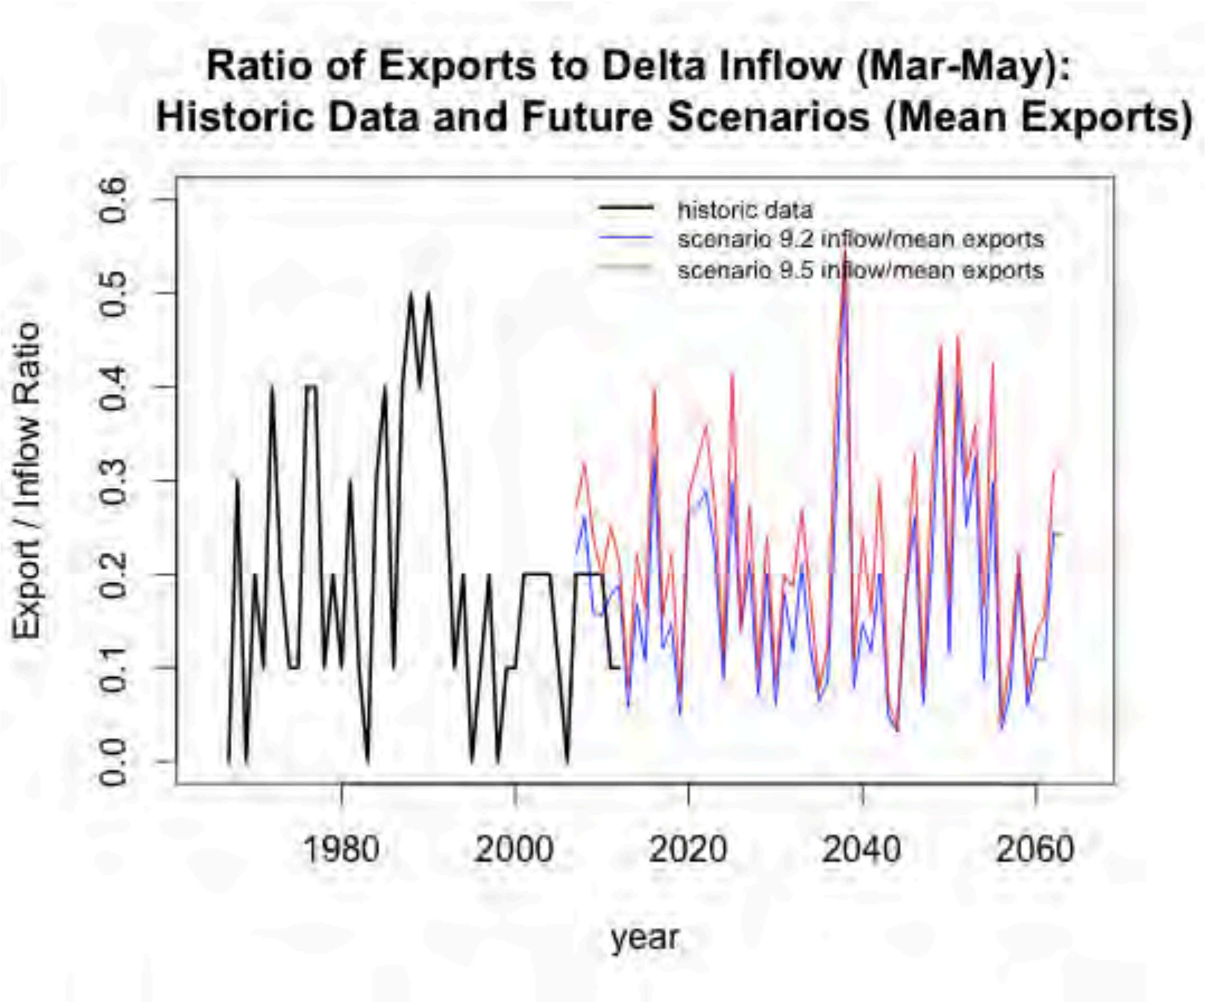

Figure B.3. Exports to inflow ratio for the Delta, averaged over March-May: historic data from 1967-2012 and climate change scenarios 9.2 and 9.5. Historic values are based on Dayflow data ((QCVP + QSWP – BBID)/ QTOT). Climate change scenarios use mean exports from 1967-2010 for the numerator, and CalSim-II Delta inflow values from OCAP Study 9.2 and 9.5 for the denominator. The CalSim-II Delta inflow values were from years 1946-2002, projected forward to 2007-2063.

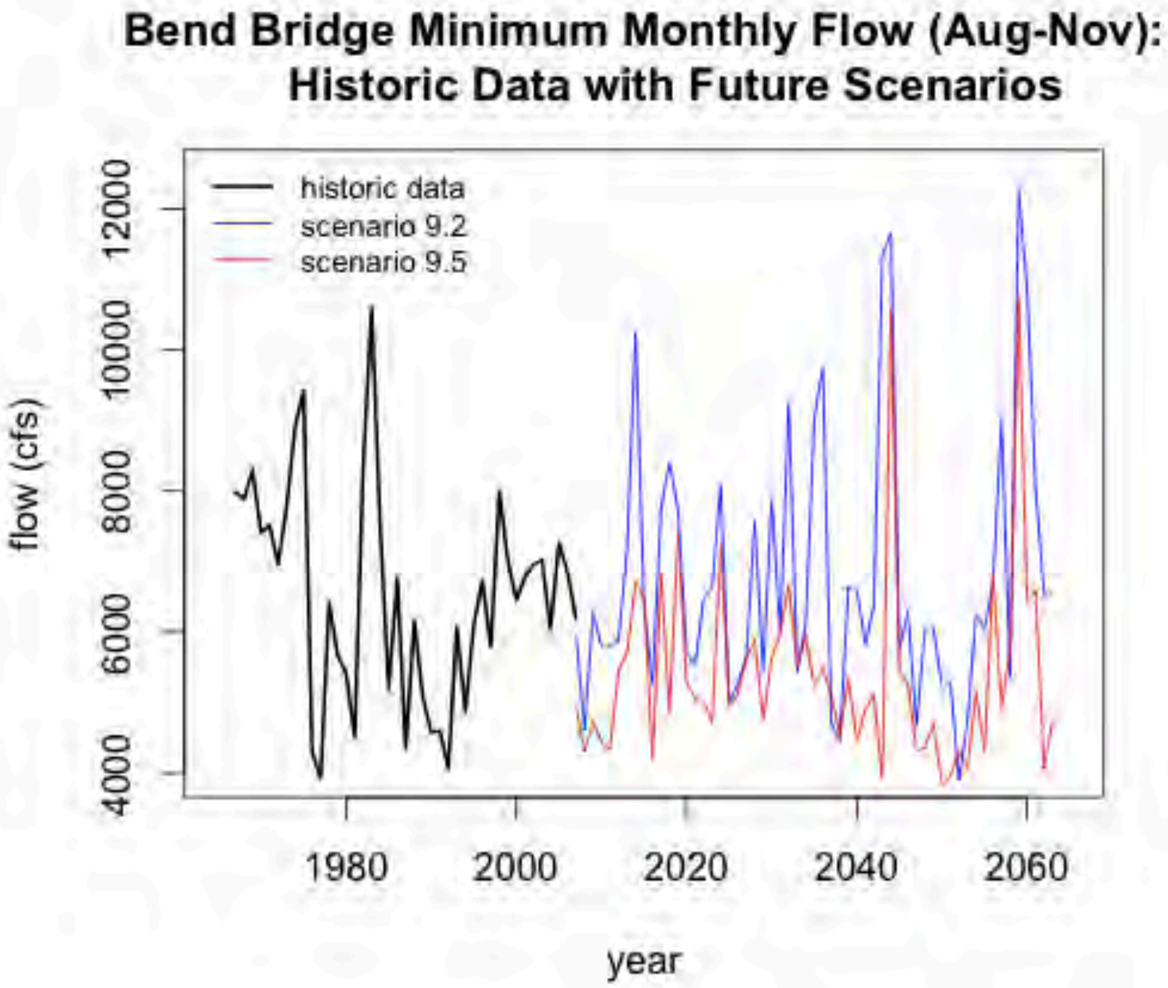

Figure B.4. Minimum monthly flow (cfs) at Bend Bridge for August-November: historic data from 1967-2007 and climate change scenarios 9.2 and 9.5. Climate change scenarios were based on CalSim-II OCAP Study 9.2 and 9.5 values from 1946-2002, which were projected forward to 2007-2063.

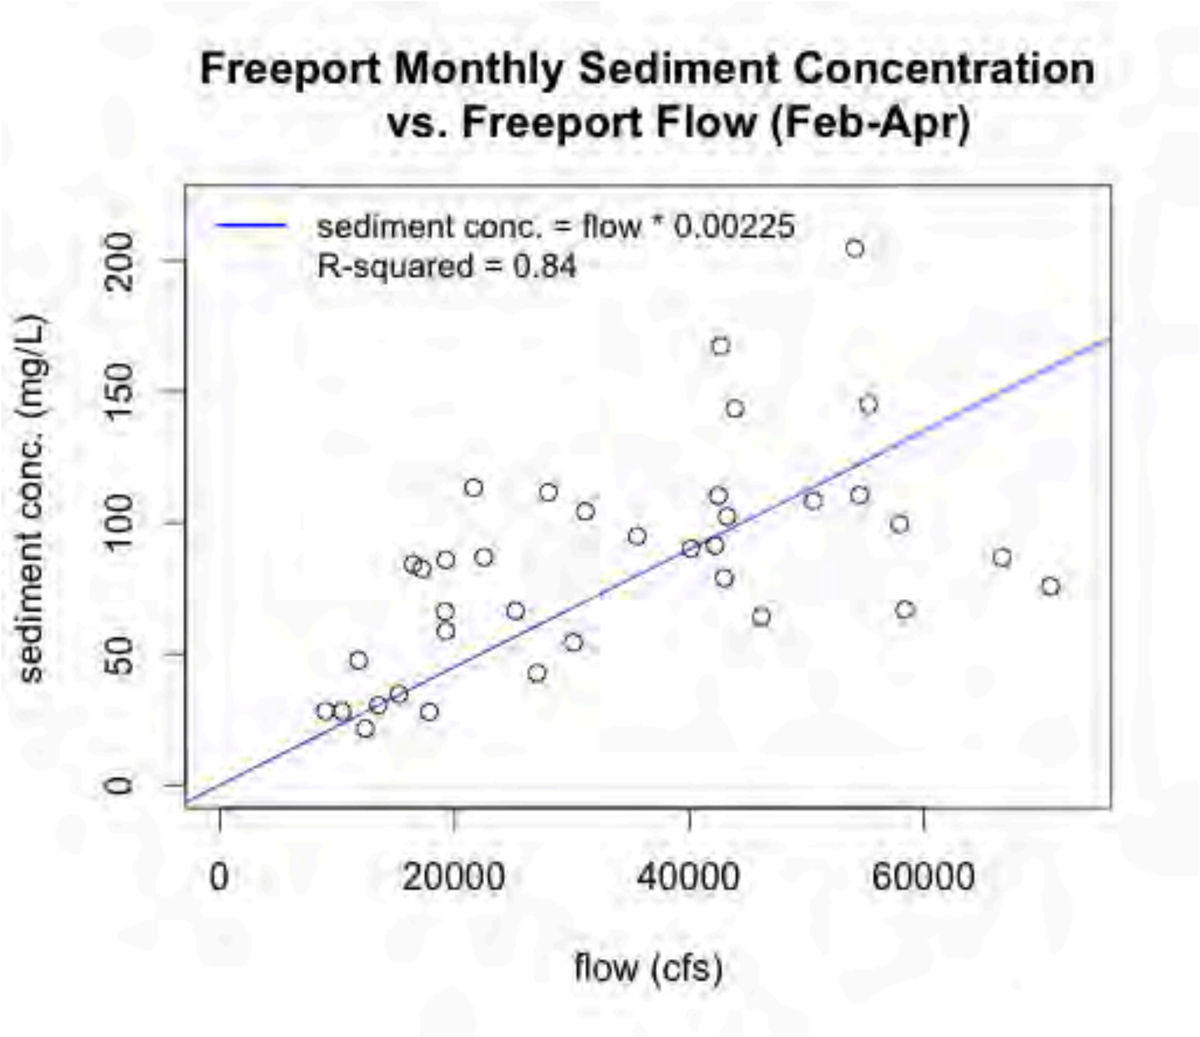

Figure B.5. Average monthly sediment concentration (mg/L) at Freeport for years 1967-2002, as a function of modelled Freeport flows (cfs) from CalSim-II OCAP scenario NAA_Existing at node C169. Each point represents one year of data, averaged over months February-April. A linear model was fit to the points, with a specified intercept of 0 (blue line):

Freeport sediment concentration = Freeport flow * 0.0022487

The adjusted R-squared for the linear model is 0.84.

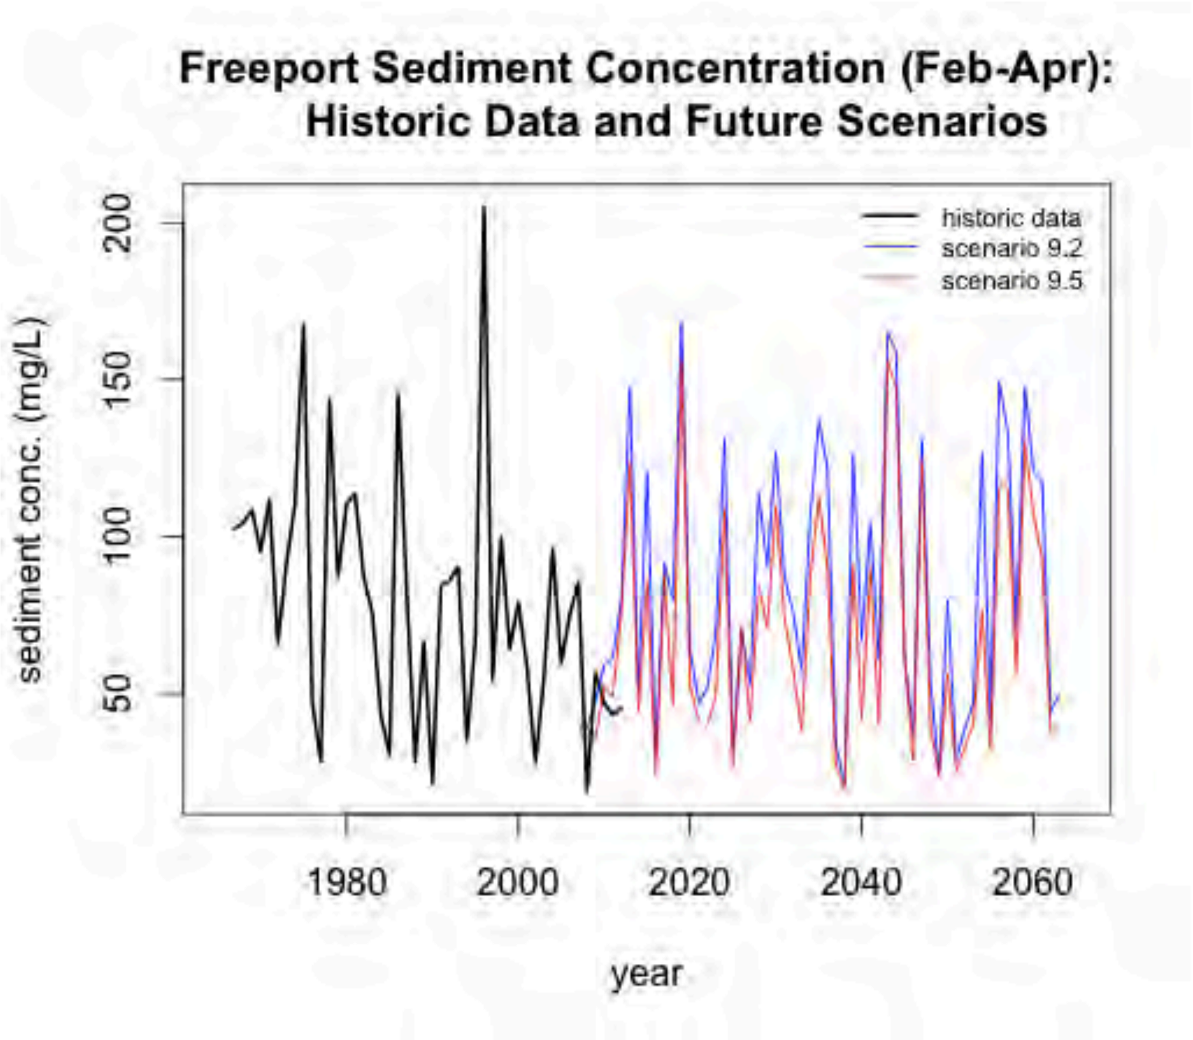

Figure B.6. Freeport sediment concentrations (mg/L) averaged over February-April: historic data from 1967-2012 and climate change scenarios 9.2 and 9.5. Climate change scenario values were obtained using Freeport flow predictions (at C169) from CalSim-II OCAP Study 9.2 and 9.5 for 1946-2002, and multiplying these values by 0.0022487 to correlate them to sediment concentrations (see Fig. B.5). The 1946-2002 climate change scenario sediment predictions were then projected forward to 2007-2063.

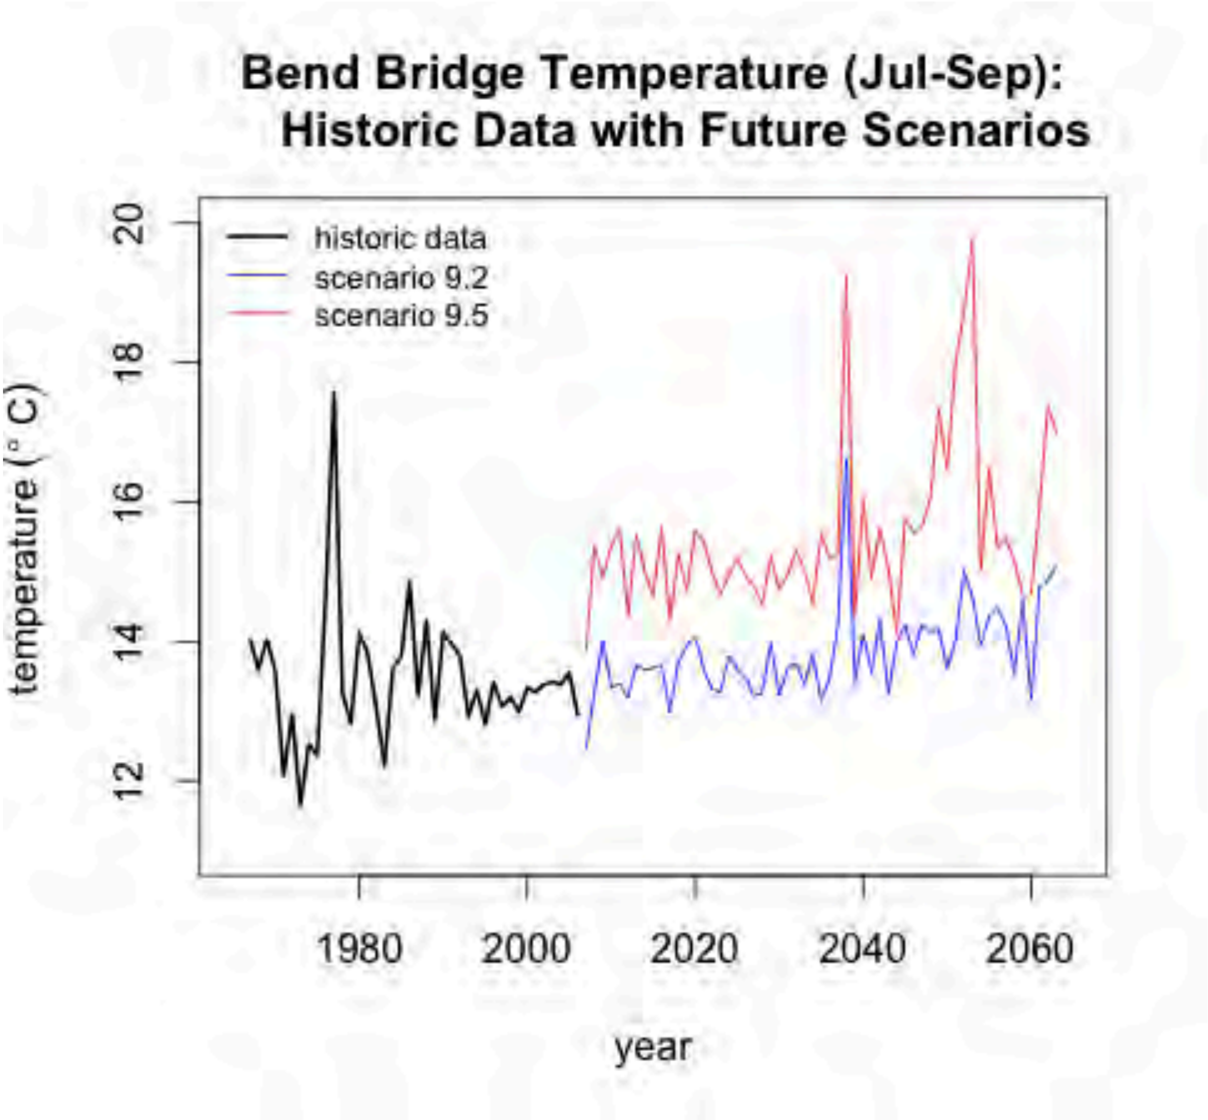

Figure B.7. Sacramento River average water temperature (° C) at Bend Bridge, averaged over July-September: historic data from 1967-2006 and climate change scenarios 9.2 and 9.5. Climate change scenarios were based on the SRWQM OCAP Study 9.2 and 9.5 values from 1946-2002, which were projected forward to 2007-2063.

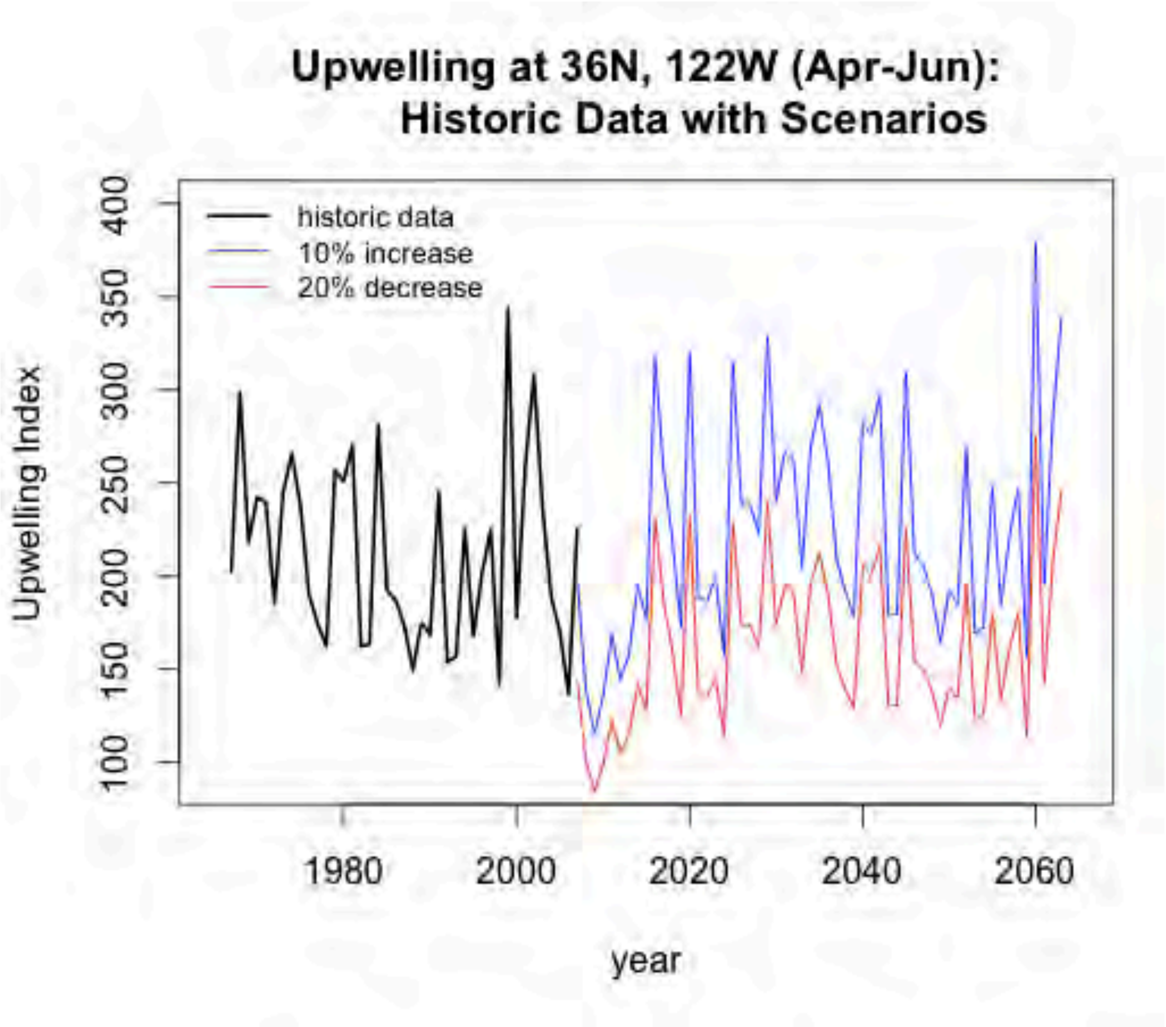

Figure B.8. NOAA upwelling index at station 36° N, 122°W averaged over April-June: historic data from 1967-2007 and two climate change scenarios. Climate change scenarios were based on historic upwelling values from 1946-2002, which were adjusted up (+20%) or down (-10%) and projected forward to 2007-2063.

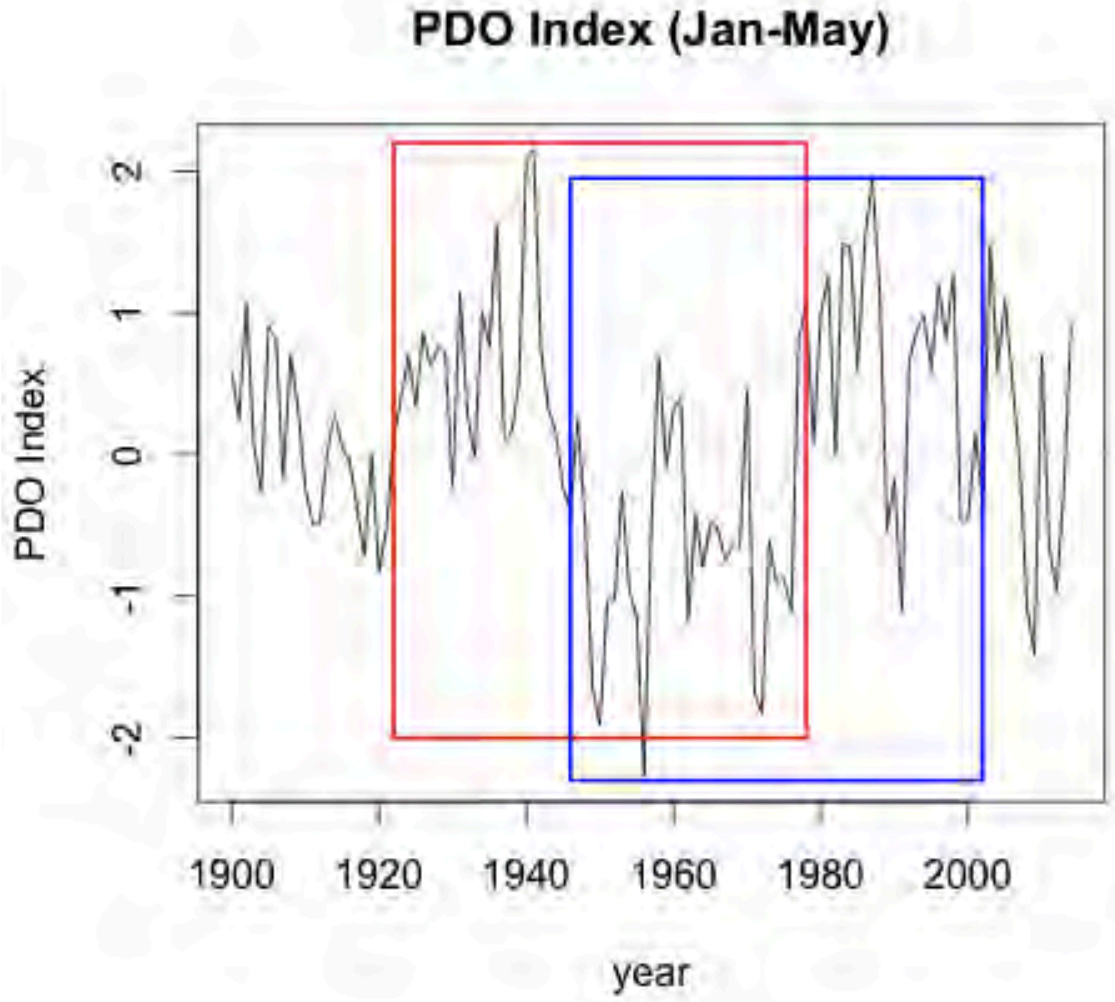

Figure B.9. Historic values of the PDO index, averaged annually over January-May. West coast salmon stocks have higher productivity during negative (cool) phases of the PDO, and lower productivity during positive (warm) phases. The sequence of years from 1922-1978 (red box) was projected forward to 2007-2063 to represent a scenario where the PDO begins in a positive cycle, while the sequence of years from 1946-2002 (blue box) was projected forward to represent a scenario where the PDO begins in a negative cycle.

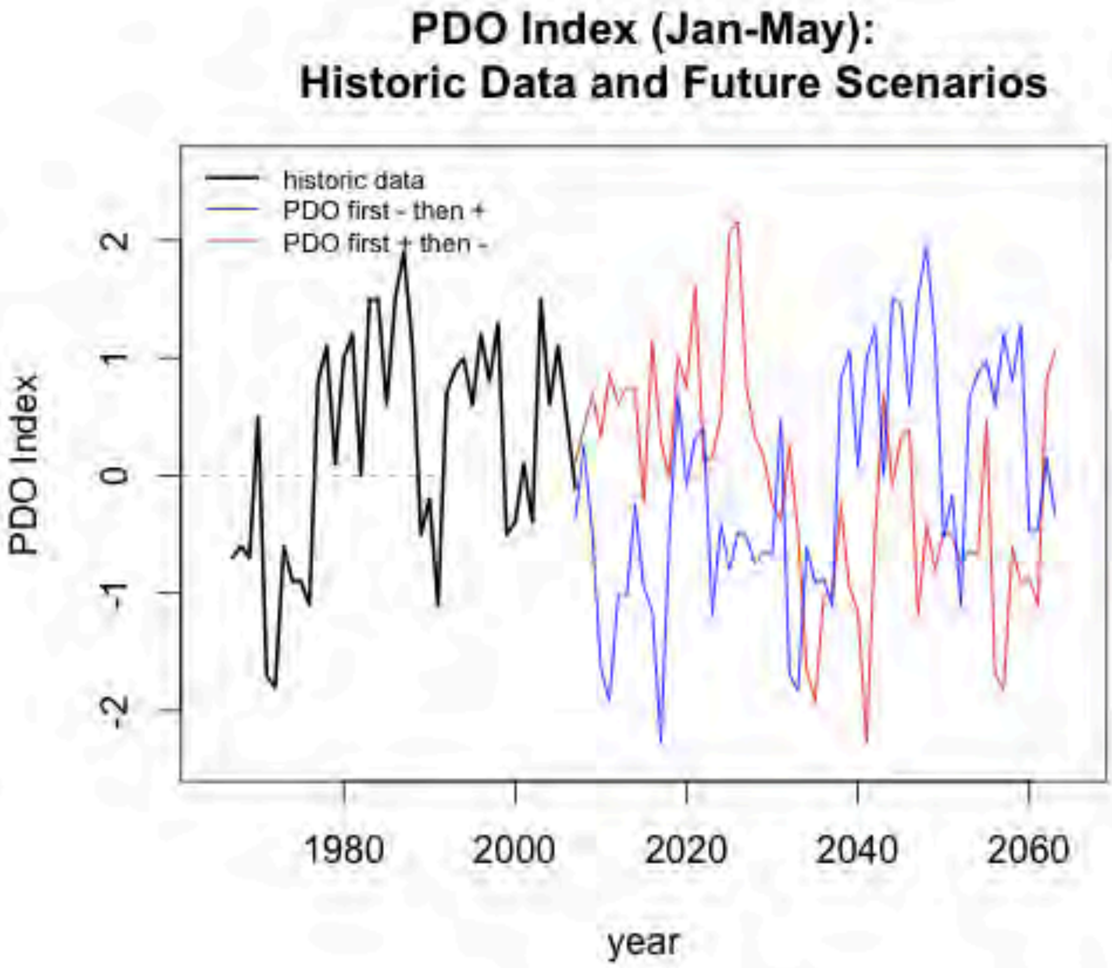

Figure B.10. PDO index averaged annually over January-May: historic data from 1967-2007 and two future scenarios. Future scenarios were projected onto 2007-2063 and consist of: 1.) a historic sequence that begins with a negative PDO index, then flips to a positive PDO index halfway through the time series (blue line: historic values from 1922-1978); and 2.) a historic sequence that begins with a positive PDO index, then flips to a negative PDO index (red line: historic values from 1946-2002).

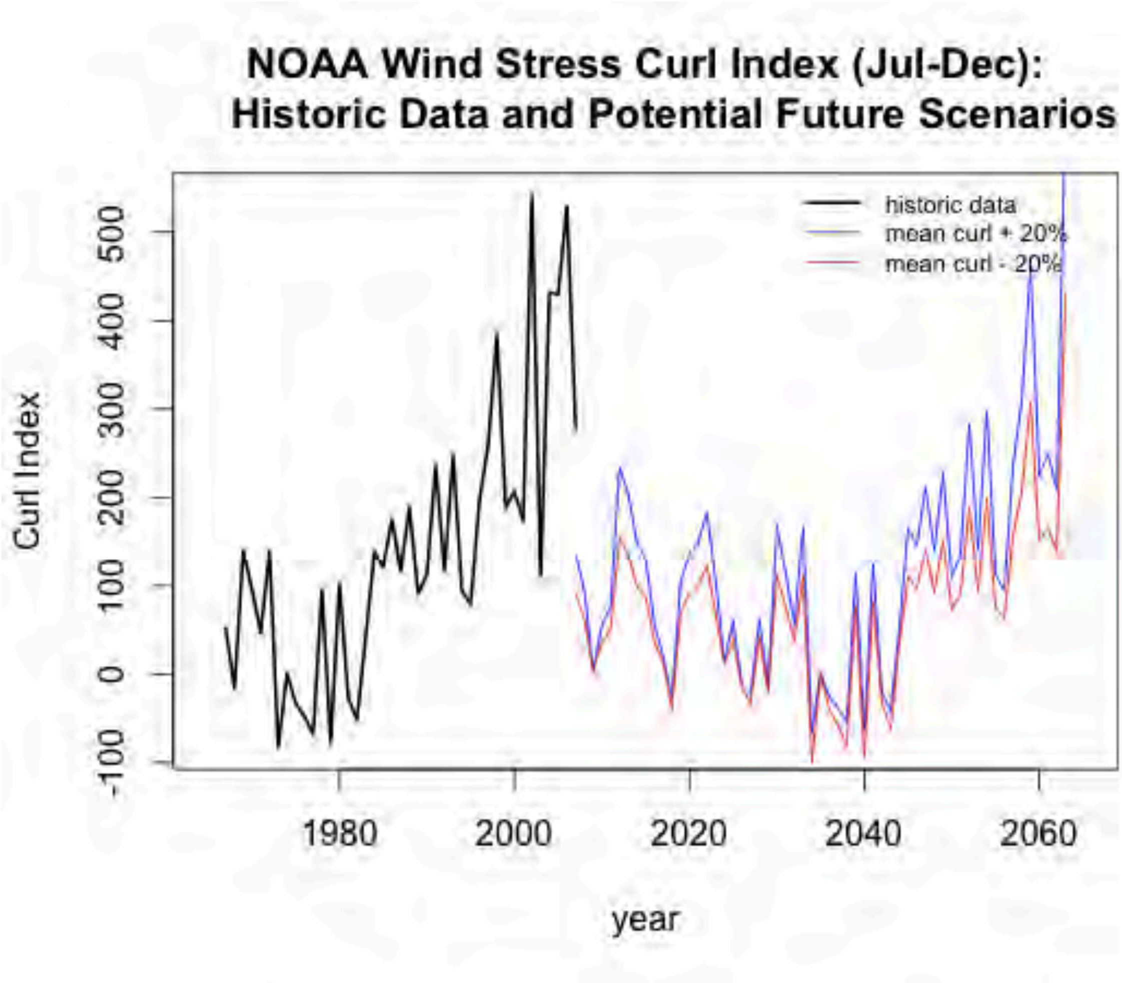

Figure B.11. NOAA wind stress curl index averaged over July-December: historic data for 1967-2007 and potential scenario values. Potential scenario values were generated by increasing (+20%) or decreasing (-20%) curl data from 1946-2002 according to the equations below, then projecting the values onto 2007-2063:

Curl + 20% = historic curl + abs value(historic curl) * 0.2

Curl – 20% = historic curl – abs value(historic curl) * 0.2

Curl index trajectories from 1967-2063 suggest a long-term autocorrelation pattern. Because we did not have compelling reasons to believe that future curl values would follow the same pattern as historic values, we set the standardized curl projections for future scenarios to 0.

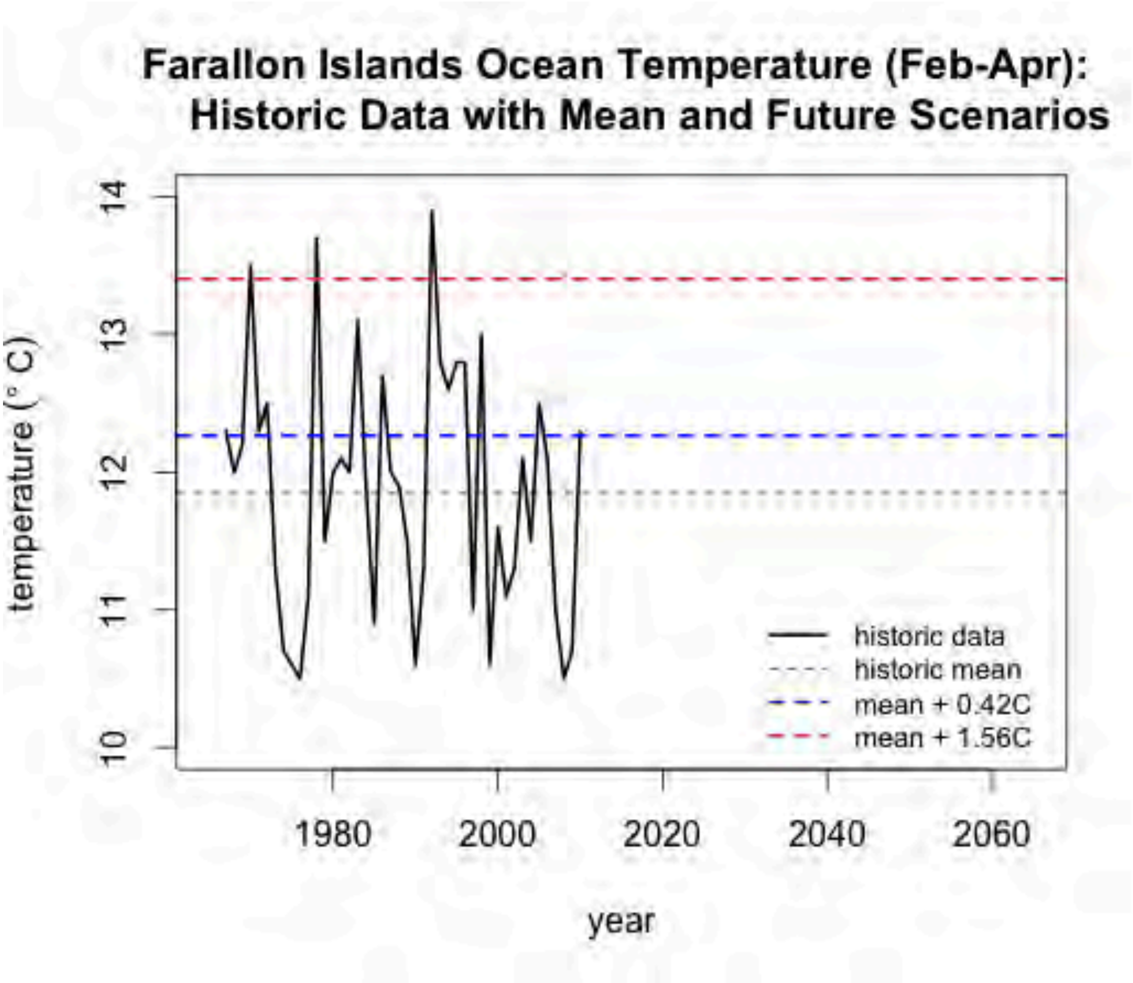

Figure B.12. Ocean temperature at the Farallon Islands averaged over February-April: historic data with mean for 1967-2010, and two climate projections: mean +0.42° C (=0.75° F, the average temperature increase for OCAP Study 9.2), and mean +1.56° C (=2.8° F, the average temperature increase for OCAP Study 9.5).

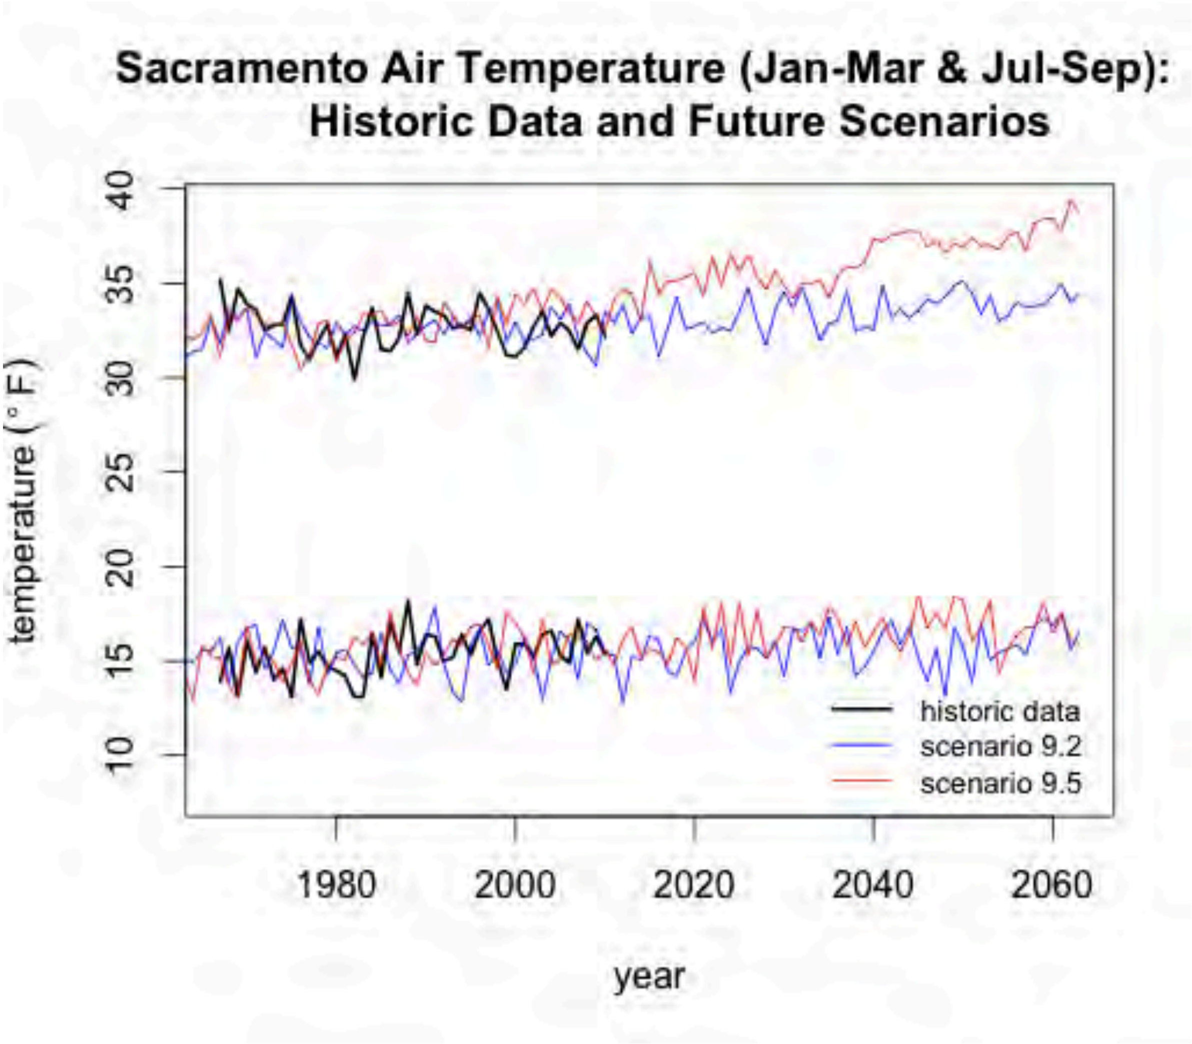

Figure B.13. Sacramento air temperature averaged over spring months (January-March, bottom lines) and summer months (July-September, top lines): historic data for 1967-2010, and future climate change predictions based on CMIP3 climate projections. CMIP3 air temperature predictions for the model cell over Sacramento were adjusted by + 4.55° F for the spring, and + 8.82° F for the summer, to spatially downscale climate projections from 1967-2010 to match the range of historic Sacramento air temperature data.

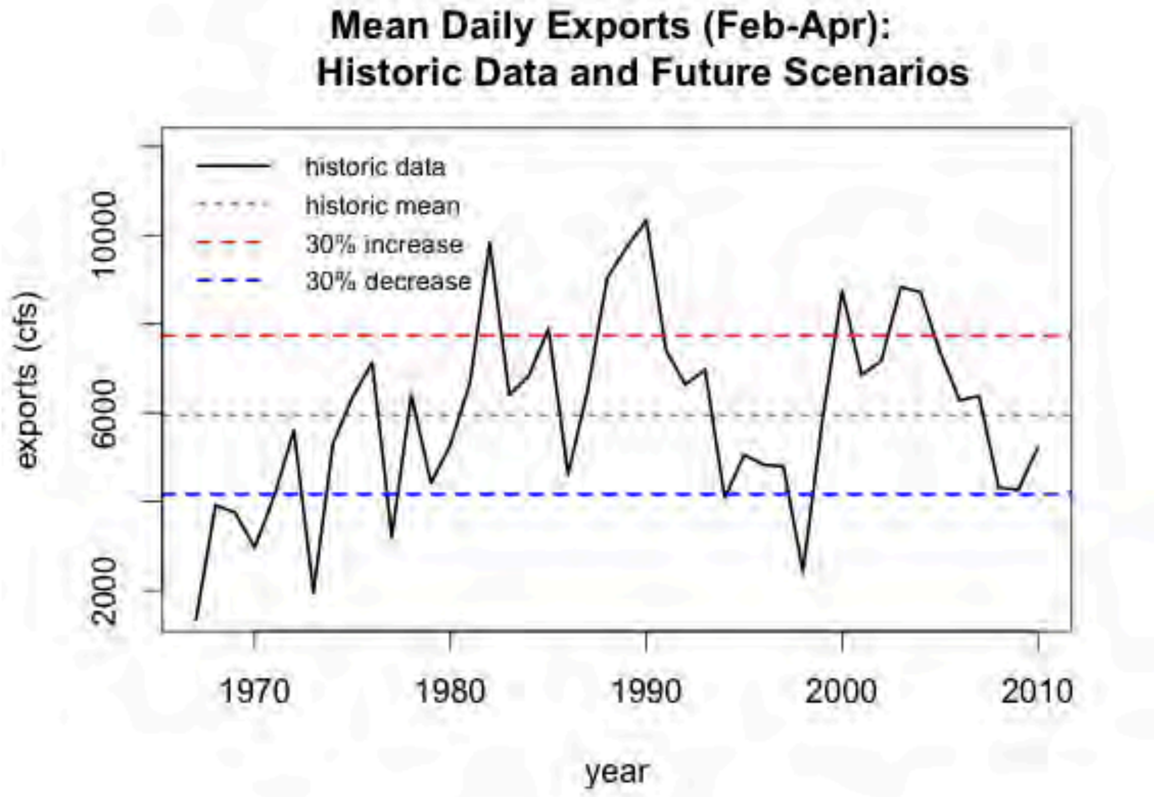

Figure B.14. Mean daily exports (cfs) averaged annually from February-April: historic data and future scenarios. Scenarios represent the following options: mean exports (1967-2010), zero exports, mean exports + 30%, mean exports - 30%.

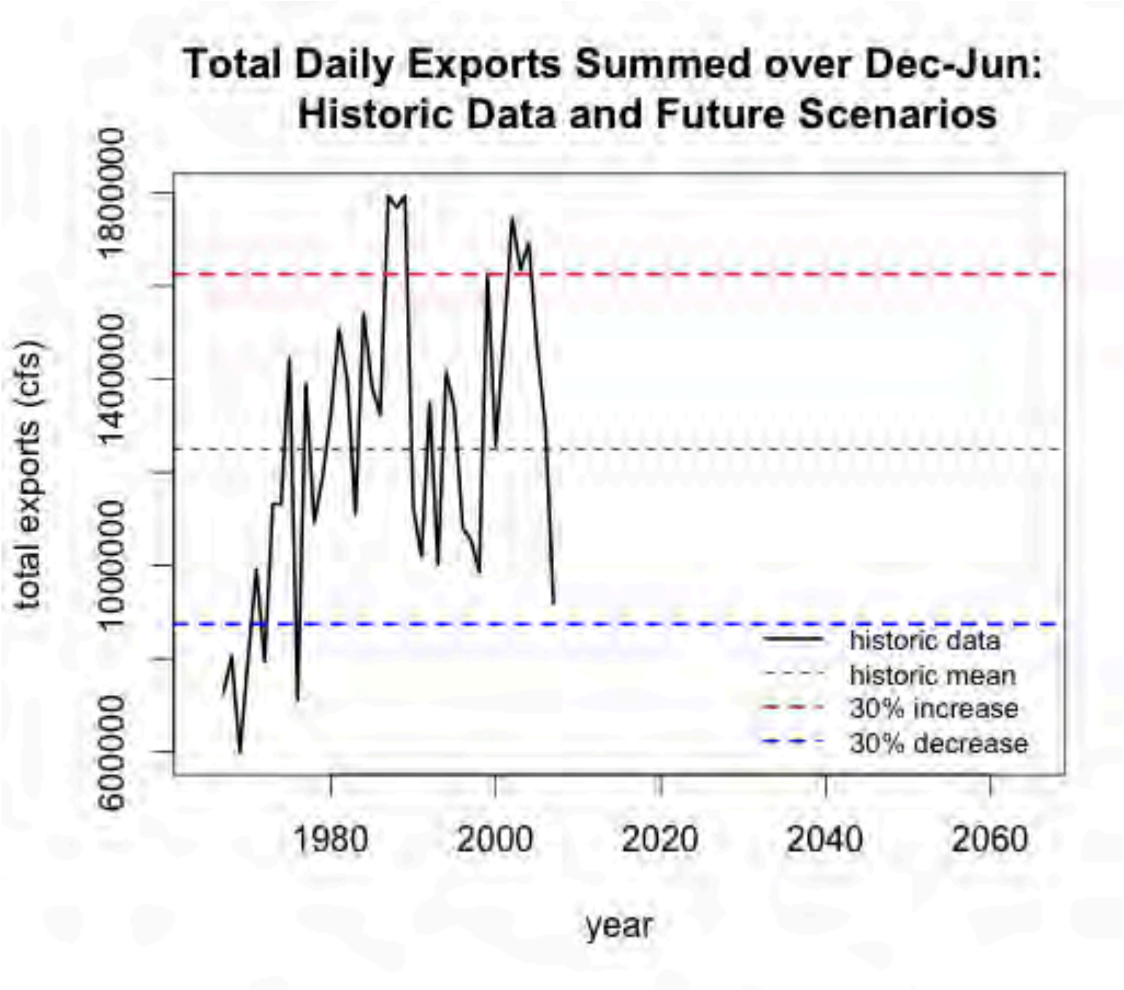

Figure B.15. Total daily exports summed over December-June: historic data and future scenarios. Scenarios represent the following options: mean total exports (1967-2010), zero exports, mean total exports + 30%, mean total exports - 30%.

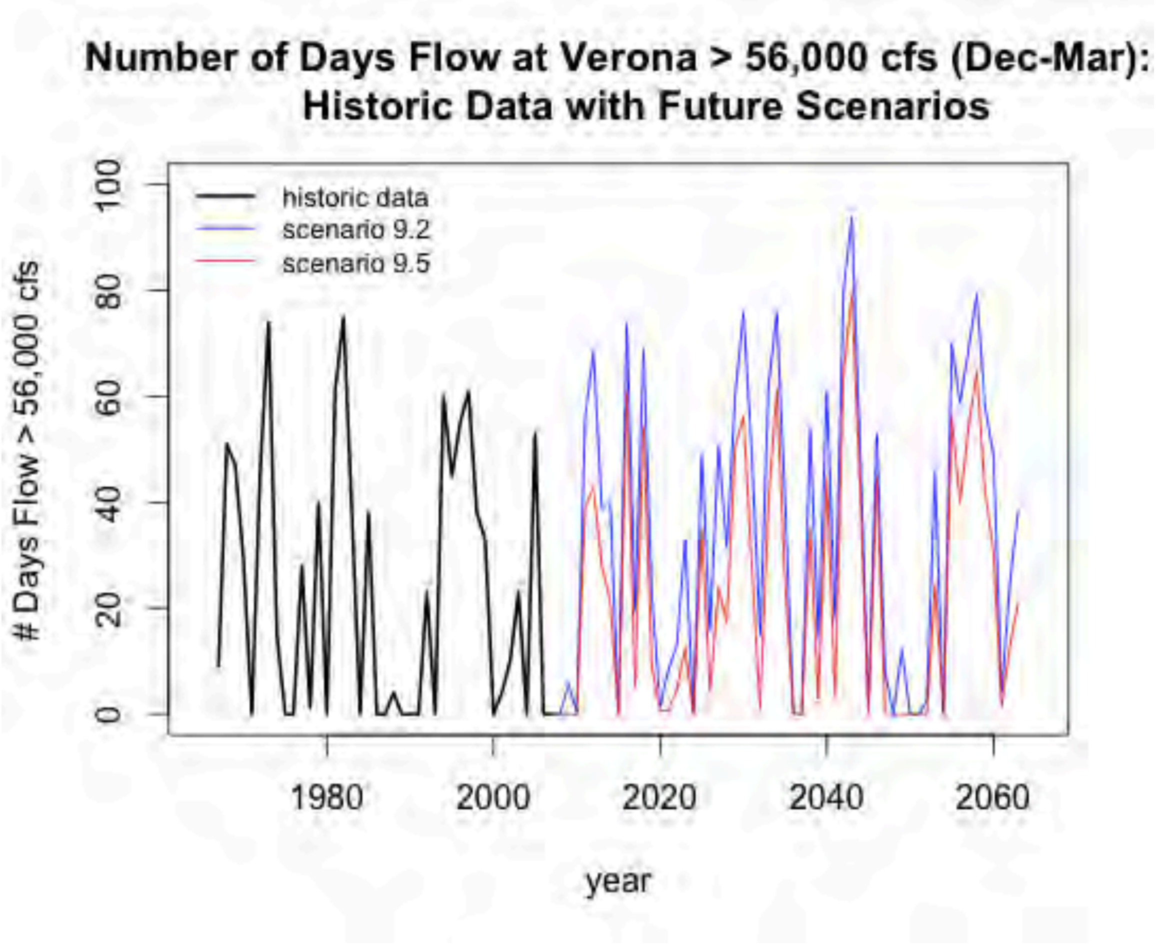

Figure B.16. Total number of days from December-March that Sacramento River flow at Verona exceeds 56,000 cfs: historic data from 1967-2007 and climate change scenarios 9.2 and 9.5. Climate change scenario values were obtained using Verona flow predictions (at C160) from CalSim-II OCAP Study 9.2 and 9.5 for 1946-2002 averaged over December-March, and adjusting these values per the linear model:

$$\#\text{ Days flow} > 56{,}000 = -25.19 + \text{CalSim-II flow at Verona} * 0.001646$$

to correlate them to the number of days that flow exceeds 56,000 cfs. The 1946-2002 climate change scenario predictions were then projected forward to 2007-2063.

TABLES

Table B.1. Scenario list with values drawn for each category of covariate.

	OCAP Study	Upwelling	Farallon Temp	PDO Index	Exports
Scenario 1	9.2	+ 10%	+ 0.42° C	- then +	Mean Level
Scenario 2	9.2	- 20%	+ 1.56° C	+ then -	Mean Level
Scenario 3	9.2	+ 10%	+ 0.42° C	- then +	Zero
Scenario 4	9.2	- 20%	+ 1.56° C	+ then -	Zero
Scenario 5	9.2	+ 10%	+ 0.42° C	- then +	Mean + 30%
Scenario 6	9.2	- 20%	+ 1.56° C	+ then -	Mean + 30%
Scenario 7	9.2	+ 10%	+ 0.42° C	- then +	Mean - 30%
Scenario 8	9.2	- 20%	+ 1.56° C	+ then -	Mean - 30%
Scenario 9	9.5	+ 10%	+ 0.42° C	- then +	Mean Level
Scenario 10	9.5	- 20%	+ 1.56° C	+ then -	Mean Level
Scenario 11	9.5	+ 10%	+ 0.42° C	- then +	Zero
Scenario 12	9.5	- 20%	+ 1.56° C	+ then -	Zero
Scenario 13	9.5	+ 10%	+ 0.42° C	- then +	Mean + 30%
Scenario 14	9.5	- 20%	+ 1.56° C	+ then -	Mean + 30%
Scenario 15	9.5	+ 10%	+ 0.42° C	- then +	Mean - 30%
Scenario 16	9.5	- 20%	+ 1.56° C	+ then -	Mean - 30%

Table B.2A. Fall and spring covariate values for Sacramento air temperature, channel depletion and smolt size at Chipps Island.

	Sacramento Air Temp (°F, Jan-Mar)		Sacramento Air Temp (°F, Jul-Sep)		Channel Depletion (cfs, Mar-May)	Size at Chipps Island (mm, Jan)
Year	Study 9.2	Study 9.5	Study 9.2	Study 9.5	Mean	Mean

APPENDIX C: GROWTH ANALYSIS AND MODELLING

In this appendix we provide a description of the methods we used to collect and analyze length information from various state and federal collection facilities in the Sacramento drainage. We assembled time series of lengths, both upstream and downstream, for both hatchery fish and combined hatchery and wild aggregates. Where possible, we used upstream and downstream lengths to obtain annual growth estimates. In the absence of a downstream growth measurement, we assembled a time series of downstream lengths. We performed regressions on growth and length estimates, evaluating impacts of environmental conditions on growth.

INTRODUCTION

The life-cycle modeling analysis in this project attempts to attribute variability in survival to environmental factors during different parts of the life history. Survival can be affected by the environment in complex ways, and can be mediated through biotic and abiotic processes. We posit that size can play a role in predicting survival, and that growth itself can be an indicator of survival as well. An obvious mechanism for size effects on survival would be that larger fish are less vulnerable to predation than smaller fish. A mechanism for growth being a predictor of survival would be that faster growing fish are likely to be experiencing better feeding conditions and bioenergetic advantages, and therefore should survive better.

In this appendix we look for relationships between environmental conditions and growth, but because growth requires two measurements (a capture and a recapture, or a release and recapture), we are not always able to get an estimate of a growth increment. Some length estimates obtained from survey data cannot be connected to later surveys, and therefore a growth estimate can't be derived from the measurements. An example of this occurs with rotary screw traps operating in tributaries, where juvenile size samples are obtained during rearing and migration. Those sizes are not directly comparable to later samples obtained downstream, because the downstream samples are aggregates of all the independent upstream sampled lengths. We might be able to document a pattern in upstream sizes over the years, but growth to the downstream measurement can't be inferred. We therefore treat size as a surrogate for growth, with the assumption that annual variability in juvenile size is in actual fact a measurement of annual variability in growth since all fish must at some point have emerged from the gravel at roughly the same sizes.

METHODS

We performed an analysis of length and growth patterns for Spring and Fall run Chinook in the Sacramento River in relation to environmental factors. We collected size at release and recapture data from state and federal agencies. We compiled records into average sizes at release for several different stock aggregates that provided adequate sample sizes for the years the data were available. In some case, it was possible to associate the length of a downstream recaptured fish with a known upstream release size to obtain a growth increment estimate, but in other cases only the downstream size record was available. Upstream length records were obtained from hatchery release information, from screw traps operated in tributaries, and from seine surveys operated throughout the Sacramento drainage. The farthest downstream sizes were obtained from Chipps Island, where mid-water trawl surveys collected size information and recorded the race of the fish based on the presence of a CWT or a length based estimated based on the length of the fish at the time the sample was obtained.

Data compilation

Length data

The Pacific States Marine Fisheries Commission manages and supports the Regional Mark Processing Center (RMPC; http://www.rmpc.org/), which in turn manages the Regional Mark Information System (RMIS). Agencies and organizations throughout the Western United States report CWT data directly to the RMIS. The Delta Juvenile Fish Monitoring Program (DJFMP) was initiated in the 1970s and is managed by the US Fish and Wildlife Service (USFWS, 2014). The program has a stated objective to monitor the effects of water projects in the Bay Delta on juvenile Chinook.

The number of juvenile salmon leaving freshwater during the spring has been sampled annually since 1978 by means of mid-water trawling in the estuary near Chipps Island (Brandes and McLain 2001). The Trawl site in Suisun Bay is sampled three days per week year round. It is sometimes sampled daily and at times two shifts per day for a total of 20 tows per day during May and June. During December and January, trawls occur 7 days per week with ten 20 minute trawls conducted daily. Catch limits are imposed when Delta Smelt catches exceed 8 individual Delta Smelt. The trawl survey records fish length at capture and creates a record of the race, origin and release location if a coded wire tag is detected.

We used data that had been collected since 1979 in mid-water boat trawls at Chipps Island, Suisun Bay (Zone 10 S UTM, 4211218N, 595531E). Data from the DJFMP is available online (http://www.fws.gov/stockton/jfmp/). USFWS tables available online contained metrics of juvenile Chinook salmon that had been marked with CWTs, released throughout the Sacramento - San Joaquin Basin and then recovered near Chipps Island in Suisun Bay (Coded *Wire Tag 1978 -2011.xls* and *Coded Wire Tag 2012 -2013.xls*). Survey records not containing CWTs can be found in the spreadsheets *Chipps Island Trawls 1976-2011.xlsx and Chipps Island Trawls 2012-2014.xlsx.*

We used the records from the Chipps Island trawls to create a database of fish lengths and growths increments for all fish with CWTs (referred to as the CWT table). Each fish with a CWT is of a known origin, so the race and the source (hatchery or wild stock origin) are also known. We used the remaining records from the Chipps Island survey to construct a database table of Chinook known to be of a given race, but where the origin is not known. These records were assembled into a table we refer to as the TRAWL table, which only distinguishes between Fall and Spring runs.

We compiled juvenile salmon length data from the Sacramento watershed and the San Francisco Bay Delta into a relational database in order to determine growth of hatchery Fall Chinook and hatchery and wild juvenile Spring Chinook. Wild Spring stocks included Deer, Mill and Butte creeks. Butte Creek fish were release and recaptured in Butte Creek, the Sutter

Bypass or near Chipps Island in Suisun Bay. Release and recovery data were compiled from three sources: California Department of Fish and Wildlife (CDFW), US Fish and Wildlife Service's Delta Juvenile Fish Monitoring Program (DJFMP) and the Regional Mark Processing Center (RMPC).

From 1995 to 2001, the CDFW captured, measured, marked, and released wild spring-run Chinook on Butte Creek (CDFG, 1999; CDFG, 2004-2; CDFG, 2004-3). The purpose of the CDFW program was to estimate adult escapement, monitor timing and abundance of juvenile outmigration, and monitor relative growth rates in the Butte Creek system. Fish were captured and marked with adipose fin clips and coded wire tags at the Parrot-Phelan Diversion Dam (PPDD; Zone 10 S UTM, 4396287N, 611463E). Releases took place at three locations, but varied from year to year. Release sites were: PPDD, Baldwin Construction Yard (approximately one mile downstream of the PPDD) and Adams Dam (approximately 7 miles downstream of PPDD). After release, marked fish were subject to recapture and sacrifice at downstream locations in Butte Creek, the Sutter Bypass and the Sacramento Delta near Chipps Island. Rotary screw traps were used to recapture fish at all locations and an off-stream fish screen outfitted with a trap box was used to collect fish at the PPDD site. Recaptured fish were sacrificed, measured for fork length and their CWTs were extracted and read. We received programmatic data formatted in a Microsoft Access database directly from the CDFW (C. Garman, personal communication, 1/30/2014).

We queried the RMIS database for juvenile Chinook that had been marked and released at any location in the Sacramento drainage. The RMIS table was then related by CWT code to Chipps Island mid-water trawl and Sacramento River recoveries. In this way, we queried recoveries with release locations only within the Sacramento Basin.

We obtained tributary measurements of juvenile lengths from rotary screw traps (RSTs) operating in Butte creek, Mill creek and Deer creek. Rotary screw traps were operated by the US Fish and Wildlife Service in Mill and Deer creeks, and by the California Department of Fish and Wildlife in Butte creek. Screw trap operation spanned 1995-2010 in the records used in this analysis. We used samples obtained from January to June of each year to obtain estimates of tributary outmigration size.

Environmental data

We compiled time series of environmental variables that pertain to the experiences of downstream migration juveniles. For Spring Run, we used discharge at the three creeks (Deer, Mill and Butte), flow, exports volumes and other export indices, and a CPUE index of bass abundance. Flow temperature and discharge were obtained from USGS gauging stations (http://waterdata.usgs.gov/nwis/inventory). Exports and other dayflow parameters were obtained from water project data available on the California department of water resources website (http://www.water.ca.gov/dayflow/output/Output.cfm). Environmental variables were normalized by subtracting the mean and dividing by the standard deviation. The variables are summarized in Table C.1 for Spring run and in Table C.2 for Fall run.

Table C.1 Environmental variables used in length and growth analysis of Spring Chinook.

Length and Growth analysis

We examined environmental factors affecting length at recapture at Chipps Island of fish with known and unknown release lengths. Where length at release was known, we examined growth rates. We associated each size and growth record with environmental factors experienced by each race of salmon each year the sizes were recorded. We compared fall and spring length at capture at Chipps Island from two separate surveys. The CWT table provided an estimate of growth for fall and spring hatchery releases. The mid-water trawls did not distinguish between wild and hatchery fish, so those analyses pertain to the race as a whole, without distinction about release locations or wild/hatchery distinctions. We also obtained sizes from DJFMP seines in Region 1 (upstream from the Delta) and compared those sizes with Chipps Island size information. Since seine samples do not distinguish between populations, growth obtained from subtracting upstream seine sizes from Chipps Island trawl sizes provide estimates of aggregate Fall and Spring run sizes, but cannot distinguish between release locations or between wild and hatchery releases.

SEINE/TRAWL - growth by race from mid-Sacramento to Chipps Island.

We queried the DJFMP seine database to obtain estimates of growth for Spring and Fall runs. Region 1 of the DJFMP beach seine runs from Colusa State Park to Elkhorn. We averaged lengths of Spring and Fall seine lengths for each year for fish collected between January and June, and compared those to Chipps Island midwater trawl sizes. The trawl survey assigned fish to Fall and Spring runs based on size ranges and records indicated that all collections occurred in May and June. We calculated the growth for each race of fish each year as the difference between the average trawl length and the average seine length. We refer to these growth estimates as the SEINE/TRAWL dataset.

We examined growth patterns in relation to environmental variables listed in Tables C.1 and C.2. We performed stepwise linear regressions of growth in relation to each variable, adding variables according to best p-value, and stopping when no further significant variables were found.

CWT –growth and length by hatchery source.

When hatchery fish are released, the average size of a sample of the release batch is used as the release length of record for fish in the batch. When recaptures occur at Chipps Island, a record for each fish recaptured can be compared to a release length record on the basis of CWT codes. To get reasonable sample sizes for recaptures, we were forced to aggregate hatchery releases such that release locations were ignored. We aggregated all release locations within the Sacramento drainage for each hatchery source. Since a release batch contains a range of lengths, it is possible for the smallest recaptured fish to be smaller than the average released fish. The growth record for each year was calculated as the average of all the recapture lengths minus the average release length. The average of release length was calculated as the weighted release length, weighted by the number released at each location at each time of release. We refer to the length and growth estimates from this method as the CWT dataset.

We tested for statistical relationships between size at recapture and environmental variables for Spring and Fall hatchery releases from Coleman National Fish Hatchery (CNFH) and Feather Fish Hatchery (FFH). We examined growth and length patterns in relation to environmental variables listed in Tables C.1 and C.2. We performed stepwise linear regressions of growth and length in relation to each variable, adding variables according to best p-value, and stopping when no further significant variables were found.

TRAWL – length by race at Chipps Island.

We selected records that were not limited to CWT tagged fish (the TRAWL dataset in this analysis) from Chipps Island, and assembled all records of Spring and Fall chinook to look at the size. By not being limited to CWT matches, the sample size was much larger than for the CWT matched database, but for the TRAWL dataset, the origin of fish could not be determined. The race of the fish was assigned by a length/timing criteria established by the DJFMP (the "Race Table" found at www.fws.gov/stockton/jfmp). Using these records we looked for temporal trends, comparisons between Spring and Fall runs, and relationships between size at capture and environmental factors. Annual average size records for Spring and Fall Chinook do not distinguish between hatchery and wild, and there is no growth estimate because the size at release is not known, and there is no way to distinguish between Butte, Mill, and Deer creeks. The TRAWL dataset provides an aggregate estimate of length at Chipps Island by race alone.

We examined growth patterns in relation to environmental variables listed in Tables C.1 and C.2. We performed stepwise linear regressions of length in relation to each variable, adding variables according to best p-value, and stopping when no further significant variables were found. We treat length as a surrogate for growth on the assumption that some initial length can be treated as a constant across and all variability can be thought of as occurring after that initial length.

RST – Lengths in tributaries

Deer, Mill, and Butte creek rotary screw trap records were queried to obtain estimates of out-migrating juvenile sizes. We took the average size of all samples obtained from the traps between January and June of each migration year. We attempted to match CWT releases from Butte Creek each year to recoveries within the Sacramento basin to obtain growth estimates at various sample locations, but found that recoveries were too few to obtain good estimates of growth. Butte Creek CWT release records with Chipps Island recapture events began in 1996, but recaptures amounted to fewer than 10 fish per year at Chipps Island. It was not possible to relate RST lengths to downstream lengths at Chipps Island for a growth estimate. We therefore limited our examination of RST data to showing temporal trends of sizes of Deer, Mill and Butte creeks.

RESULTS

SEINE/TRAWL - growth by race from mid-Sacramento to Chipps Island.

The average growth of Spring and Fall Chinook are shown in Figure C.1 along with the time elapsed between Seine surveys and mid-water trawls. The temporal trend in growth is shown in Figure C.2. Fall Chinook appear to be slightly larger and on average seen in seine surveys about half of a month later. Predominantly, Fall Chinook appear to grow slightly more between Seine and mid-water trawl surveys, which is noteworthy, since they do so in less time as seen in the average month seined calculation.

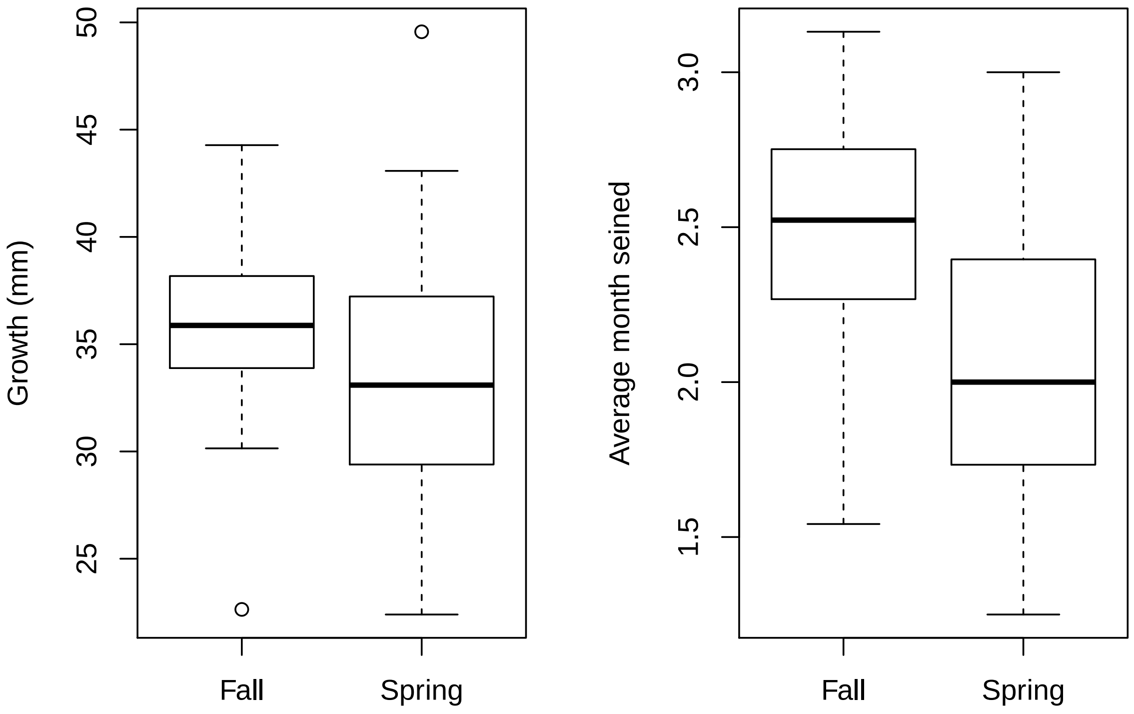

Figure C.1 Growth between release and sampling at Chipps Island (left panel) and month at which Region 1 seine was sampled (right panel).

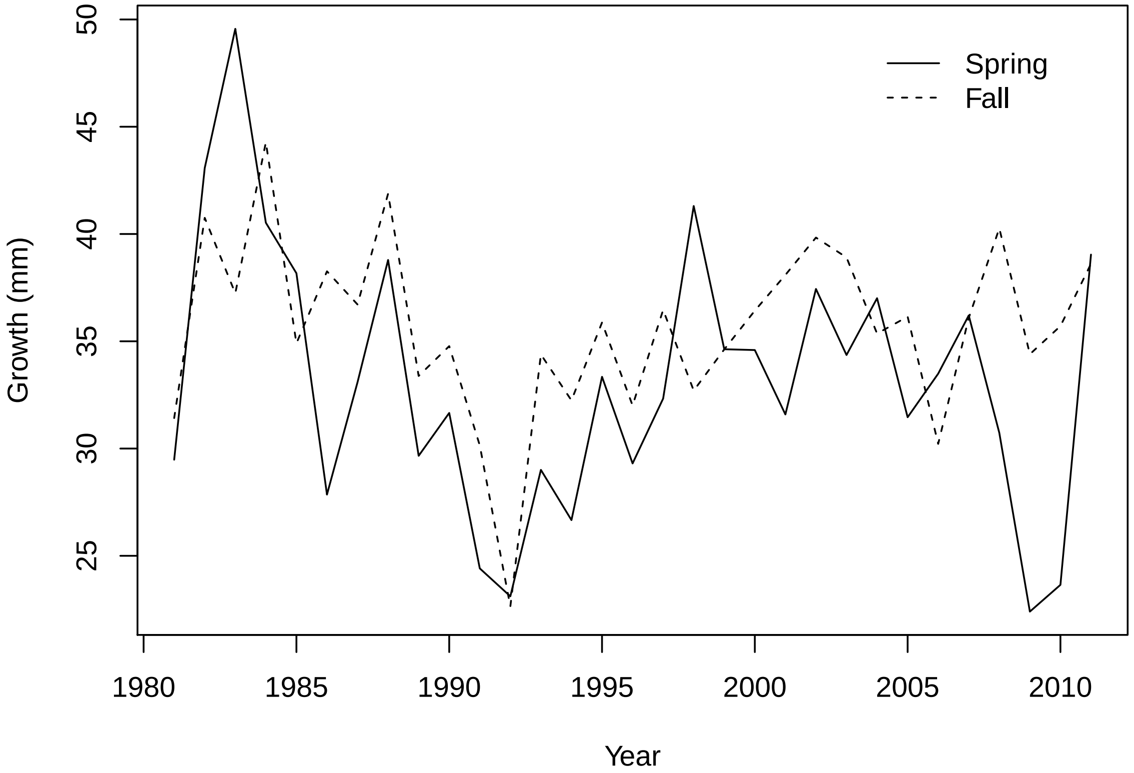

Figure C.2 Temporal trends in Spring and Fall Chinook growth evaluated from beach seine and mid-water trawl surveys.

Table C.3 shows the results of stepwise linear regressions. The regression results show that there are significant effects of Bass, Central Valley Project exports, race (spring or fall run) , and the export to inflow ratio (EXPIN). The bass index shows a positive effect on growth. Central Valley Project exports also show a positive effect, but the export to inflow ratio shows a negative effect. The adjusted R-squared value for the fit was 0.4068. The diagnostic plot of the fit is shown in Figure C.3.

Table C.3 Regression results of growth in SEINE/TRAWL data in relation to environmental variables. Intercept in parentheses.

Coefficients:	Estimate	Std. Error	t value	Pr(>|t|)	Signif
(int-Fall)	38.3357	0.9227	41.546	<2.00E-16	***

Figure C.3 Diagnostic plot of best fitting model of seine-trawl growth of Spring and Fall chinook.

CWT –growth and length by hatchery source.

Feather Fish Hatchery (FFH) spring Chinook and Coleman National Fish Hatchery (CNFH) fall Chinook growth and lengths at Chipps Island are shown in Figure C.4. We see that there is considerable variability in growth, and that Spring run fish appear to have grown faster than Fall run until the early 1990's, but are now growing less than Fall run (see Figure C.4 upper panel). Table C.4 shows the results of stepwise regressions of length against all Spring and Fall run covariates. The export to inflow ratio was the only significant predictor of catch length in the Chipps Island trawl, with EXPIN having a positive effect. The adjusted R-squared for the best fitting model shown was 0.3414. Diagnostic plots of the best fit are shown in Figure C.5, where we can see that the residuals are normal. Regressions show a hatchery effect, finding that FFH fish arrive at Chipps Island 3.5 mm larger than CNFH fish, but FFH fish included Spring run, which were larger. Despite growth of Spring run recoveries appearing to decline from 1985, the lengths of Spring run fish at Chipps Island appears to be relatively constant. We found no significant relationships between growth and environmental variables.

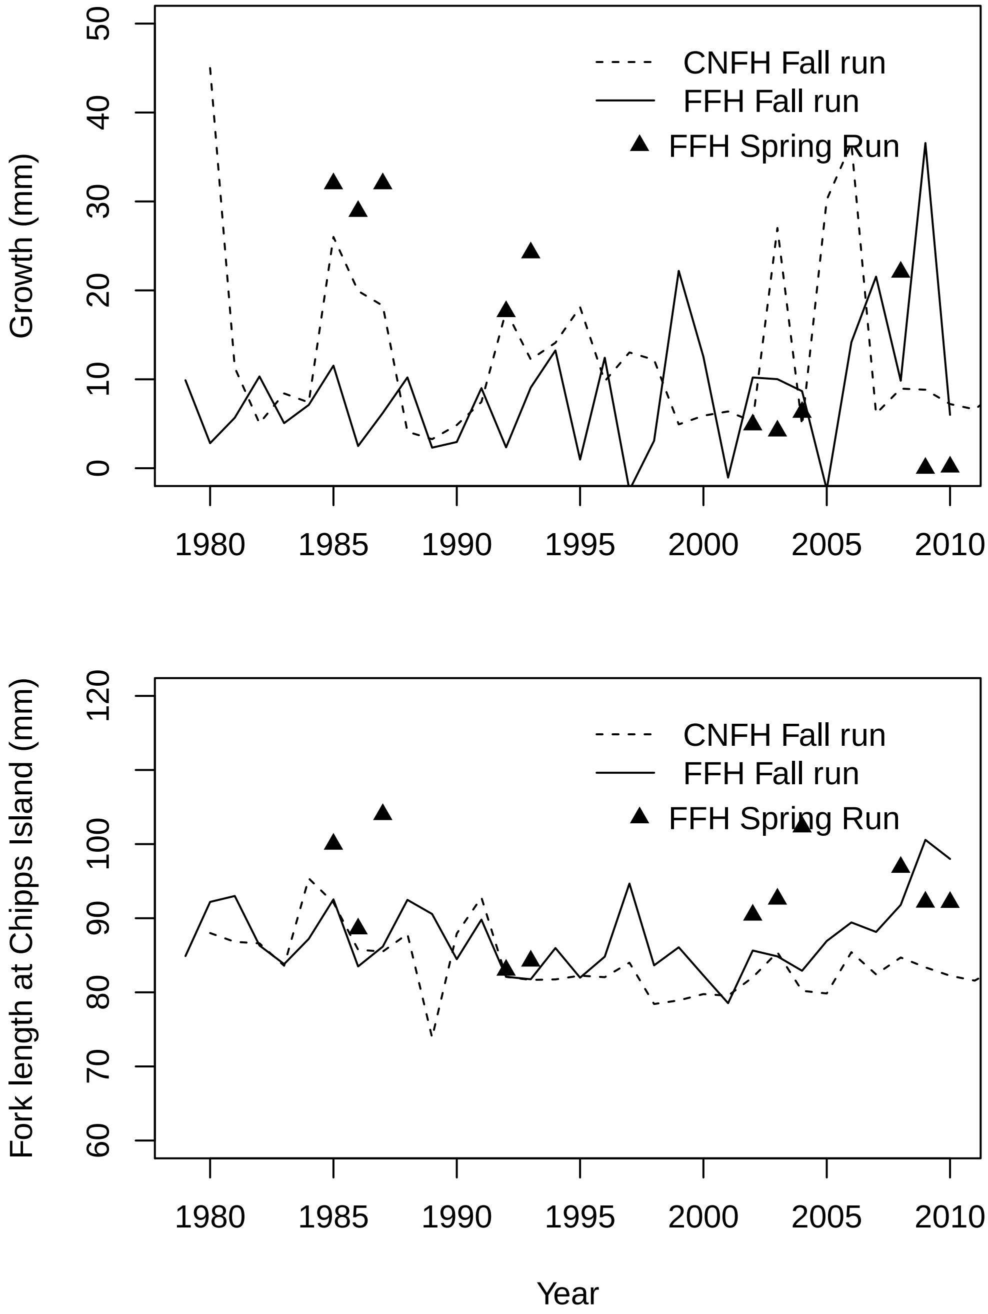

Figure C.4 Growth of CNFH and FFH Fall runs, and FFH Spring run (upper panel) and length at Chipps Island (lower panel).

Figure C.5 Diagnostic plots of best fit of length at recapture at Chipps Island to environmental variables.

TRAWL – length by race at Chipps Island.

Unlike the CWT lengths from hatchery specific releases, the aggregated relative Spring and Fall lengths remain consistent from the 1980's until present. Spring run appear to be consistently larger that Fall run (see Figure C.6). Regression results are shown in Table C.5 and indicate that Yolo flow, the Central Valley Project exports, the export to inflow ratio, water passing via the Delta Cross Channel, and the bass index are all significant predictors of size. The Adjusted R-squared of the best fit shown is 0.785. The diagnostic plots of the best fit is shown in Figure C.7. The TRAWL dataset had the largest samples, and despite being aggregated wild and hatchery fish, and despite not identifying source drainages, the regression results yield the highest R-squared. The diagnostics show normality in residuals as well as the majority of residuals concentrated on predicted theoretical quantiles.

Figure C.7 Diagnostic plot of best fitting model of relationship between length at Chipps Island mid-water trawl and environmental variables.

RST – Lengths in tributaries

Mill, Deer, and Butte creek Spring run average fish sizes from rotary screw trap operations are shown in Figure C.8. We see that Mill, Deer and Butte creeks are on average about 45-55 mm in length between January and June when records were aggregated for outmigration estimates. The temporal pattern in sizes is shown in Figure C.9. We see no major trend in size in tributaries between January and June, only that Butte creek fish appear to run a bit smaller.

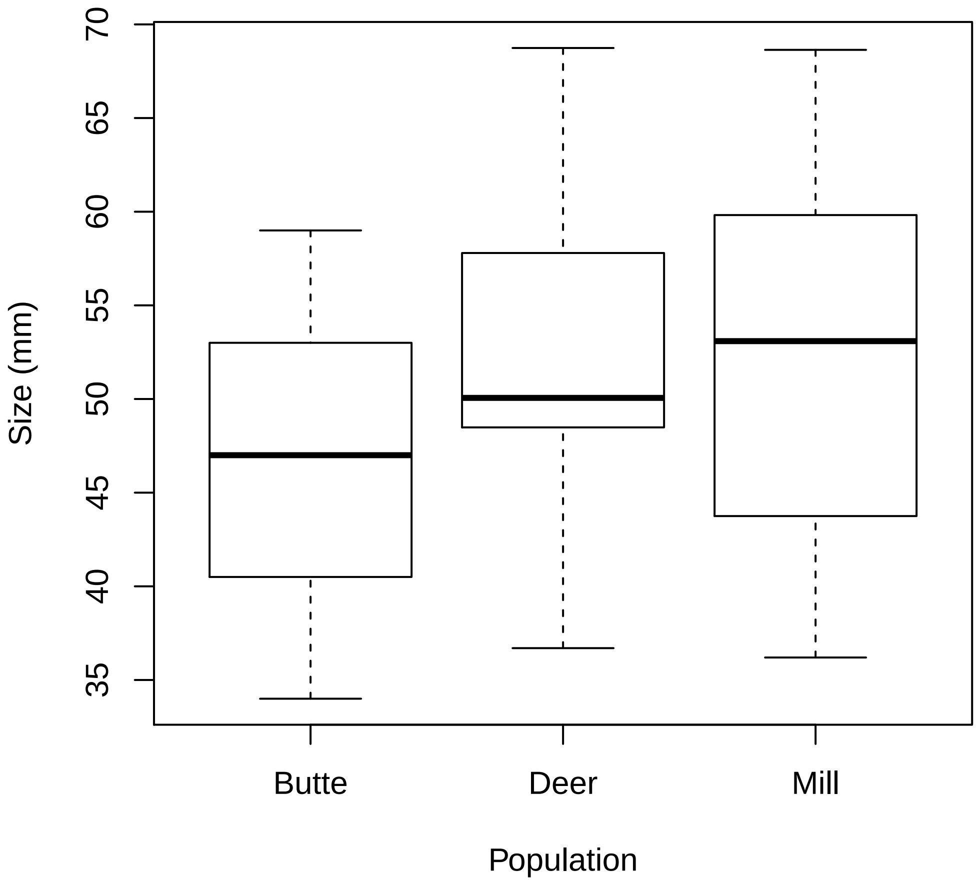

Figure C.8 Average size of juveniles obtained from rotary screw traps operating in Butte, Deer and Mill creeks between January and June.

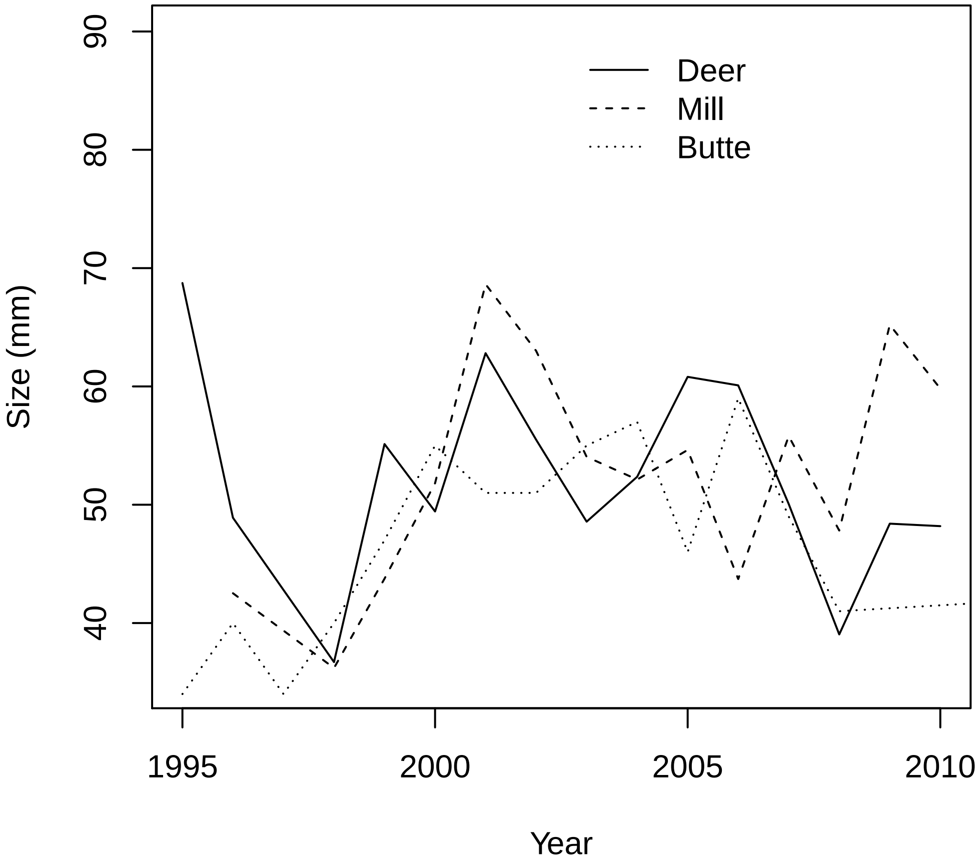

Figure C.9 Temporal trend in juvenile sizes obtained from rotary screw traps operating in Deer, Butte and Mill creeks between January and June.

DISCUSSION

This analysis drew upon varied sources of fish length information in the Sacramento River drainage. The summary of rotary screw trap lengths indicates that Spring run out-migrating Chinook from Deer, Mill and Butte creeks are approximately the same size, and have been stable at approximately 55 mm in recent years. Regression analysis of recoveries from mid-water trawl surveys at Chipps Island indicates that growth of fish from North of the Delta to Chipps Island, as well as the length at recapture in Chipps Island trawls varied in relation to environmental variables. Regression analyses showed that the length at Chipps Island from the perspective of two different types of length statistics proved to be related to environmental variables regardless of the data source of the length estimates.

We used two different growth metrics. One growth metric came from lengths of CWT recoveries and releases of hatchery fish, and the other came from seine and trawl surveys. The CWT growth was derived from average recovery length at Chipps Island and average release lengths at various release locations and times. The average recovery length is a statistic based on a very small sample size relative to the release length statistic. If you consider the how many fish are released relative to recaptured, and if you consider that tagged fish are released at various locations and at different times, it is easy to see how biased the growth estimate might be. The SEINE/TRAWL growth estimate made no distinction between hatchery and non-hatchery fish and it represents an estimate of the growth of all Fall or Spring run fish between Region 1 seines and Chipps Island. In comparison to the CWT estimate, it will be more complex in it's stock composition (with hatchery and non-hatchery fish of all origins), but it is much simpler in upstream capture and release size sampling. All stocks were sampled from the same locations for sizing regardless of origin. We found a relationship between SEINE/TRAWL growth and environmental variables, but no relationship between CWT growth and environmental variables. This may be due to the complexity of how the release length was calculated for the CWT growth estimate.

The environmental predictors that best explained growth were the Central Valley Project exports (CVP), the ratio of combined state and federal exports to the total Delta inflow (EXPIN), and the bass index. CVP and EXPIN are both related to flows in complex ways. CVP is related to flow because exports would tend to be less restricted at higher flows, but would have its highest impact when flows are low. We would expect that juvenile salmon growth could be high when CVP is highest under that logic. EXPIN is related to flow by a similar logic, but since EXPIN is a ratio, we would expect the largest fraction of flows to be exported when flows are low (for a given level of exports). We would expect juvenile salmon growth to be lowest when EXPIN is highest at the lowest flows.

Figure C.10 illustrates some the general patterns in environmental covariation. In the upper left panel we see that CVP has the greatest degree of variability at the lowest flows (with Yolo flow being used as a surrogate for average flow at export locations). Across a range of flow values we can see that the lower bound of CVP increases. This is consistent with a general tendency of reducing exports at lower flows. The relative impact of exports at a given flow is seen with EXPIN, which we see (lower left) diminishes at higher flows. We also see that more water reaches downstream to the Mokelumne river when EXPIN is lower (lower right panel). Finally, there is a general pattern of CVP being larger when EXPIN is higher, but recall that the highest EXPIN may coincide with low flows.

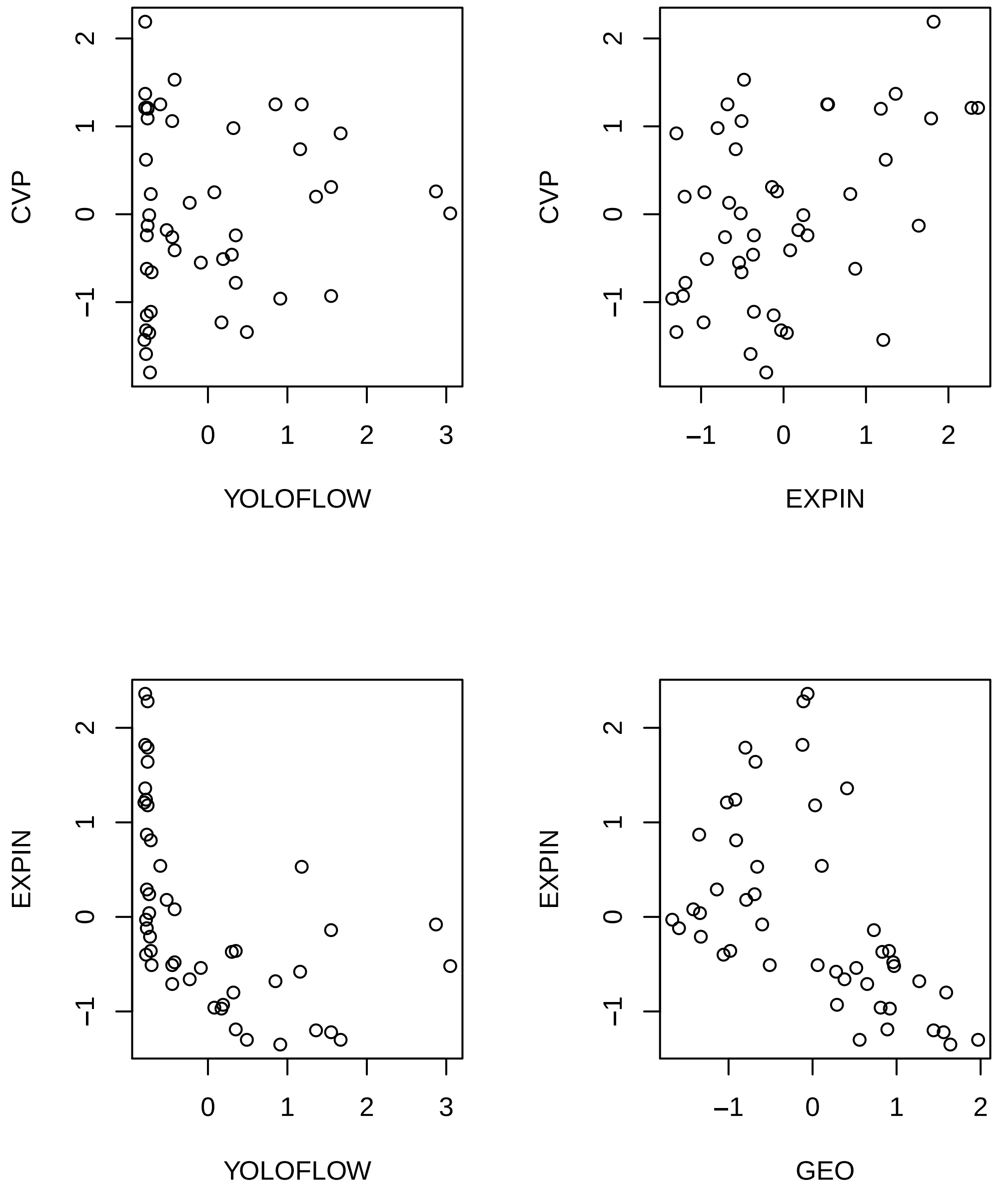

Figure C.10 Covariation between significant environmental predictors.

EXPIN was a significant predictor of length when both CWT and TRAWL datasets were used. It was significant with p<0.01 in both cases. EXPIN was also a significant predictor (p<0.01) of growth estimates of Fall and Spring aggregates obtained from the SEINE/TRAWL dataset. The CWT length regression is in conflict with the SEINE/TRAWL growth regression and the TRAWL length regression though. The CWT result predicts a positive effect of EXPIN, versus a negative effect for the other two regression analyses. A possible reason for this would be that the CWT dataset was exclusively measuring hatchery fish (although hatchery fish would also have been present in the other two analyses). If EXPIN has a positive effect on hatchery fish length at Chipps Island as shown in the CWT length regression, and a negative effect on the aggregate of both hatchery and non-hatchery fish seen in the TRAWL length and SEINE/TRAWL growth analysis, it might suggest that that the negative effect on non-hatchery growth is even stronger than seen in the TRAWL surveys. It could also be a size related issue. If hatchery fish are smaller and more vulnerable to entrainment, removal of the smaller fish from the out-migrating cohort would make it appear as if they grew on average, when in fact it was just the smaller ones that did not make it into the downstream survey sample.

The relationship between flows and exports, and resulting growth and survival are complex. We found that growth and length are negatively related to EXPIN, but positively related to CVP. A possible mechanism, is that there is a threshold flow/export relationship where in smaller fish become more vulnerable to entrainment. Such a mechanism would predict that more larger fish than smaller fish make it downstream to be sampled at Chipps Island, which has the effect of making the growth appear larger on the basis of the average recovery size. This would appear to be favorable growth conditions despite the fact that all individuals did not grow better on those conditions. If a relatively high CVP export year were where to coincide with an average flow year, and if more small fish were entrained, it would appear that fish where larger at Chipps Island.

Results also indicated that Spring run were longer at Chipps Island, despite the fact that the SEINE/TRAWL regression showed that Spring run growth was less than Fall run. Total Central Valley Projects (combined state and federal) exports showed positively effect on growth in the SEINE/TRAWL regression and length in the TRAWL analysis. Since there was a negative effect from the export to inflow ratio, it may be suggest that total flows have a positive effect, and that there may be a relationship between exports and flows that is dictated by water extraction policies.

It is interesting that regression results show that bass has a positive effect on the growth estimates evaluated from the SEINE/TRAWL, yet has a negative effect on lengths estimated from the TRAWL data. Since the bass index is not standardized to effort, it can’t imply a direct predation rate change on a size class of Chinook juveniles, but depending on the relationship between the index and the size of the bass caught, it might imply a shift in the size of Chinook vulnerable to bass predation at a given abundance of bass. It could be that smaller fish are more vulnerable and predation biases the growth estimate by removing smaller fish.

Our examination of length/growth sensitivity to environmental variation points to a few results. First, EXPIN is a statistically significant predictor of size and growth, with a negative effect on both. Our samples conflate the story a bit, but if you consider that the only positive effect was seen in the length of hatchery fish, and if you consider that the CWT dataset had race and hatchery factors, the positive effect of EXPIN in the regression result of the CWT data should not detract from the regression results found in both the SEINE/TRAWL and TRAWL dataset. It should be noted however, that the highest regression coefficient value for an environmental effect in any of our regressions was about 5, meaning that about 5 mm per standard deviation was the maximum variability in size predicted by variability in an environmental effect. This implies that at the extreme of 2 standard deviations, only 10 mm of net difference in size at Chipps Island would be predicted. Still, two standard deviations explains about 95% of the variation in environmental factors, and 10 mm explains 10-15% of the variability in length at Chipps Island (assuming 85 mm length at Chipps Island). Since the same environmental variables explain significant variation in rearing survival, it is feasible that length may be an instrumental in the mechanism of rearing survival.

APPENDIX C: GROWTH ANALYSIS AND MODELLING

In this appendix we provide a description of the methods we used to collect and analyze length information from various state and federal collection facilities in the Sacramento drainage. We assembled time series of lengths, both upstream and downstream, for both hatchery fish and combined hatchery and wild aggregates. Where possible, we used upstream and downstream lengths to obtain annual growth estimates. In the absence of a downstream growth measurement, we assembled a time series of downstream lengths. We performed regressions on growth and length estimates, evaluating impacts of environmental conditions on growth.

INTRODUCTION

The life-cycle modeling analysis in this project attempts to attribute variability in survival to environmental factors during different parts of the life history. Survival can be affected by the environment in complex ways, and can be mediated through biotic and abiotic processes. We posit that size can play a role in predicting survival, and that growth itself can be an indicator of survival as well. An obvious mechanism for size effects on survival would be that larger fish are less vulnerable to predation than smaller fish. A mechanism for growth being a predictor of survival would be that faster growing fish are likely to be experiencing better feeding conditions and bioenergetic advantages, and therefore should survive better.

In this appendix we look for relationships between environmental conditions and growth, but because growth requires two measurements (a capture and a recapture, or a release and recapture), we are not always able to get an estimate of a growth increment. Some length estimates obtained from survey data cannot be connected to later surveys, and therefore a growth estimate can’t be derived from the measurements. An example of this occurs with rotary screw traps operating in tributaries, where juvenile size samples are obtained during rearing and migration. Those sizes are not directly comparable to later samples obtained downstream, because the downstream samples are aggregates of all the independent upstream sampled lengths. We might be able to document a pattern in upstream sizes over the years, but growth to the downstream measurement can’t be inferred. We therefore treat size as a surrogate for growth, with the assumption that annual variability in juvenile size is in actual fact a measurement of annual variability in growth since all fish must at some point have emerged from the gravel at roughly the same sizes.

METHODS

We performed an analysis of length and growth patterns for Spring and Fall run Chinook in the Sacramento River in relation to environmental factors. We collected size at release and recapture data from state and federal agencies. We compiled records into average sizes at release for several different stock aggregates that provided adequate sample sizes for the years the data were available. In some case, it was possible to associate the length of a downstream recaptured fish with a known upstream release size to obtain a growth increment estimate, but in other cases only the downstream size record was available. Upstream length records were obtained from hatchery release information, from screw traps operated in tributaries, and from seine surveys operated throughout the Sacramento drainage. The farthest downstream sizes were obtained from Chipps Island, where mid-water trawl surveys collected size information and recorded the race of the fish based on the presence of a CWT or a length based estimated based on the length of the fish at the time the sample was obtained.

Data compilation

Length data

The Pacific States Marine Fisheries Commission manages and supports the Regional Mark Processing Center (RMPC; http://www.rmpc.org/), which in turn manages the Regional Mark Information System (RMIS). Agencies and organizations throughout the Western United States report CWT data directly to the RMIS. The Delta Juvenile Fish Monitoring Program (DJFMP) was initiated in the 1970s and is managed by the US Fish and Wildlife Service (USFWS, 2014). The program has a stated objective to monitor the effects of water projects in the Bay Delta on juvenile Chinook.

The number of juvenile salmon leaving freshwater during the spring has been sampled annually since 1978 by means of mid-water trawling in the estuary near Chipps Island (Brandes and McLain 2001). The Trawl site in Suisun Bay is sampled three days per week year round. It is sometimes sampled daily and at times two shifts per day for a total of 20 tows per day during May and June. During December and January, trawls occur 7 days per week with ten 20 minute trawls conducted daily. Catch limits are imposed when Delta Smelt catches exceed 8 individual Delta Smelt. The trawl survey records fish length at capture and creates a record of the race, origin and release location if a coded wire tag is detected.

We used data that had been collected since 1979 in mid-water boat trawls at Chipps Island, Suisun Bay (Zone 10 S UTM, 4211218N, 595531E). Data from the DJFMP is available online (http://www.fws.gov/stockton/jfmp/). USFWS tables available online contained metrics of juvenile Chinook salmon that had been marked with CWTs, released throughout the Sacramento - San Joaquin Basin and then recovered near Chipps Island in Suisun Bay (Coded *Wire Tag 1978 -2011.xls* and *Coded Wire Tag 2012 -2013.xls*). Survey records not containing CWTs can be found in the spreadsheets *Chipps Island Trawls 1976-2011.xlsx and Chipps Island Trawls 2012-2014.xlsx.*

We used the records from the Chipps Island trawls to create a database of fish lengths and growths increments for all fish with CWTs (referred to as the CWT table). Each fish with a CWT is of a known origin, so the race and the source (hatchery or wild stock origin) are also known. We used the remaining records from the Chipps Island survey to construct a database table of Chinook known to be of a given race, but where the origin is not known. These records were assembled into a table we refer to as the TRAWL table, which only distinguishes between Fall and Spring runs.

We compiled juvenile salmon length data from the Sacramento watershed and the San Francisco Bay Delta into a relational database in order to determine growth of hatchery Fall Chinook and hatchery and wild juvenile Spring Chinook. Wild Spring stocks included Deer, Mill and Butte creeks. Butte Creek fish were release and recaptured in Butte Creek, the Sutter

Bypass or near Chipps Island in Suisun Bay. Release and recovery data were compiled from three sources: California Department of Fish and Wildlife (CDFW), US Fish and Wildlife Service's Delta Juvenile Fish Monitoring Program (DJFMP) and the Regional Mark Processing Center (RMPC).

From 1995 to 2001, the CDFW captured, measured, marked, and released wild spring-run Chinook on Butte Creek (CDFG, 1999; CDFG, 2004-2; CDFG, 2004-3). The purpose of the CDFW program was to estimate adult escapement, monitor timing and abundance of juvenile outmigration, and monitor relative growth rates in the Butte Creek system. Fish were captured and marked with adipose fin clips and coded wire tags at the Parrot-Phelan Diversion Dam (PPDD; Zone 10 S UTM, 4396287N, 611463E). Releases took place at three locations, but varied from year to year. Release sites were: PPDD, Baldwin Construction Yard (approximately one mile downstream of the PPDD) and Adams Dam (approximately 7 miles downstream of PPDD). After release, marked fish were subject to recapture and sacrifice at downstream locations in Butte Creek, the Sutter Bypass and the Sacramento Delta near Chipps Island. Rotary screw traps were used to recapture fish at all locations and an off-stream fish screen outfitted with a trap box was used to collect fish at the PPDD site. Recaptured fish were sacrificed, measured for fork length and their CWTs were extracted and read. We received programmatic data formatted in a Microsoft Access database directly from the CDFW (C. Garman, personal communication, 1/30/2014).

We queried the RMIS database for juvenile Chinook that had been marked and released at any location in the Sacramento drainage. The RMIS table was then related by CWT code to Chipps Island mid-water trawl and Sacramento River recoveries. In this way, we queried recoveries with release locations only within the Sacramento Basin.

We obtained tributary measurements of juvenile lengths from rotary screw traps (RSTs) operating in Butte creek, Mill creek and Deer creek. Rotary screw traps were operated by the US Fish and Wildlife Service in Mill and Deer creeks, and by the California Department of Fish and Wildlife in Butte creek. Screw trap operation spanned 1995-2010 in the records used in this analysis. We used samples obtained from January to June of each year to obtain estimates of tributary outmigration size.

Environmental data

We compiled time series of environmental variables that pertain to the experiences of downstream migration juveniles. For Spring Run, we used discharge at the three creeks (Deer, Mill and Butte), flow, exports volumes and other export indices, and a CPUE index of bass abundance. Flow temperature and discharge were obtained from USGS gauging stations (http://waterdata.usgs.gov/nwis/inventory). Exports and other dayflow parameters were obtained from water project data available on the California department of water resources website (http://www.water.ca.gov/dayflow/output/Output.cfm). Environmental variables were normalized by subtracting the mean and dividing by the standard deviation. The variables are summarized in Table C.1 for Spring run and in Table C.2 for Fall run.

Length and Growth analysis

We examined environmental factors affecting length at recapture at Chipps Island of fish with known and unknown release lengths. Where length at release was known, we examined growth rates. We associated each size and growth record with environmental factors experienced by each race of salmon each year the sizes were recorded. We compared fall and spring length at capture at Chipps Island from two separate surveys. The CWT table provided an estimate of growth for fall and spring hatchery releases. The mid-water trawls did not distinguish between wild and hatchery fish, so those analyses pertain to the race as a whole, without distinction about release locations or wild/hatchery distinctions. We also obtained sizes from DJFMP seines in Region 1 (upstream from the Delta) and compared those sizes with Chipps Island size information. Since seine samples do not distinguish between populations, growth obtained from subtracting upstream seine sizes from Chipps Island trawl sizes provide estimates of aggregate Fall and Spring run sizes, but cannot distinguish between release locations or between wild and hatchery releases.

SEINE/TRAWL - growth by race from mid-Sacramento to Chipps Island.

We queried the DJFMP seine database to obtain estimates of growth for Spring and Fall runs. Region 1 of the DJFMP beach seine runs from Colusa State Park to Elkhorn. We averaged lengths of Spring and Fall seine lengths for each year for fish collected between January and June, and compared those to Chipps Island midwater trawl sizes. The trawl survey assigned fish to Fall and Spring runs based on size ranges and records indicated that all collections occurred in May and June. We calculated the growth for each race of fish each year as the difference between the average trawl length and the average seine length. We refer to these growth estimates as the SEINE/TRAWL dataset.

We examined growth patterns in relation to environmental variables listed in Tables C.1 and C.2. We performed stepwise linear regressions of growth in relation to each variable, adding variables according to best p-value, and stopping when no further significant variables were found.

CWT –growth and length by hatchery source.

When hatchery fish are released, the average size of a sample of the release batch is used as the release length of record for fish in the batch. When recaptures occur at Chipps Island, a record for each fish recaptured can be compared to a release length record on the basis of CWT codes. To get reasonable sample sizes for recaptures, we were forced to aggregate hatchery releases such that release locations were ignored. We aggregated all release locations within the Sacramento drainage for each hatchery source. Since a release batch contains a range of lengths, it is possible for the smallest recaptured fish to be smaller than the average released fish. The growth record for each year was calculated as the average of all the recapture lengths minus the average release length. The average of release length was calculated as the weighted release length, weighted by the number released at each location at each time of release. We refer to the length and growth estimates from this method as the CWT dataset.

We tested for statistical relationships between size at recapture and environmental variables for Spring and Fall hatchery releases from Coleman National Fish Hatchery (CNFH) and Feather Fish Hatchery (FFH). We examined growth and length patterns in relation to environmental variables listed in Tables C.1 and C.2. We performed stepwise linear regressions of growth and length in relation to each variable, adding variables according to best p-value, and stopping when no further significant variables were found.

TRAWL – length by race at Chipps Island.

We selected records that were not limited to CWT tagged fish (the TRAWL dataset in this analysis) from Chipps Island, and assembled all records of Spring and Fall chinook to look at the size. By not being limited to CWT matches, the sample size was much larger than for the CWT matched database, but for the TRAWL dataset, the origin of fish could not be determined. The race of the fish was assigned by a length/timing criteria established by the DJFMP (the "Race Table" found at www.fws.gov/stockton/jfmp). Using these records we looked for temporal trends, comparisons between Spring and Fall runs, and relationships between size at capture and environmental factors. Annual average size records for Spring and Fall Chinook do not distinguish between hatchery and wild, and there is no growth estimate because the size at release is not known, and there is no way to distinguish between Butte, Mill, and Deer creeks. The TRAWL dataset provides an aggregate estimate of length at Chipps Island by race alone.

We examined growth patterns in relation to environmental variables listed in Tables C.1 and C.2. We performed stepwise linear regressions of length in relation to each variable, adding variables according to best p-value, and stopping when no further significant variables were found. We treat length as a surrogate for growth on the assumption that some initial length can be treated as a constant across and all variability can be thought of as occurring after that initial length.

RST – Lengths in tributaries

Deer, Mill, and Butte creek rotary screw trap records were queried to obtain estimates of outmigrating juvenile sizes. We took the average size of all samples obtained from the traps between January and June of each migration year. We attempted to match CWT releases from Butte Creek each year to recoveries within the Sacramento basin to obtain growth estimates at various sample locations, but found that recoveries were too few to obtain good estimates of growth. Butte Creek CWT release records with Chipps Island recapture events began in 1996, but recaptures amounted to fewer than 10 fish per year at Chipps Island. It was not possible to relate RST lengths to downstream lengths at Chipps Island for a growth estimate. We therefore limited our examination of RST data to showing temporal trends of sizes of Deer, Mill and Butte creeks.

RESULTS

SEINE/TRAWL - growth by race from mid-Sacramento to Chipps Island.

The average growth of Spring and Fall Chinook are shown in Figure C.1 along with the time elapsed between Seine surveys and mid-water trawls. The temporal trend in growth is shown in Figure C.2. Fall Chinook appear to be slightly larger and on average seen in seine surveys about half of a month later. Predominantly, Fall Chinook appear to grow slightly more between Seine and mid-water trawl surveys, which is noteworthy, since they do so in less time as seen in the average month seined calculation.

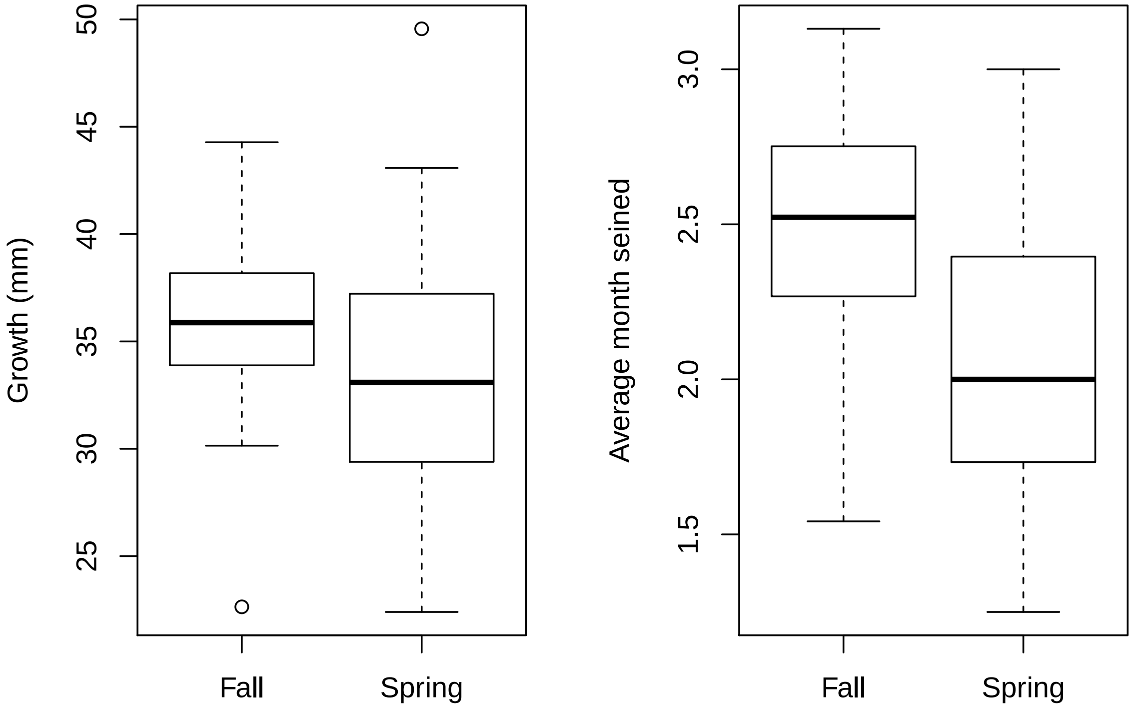

Figure C.1 Growth between release and sampling at Chipps Island (left panel) and month at which Region 1 seine was sampled (right panel).

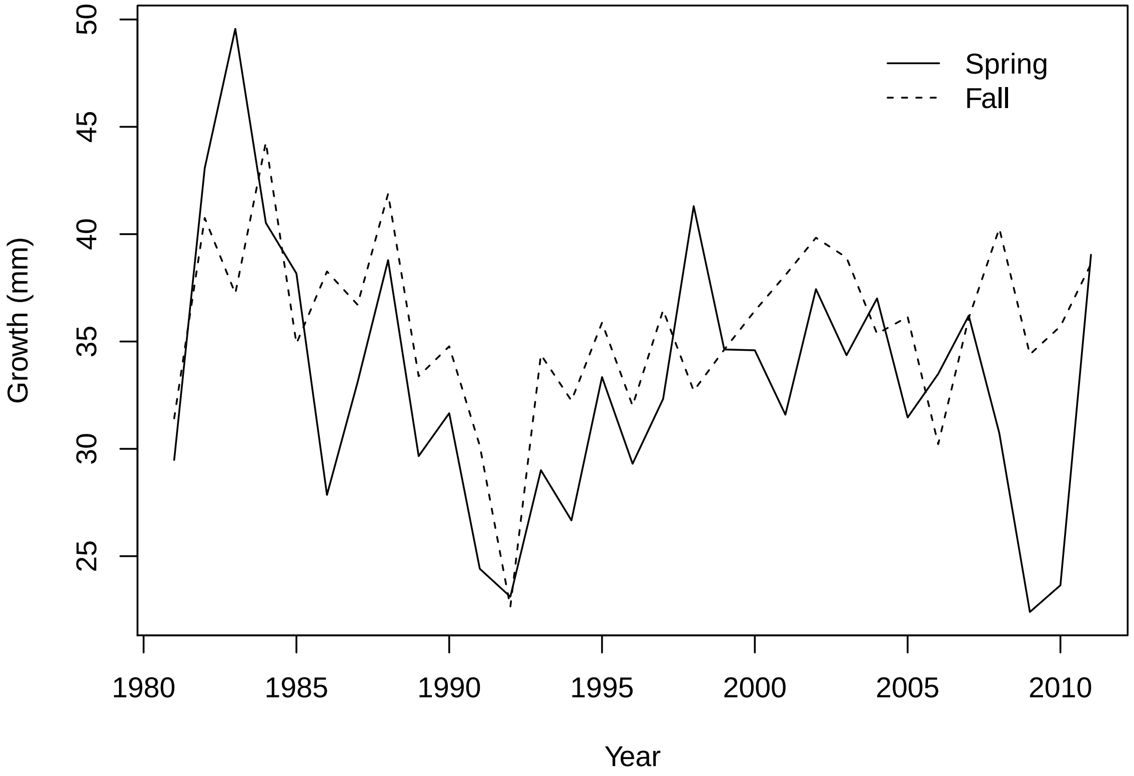

Figure C.2 Temporal trends in Spring and Fall Chinook growth evaluated from beach seine and mid-water trawl surveys.

Table C.3 shows the results of stepwise linear regressions. The regression results show that there are significant effects of Bass, Central Valley Project exports, race (spring or fall run) , and the export to inflow ratio (EXPIN). The bass index shows a positive effect on growth. Central Valley Project exports also show a positive effect, but the export to inflow ratio shows a negative effect. The adjusted R-squared value for the fit was 0.4068. The diagnostic plot of the fit is shown in Figure C.3.

Table C.3 Regression results of growth in SEINE/TRAWL data in relation to environmental variables. Intercept in parentheses.

CWT –growth and length by hatchery source.

Feather Fish Hatchery (FFH) spring Chinook and Coleman National Fish Hatchery (CNFH) fall Chinook growth and lengths at Chipps Island are shown in Figure C.4. We see that there is considerable variability in growth, and that Spring run fish appear to have grown faster than Fall run until the early 1990’s, but are now growing less than Fall run (see Figure C.4 upper panel). Table C.4 shows the results of stepwise regressions of length against all Spring and Fall run covariates. The export to inflow ratio was the only significant predictor of catch length in the Chipps Island trawl, with EXPIN having a positive effect. The adjusted R-squared for the best fitting model shown was 0.3414. Diagnostic plots of the best fit are shown in Figure C.5, where we can see that the residuals are normal. Regressions show a hatchery effect, finding that FFH fish arrive at Chipps Island 3.5 mm larger than CNFH fish, but FFH fish included Spring run, which were larger. Despite growth of Spring run recoveries appearing to decline from 1985, the lengths of Spring run fish at Chipps Island appears to be relatively constant. We found no significant relationships between growth and environmental variables.

TRAWL – length by race at Chipps Island.

Unlike the CWT lengths from hatchery specific releases, the aggregated relative Spring and Fall lengths remain consistent from the 1980's until present. Spring run appear to be consistently larger that Fall run (see Figure C.6). Regression results are shown in Table C.5 and indicate that Yolo flow, the Central Valley Project exports, the export to inflow ratio, water passing via the Delta Cross Channel, and the bass index are all significant predictors of size. The Adjusted R-squared of the best fit shown is 0.785. The diagnostic plots of the best fit is shown in Figure C.7. The TRAWL dataset had the largest samples, and despite being aggregated wild and hatchery fish, and despite not identifying source drainages, the regression results yield the highest R-squared. The diagnostics show normality in residuals as well as the majority of residuals concentrated on predicted theoretical quantiles.

RST – Lengths in tributaries

Mill, Deer, and Butte creek Spring run average fish sizes from rotary screw trap operations are shown in Figure C.8. We see that Mill, Deer and Butte creeks are on average about 45-55 mm in length between January and June when records were aggregated for outmigration estimates. The temporal pattern in sizes is shown in Figure C.9. We see no major trend in size in tributaries between January and June, only that Butte creek fish appear to run a bit smaller.

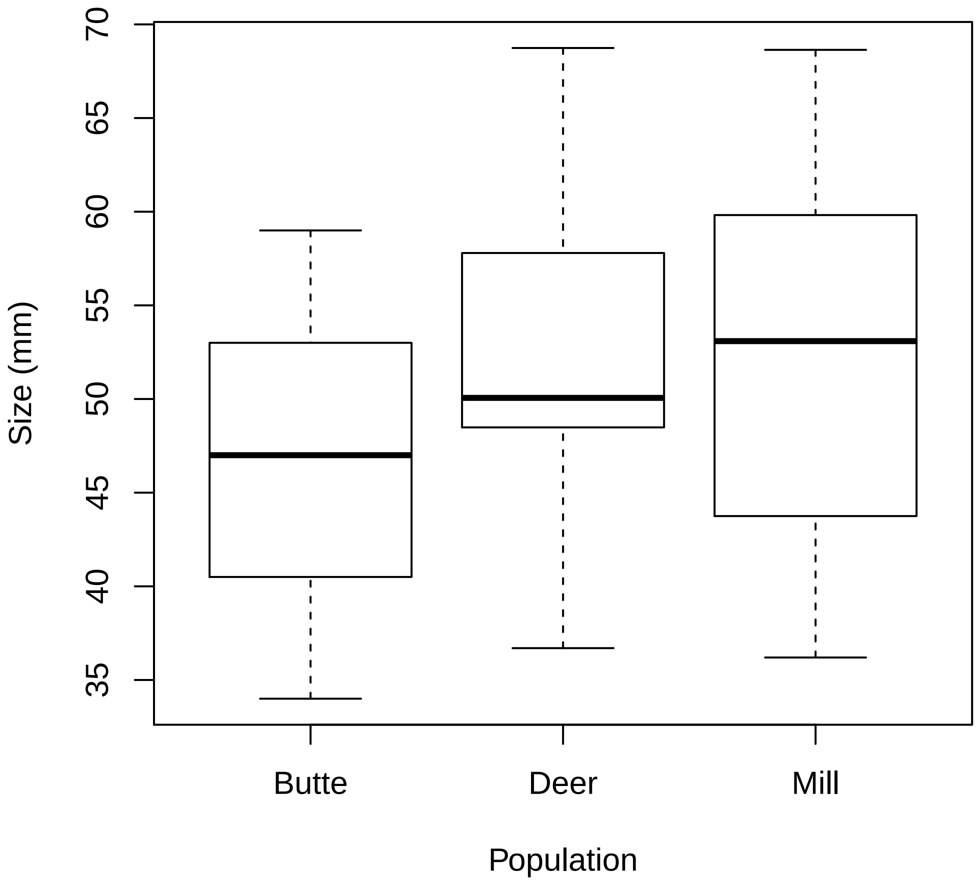

Figure C.8 Average size of juveniles obtained from rotary screw traps operating in Butte, Deer and Mill creeks between January and June.

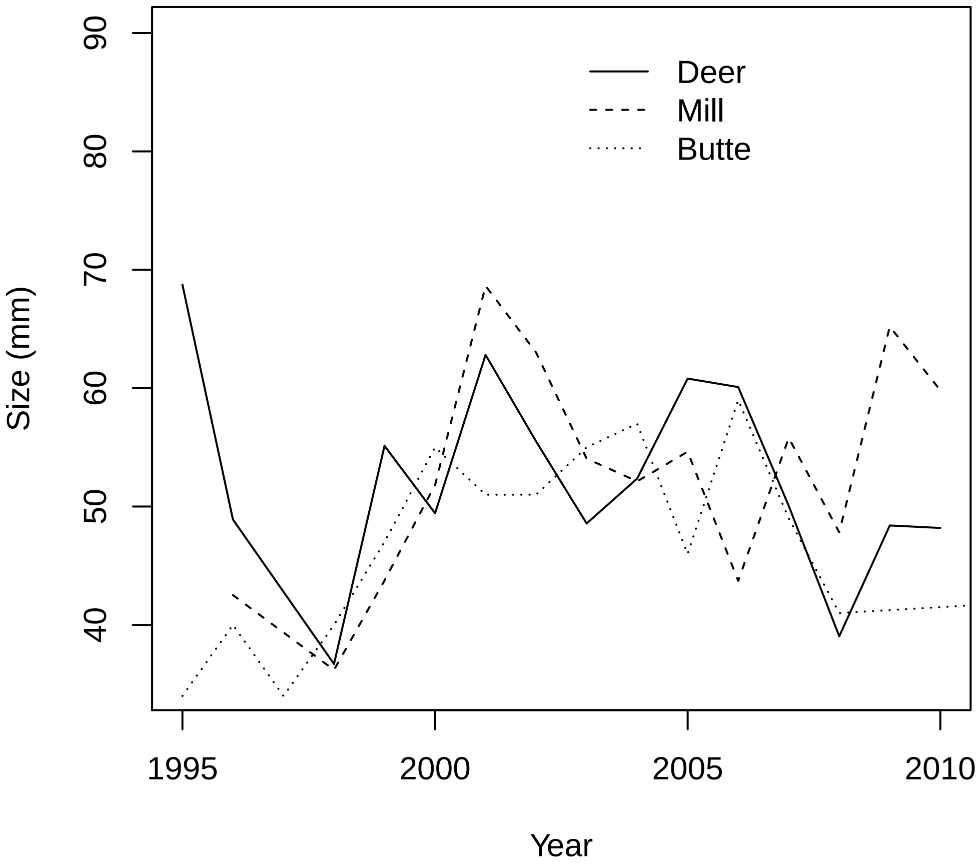

Figure C.9 Temporal trend in juvenile sizes obtained from rotary screw traps operating in Deer, Butte and Mill creeks between January and June.

DISCUSSION

This analysis drew upon varied sources of fish length information in the Sacramento River drainage. The summary of rotary screw trap lengths indicates that Spring run out-migrating Chinook from Deer, Mill and Butte creeks are approximately the same size, and have been stable at approximately 55 mm in recent years. Regression analysis of recoveries from mid-water trawl surveys at Chipps Island indicates that growth of fish from North of the Delta to Chipps Island, as well as the length at recapture in Chipps Island trawls varied in relation to environmental variables. Regression analyses showed that the length at Chipps Island from the perspective of two different types of length statistics proved to be related to environmental variables regardless of the data source of the length estimates.

We used two different growth metrics. One growth metric came from lengths of CWT recoveries and releases of hatchery fish, and the other came from seine and trawl surveys. The CWT growth was derived from average recovery length at Chipps Island and average release lengths at various release locations and times. The average recovery length is a statistic based on a very small sample size relative to the release length statistic. If you consider the how many fish are released relative to recaptured, and if you consider that tagged fish are released at various locations and at different times, it is easy to see how biased the growth estimate might be. The SEINE/TRAWL growth estimate made no distinction between hatchery and non-hatchery fish and it represents an estimate of the growth of all Fall or Spring run fish between Region 1 seines and Chipps Island. In comparison to the CWT estimate, it will be more complex in it's stock composition (with hatchery and non-hatchery fish of all origins), but it is much simpler in upstream capture and release size sampling. All stocks were sampled from the same locations for sizing regardless of origin. We found a relationship between SEINE/TRAWL growth and environmental variables, but no relationship between CWT growth and environmental variables. This may be due to the complexity of how the release length was calculated for the CWT growth estimate.

The environmental predictors that best explained growth were the Central Valley Project exports (CVP), the ratio of combined state and federal exports to the total Delta inflow (EXPIN), and the bass index. CVP and EXPIN are both related to flows in complex ways. CVP is related to flow because exports would tend to be less restricted at higher flows, but would have its highest impact when flows are low. We would expect that juvenile salmon growth could be high when CVP is highest under that logic. EXPIN is related to flow by a similar logic, but since EXPIN is a ratio, we would expect the largest fraction of flows to be exported when flows are low (for a given level of exports). We would expect juvenile salmon growth to be lowest when EXPIN is highest at the lowest flows.

Figure C.10 illustrates some the general patterns in environmental covariation. In the upper left panel we see that CVP has the greatest degree of variability at the lowest flows (with Yolo flow being used as a surrogate for average flow at export locations). Across a range of flow values we can see that the lower bound of CVP increases. This is consistent with a general tendency of reducing exports at lower flows. The relative impact of exports at a given flow is seen with EXPIN, which we see (lower left) diminishes at higher flows. We also see that more water reaches downstream to the Mokelumne river when EXPIN is lower (lower right panel). Finally, there is a general pattern of CVP being larger when EXPIN is higher, but recall that the highest EXPIN may coincide with low flows.

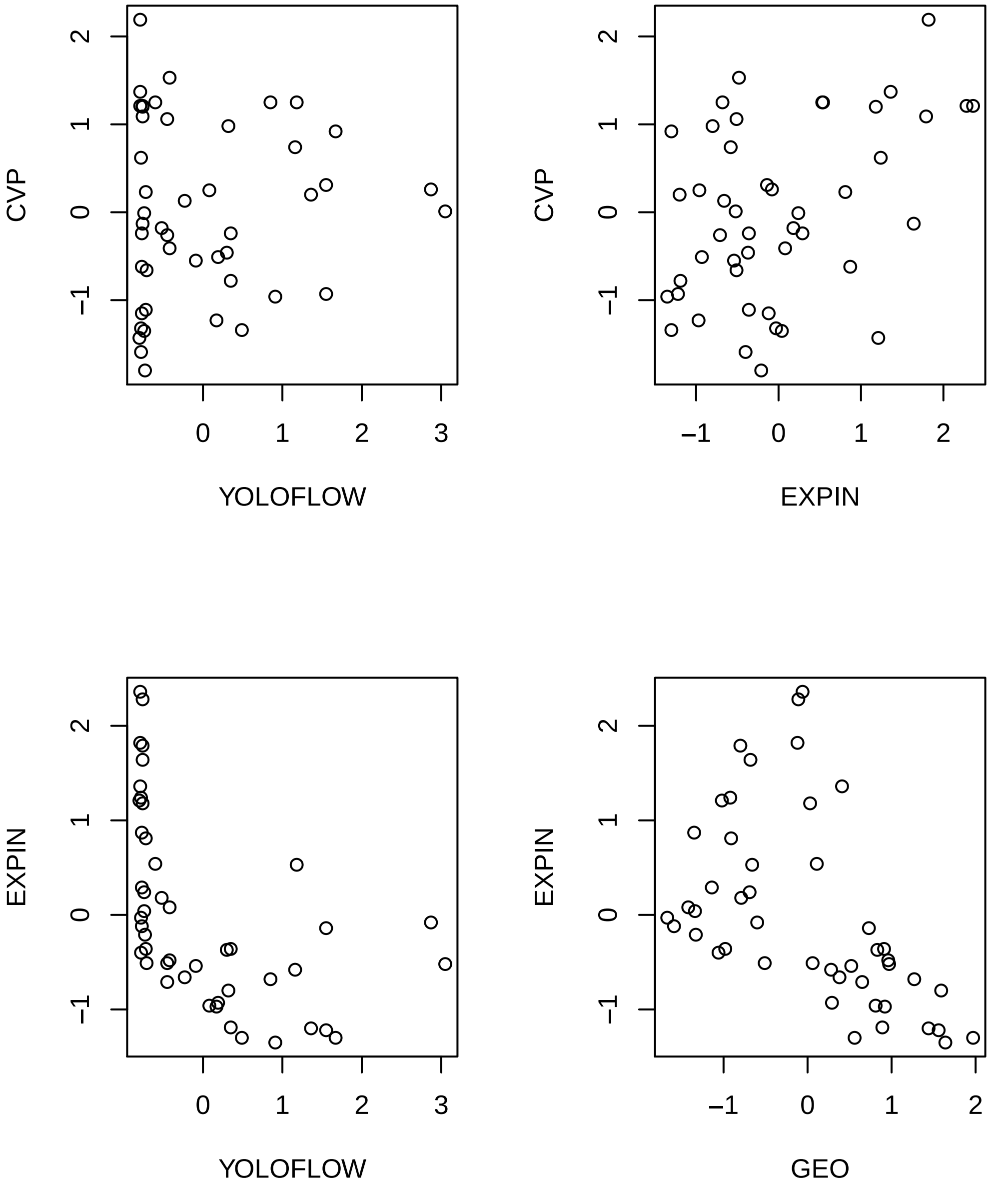

Figure C.10 Covariation between significant environmental predictors.

EXPIN was a significant predictor of length when both CWT and TRAWL datasets were used. It was significant with p<0.01 in both cases. EXPIN was also a significant predictor (p<0.01) of growth estimates of Fall and Spring aggregates obtained from the SEINE/TRAWL dataset. The CWT length regression is in conflict with the SEINE/TRAWL growth regression and the TRAWL length regression though. The CWT result predicts a positive effect of EXPIN, versus a negative effect for the other two regression analyses. A possible reason for this would be that the CWT dataset was exclusively measuring hatchery fish (although hatchery fish would also have been present in the other two analyses). If EXPIN has a positive effect on hatchery fish length at Chipps Island as shown in the CWT length regression, and a negative effect on the aggregate of both hatchery and non-hatchery fish seen in the TRAWL length and SEINE/TRAWL growth analysis, it might suggest that that the negative effect on non-hatchery growth is even stronger than seen in the TRAWL surveys. It could also be a size related issue. If hatchery fish are smaller and more vulnerable to entrainment, removal of the smaller fish from the outmigrating cohort would make it appear as if they grew on average, when in fact it was just the smaller ones that did not make it into the downstream survey sample.

The relationship between flows and exports, and resulting growth and survival are complex. We found that growth and length are negatively related to EXPIN, but positively related to CVP. A possible mechanism, is that there is a threshold flow/export relationship where in smaller fish become more vulnerable to entrainment. Such a mechanism would predict that more larger fish than smaller fish make it downstream to be sampled at Chipps Island, which has the effect of making the growth appear larger on the basis of the average recovery size. This would appear to be favorable growth conditions despite the fact that all individuals did not grow better on those conditions. If a relatively high CVP export year were where to coincide with an average flow year, and if more small fish were entrained, it would appear that fish where larger at Chipps Island.

Results also indicated that Spring run were longer at Chipps Island, despite the fact that the SEINE/TRAWL regression showed that Spring run growth was less than Fall run. Total Central Valley Projects (combined state and federal) exports showed positively effect on growth in the SEINE/TRAWL regression and length in the TRAWL analysis. Since there was a negative effect from the export to inflow ratio, it may be suggest that total flows have a positive effect, and that there may be a relationship between exports and flows that is dictated by water extraction policies.

It is interesting that regression results show that bass has a positive effect on the growth estimates evaluated from the SEINE/TRAWL, yet has a negative effect on lengths estimated from the TRAWL data. Since the bass index is not standardized to effort, it can’t imply a direct predation rate change on a size class of Chinook juveniles, but depending on the relationship between the index and the size of the bass caught, it might imply a shift in the size of Chinook vulnerable to bass predation at a given abundance of bass. It could be that smaller fish are more vulnerable and predation biases the growth estimate by removing smaller fish.

Our examination of length/growth sensitivity to environmental variation points to a few results. First, EXPIN is a statistically significant predictor of size and growth, with a negative effect on both. Our samples conflate the story a bit, but if you consider that the only positive effect was seen in the length of hatchery fish, and if you consider that the CWT dataset had race and hatchery factors, the positive effect of EXPIN in the regression result of the CWT data should not detract from the regression results found in both the SEINE/TRAWL and TRAWL dataset. It should be noted however, that the highest regression coefficient value for an environmental effect in any of our regressions was about 5, meaning that about 5 mm per standard deviation was the maximum variability in size predicted by variability in an environmental effect. This implies that at the extreme of 2 standard deviations, only 10 mm of net difference in size at Chipps Island would be predicted. Still, two standard deviations explains about 95% of the variation in environmental factors, and 10 mm explains 10-15% of the variability in length at Chipps Island (assuming 85 mm length at Chipps Island). Since the same environmental variables explain significant variation in rearing survival, it is feasible that length may be an instrumental in the mechanism of rearing survival.

Abstract

We developed a general state-space modeling framework to evaluate the influence of factors on trends in abundance of multiple life-history stages of salmon. The model utilizes Beverton-Holt transitions among life stages, and incorporates factors into the transitions by modeling the dependence of the Beverton-Holt productivity p (survival) and capacity K parameters as functions of driving factors. We estimated model coefficients in a Bayesian framework to provide inference on factors hypothesized to affect the population dynamics by fitting to indices of abundance. We call the modeling framework Oncorhynchus Bayesian Analysis (OBAN), and we applied it to winter run Chinook in the Sacramento River, California, a salmon run listed as endangered in 1994. Using the OBAN framework we were able to place probability statements on the relationships between certain environmental and anthropogenic factors and winter-run population dynamics. We found that temperatures and minimum flow in the spawning reaches and ocean productivity had a high probability of affecting survival (≥ 0.8), whereas water diversions and water routing had lower probabilities of affecting survival. The OBAN framework provides a means for understanding how historical management of hydrology and harvest coupled with environmental variability shape the trends in abundance, and thus facilitates understanding how future management actions may affect population recovery.

Keywords: state-space, WinBUGS, Bayesian, winter-run, California, water management

Introduction

Recovery of endangered animals requires an analysis of the factors responsible for affecting the population dynamics historically and modifying those factors to facilitate recovery of the population. This is particularly true of salmon populations that have seen decreases in their abundances through the majority of their range, but particularly in the southerly portions of their distribution (NMFS 2014). Understanding what factors have lead to the decline in abundances is an important step toward developing future management actions. Incorporation of uncertainty is important when evaluating these factors to be able to identify the level of confidence that one has in the relationship between historical factors and changes in population abundance. An additional complication arises when abundance measurements are made with relatively poor accuracy. Furthermore, natural variability in the population dynamics (i.e., spawner recruitment relationships) may obfiscate the signal between causative factors and the response of the population to such factors. To address these needs, we developed a state-space modeling framework that is capable of reflecting uncertainty in the factors affecting salmon population dynamics.

The population dynamics uses stages to structure the chronology of factors affecting different portions of the life cycle with density dependence among stages described by Beverton-Holt transitions (Moussalli and Hilborn 1986, Scheuerell et al. 2006, Greene and Beechie 2004). The dynamics incorporate process noise to reflect natural variability in the dynamics of the population and an observation process that describes a state-space modeling framework (Newman et al. 2014). Although the parameters of such models can be estimated using maximum likelihood methods (Maunder et al. 2011) we estimate the model parameters in a Bayesian framework to allow prior knowledge and the observation process to inform the parameter estimates (i.e., using posterior distributions to integrate information from these two sources). Fitting such non-linear state-space models in a Bayesian context is becoming relatively commonplace (King et al. 2010, Newman and Lindley 2006) and this is an extension of those methods.

The development of this modeling framework arises from a practical problem related to a population that may have a moderate probability of extinction (Lindley et al. 2007, Botsford and Brittnacher 1998). The Sacramento River winter-run Chinook (*Oncorhynchus tshawytscha*) currently listed as endangered under the Federal and California Endangered Species Acts, and it has seen a decline in escapement since the 1970's. Like many salmon populations in decline, a list of factors that could potentially affect winter-run (and other salmon transiting the Sacramento River and the San Francisco Delta) have been compiled. Some of these factors include: 1) thermal mortality of eggs and alevin in the spawning reaches; 2) flow related survival after emergence; 3) rearing in off-channel areas such as the Yolo bypass (Sommer et al. 2005); 4) entrapment into the interior delta due to positioning of channel flow gates (Perry et al. 2010); 5) alterations in the outmigration flow vectors due to exportation of water from the system (Newman and Brandes 2010; Newman 2003); 6) predation from piscivorous fishes such as striped bass (*Morone saxatilis*) (Newman and Lindley 2006). Salmon exiting the Bay-Delta ecosystem enter the Gulf of the Farallones and transition to a near-shore environment with annual variability in productivity tied to the strength and location of upwelling (Wells et al. 2007). Once winter-run attain an age of 3 years (2-ocean), they are vulnerable to the west coast salmon fishery that primarily targets fall-run Chinook from the Klamath River, OR and Sacramento Rivers but also catches winter-run (O'Farrell 2012); however, timing and area closures to minimize fishery impacts on winter-run have been in place since the late 1990's (O'Farrell 2012). Yet, the ability to quantitatively evaluate the importance of all of these factors for explaining trends in winter-run escapament has not occurred.

The objectives of our work is to provide a general overview of the Onchorynchus Bayesian Analysis (OBAN) modeling framework and to provide an analyiss of the winter-run Chinook in the Sacramento River as an example of how the framework was utilized.

Methods

Population Dynamics Model

The OBAN modelling framework provides a quantitative tool to evaluate historical patterns in salmon abundance as a function of hypothesized explanatory factors. Specifically, the model: 1) estimates model coefficients by fitting predictions of the population dynamics model to observed indices of abundance; 2) evaluates factors that may explain dynamic vital rates; 3) accounts for mortality during all phases of the salmon life history; and 4) incorporates uncertainty in the estimation of model coefficients by fitting in a Bayesian framework.

The first step to the modeling framework is to define the life-history stages. The OBAN model structure can define life-history stages based on management objectives, such as important locations of anthropogenic or environmental driving factors by the locations where indices of abundance are observed. The number of life-stages is application specific, but it has to incorporate at least two stages for freshwater (egg and juvenile stages), and an ocean stage for each age of returning adult (e.g., a stage for each of the age $2, ..., L$ ages of escaping adults). The OBAN model uses temporally implicit stage durations. Each freshwater stage may be defined such that it reflects the duration that the salmon are within that stage, thus stages do not need to be the same duration. As a consequence, inference on the population vital rates for that stage are predicated on its duration.

The OBAN framework begins with eggs as the first stage and defines the egg abundance as a function of the escapment.

$$N_{1,t} = E_t \times f_t \tag{D.1}$$

where $N_{1,t}$ is the first stage (egg) abundance, E_t is the escapement, and f_t is the fecundity at time t. If only females are being modeled, then the fecundity reflects estimates of eggs per female. Alternatively, if escapement is not sex-specific then fecundity can be defined in terms of fecundity per adult.

The OBAN framework uses Beverton-Holt transitions to calculate the density-dependent transition in abundance among freshwater life stages $(1, ..., M)$ after the egg stage.

$$N_{i,t+1} = N_{i,t} \times \frac{p_{i,t}}{1 + \frac{p_{i,t} N_{i,t}}{K_{i,t}}} \tag{D.2}$$

where $p_{i,t}$ is the productivity parameter, $K_{i,t}$ is the capacity parameter of the Beverton Holt transition and $K_{i,t}$ is the capacity parameter for stage $i = 2, ..., Q$ in year t. Because the production of eggs is captured in equation (1), productivities are equivalent to survival rates in the absence of density dependence and are confined to the range $(0, 1)$. If density dependence is not expected to occur between two stages, the $K_{i,t}$ parameter can be set to a large value to effectively remove the density-dependent portion of the equation.

The productivity parameter ($p_{i,t}$) and capacity parameter ($K_{i,t}$) in a given life stage i from brood year t can be modeled as 1) a constant value; 2) as a constant value with annual variation via random effects; or 3) as a dynamic rate with dependence on a set of time-varying covariates ($X_{j,t}$ for factor j in year t). By using the final formulation, the influence of anthropogenic and environmental factors on specific life history stages can be evaluated. The productivity parameter can be influenced by independent factors acting simultaneously on the life history stage to drive demographic rates, for example environmental variables that represent water conditions such as temperature or flow, biotic factors such as predator abundance, food abundance, or anthropogenic factors such as diking, water diversions, and harvest.

The dynamic productivities are modeled as a function of various factors by using a logit transformation, which ensures that the productivities remain between 0 and 1.

$$\text{logit}(p_{i,t}) = \sum_{j=1}^{F} \beta_j X_{j,t} \tag{D.3}$$

where β_j is the coefficient associated with factor $X_{j,t}$.

Likewise, there may be processes occuring that affect annual stage-specific capacities, such as the amount of available spawning area or the amount of flooded off-channel rearing habitat. To model the dynamic capacities, a log transformation is used, which causes the capacities to remain between 0 and ∞, which is the appropriate parameter space for capacity.

$$\log(K_{i,t}) = \sum_{j=1}^{F} \gamma_j X_{j,t} \tag{D.4}$$

where γ_j is the coefficient associated with factor $X_{j,t}$.

After Chinook enter the ocean, they mature and can return to spawn after a single summer or after overwintering in the ocean for multiple years (Healey 1991). When Chinook enter the ocean, we shift the notation to O_{age} to reflect the fact that some Chinook will remain in the ocean, whiles others will mature and migrate back to freshwater after escaping the fishery. The transition from juvenile rearing to ocean stages occurs via the following transition equation

$$O_{2,t} = N_{M,t} \times \frac{p_{M,t}}{1 + \frac{p_{M,t} O_{i,t}}{K_{M,t}}} \tag{D.5}$$

Maturations of ocean stages for ages $2, ..., L$ are calculated using the following equation:

$$M_{t+age} = O_{age,t} \phi_{age} z_{age} \tag{D.6}$$

where M_{age} is the maturation of the adults at a specific age returning to freshwater according to the conditional maturation rate ϕ_{age}. The number of fish remaining in the ocean $O_{age,t}$ is a function of those that remain and survive to the following year. Because harvest is one of the major sources of mortality in the ocean stages, the above formulation assumes that harvest occurs before maturation; however, this order could be altered to reflect the specific dynamics of the stock of Chinook being modeled.

$$O_{age+1,t} = (1 - h_{age,t})(1 - \phi_{age})O_{age,t} \times \frac{p_{age,t}}{1 + \frac{p_{i,t}O_{age,t}}{K_{age,t}}} \tag{D.7}$$

In the final stage, all Chinook of age L return, thus $M_{t+L} = O_{L,t}$. Survival and capacities can be modelled in the ocean stages just as in the freshwater stages to reflect the effects of localized nearshore productivity. Furthermore the conditional maturation rates may also be modeled as a function of factors using logistic regression. For example, due to differential size at ocean entry or size at release in the case of modeling a hatchery population.

$$\text{logit}(\phi_{age,t}) = \sum_{j=1}^{F} \delta_j X_{j,t} \tag{D.8}$$

where δ_j is the coefficient associated with factor $X_{j,t}$.

Finally, the escapement in calendar year y is the sum of the mature fish returning from the ocean at ages $2, ..., L$ from brood years $y - 2, ..., y - L$.

$$E_y = \sum_{age=2}^{L} M_{age,t} \tag{D.9}$$

Process noise can be added to the stage-specific survivals and capacities by allowing them to vary as a random effect. For example, extra variability could be incorporated through a residual error term in either equation (1) or equation (2) to add variability in the production (fecundity) relationship or in the stage transitions, respectively. To implement process noise, stage-specific random effects, e.g., $Z_{i,t}\ N(0, \sigma^2_{i,p})$ can be added to the equation to express annual variation, where $\sigma^2_{i,p}$ reflects the variance due to process noise in stage i. The amount of process noise may require some additional structure (e.g., through prior specification), otherwise, all the observed data may ostensibly be fitted exactly by allowing the variance in the process noise to be sufficiently large.

Finally, the timing of the influence of factors has to be matched with the timing of the life stages such that the factors are affecting the appropriate cohort. The time subscript t refers to the brood year, thus the covariates, which are typically provided by calendar year y, are lagged appropriately for the population under study.

Bayesian Estimation

Estimation of the model parameters occurs by comparing model predictions to observed data across multiple competing "states of nature" or parameter values. This is achieved through Bayesian estimation of the likelihood of observing the data times the prior probability of the model parameter values (Gelman et al. 2004). The general framework described above is used to compute predicted abundances that are then compared with observed abundances obtained through some sampling method. As a result, a sampling model is defined for each observation. The stage abundances are related to the observed indices of abundance through a sampling model $g()$. The framework is relatively flexible in that any type of sampling data can be incorporated by specifying an appropriate sampling model. Multiple types of abundance indices, $I_{i,k,y}$ for stage i of index type k in year y, can be included in the modeling framework by defining the observation process $g()$ as a function of the sampling model and observation error σ_k^2. For example, the observation process $g()$ could be defined as a lognormal for abundances or biomass, Poisson or negative binomial for counts, or Binomial for capture-recapture studies. Note that if the observation process is modeled with lognormal errors, the variance can be defined in terms of the coefficient of variation (CV = mean/standard deviation) as $\sigma_k^2 = \log(CV_k^2 + 1)$.

$$I_{i,k,t} \sim g(N_{i,t}, \sigma_k^2) \tag{D.10}$$

Priors

Prior probability distributions are required for all model coefficients that are estimated within the modeling framework. For example the coefficients of the logistic regression to define stage-specific survival rates (β_j's) and coefficients of the log-linear model (γ_j 's) to define stage-specific capacities will require prior probability distributions; normal distributions can be used to define the prior probabilities for both of these coefficients due to the transformations used in equations (3) and (4). Care should be taken in specifying the priors for the β coefficients given their inclusion into a logit() transformation, however. King et al. (2010) suggest that N(0,2.5) priors may be used in the coefficients of logistic regression to ensure that excessive mass is not placed in the values near 0 and 1 (as might be the case with a more diffuse normal prior). The conditional maturation rates ϕ_{age} are required to be in the interval $(0, 1)$; therefore, Beta distributions can be used as priors for these coefficients. Finally, the variance of the measurement error on the observation process (σ_k^2) and the variance of any process noise ($\sigma_{i,p}^2$ for stage i) will also require a prior and can be specified as either inverse gamma on the variance or alternatively as a uniform prior on the standard deviation of the variance (Gelman et al. 2006).

Implementation of Bayesian Estimation

The posterior distributions of the model parameters can be estimated by drawing samples from the full conditional distributions of each parameter given values of all other parameters through a Metropolis within Gibbs Markov Chain Monte Carlo (MCMC) approach (Gelman et al. 2004, Gilks and Spiegelhalter 1996). If conjugate priors are used, then the Gibbs sampler can be employed; however, if posterior distributions for the parameters can not be updated using the Gibbs sampler (Roberts and Polson 1994), they can instead updated by using distribution-free adaptive rejection Metropolis steps (Gilks and Spiegelhalter 1996, Spiegelhalter et al. 2003) which is the approach adopted in WinBUGS (Spiegelhalter et al. 2003).

To evaluate if the posterior draws were arising from a stationary target distribution, multiple chains were run from dispersed initial values for each model and the scale reduction factor (SRF, Gelman et al. 2004) was computed for all monitored quantities (model coefficients and abundance estimates). The diagnostics were implemented using the R2WinBUGS package (Sturtz et al. 2005) in R (R Core Team 2013). Monitored parameters in all models had SRF values that indicated samples were being drawn from the target distribution (i.e. SRF $\approx$ 1) by 75,000 samples (Gelman and Rubin 1992). The initial 50% of the samples were used to reach the stationary target distribution and were discarded with the subsequent samples thinned to produce approximately 1,000 draws from the stationary target distributions. The 1,000 draws were used to compute the posterior mean and symmetric 95% probability intervals or credible intervals (95% CrI).

Application of Model to Winter Run Chinook

We defined 7 life-history stages in the winter-run OBAN model including 6 freshwater and marine transition stages and 3 annual ocean stages: 1) eggs, 2) fry 3) juveniles in the Delta (delta), 4) juveniles in the Gulf of the Farallones (gulf) 5) age 2 in the ocean, 6) age 3 in the ocean, and 7) age 4 in the ocean. The escapement was composed of mature individuals that returned at age 2, 3, and 4 (Table D.1).

Fecundity was assumed to vary annually, and the annual values were sampled from probability distribution, i.e., $f_t \sim logN(\mu_f, \sigma_p^2)$. This formulation allowed process noise to be incorporated into the population dynamics, but empirical information on fecundity restricted the range of process noise in the model. Multiple environmental and anthropogenic factors were incorporated into the winter-run model at different stages in the life-history based on hypotheses about factors affecting (Table D.2). The mean fecundity is calculated by assuming that each adult spawner produces 2,450 eggs (Williams 2006, Winship et al. 2014).

Winter Run Abundance Indices

Estimates of winter-run escapement in the Central Valley have been conducted since 1967, and we used an escapement abundance index from 1967 to 2008. Different methods were used to estimate escapement over this period, which may affect the precision of the spawner escapement estimates (Williams 2006, Botsford and Brittnacher 1998). Prior to 1987, all returning spawners passed via a counting ladder at Red Bluff Diversion Dam (RBDD, Figure D.1). From 1987 onward the gates of the diversion dam have been opened to enhance upstream survival of winter-run Chinook salmon, but also likely improved access to areas above RBDD. The current operation of RBDD makes counts of winter-run Chinook salmon after closing the gates on May 15. On average, 15% of the winter run passed RBDD by May 15, but the specific percentage in a given year was as low as 3% or as high as 48% (Snider et al. 2000). Since 2001 the annual escapement estimates have been calculated using a Jolly-Seber estimator derived from the carcass count data (California Department of Fish and Game 2004). Juvenile production indices were calculated from rotary screw trap samples and trap capture probabilities at Red Bluff Diversion Dam for 1995 through 1999 and 2002 through 2008 (Poytress and Carrillo 2011).

Winter Run Factors

Several environmental and anthropogenic factors were used to help describe variability in winter-run juvenile and adult abundance indices (Table D.2). Because the abundance indices occur at RBDD, which coincides with the fry stage, a basal survival rate could be estimated for the egg to fry stages and a second basal rate for the fry to escapement stages. Explanatory factors were incorporated into the survival during the fry stage, delta stage, and gulf stages (Table D.2). We provide a short rationale for the inclusion of each of the factors here.

Water temperatures in the spawning reach above RBDD can sometimes reach stressful levels, thus July through September mean daily water temperature (C) in the Sacramento River at Bend Bridge (TEMP) was used to explain annual variability in egg to fry survival. In addition, low flow can affect survival rates of alevin, so August through November minimum monthly flow in the Sacramento River at Bend Bridge was also used to affect egg to fry survival. In addition, an interaction term of TEMP:FLOW was incorporated into the model to determine if there was some additional mortality associated with either high temperatures or low flow.

In the delta stage, several factors may affect winter-run survival rates. Access to the Yolo bypass, a large floodplain that provides the potential for increased survival and growth of fall-run Chinook (Sommer et al. 2005), may also provide similar benefits for winter-run via bypassing the delta. The Yolo bypass floods when flows on the Sacramento River surpass 56,000 cfs; each day when flows were great enough to enter the Yolo bypass between December and March was a potential opportunity for winter-run to enter the floodplain habitat (YOLO). The Delta Cross Channel is a dual gate structure that conveys water to the interior delta, and late-fall Chinook salmon that enter the interior delta have lower survival rates relative to those that migrate down the Sacramento River (Perry et al. 2010). In the southern delta, the Central Valley Project and State Water Project export water from the delta to supply agricultural and municipal water needs. The levels of exports can vary annually and have been associated with differential survival rates of fall run Chinook (Newman and Brandes 2010, Newman 2003).

Finally, nearshore ocean processes can have important consequences for Chinook salmon (Wells et al. 2007, Woodson et al. 2013), and here we evaluated upwelling in a region south of the entrance to San Francisco Bay (UPW) and the sea surface temperature in the Gulf of the Farallones (FARA).

The ocean stages were modeled as a function of maturation rates and age-3 impact rates. Information for the maturation rates were taken from an analysis of 1998, 1999, and 2000 coded wire tag (CWT) data (Grover et al. 2004) and more recent analyses of maturation rates (O'Farrell et al. 2012). Age-3 impact rates for winter-run were calculated for 1978 - 2011 from a combination of estimated impact rates from CWT returns (1998 - 2008) and from a hindcast of impact rates given spatial allocation of fishing effort (O'Farrell, M., NMFS unpublished data). Until 1987, there was little regulation of the Central Valley Chinook salmon shery and estimates of the mortality rate on winter-run Chinook salmon in the ocean shery were approximately 0.7 of the mortality rate experienced by fall-run Chinook salmon.

Most winter-run Chinook salmon return to spawn as 3-year-olds; however, the winter-run age-4 oceannstages are more likely to be captured in the commercial fishery because of their larger size. Grover et al. (2004) found that the harvest-related mortality of age-4 winter-run Chinook salmon was 2.5 to 3.7 times the rate of age-3. The age-4 impact rate in a calendar year y was assumed to be double the instantaneous rate of age-3 ($h_{4,y} = \exp(\log(h_{3,y}/2))$).

Results

Observed winter-run escapement was on the order of several tens of thousands in the late 1960's and early 1970's and declined to levels in the low thousands during the 1980's with a low abundance estimate of 194 in 1994. Since the mid-1990's the population has recovered to some degree with escapements in the mid 2000's on the order of several thousands. The winter-run OBAN model captured this declining trend and recovery in escapement (Figure D.2). In particular, the model was able to capture the decline in the late 1970's (along with the spike in escapement in 1980), the continued decline through the mid-1990s, and the subsequent increase through early 2000. The three different sampling methods had median estimated CV's ranging from 0.68 for the early period, 1.34 for the middle period, and 0.97 for the later period. As a result, the model was more sensitive to those sampling methods with higher precision (lower CV). In particular, the model fits to the intermediate period (in which counts were expanded assuming 15% passed RBDD by May 15) indicated that the escapement in 1990, 1991, and 1994 was underestimated relative to model predictions (Figure D.2). In contrast, the winter-OBAN model predictions of escapements during the early period (1967 - 1987) and the later period (2001-2008) fit the annual variability in escapement estimates more closely. The winter-OBAN model also fit well to patterns in the juvenile abundance index at RBDD from 1995 to 2007. The median estimated CV on the juvenile index data was 1.2, indicating that the model had intermediate sensitivity to the juvenile indices relative to escapement. The winter-run model predictions of juveniles at RBDD captured the relatively low production of fry during the late 1990's, subsequent increase in early 2000's due to higher escapements, and the declline in the index in 2007 (Figure D.3).

Annual patterns in stage-specific survivals

To predict escapement and juvenile index values, stage-specific survivals were estimated as a function of the environmental and anthropogenic factors. The estimated survival from egg to fry at RBDD averaged 0.24 95%CrI(0.11, 0.48) (Table D.3); however, survival from the 1970's to mid-1990's was highly variable. There were two years in the late 1970's where median survival was predicted to be approximately zero and periods in the early 1980's and early 1990's when survival in the alevin stage was also low (Figure D.4). Since the mid-1990's the survival rates for alevin have been more stable relative to the prior periods. Survival through the delta stage, which spans fry at RBDD to the nearshore ocean, was 0.0097 (95%CrI: 0.0041, 0.022) (Table D.3). Within the delta, annual variability was less pronounced with median survival ranging from a high of 0.017 in 1969 to a low of 0.0063 in 2004. Median delta survivals were relatively stable at approximately 0.009 through the 1980's and 1990's with slightly lower survivals during 2001 to 2004 of approximately

0.006 (Figure D.4). Average survival in the gulf stage was assumed to be 0.5 and variability in survival among years was reflective of ocean productivity. For winter-run Chinook the mid 1980's and mid 1990's were periods of poor survival, whereas 1998 and 2000 - 2001 were years of relatively good survival. Finally, patterns in age-3 survival rates (which were a deterministic function of harvest rates and annual survival rate of 0.8) indicated relatively low survival rates for brood years through the mid-1990's, with improving ocean survival for brood years after 1995 (Figure D.4).

Although the magnitude of the effect from each factor cannot be evaluated directly via the magnitude of the coefficient estimate (due to dependence on the stage-specific intercept), the sign of the coefficients associated with factors provide an indication of the effect of the factor: positive values increase survival relative to the average and negative values decrease survival. Because the winter-run OBAN model was fit in a Bayesian framework, the coefficients are described by posterior distributions and the probability that the coefficent value was positive was calculated (Table D.3). In the egg to fry stage, temperatures in the spawning reaches (TEMP) had a consistent negative effect on survival, whereas minimum flows (FLMIN) had a consistent positive effect on survival (Table D.3). A positive TEMP:FLMIN interaction term of flow and temperature would exacerbate the negative effect of high temperatures and low minimum flows, and the interaction term had a 0.73 probability of being positive. In the delta stage, access to the Yolo bypass (YOLO) and DCC gate position open (DCC) had a positive effect on survival, whereas export levels (EXPT) were negative. Finally, in the gulf stage, high tempeartures in the Farallone Islands (FARA) had a negative effect on winter-run survival, whereas upwelling south of the entrance to San Francisco Bay (UPW) had a positive effect on survival (Table D.3). Several additional parameters were given informative priors to structure the winter-run OBAN model, although if the data were informative on the coefficients, this would be reflected in the posterior. The posteriors on the conditional maturation rates largely reflected the informative priors. as did the CV on the process error (Table D.3).

The magnitude of the effect for each of the factors can not be discerned directly from the magnitude of the coefficient estimate (e.g., in Table D.3), because the coefficients associated with the covariates are dependent upon the intercept terms. To understand how the various factors affect the overall survival of winter-run Chinook, we increased each of the covariates one at a time by 1 standard deviation (SD). The survival rates under the one-at-a-time increases were compared to a baseline case, which was the survival rate with all factors at their mean 1967 to 2008 level. The survival rates began at the egg stage and ended at the end of age 2, prior to harvest affecting survival. To facilitate comparison, we calculated the percent change relative to the baseline survival (i.e., $(alt_k - base)/base \times 100\%$), where alt_k describes a model with factor k increased by 1 SD. Minimum flow had the largest effect per unit SD on winter-run survival with a median increase of 128% (Figure D.5). Temperature also had a strong effect with a negative median effect of -96.7% per unit SD. The other notable factors were exports which had a negative effect of - 12.4% per unit SD, Yolo with a median positive effect of 11.3% and upwelling with a positive effect of 42.3% per unit SD (Figure D.5). The standard deviations are not the same on a percentage basis among factors, however. For example 1 SD of TEMP is equal to 6.8% of the mean, whereas 1 SD of EXPT is equal to 25.6% of the mean. Calculations of the effects of each factor on a percent basis indicated that temperature provides the largest effect with an 11.9% decrease in survival per percent increase in temperature. Minimum flows in the spawning reach provided a median 5.73% change, temperature in the Farallones provided a median -1.55%, and upwelling provided a median 1.78% change, whereas all other factors provided a less than 1% change in survival for a 1% increase in the factor (EXPT -0.48%, YOLO 0.10%, and DCC 0.16%).

Correlation among coefficients was generally low with the exception of the two intercept terms β_{alevin} and β_{delta} (Pearson correlation coefficient on posterior samples = - 0.685). Despite juvenile data being present for the latter portion of the time series, some negative correlation among these two coefficients was expected due to the model structure. This correlation did not inhibit the MCMC algorithm from converging, however. All scale reduction factors on monitored parameters were approximately 1, which indicated that the 3 chains had converged to a stable distribution.

Discussion

The winter-OBAN framework provided a means to evaluate the importance of several anthropogenic and environmental factors hypothesized to affect winter-run Chinook in the Central Valley. The model results support the importance of the environmental conditions in the natal spawning and rearing area and early ocean conditions with important but more subtle effects of delta survival. Our results are comparable with previous models of winter-run Chinook, providing some justification of the overall model structure and its inference. Our estimate of delta survival can be compared with Winship et al. (2014), who estimated the fry to end of age 2 survival rate for 1996 - 2008 of 0.4%. In comparison, our delta survival rate was 0.9% times the average age 2 value of 0.5 equals a 0.45% estimate for our model from fry to the end of age 2.

Median egg to fry survivals were slightly lower than estimated by Winship et al. (2014), in which the median egg to fry survival was 0.30. Furthermore, they found little variability in annual egg to fry survival. Similar fry data were used for both models; however, the winter-run OBAN model was able to use the

1995-2008 survival relationships to improve inference on factors affecting egg to fry survival in the 1970's to mid-1990's, prior to the analysis of Winship et al. (2014). We too found low variability among years in egg to fry survival from 1996 to 2008, but in contrast we found that there was high variability in survival prior to 1995 due to temperature and flow effects, and it played an important role in the decline of winter-run Chinook during the late 1970's and 1980's.

The factors leading to the decline in winter-run abundance during the 1970's can be explained by several periods of poor egg to fry survival tied to low flows and high water temperatures in the spawning reaches. While survival through the delta did not vary dramatically, survival at early ocean entry also had several periods with generally poor survival. Concurrent with this period of episodic recruitment failure and variable ocean conditions, impact rates of age-3 winter-run averaged 0.38 from 1969 to 1997. The recovery of winter run beginning in the late 1990's and early 2000 can be attributed to several managment actions and good ocean productivity from 2001 - 2003. The installation of a temperature control device in 1991 has generally reduced the variability in temperature with subsequent reduction in variability of egg to fry survival since 1993 (Figure D.4). Concurrent with the installation of the temperature control device, harvest rate management reduced the impact rates on winter-run (1998-2009 average of 0.153) (O'Farrell et al. 2012). In addition, survival through the delta was generally better during the 1996 to 1998 period due to lower than average exports and greater than average access to Yolo bypass.

Model Critique

Although the OBAN modeling framework can incorporate density dependence in the model structure, the winter-run implementation here did not include it based on previous work fitting density dependence to winter-run abundance indices. Estimation of the density dependence requires a signal in the data, namely the reduction in survival as a function of abundance. Previous efforts to include density dependence in models of winter-run population dynamics have had mixed results. Newman and Lindley (2006) included density dependence in the egg to fry transition and found little support for density dependence in a model without process noise, but they found strong evidence when process noise was included as a random effect in each stage under a state-space formulation. The information in the data to support the density dependence came from accounting for autocorrelation in the juvenile abundance state variables as well as measurement errors. Winship et al. (2014) found little support for density dependence in the egg to fry stage using a state-space model that estimated process noise, but fixed measurement error based on estimates of CV from sampling design. Based on the similarity of our model design to Winship et al. (2014), we did not include capacity in the model structure. We return to the topic of density dependence below.

We also did not include hatchery output explicitly in the winter-run OBAN implementation. We did, however, incorporate a process noise component to the egg production stage, which was able to vary among years. Hatchery supplementation should be reflected in deviations of recruitment variability, if it was in fact improving the productivity of the population. Hatchery supplementation was initiated in 1991 with some releases in 1994 and 1995; however, production began in ernest in 2000 with between 20 to 57 natural origin females removed from the spawning population for hatchery brood stock (Winship et al. 2014). A more direct approach would be to include a dummy factor in the egg production equation that identified years of hatchery production. The hatchery term could be restricted to have a positive value, reflecting a hypothesized expected benefit of hatchery supplementation, or allowed to be positive or negative reflecting the potential for negative hatchery effects on production of natural origin juveniles.

Recovery

Recovery of winter-run is likely to occur through management of factors under human control while being aware of the influence of uncontrollable environmental conditions (e.g., upwelling). Winter-run appear to be particularly sensitive to temperatures and flows in the spawning reaches. Estimates of the temperature during 1977 indicated that it was 4 standard deviations above the mean (17.6 C) during the July to September period. Mortality in the egg to fry stage was similar in 1976, though, when the temperature was only 1.2 standard deviations (14.6 C) above the mean. The installation of a temperature control device at Shasta Dam provides the ability to decouple water temperatures from flow out of the dam, and manages tempeatures by mixing cold hypolimnetic water with warmer surface water. While this provides a method for controlling temperatures, the operations of the control device may be complicated by the multi-year climate cycles that affect the reservoir storage and thus the amount of cold water available. Still, the winter-run OBAN model results suggest that small deviations in temperature can have substantial impacts on survival from the egg to fry stage, and managing thermal mortality can have important consequences for the population dynamics.

Management of factors in the delta appear to also affect winter-run, but to a lesser degree than the temperature and flow effects during egg to fry survival. Within the delta, increasing access to Yolo bypass and reducing exports can have a positive effect on survival. Water flows into the Yolo bypass over an approximately 1.5 mile weir when flows on the Sacramento River exceed 56,000 cfs at Verona. Winter-run juveniles rear above the weir location and their downstream movement is triggered by flow cues (del Rosario et al. 2013). Access to the Yolo bypass occurs when these flow pulses are also substantial enough to overtop the weir. Given the general lack of off-channel rearing area for salmonids in the Central Valley, improving access to Yolo bypass has been identified as an important management action for recovery of Central Valley salmonids, and winter-run in particular (NMFS 2014).

For the model with a density dependent effect in Newman and Lindley (2006), a Beverton-Holt model was used and the estimated capacity was on the order of 11.5 million fry. Using these values of capacity for fry, estimated fry to age-2 survival of 0.45% and ocean age 2 and age 3 survival rates of 0.5, and 0.8 respectively would suggest a capacity of approximately 20,500 winter-run in the absence of harvest. This capacity level was exceeded every year from 1967 to 1977; thus it may not be an appropriate capacity estimate for that period, but could potentially reflect more recent conditions as the Newman et al. (2006) model focused on 1992 to 2003. More importantly, the existence of a carrying capacity at this level may have important implications for modeling the expected responses to recovery of winter-run. Both the Newman and Lindley (2006) and Winship et al. (2014) models included density dependence in the egg to fry stage, presumably because spawner and juvenile data were available. Yet density dependence could more likely be in the spawning stage given that winter-run are currently spawning below Keswick dam, rather than in their natal tributaries surrounding Mt. Shasta (Yoshiyama et al. 2001). For evaluating the potential for reconnecting winter-run populations to their natal spawning reaches, such an analysis could provide information on potential population sizes under expanded habitat.

The state-space modeling framework has proven to be an important component to ecological modeling due to its ability to reflect uncertainties in the biological processes via process noise and in the observation process via measurement error. In most applications, the process noise is ascribed to random effects (e.g. Newman and Lindley 2006, Winship et al. 2014), but some of the variation in process noise may be explained by realtionships to anthropogenic and environmental factors. Thus, the OBAN framework attempts to move inference toward evaluating hypotheses by formally laying out a framework by which stage-specific variability can be ascribed to explanatory factors rather than to random effects. This linkage can be particularly powerful if some of the factors affecting the population dynamics can be managed for salmonid recovery.

Acknowledgements

We thank the School of Aquatic and Fisheries Sciences at the University of Washington for providing feedback through their Quantitative Seminar series, Eva Jennings for providing help with data management, and Curry Cunningham for thoughtful discussions on state-space modeling and Chinook population dynamics. Support for this project was received under Grant Agreement 2039 from the Delta Stewardship Council.

Table D.1: Model parameters, state variables, and observable indices of abundance for winter-run OBAN model.

Symbol	Value	Description
Indices		
i	egg, alelvin, fry, delta, bay, gulf	freshwater stages
j		covariate index
k		gear type for observation process
t	1967, .., 2004	brood year
y	1967, .., 2008	calendar year
age	2, 3, 4	ocean age
State Variables		
$N_{i,t}$		abundance of freshwater stage
$O_{age,t}$		abundance of ocean stage
$M_{age,t}$		abundance of mature fish
Parameters		
$\beta_{i,j}$		coefficient relating factor j to survival in stage i
$\gamma_{i,j}$		coefficient relating factor j to capacity in stage i
$\delta_{age,j}$		coefficient relating factor j to maturation at age
ϕ_{age}	(0,1)	conditional maturation in age age
$CV_{E,k}$		coefficient of variation for escapement observation process k
CV_J		coefficient of variation for juvenile observation process k
CV_p		coefficient of variation of process noise
f_t	2450	fecundity per spawner
$h_{age,t}$		impact rate due to harvest
$p_{i,t}$	$(0, 1)$	productivity in stage i and brood year t
$K_{i,t}$	$(0, \infty)$	capacity in stage i and brood year t
z_2	0.5	age 2 average natural survival rate
z_3	0.8	age 3 average natural survival rate
z_4	0.8	age 4 average natural survival rate
Observables		
$I_{y,E}$		Escapement 1967 - 2008
$I_{y,J}$		Juvenile abundance at Red Bluff Diversion Dam 1995 - 1999, 2002-2007

ABSTRACT

Outmigration survival of acoustic tagged hatchery-origin Sacramento River late-fall run Chinook salmon (*Oncorhynchus tshawytscha*) smolts was estimated for five years (2007-2011) using a receiver array spanning the entire outmigration corridor, from the upper river, through the estuary, and into the coastal ocean. The first four years of releases occurred during below-average river flows, while the fifth year (2011) occurred during above-average flows. In 2011, overall outmigration survival was two to five times higher than survival in the other four years. Regional survival estimates indicate that most of the improved survival seen in 2011 occurred in the riverine reaches of the outmigration corridor, while survival in the brackish portions of the estuary did not significantly differ among the five years. For the four low flow years combined, survival rate in the river was lower in the more anthropogenically-modified upper reaches; however, across all regions, survival rate was lowest in the brackish portion of the estuary. Even in the high flow year, outmigration survival was substantially lower than yearling Chinook salmon populations in other large rivers. Potential drivers of these patterns are discussed, including channelization, water flow, and predation. Finally, management strategies are suggested to best exploit survival advantages described in this study.

INTRODUCTION

Knowing where excessive mortality is occurring is crucial to designing effective conservation measures for salmon populations. Salmon utilize many different habitats during the different stages of their life cycle, but it is the degradation of freshwater or estuarine habitats that is commonly cited as the cause of population declines (Nehlsen et al. 1991). Of particular concern is the high mortality often experienced in these habitats during one of the most vulnerable stages in the salmon life cycle: the downstream migration of juveniles ('smolts') heading to the ocean from their riverine birthplace (Healey 1991).

There has been extensive research on juvenile salmonid smolt survival in large rivers of the west coast of North America, most notably in the Columbia and Fraser Rivers (McMichael et al. 2010; Muir et al. 2001; Rechisky et al. 2013; Skalski et al. 1998; Welch et al. 2009; Welch et al. 2008). These studies have indicated that outmigration survival can vary widely from year to year and population to population, and further research in these rivers has shown that survival rates often correlate with environmental variables such as flow, turbidity and temperature (Giorgi et al. 1997; Gregory and Levings 1998; Smith et al. 2003). This information has proved crucial for improving salmon survival in the Columbia River, through improvements in fish passage structures and changes in dam operations (Connor et al. 2003).

California's Sacramento River, in contrast, is critically lacking in smolt outmigration survival information. The Sacramento River, compared to the Columbia and Fraser Rivers, has an order of magnitude lower discharge, exists in a warm and dry Mediterranean climate, and yet is the primary source of water to the state's industrial, domestic and agricultural sectors. The Sacramento River and its estuary are currently the objects of intense conservation concern due to the poor status of some of its salmon and steelhead populations (among other native species) and habitats. In spite of these problems, the Sacramento River is still an important contributor to west coast Chinook salmon (*Oncorhynchus tshawytscha*) fisheries, largely due to extensive hatchery propagation efforts (O'Farrell et al. 2013). Several very large water and habitat management projects are under consideration that are expected by their proponents to contribute to the restoration of Chinook salmon populations, yet survival rates across the life cycle of these populations are poorly known. Several coded-wire and acoustic tagging studies have assessed Chinook salmon smolt survival in the Sacramento-San Joaquin Delta (the freshwater portion of the estuary), which is the hub of water infrastructure for the majority of southern California and a location where anthropogenic modifications are extensive and salmonid losses are great (Baker and Morhardt 2001; Brandes and McLain 2001; Perry et al. 2010). However, no study has assessed smolt survival through the entirety of the outmigration corridor, from the upper limit of anadromy to the Pacific Ocean.

In this study, we quantify the spatial and temporal patterns of hatchery late-fall run Chinook salmon smolt survival in the Sacramento River system. Utilizing an extensive network of acoustic receivers, we estimated survival through the river and estuary over 5 years at a fine-scale spatial resolution previously not possible. This resolution allowed us to discern regional and temporal differences in survival that cannot be obtained using traditional tagging methods.

METHODS

Study area

The Sacramento River is the longest and largest (measured by flow discharge) river that is fully contained within the state of California, and is the third largest river that flows into the Pacific Ocean in the contiguous United States (Fig. 1). The headwaters are located just south of Mount Shasta in the lower Cascade Range and the river enters the ocean through the San Francisco Estuary at the Golden Gate. The total catchment area spans approximately 70,000 km^2. The Sacramento River and its tributaries have been heavily dammed and otherwise impacted by human activities; it is estimated that 47% of the historic spawning, migration and/or rearing area is no longer accessible to Chinook salmon (Yoshiyama et al. 2001).

The Sacramento River watershed includes diverse habitats, from relatively pristine run-riffle reaches in the north, to a heavily channelized and impacted waterway further south, and finally to the San Francisco Estuary, the largest and most modified estuary on the west coast of North America (Nichols et al. 1986). The San Francisco Estuary is comprised of an expansive tidally-influenced freshwater delta upstream of its confluence with the San Joaquin River and a series of increasingly saline bays. The sheer size and physical differences between these two sections of the estuary merit separate consideration with respects to their influence on salmon survival, therefore, we use the terms “delta” and “bays” to differentiate between the two.

The annual mean daily discharge for the Sacramento River from 1956 to 2008 was 668 m^3s^{-1} (Interagency Ecological Program, 2004). However, this water does not continue downstream unimpeded; due to one of the world’s largest water storage and water transportation infrastructures, replete with abundant dams, reservoirs, diversions and aqueducts, it is estimated that current discharge of the Sacramento and San Joaquin Rivers combined is less than 40% of the pre-development discharge (Nichols et al. 1986). The damming and water diversions of the Sacramento River and its tributaries have also homogenized river flows throughout the year, reducing winter high flows and flooding while increasing flows in the summer and fall (Buer et al. 1989).

The study area included approximately 92% of the current outmigration corridor of late-fall run Chinook salmon, from release to ocean entry. Specifically, the study area’s furthest upstream release site at Jelly’s Ferry (518 km upstream from the Golden Gate Bridge) is only 47 km downstream from Keswick Dam, the first impassable barrier to adult salmon returning to spawn on the Sacramento River.

Central Valley late-fall run Chinook salmon

The late-fall run is one of the four Chinook salmon runs occurring in the Sacramento River drainage, and is the only run to exhibit a predominately yearling migrant life history (Moyle 2002). Following emergence from the gravel, wild late-fall run juveniles exhibit a river residency of 7 to 13 months, after which smolts (juvenile salmon that are actively migrating to the ocean) will migrate to the ocean between the months of October and May at a fork length of 90 to 170 mm (Fisher 1994; Snider and Titus 2000a, b). In contrast, the subyearling life history demonstrated by a 4 to 7 months freshwater residency is the more common life history strategy used by the other salmon populations in the Sacramento River. Moyle et al. (1995) outlined six major threats to the late-fall run Chinook salmon population, one of which was mortality during outmigration, potentially due to water diversions and increased predation in bank-altered areas. In 2004, the fall/late-fall run Chinook salmon Evolutionarily Significant Unit (ESU) was designated a “species of concern” by the United States Endangered Species Act.

The United States Fish and Wildlife Service’s (USFWS) Coleman National Fish Hatchery (Anderson, CA) is the only hatchery to produce late-fall run Chinook salmon, releasing approximately one million smolts a year between mid-December and mid-January. Annual escapement for this population can vary from just several hundred to 42,000; the average annual escapement from the winter of 1973/1974 to the winter of 2007/2008 is 12,386 individuals (Azat 2015). Little information exists regarding what proportion of the late-fall run adult population is of hatchery origin versus wild origin. Palmer-Zwahlen and Kormos (2013) estimated that in 2011, 100% of late-fall run adults returning to Coleman National Fish Hatchery were hatchery fish while 44% of late-fall adults recovered during carcass surveys on the Sacramento River were hatchery origin.

Fish Tagging and Releases

For five consecutive winters, from January 2007 to December 2010/January 2011 (henceforth referred to as 2007, 2008, 2009, 2010 and 2011 seasons, based on the year during which January tagging occurred), 200 to 304 late-fall run Chinook salmon smolts from Coleman National Fish Hatchery were implanted with acoustic tags and released into the Sacramento River. Release times were scheduled to be within a few days of the release times of the general production of hatchery fish. Only smolts 140 mm or larger were tagged to keep the tag weight to less than 6% of the fish weight. Therefore, tagged smolts were representative of the larger hatchery individuals; specifically, from 2007 to 2011, smolts at or above the 140 mm cutoff represented 23.5%, 38.4%, 50.2%, 29.6, and 50.9% of the total hatchery production. In the rare instance that a smolt had severe descaling, fin erosion, or other obvious injuries, the smolt was discarded and not tagged.

Acoustic tags were surgically implanted into the peritoneal cavity of anesthetized fish. The tag was inserted through a 12 mm incision anterior to the pelvic girdle and 3 mm to the side of the *linea alba*. The incision was then closed with two simple interrupted stitches tied with square knots of non-absorbable nylon cable-type suture. All fish were allowed to recover for a minimum of 24 hours before release. Additional surgery details can be found in Ammann et al. (2013). In study years 2008 and 2009, an additional group of smolts from the same hatchery were tagged with dummy acoustic transmitters to monitor tag effects and tag retention in laboratory trials. No fish shed their tags over 221 and 160 days (the entire length of the trial in both years respectively) and tagged fish growth and survival was not significantly different than untagged fish (Ammann et al. 2013). Since fish in the field and captive studies had similar tag burdens (1.6 to 6.3% for field study, 2.6 to 5.6% for captive study), we assumed that mortality in the field study was not tag related.

In the first year (2007), a total of 200 fish were released in small batches (13-14 fish each) every weekday afternoon for the third, fourth and fifth weeks of January 2007 at the Coleman National Fish Hatchery into Battle Creek (river km 534 - “rkm” is distance from ocean), a tributary to the Sacramento River (Table 1). In the following four years, fish were released in two groups. In 2008-2010 a total of approximately 300 fish was released: ~50 fish were simultaneously released at dusk at three release sites in the upper 150 km of the mainstem Sacramento River (rkm 518, 412, 363) in mid-December and early January allowing the lower release groups to reach the lower river and estuary in larger numbers, which improved statistical precision of the survival estimation. In 2011, 240 fish were released: 120 fish were released in mid-December and early January at dusk at Jelly’s Ferry (rkm 518), a site on the mainstem Sacramento River, only 7.3 kilometers downstream of the confluence with Battle Creek. Fish were transported to the release sites by truck at low densities (~ 10 $g•l^{-1}$) in coolers with aerators. In years with multiple release sites, transport times were extended for closer sites to keep potential transport stress equal among all release groups.

Acoustic Telemetry

Acoustic tagging technology was used to acquire high-resolution movement data and survival estimates. Uniquely coded Vemco 69 kHz V7-2L acoustic tags (1.58g ± 0.03 S.D. in air, 7mm diameter by 20mm long; Amirix Systems, Inc., Halifax, Nova Scotia, Canada) and Vemco

VR2/VR2W receivers were used to tag and track fish. The tags transmitted every 30 to 90 seconds (with a mean of 60 seconds) in the first year of the study, then transmitted every 15 to 60 seconds (with a mean of 45 seconds) in the following four years. Battery life tests were conducted in 2007, 2010, and 2011 with a subset of tags from the same batch used for tagging smolts. In 2007, tag life of 11 test tags ranged from 138 to 749 days with a mean of 513; in 2010, tag life of 20 test tags ranged from 127 to 297 days with a mean of 194; in 2011, tag life of 25 test tags ranged from 98 to 214 days, with a mean of 172. For the purposes of verifying that tag life was sufficient to last the entire migration of all smolts, the time elapsed from release to last known detection was calculated for each smolt for all five years of the study. Last known detection for smolts was either last known detection before disappearance, or time of arrival to the Golden Gate receiver location (considered the end of the outmigration in this study). The longest outmigrating individual per year took 32, 89, 67, 97, and 79 days respectively for the years 2007-2011, with 99.2% of smolts successfully outmigrating or disappearing within the first 60 days after release. Therefore, we believe the battery life for our tags were sufficient to last the entire outmigration period of our tagged smolts.

The receiver array spanned 550 km of the Sacramento River watershed from below Keswick Dam to the entrance to the ocean (Golden Gate) and beyond to Point Reyes. This network of approximately 300 receivers at 210 receiver locations was maintained by the California Fish Tracking Consortium (http://californiafishtracking.ucdavis.edu), a group of academic, federal and state institutions, and private consulting firms. We selected a subset of these receiver locations for the final survival analyses, as per the selection criteria described in the Data Analysis section of the methods.

The acoustic receivers automatically process all detection data and drop most false detections or incomplete codes from the detection file. All detections were then subject to standardized quality control procedures to remove any remaining false detections (see Michel et al. (2013)).

Data Analysis

Survival in each reach

Juvenile Chinook salmon express obligate anadromy, meaning that they will travel toward the ocean once the emigration has begun with scarce exceptions (Healey 1991). Therefore, in a linear system such as the Sacramento River, if receiver locations were capable of detecting every passing tag, then if a fish is detected at one receiver location but is never detected thereafter, we could assume that the fish has died somewhere in the reach between the receiver location where it was last detected and the next downstream receiver location.

However, receiver locations rarely operate perfectly, necessitating the estimation of detection and survival probabilities at each receiver location. We used the Cormack-Jolly-Seber (CJS) model for live recaptures (Cormack 1964; Jolly 1965; Seber 1965) within Program MARK (White and Burnham 1999) using the RMark package (Laake and Rexstad) within program R (v. 3.0.1; R Development Core Team 2013). The CJS model was originally conceived to calculate survival of tagged animals over time, by re-sampling (recapturing) individuals and estimating survival and recapture probabilities using maximum likelihood. For species that express an obligate migratory behavior, a spatial form of the CJS model can be used, in which recaptures (i.e., tagged fish detected acoustically downstream from release) occur along a migratory corridor (Burnham 1987). The model determines if fish not detected at certain receivers were ever detected at any receiver downstream of that specific receiver, thus enabling calculation of maximum-likelihood estimates for detection probability of all receiver locations (p), survival (Φ), and 95% confidence intervals for both (Lebreton et al. 1992).

An initial run of the model with all possible river receiver locations together with the major estuary receiver locations was performed for each individual year separately, after which a subset of the river receiver locations that had consistently high tag detection probabilities through the years and that were strategically located were chosen to delimit the river reaches that were used in the spatial survival analysis. Additionally, because survival between the Battle Creek release site and Jelly's Ferry receiver location was only estimated in 2007, and because Jelly's Ferry was the furthest upstream release site for all following years, only fish known to have reached the Jelly's Ferry receiver location in 2007 were included in all survival analyses, and Jelly's Ferry was considered to be their release location. In total, 145 of the 200 smolts released in 2007 were known to have reached the Jelly's Ferry release location and were included in survival analyses. A total of 19 receiver locations were chosen, extending from just below the most upstream release site, Jelly's Ferry, to the Golden Gate (Fig. 1; Table 2). Between them, we delineated 17 reaches in which mortality can be accurately estimated (the detection probability and survival of the 18th and last reach can only be estimated jointly as there is no detection information beyond this point in which to assess the final receiver location).

Parallel receiver lines were installed at the Golden Gate approximately 1 km apart in order to estimate detection probability and survival at the inner (East) Golden Gate receiver line by using the western line to assess performance of the eastern line. After the 2008 outmigration season, a coastal ocean receiver line was deployed across the continental shelf at Point Reyes, approximately 60 km north of the Golden Gate. Detections from this receiver line were included in the encounter history for the Golden Gate West line to improve accuracy in the estimation of survival and detection probability to the Golden Gate East line. However, because the Point Reyes receiver location did not exist in the 2007 or 2008 season, and few fish were detected there in subsequent years, it was not formally included as a receiver location in the survival analyses.

Survival per 10 km, regional survival and overall survival

For each year, we used the 18 receiver locations to estimate reach survival (“ϕ_R”) for 17 reaches, using the fully time-varying CJS model, which in this case actually varies over space, specifically each reach has a parameter (“reach model”). Detection probabilities were also allowed to vary by reach. These survival estimates were then standardized by reach lengths *l* (giving survival per 10 km, “ϕ_{10}”) to allow inter-reach survival comparisons. This was done by setting the time intervals (in reality, space intervals for this application) in the process.data() function of RMark package to a vector of reach lengths (in units of 10 km). The per 10 km survival estimates are calculated by RMark according to this formula (Eqn 1):

$$(1) \qquad \phi_{10} = \sqrt[l]{\phi_R}$$

To account for the propagation of error, standard errors for *n*th root parameter estimates were calculated by the RMark package using the delta method (Powell 2007; Seber 1982).

Regional (river, delta, and bays) and overall (from the release site to the Golden Gate) survival was then assessed for each year. We did this by taking the product of the reach survival estimates that fall inside the spatial extent of interest, and we present this as percent survival. To account for the propagation of error, standard errors of the cumulative products of survival estimates were also calculated using the RMark package, using the deltamethod.special() function. When using the delta method for estimating the variance of the product of survival estimates, the variance-covariance matrix for the survival estimates must be included in the estimation. Confidence intervals for the product of survival estimates must be calculated on the logit scale, then back-transformed to the real probability scale. Therefore, to estimate 95% confidence intervals, we used our product of survival estimates ($\widehat{\phi}$) along with its respective standard error of the beta estimate ($\widehat{SE}logit(\widehat{\phi})$) by using the formula (Eqn 2):

$$(2) \qquad expit[logit(\widehat{\phi}) \pm 1.96 \times \widehat{SE}logit(\widehat{\phi})]$$

The influences of different spatial and temporal factors on survival rates were assessed by modeling ϕ_R as a function of the factor in question. Specifically, the influence of these factors was assessed by allowing each release group (e.g., five groups for the release year model: 2007, 2008, 2009, 2010 and 2011) within each model to have its own set of survival parameters. Each factor-specific survival model was compared to one another and to a base model (a model with no factor-specific parameters) using Akaike's Information Criterion corrected for small sample sizes (AICc). Goodness-of-fit was assessed by estimating the $\hat{c}$ variance inflator factor of the base model. For this we used two different methods, and adopted the more conservative estimate. Firstly, we simulated $\hat{c}$ and deviance from 100 simulations using the bootstrap procedure. Then, we estimated $\hat{c}$ in two ways, first by dividing the deviance estimate from the original data by the mean of simulated deviances, giving a $\hat{c}$ of 1.309, then by dividing the $\hat{c}$ from the original data by the mean $\hat{c}$ from the bootstraps, giving a $\hat{c}$ of 1.494. We therefore adopted the more conservative $\hat{c}$ of 1.494 and used it to adjust all AIC values for overdispersion (herafter called QAICc). As a rule of thumb, if a test model lowered QAICc relative to the base model by a difference of more than seven, the test model was deemed substantially more parsimonious, and therefore supported over the base model.

The effects of reach (n=17), release year (n=5), release site (n=3), and all interactions of those factors were tested (Table 3 for models). This was done by comparing the QAICc score of each model to the QAICc score of a version of the "reach model" that combines data from all five years, which henceforth will be considering the "*base* model". We used the reach model as our base model under the assumption that survival must vary through space given the spatial heterogeneity of the study system. To test this assumption, a "null model" was also included for comparison. This model only allowed one parameter for survival (representing the null hypothesis: constant survival through space and time). An initial run of several models that allowed for different parameterization of the detection probability terms, while keeping the survival terms the same, indicated that the model allowing for detection probability to vary by reach and year was the best supported. Therefore, all survival models presented in Table 3 allow detection probability to vary by reach and year [*p(*reach*year)].

In order to better understand whether annual fluctuations in survival occurred on a regional scale, we also included three models that allowed survival to vary per reach and per year (reach*year) in only the river, the delta (the delta being the freshwater portion of the estuary) or the bays (Suisun, San Pablo and San Francisco Bays, i.e. the brackish portion of the estuary). These models allowed survival to vary by reach in the remaining regions, and are therefore also comparable with the base model.

Finally, the influence of individual covariates (fork length (mm) and weight (g)) on survival was assessed. The model selected *a priori* to include these covariates was the base model. The individual covariates were added both as an additive factor (different intercept per reach, but common slope), and as factor including the interaction term (different intercept and different slope). These models were then compared using QAICc to the base model without any individual covariates to determine whether fish size and weight affects survival.

For the purpose of considering migration rate as a potential driver for survival rates, mean successful migration movement rate (km/day MSMMR; (Michel et al. 2013)) was calculated per year. Migration movement rate from release site to the West Golden Gate receiver line (i.e., entry to the Pacific Ocean) was calculated for every fish that was detected (i.e., successfully reached the ocean) at either of the Golden Gate receiver lines. These values were then averaged per year and compared to the overall survival for that year in Table 4.

RESULTS

Overall survival of late-fall run Chinook through the entire migration corridor (rkm 518 to rkm 2) per year ranged from 2.8 to 15.7%, with 2011 having the highest survival (Table 4). The MSMMR values indicate that the first four years of the study had relatively similar migration rates, ranging from 17.5 to 23.5 kilometers per day, whereas 2011 had a faster migration rate of 36 kilometers per day.

Survival rate on a reach-by-reach basis was quite variable. During the first four years of the study, the upper river reaches (reaches 1 through 8; rkm 518 to 325) had some of the lowest survival per 10 km and the lower reaches of the river (reaches 9-12; rkm 325-169) had the highest. The delta was comparable to the upper river, and the San Francisco and Suisun Bays (reaches 13-17; rkm 169-2) had the lowest survival rates (Fig. 2). During these same four years, detection probabilities per year and per receiver location throughout the watershed ranged from

4% to 100%, with 90% of all detection probabilities being larger than 50%. In the fifth year, river flows at the time of release were much higher than in the previous four years (Fig. 3), and as a result detection rates were much lower in the river, with only three of the twelve river receiver locations having a detection probability higher than 1%. Therefore 2011 reach-specific survival in the river was not estimable.

Region-specific survival estimates were calculated using the product of all reach-specific survival estimates within the region of interest (Fig. 4; Table 4). Although reach specific survival parameters could not be estimated for the river region in 2011, detection probability improved downstream as water velocity decreased, allowing the estimation of reach specific and region specific survival estimates downstream of the river region. To estimate river region survival in 2011, and to further investigate differences in survival between 2011 and the previous years, the detection data was simplified for a post-hoc CJS modeling exercise that would allow the inclusion of 2011. We simplified the detection data by only including detections from four receiver locations separating the major watershed regions: Freeport at the downstream end of the river region, Chipps Island at the downstream end of the delta region, and the two parallel Golden Gate receiver lines at the downstream end of the bays region. Additionally, only fish released at the Jelly's Ferry site were included for all years since the other release locations did not have associated receiver locations. A preliminary model that allowed survival and detection probability to vary by region and by year (region*year) allowed us to estimate survival in the river region in 2011 (Fig. 4; Table 4). This estimate revealed that survival in the river in 2011 was much higher than in all previous years, while survival in the delta and bays was similar among all five years. We also constructed a set of similar models where one year was given its own set of region specific survival parameters, while the remaining four years shared the same region specific survival parameters. These models allowed detection probability to vary by region and by year. Five models were constructed, each one allowing a different year to have its own survival parameters. The model allowing 2011 to have its own region-specific survival parameters while the other four years shared the same region-specific parameters was substantially better supported (ΔQAICc >7) than all the other models of the same type, as well as the preliminary model (permitting all years to have different region-specific survival parameters).

In the analysis of the effect of different spatial and temporal factors on survival, 2011 data was omitted due to the lack of detection data available in the river portions of the watershed. The influence of reach on survival rates (base model) was found to have substantially better support (ΔQAICc >>7) than the null model (constant survival through space and time; Table 3). The reach models that included release site or year ("Reach*release" and "Reach*year", respectively), as well as the interaction model ("Reach*year*release"), did not improve their support over the base model. The year model was better supported than the release model. The only model that had substantially better support than the base model was the model that allowed for river survival to have a year effect, while delta and bays survival was held constant through time. ("(River survival*year)*reach"). The model allowing only the delta reach to have a year effect ("(Delta survival*year)*reach") was marginally better supported than the base model (ΔQAICc <2).

Tagged fish weight and fork length varied significantly among years (P<0.001), and pairwise hypothesis testing using Bonferroni and Tukey's honestly significant difference tests both indicate that fish sizes were statistically different among all years (with the exception of the 2009/2010 pair) (Table 1). However, the addition of individual covariates (weight, length) as factors to the base model did not improve parsimony in any circumstance, although the length model did fit the data better than the weight model. A model adding length as an additive factor had more support than the other covariate models, and had approximately equal support with the base model (ΔQAICc <0.1; Table 3). Therefore the significant differences in weight and fork length among years did not appear to affect survival.

DISCUSSION

This study used high resolution fish tracking and environmental data to provide the first reach-specific survival estimates of Chinook salmon smolts in the Sacramento River over the entire migration corridor. Survival was relatively high in the lower river compared to other areas, a somewhat unexpected finding given that this reach is channelized and rip-rapped. Also, and in contrast with the commonly-held belief that mortality during the Central Valley smolt outmigration is greatest in the delta (Williams 2006), we observed relatively high mortality in the upper river and especially in the bays downstream of the delta. We found that survival over the entire migration route was much lower in four low-discharge years (2.8 – 5.9%) than in one high-discharge year (15.9%; Fig. 3); higher survival in the high-discharge year was due mainly to increased survival in the river region. This suggests that riverine survival dynamics may be playing an underappreciated role in determining annual salmon stock abundance, as shown with Cheakamus River steelhead stock in British Columbia (Melnychuk et al. 2014).

One potential reason why the lower Sacramento River had higher survival than expected may be due to channelization. Levees, riprap, and channelization have been considered detrimental for salmon populations due to their degradation of spawning grounds (reduced input of gravel), the paucity of prey to feed upon, and an absence of cover that results in a greater frequency of predation on juveniles (Buer et al. 1989; Chapman and Knudsen 1980; Garland et al. 2002; Schmetterling et al. 2001)). However, Michel (2010) found a strong positive correlation between channelized reaches and smolt survival. Given limited rearing potential, smolts likely migrate through channelized reaches, reducing the period of exposure to sources of mortality. The majority of potential predator species in the watershed are typically found associated with submerged structure and vegetation, which in the lower Sacramento River are mostly limited to the riprapped littoral zone. A smolt travelling downstream in the lower Sacramento River only needs to avoid the channel margins to minimize exposure to predators. Outmigrating Chinook salmon smolts in the Sacramento River travel disproportionally more in the center of the channel (Sandstrom et al. 2013). Similarly, smolt survival was higher in deep impoundments compared to shallower undammed reaches of the Columbia River (Welch et al. 2008).

Previous studies of salmon survival in the Sacramento River and estuary, based primarily on coded-wire tags, suggested significantly lower mortality in the bays, but higher mortality in the river. Brandes and McLain (2001) found survival of sub-yearling fall-run Chinook salmon smolts from Port Chicago to the Golden Gate (roughly equal to our bays region) during the 1984-1986 years to vary between 76% and 84%, compared to a range of 26% to 43% in this study. California Department of Fish and Wildlife monitored survival rates of late-fall Chinook salmon from Battle Creek to rkm 239 (within the river region) during the 1996-2000 years using coded-wire tag recoveries at rotary screw traps. They estimated survival rates to vary between 1.1% and 2.7% (Snider and Titus 1998, 2000a, b, c; Vincik et al. 2006), compared to a range of 15.5% to

63.2% over a longer distance in this study. Reasons for these discrepancies could lie in the conditions during the years compared, or could have to do with the difference in sampling protocol and survival estimation.

Overall survival of outmigrating late-fall run Chinook salmon smolts in the Sacramento River is low in comparison to the Columbia and Fraser rivers, in spite of those rivers having substantially longer migration corridors. Welch et al. (2008) found that yearling Chinook salmon smolts from the Snake River (a tributary to the Columbia River) had an overall survival of 27.5% (± 6.9% S.E.) to the ocean over a distance of 910 km in 2006. That study also found that overall survival for yearling Chinook salmon smolts from various tributaries of the Fraser River to the ocean over distances ranging from 330.8 to 395.2 km had an overall survival varying from 2.0% (± 3.6 S.E.) to 32.2% (± 20.7 S.E.), with the majority of the tributary and year-specific survival estimates above 15%. Rechisky et al. (2009) found that outmigrating yearling Chinook salmon smolts from the Yakima River (a tributary to the Columbia River) had an overall survival of 28% (± 5 S.E.) to the ocean over a distance of 655 km.

There are also striking differences in the spatial patterns of survival between the Sacramento River and the Columbia and Fraser Rivers. Columbia River tagging studies have found survival for yearling Chinook salmon through the lower river and estuary to vary between 82% and 100% (or between 98.3% and 100% per 10km), depending on the year and population (Harnish et al. 2012; Rechisky et al. 2013). Similarly-sized sockeye salmon (*Oncorhynchus nerka*) smolts experienced little to no mortality during outmigration through the mainstem Fraser River (including the estuary) during the years 2010-2013 (Rechisky et al. 2014). In our study, survival through the estuary (delta and bays region combined) ranged from 15.1% to 23.4% (89.3%-91.7% per 10 km).

There are a number of possible explanations for why the survival of Chinook smolts in the Sacramento River is generally lower than in other west coast rivers. Flows in the Sacramento River are highly regulated by large water storage dams, and peak discharge is typically much reduced in the outmigration period (Buer et al. 1989; Larry and Marissa 2009). In contrast, no dams exist on the mainstem Fraser River, and the dams on the Columbia River are used for hydropower and do not reduce or homogenize flows to the same extent as water storage dams. It is only in wet years such as 2011 that water flows are high enough for water managers to allow significant dam releases in the Sacramento River. We observed much higher in-river survival during 2011, and other studies have shown positive relationships between survival and river flow (Connor et al. 2003; Smith et al. 2003). Higher flows correspond to higher velocities and faster travel times, reducing the time smolts are exposed to predators (Hogasen 1998). High flows may also be correlated to higher turbidities, which can reduce the effectiveness of visual predators (Ferrari et al. 2014; Gregory and Levings 1998).

Differences in the condition of estuaries offer another explanation. Magnusson and Hilborn (2003) found that in comparing the survival of subyearling Chinook salmon smolts in 27 different small to medium sized estuaries in the U.S. Pacific Northwest, there was a significant positive relationship between survival and the percentage of the estuary that was in pristine condition. They also note that according to MacFarlane and Norton (2002), estuary use by subyearling Chinook salmon smolts was less in the brackish portion of San Francisco Estuary than other estuaries in the Pacific Northwest, potentially due to the poor condition of the estuary.

Nichols et al. (1986) posited that the San Francisco estuary is the most modified estuary on the west coast of the United States, which suggests that the low survival estimates seen in this study are consistent with Magnusson and Hilborn's findings. Cohen and Carlton (1998) suggested that the extensive modification of the San Francisco Estuary contributes to it being perhaps the most invaded estuary in the world. Invaders include a number of piscivorous fish species that likely prey on migrating juvenile salmon. The role of predation clearly warrants study.

Survival rates during drought years observed in this study, if applicable to natural populations, suggest that populations are likely contracting. Bradford's (1995) review of Pacific salmon mortality rates suggested that typical fished Chinook salmon populations have a total mortality rate of 6.76 (based on fecundity) and an average observed egg-to-smolt mortality rate of 2.56. Average smolt mortality rate ($-\log_e(\mathit{survival})$) during the first four years of our study was 3.23. A stable population subject to these mortality rates would require total mortality to be no more than 0.97 (or no less than 38% survival) for the period between ocean entry and reproduction, a period of two to four years for late-fall Chinook subject to significant ocean harvest rates.

Our results have implications for the management of Central Valley salmon hatcheries. Much of the hatchery production in the Central Valley is transported by tanker truck to the bays in order to avoid mortality incurred during the migration through the river and delta. Offsite release leads to undesirable levels of straying, and a recent independent review of California salmon hatchery practices recommends on-site release of hatchery production (CHSRG 2012). Salmon smolts have long been known to migrate during peak flows (Healey 1991; Hogasen 1998; Kjelson et al. 1981). Our study has shown that fish migrating during high flows have higher survival. Hatcheries could employ a “release window” strategy during which they wait for a peak flow, or coordinate their operations with releases from upstream reservoirs that could create artificial pulse flows. Reservoir releases have been shown to improve subyearling Chinook salmon smolt survival (Zeug et al. 2014), although evidence for improved yearling survival is not as clear (Giorgi et al. 1997; Young et al. 2011). The efficacy of reservoir release will depend on the degree to which survival benefits of migrating during freshets are due to decreased travel time versus higher turbidity, which may not be easily manipulated through reservoir operations.

Our study has demonstrated remarkably low survival rates for late-fall run Chinook salmon smolts in the Sacramento River. The Sacramento River is also home to three other runs of Chinook salmon that migrate at smaller sizes and later in the season (Fisher 1994), when water temperatures are higher and predators may be more active. These other runs may therefore be experiencing even lower survival. Furthermore, most mortality in this study occurred in a 1-2 week period for hatchery fish. This has disconcerting implications for wild fish that must spend several months to a year rearing in the watershed. As tags become smaller, the study design utilized here can be applied to document spatial and temporal patterns of survival in these other runs that are of significant conservation and fishery concerns, providing resource managers with valuable information on where and when survival problems are occurring - information necessary to effective mitigation of survival problems.

ACKNOWLEDGEMENTS

Funding for the project was provided by a CALFED Bay Delta program grant, project U-05-SC-047 (A.P.K and R.B.M principle investigators). We are grateful for the help from many technicians and volunteers including (but not limited to): Ian Cole, Alison Collins, Nicholas Delaney, Heidi Fish, Alex Hearn, Andrew Jones, and Ian Ralston. Special thanks to Kevin Niemela, Kurtis Brown, and Scott Hamelburg of U.S. Fish and Wildlife Service (USFWS) and the helpful staff of the Coleman National Fish Hatchery for providing late-fall run Chinook salmon smolts and logistical support for this study. The California Fish Tracking Consortium allowed the realization of this project through the collaboration and data sharing of several academic, federal, and state institutions. Sean Hayes, Ann-Marie Osterback, and anonymous reviewers provided valuable comments that improved the manuscript.

Fig. 2. Percent survival per 10 km per reach for the 2007-2010 study years combined. Figure and map are delimited based on the regions (from upstream to downstream): upper Sacramento River, lower Sacramento River, Sacramento – San Joaquin River Delta, and Suisun/San Pablo/San Francisco Bays. The Sacramento River was delimited into an upper and lower section to highlight the shift in survival rates. Error bars represent 95% confidence intervals. 2011 data was omitted due to poor detection probabilities.

Fig 3. Hydrograph at the Bend Bridge gauging station, 14 rkm downstream from furthest upstream release site (Jelly's Ferry), for each of the five years of the study. The median daily flow values over a 43 year period (including the study years) are represented with a dotted line. Black dots represent release date for tagged smolts in relation to the respective year's hydrograph. Hydrographs are only depicted as long as 90% of released smolts are still actively migrating in the river region; in some years December released fish have all died or outmigrated before January release, and therefore some yearly hydrographs are not continuous.

Fig. 4. Percent survival per major region for all five study years. Regions include river, delta, bays, and the percent survival for the entire watershed "All". Error bars represent 95% confidence intervals.

Abstract

Many factors have been implicated in the decline of Delta Smelt *Hypomesus transpacificus* in the upper San Francisco Estuary, and the importance of each factor is difficult to determine using field data alone. We describe a spatially explicit, individual-based population model of Delta Smelt configured for the upper estuary. The model followed the reproduction, growth, mortality, and movement of individuals over their entire life cycle on the same spatial grid of cells as the Delta Simulation Model (DSM2) hydrodynamics model. Daily values of water temperature, salinity, and densities of six zooplankton prey types were represented on the spatial grid. Reproduction was evaluated daily, and new individuals were introduced into the model as yolk sac larvae. Growth of feeding individuals was based on bioenergetics and zooplankton densities. Mortality sources included natural mortality, starvation, and entrainment in water diversion facilities. Movement of larvae was determined using a particle tracking model, while movement of juveniles and adults was based on salinity. Simulations were performed for 1995–2005. The baseline simulation was generally consistent with the available data. Predicted daily fractions of larvae entrained and annual fractions of adults entrained were similar in magnitude to data-based estimates but showed less interannual variation. Interannual differences in mean length at age 1 had large effects on maturity and subsequent egg production. Predicted and observed spatial distributions in the fall showed moderately good agreement for extremely low- and high-outflow years. As indicated by the population growth rate, 1998 was the best year and 2001 was the worst year. Water year 1998 (i.e., October 1997–September 1998) was characterized by fast growth in fall 1997, low entrainment, and high stage-specific survival rates, whereas water year 2001 had opposite conditions. Our analysis further shows how multiple factors can operate simultaneously to result in the decline in abundance of Delta Smelt.

Understanding the critical drivers and environmental changes that influence the population dynamics of fish is vital for effective resource management and restoration. Most fish species live multiple years and show ontogenetic shifts in the habitats they utilize, which exposes them to multiple environmental and biological factors spread over several points in their life cycle (Rose 2000). Identification of the relative importance of these factors and how they may interact with each other is an important step toward understanding and managing fish populations. A major debate is underway about the status of many harvested marine and coastal fish populations (Myers and Worm 2003; Hilborn 2007; Worm et al. 2009), as human development of coastal areas (McGranahan et al. 2007) and demand for high-quality freshwater (Vörösmarty et al. 2000) continue to accelerate. Identification of the major factors affecting population dynamics (especially declines in population) is critical because the high economic costs of protection and restoration demand efficient and effective responses.

The need to understand mechanisms of population decline for Delta Smelt *Hypomesus transpacificus* in the San Francisco Estuary is critical. This endemic species is listed as threatened under the U.S. Endangered Species Act and is listed as endangered under the California Endangered Species Act. Delta Smelt have generally been at low abundance since the 1980s and showed an even further sharp decrease starting in about 2002 (Bennett 2005; Sommer et al. 2007; Thomson et al. 2010). Delta Smelt have also become the focus of contentious debate because of perceived conflicts between the conservation of this species and the operation of facilities that divert water from the Delta Smelt's habitat for agricultural and urban uses (Brown et al. 2009; NRC 2010). These facilities alter seasonal patterns of flow, and they entrain and kill large numbers of Delta Smelt (Kimmerer 2008).

Many factors may be involved in the decline of Delta Smelt, and quantifying the importance of each factor has proven to be elusive despite the availability of extensive long-term field data (NRC 2012). Factors examined as possible contributors to the decline include entrainment of Delta Smelt by the two large water diversion facilities in the Sacramento–San Joaquin River Delta (hereafter, "the Delta"), shifts in the composition and densities of the zooplankton (prey) community, and changes in physical habitat related to salinity and turbidity (Baxter et al. 2010). A sharp decline in four fish species (juvenile Striped Bass *Morone saxatilis*; Longfin Smelt *Spirinchus thaleichthys*; Threadfin Shad *Dorosoma petenense*; and Delta Smelt) within the upper San Francisco Estuary beginning in approximately 2000 led to a substantial effort at synthesizing existing data to determine the cause (Sommer et al. 2007). The results to date have narrowed the possible factors to some extent (e.g., contaminant effects are likely small) and have facilitated the conclusion that the recent decline in Delta Smelt was due to multiple factors acting together (Baxter et al. 2010). Two statistical analyses (Mac Nally et al. 2010; Thomson et al. 2010) examined the dynamics of the four fish species by using monitoring data collected from the 1970s to 2007. Both analyses, which used similar data but different statistical methods, showed several covariates that were related to abundance of the fish, but they could not resolve the cause of the recent declines.

An alternative approach to the analysis of the effects of multiple factors on fish populations is simulation modeling of the growth, mortality, reproduction, and movement processes underlying the population dynamics. Population modeling allows the investigator to control everything and thus to perform simulation experiments for isolating the effects of individual factors and for exploring the effects of previously unobserved combinations of conditions (Rose et al. 2009). However, model results must be interpreted with caution because models are always simplifications of reality, and their predictions can be biased by decisions about which processes to include and at what temporal and spatial scales to represent those processes.

In this paper, we describe a spatially explicit, individual-based population model of Delta Smelt configured for the upper San Francisco Estuary. We chose this approach because many of the factors that are thought to contribute to the Delta Smelt's decline vary in space (Baxter et al. 2010), and simulating fish movement is more straightforward with an individual-based approach than with other modeling approaches (Tyler and Rose 1994). We first briefly describe the San Francisco Estuary and the life cycle of Delta Smelt. We then describe the spatial grid, environmental conditions, and reproduction, growth, mortality, and movement processes that are represented in the individual-based model. Hydrodynamic model output for the spatial grid and field data for temperature, salinity, and zooplankton densities were used as inputs to the population model for simulation of the period 1995–2005. The results of the baseline simulation are compared with the observed data, and we contrast the conditions between a "good year" and a "bad year" for Delta Smelt growth and survival within the baseline simulation. We conclude with a discussion of our results relative to other analyses and the strengths and weaknesses of our current model formulation. In our companion paper (Rose et al. 2013, this issue), we show that the results presented here are robust to alternative baseline assumptions, and we further explore the factors causing good and bad years by using a simulation experiment approach.

UPPER SAN FRANCISCO ESTUARY AND DELTA SMELT

The San Francisco Estuary is the largest estuary on the U.S. Pacific coast, with a watershed covering approximately 40% of California (Figure 1). The estuary connects the Sacramento and San Joaquin rivers through San Francisco Bay to the Pacific Ocean. Freshwater enters via the Sacramento River from the north and the San Joaquin River from the south; the confluence is roughly the landward limit of ocean salt penetration (Kimmerer 2004). We focus on the upper portion of the estuary (including the Delta and Suisun Bay), which encompasses the entire range of the Delta Smelt.

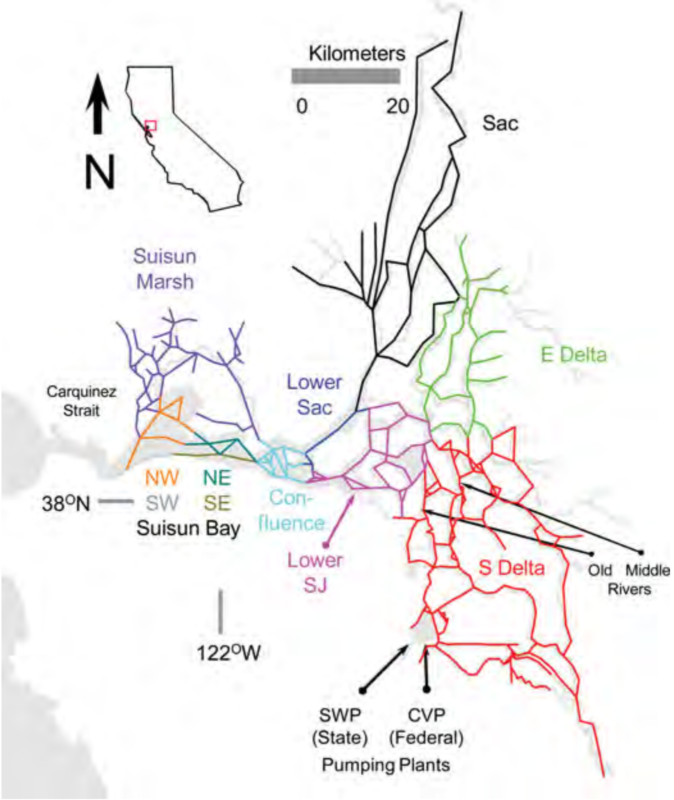

FIGURE 1. Location of the San Francisco Estuary, California, and the spatial grid and boxes used in the model. Gray represents the outline of the estuary. The 11 boxes are color coded and refer to (in numerical order): (1) Sacramento River region (Sac) of the Sacramento–San Joaquin Delta; (2) eastern Delta (E Delta); (3) southern Delta (S Delta); (4) lower Sacramento River region (Lower Sac); (5) lower San Joaquin River region (Lower SJ); (6) confluence (westernmost box in the Delta); (7) southeast Suisun Bay (SE); (8) northeast Suisun Bay (NE); (9) Suisun Marsh; (10) southwest Suisun Bay (SW); and (11) northwest Suisun Bay (NW). Additional labels show the Old River, Middle River, Carquinez Strait, and the State Water Project (SWP) and Central Valley Project (CVP) pumping plants.

The San Francisco Estuary has been described as one of the most highly altered estuarine ecosystems in the world (Nichols et al. 1986; Lund et al. 2010). Over the past 150 years, approximately 95% of the marshes surrounding the estuary have been isolated from tidal action, and numerous nonnative species have been introduced—some with substantial ecological effects (e.g., Nichols et al. 1990; Winder and Jassby 2011). The Delta, which formerly consisted of tidal marsh, is now a complex network of linked channels and sloughs surrounding islands that are protected by a constructed levee system. During the past 60 years, the upper estuary has increasingly been managed through large-scale manipulation of river flows in order to provide freshwater for agricultural, municipal, and industrial uses.

The two large water diversions in the south Delta have exported an average of 30% of the available flow into the Delta during 1960–2000, with the percentage generally increasing through time and exceeding 60% in some years and seasons (Kimmerer 2004). The State Water Project (SWP) facility provides drinking water for over 23 million Californians, and together the two diversion facilities (the SWP and the Central Valley Project [CVP]) fuel an estimated \$25 × 10^9 annual agricultural economy (Grimaldo et al. 2009). Elaborate fish recovery facilities attempt to screen fish from the diverted water but with mixed success (Kimmerer 2011). All of these changes have substantially altered both the physical and ecological aspects of the system (Nichols et al. 1986; Hollibaugh 1996; NRC 2012).

The life history of the Delta Smelt is summarized briefly here based on several sources (Moyle et al. 1992; Moyle 2002; Bennett 2005). The Delta Smelt has a relatively unusual life history strategy (Bennett 2005), as it exhibits the small size and short life span that are typical of an opportunistic life history strategy, but it has low reproductive rates that are more similar to those of an equilibrium strategist (Winemiller and Rose 1992). The Delta Smelt's life history also somewhat resembles those of salmonids (McCann and Shuter 1997) but without parental care. The geographic range of the Delta Smelt is confined to the upper San Francisco Estuary. It is primarily an annual species but with some small fraction of the population surviving a second year to spawn. Spawning takes place in freshwater during February–May at temperatures between 12°C and 20°C; spawning appears to be clustered in 2-week intervals, presumably related to the spring–neap tidal cycle. Eggs are demersal and attached; larval stages generally rear in freshwater before being transported to brackish waters, which are typically located between the confluence of the San Joaquin and Sacramento rivers and Carquinez Strait at the seaward margin of Suisun Bay (Figure 1). All life stages remain at a salinity of about 0.5–6.0 psu (the low-salinity zone) until the end of the year, when migration to freshwater begins. Delta Smelt eat primarily zooplankton throughout their lives, although adults also eat epibenthic crustaceans, such as amphipods. Delta Smelt are consumed by a variety of fish, principally visual predators.

MODEL DESCRIPTION

Overview

The model followed the reproduction, growth, mortality, and movement of individual Delta Smelt over their entire life cycle on a spatial grid of cells (Figure 1). The spatial grid was a one-dimensional network of 517 channels and 5 reservoirs used in the Delta Simulation Model (DSM2) hydrodynamic model (California Department of Water Resources [CDWR]). This one-dimensional model simulates non-steady-state hydrodynamics in a network of channels and has been widely used for analyses and water supply planning for the Delta (Kimmerer and Nobriga 2008). Simulations from DSM2 provided (1) hourly water velocities and water levels at the ends of channels and (2) hourly water flows into and out of the reservoirs. Daily water temperature, salinity, and densities of six zooplankton prey types as estimated from field data were also represented on the same spatial grid.

Each 365-d model year began on October 1, the start date for each water year. Individuals were aged on January 1 of each year. Whenever we refer to a year, it is the year that includes the summer period (e.g., model year 1996 extended from October 1, 1995, to September 30, 1996). Multiyear simulations were performed using reproduction to introduce the new individuals each year.

Reproduction was evaluated daily during the spring spawning season, and eggs developed as a daily cohort at a temperature-dependent rate. Upon hatching, new yolk sac larvae were pooled for each day and were introduced as model individuals. Individuals developed through life stages of yolk sac larva, larva, postlarva, juvenile, and adult. Growth was based on bioenergetics and zooplankton densities in the grid cells. Mortality included a stage-specific mortality rate, starvation, and mortality due to entrainment at the water diversion facilities. Movement of yolk sac larvae, larvae, and postlarvae was determined hourly by using a particle tracking model (PTM) that incorporates water velocities from the DSM2 hydrodynamic model. Movement of juveniles and adults was based entirely on a behavioral response to salinity, and the locations of individual fish on the grid were updated every 12 h.

All simulations used hydrodynamic conditions, temperature, salinity, and zooplankton densities for the period 1995–2005. This period was selected because (1) it encompasses the main period of Delta Smelt decline, (2) hydrodynamic simulations were available, and (3) field data on zooplankton and Delta Smelt were relatively complete.

Environment

A second grid of 11 coarser boxes was overlaid onto the channel grid (Figure 1) so that the more sparsely sampled field data could be used to specify daily water temperature, salinity, and zooplankton densities. The 11 boxes were determined based on previously identified regions of hydraulic similarity (e.g., Miller et al. 2012) and the availability of enough stations to ensure that at least several stations were present in each box.

Daily values of temperature, salinity, and zooplankton densities were estimated for each box and then were assigned to each channel within each box on each day (see details in Supplement A in the online version of this article). Final daily temperature and salinity values for each box are shown in Figure 2 for a year with high freshwater outflow (1998) and a year with low freshwater outflow (2001). All channels within a given box were assigned the box values. Temperature did not vary much among sampling stations within boxes, and the sampling density was too low to represent the within-box (channel-level) spatial gradients in salinity.

The food environment was represented by the biomasses of six zooplankton types: adults of *Limnoithona* spp. (calanoid copepods), calanoid copepodids, other calanoid adults, adult *Eurytemora* (calanoid copepods), adult *Acanthocyclops vernalis* (cyclopoid copepods), and adult *Pseudodiaptomus* (calanoid copepods). We included random variation when we used the boxwide mean to assign values to the channels within each box (see Supplement A). Daily zooplankton biomass densities in each box are presented for the same high-outflow (Figure 3) and low-outflow (Figure 4) years as were shown for temperature and salinity.

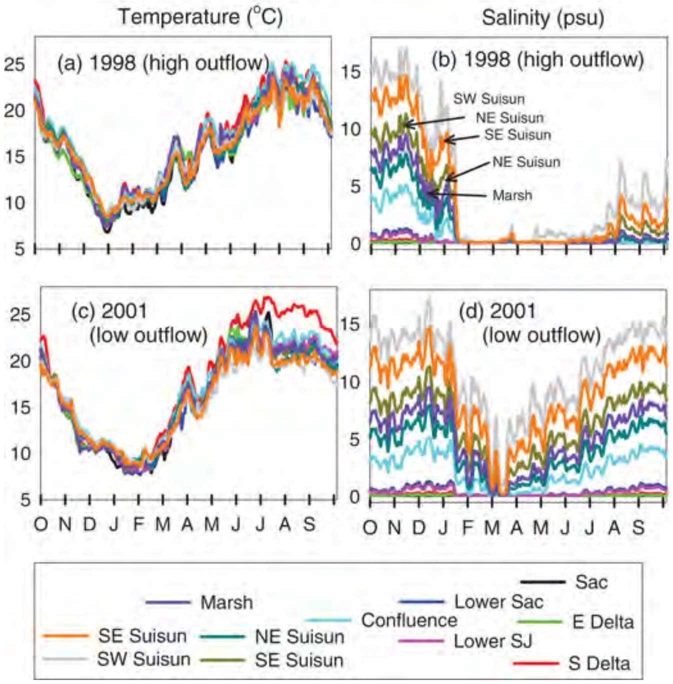

FIGURE 2. Daily temperature and salinity values in each box for **(a)**, **(b)** 1998 (a year of high outflow) and **(c)**, **(d)** 2001 (a year of low outflow). See Figure 1 for definition of box abbreviations. [Figure available online in color.]

Spawning

Each female individual that was longer than 60 mm TL at the start of the spawning season was allowed to spawn up to two times within the spawning season. We used a simple threshold of 60 mm because it was well supported by data (Bennett 2005) and because the manner in which maturity varies around the 60-mm length was uncertain. We explore a smoother maturity function in our companion paper (Rose et al. 2013).

The earliest day of spawning was first determined each year on October 1 by looking ahead at temperatures and finding the first day on which temperature exceeded 12°C in any box. On the earliest possible day of spawning in each year, a temperature of first actual spawning was assigned to each mature individual from a uniform distribution between 12°C and 20°C. To mimic the clustering of spawning on spring–neap tidal cycles, an individual spawned at the end of the 14-d tidal cycle that followed the day when water temperature in that individual's channel exceeded its assigned spawning temperature. By the time of spawning, the migratory movement algorithm based on salinity had put adults near or into freshwater boxes.

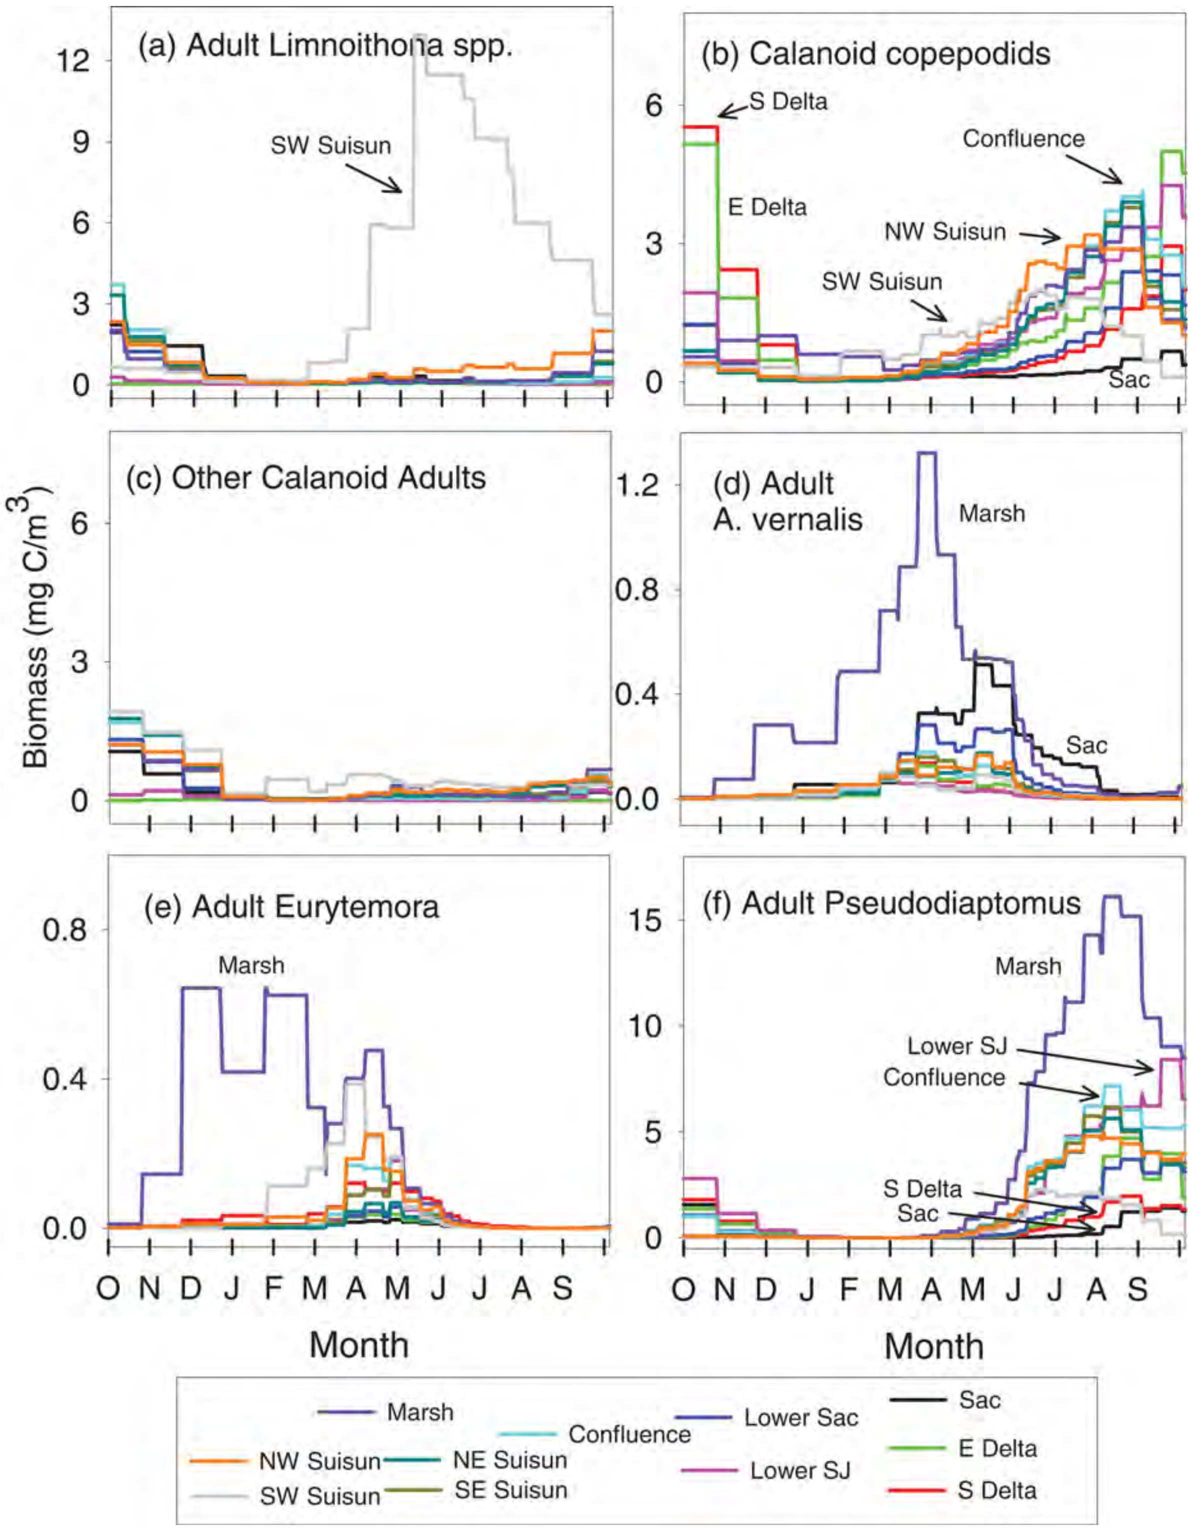

FIGURE 3. Daily biomass density values (mg C per m^3 of water) for each of the six zooplankton groups in each spatial box during a year of high outflow (1998): **(a)** adults of *Limnoithona* spp., **(b)** calanoid copepodids, **(c)** other calanoid adults, **(d)** adult *Acanthocyclops vernalis*, **(e)** adult *Eurytemora*, and **(f)** adult *Pseudodiaptomus*. See Figure 1 for definition of box abbreviations. [Figure available online in color.]

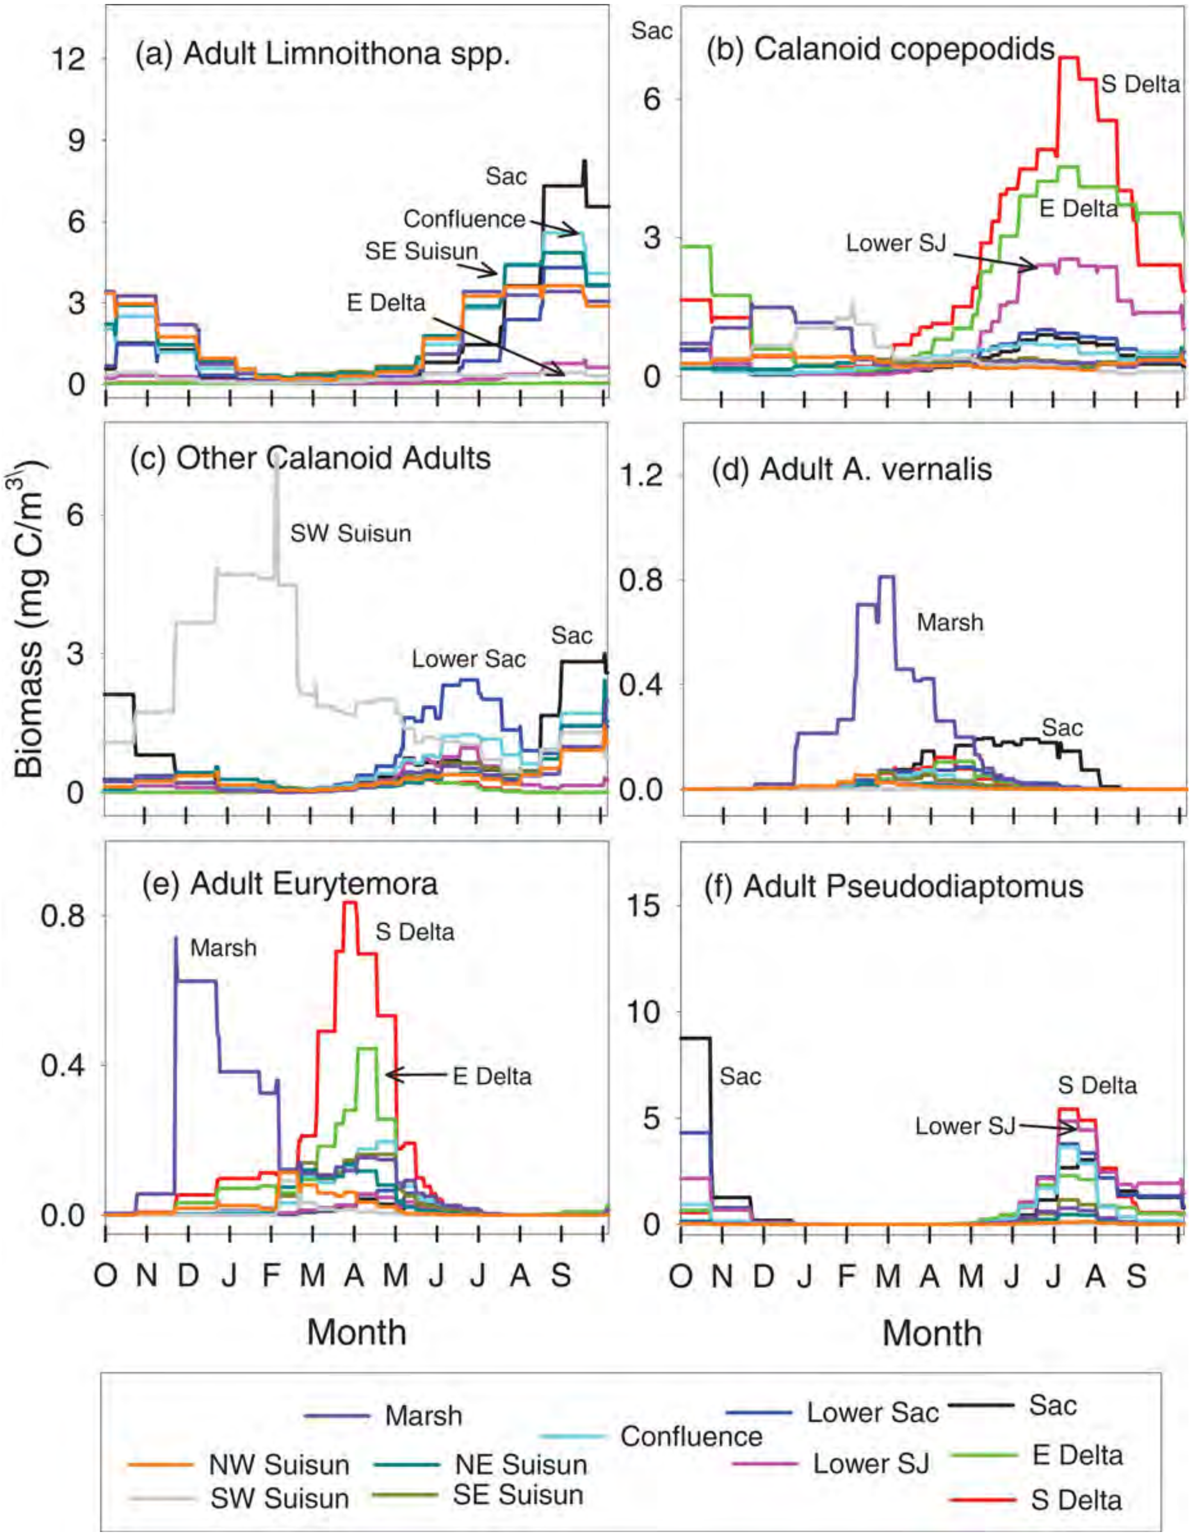

FIGURE 4. Daily biomass density values (mg C per m^3 of water) for each of the six zooplankton groups in each spatial box during a year of low outflow (2001): **(a)** adults of *Limnoithona* spp., **(b)** calanoid copepodids, **(c)** other calanoid adults, **(d)** adult *Acanthocyclops vernalis*, **(e)** adult *Eurytemora*, and **(f)** adult *Pseudodiaptomus*. See Figure 1 for definition of box abbreviations. [Figure available online in color.]

Fecundity (D; eggs/female) depended on the individual's weight on the day of spawning (Bennett 2005),

$$D = 175.4e^{\frac{L_{equiv}}{28.3}}, \tag{1}$$

where L_{equiv} (mm) is the length based on the actual weight of the fish. Upon spawning, the body weight of the individual Delta Smelt was reduced by 15%. We treated males the same as females (i.e., spawning temperatures and weight loss), but without any contribution of eggs, to produce similar weights at age.

After their first spawning event, females were evaluated daily to determine whether they would spawn a second time. Second spawning occurred if (1) the individual had regained enough weight (>95% of the weight expected from its length), (2) 14 or more days had passed since the first spawning, and (3) it was not too late (too warm) in the season for that individual to spawn in its box. The last possible day of spawning in each box was calculated as the first day after temperature exceeded 20°C plus 14 d to allow for the final tidal cycle to complete. The fecundity relationship used for the second spawning was the same as that for the first spawning, and weight was again reduced by 15%.

Eggs

Each female's first and second (if it occurred) spawns of eggs were followed separately as cohorts until hatching, when they became yolk sac larvae. Day of hatching was determined for each cohort by accumulating the daily fractional egg development (DV_e) until the degree of development exceeded 1.0. The daily fractional development towards hatching was based on temperature (Bennett 2005),

$$DV_e = \frac{1}{28.1 - 1.1 \cdot T}, \tag{2}$$

where T is the daily temperature (°C) in the box where spawning occurred. Spawning box temperature (which varied daily) was used because the eggs are attached. All eggs in each cohort that was spawned in a given box on a given day hatched on the same day. Daily egg mortality rates (M; d^{-1}) were calculated by converting hatch rates observed at constant temperature in the hatchery to daily mortality (Bennett 2005),

$$M = \frac{-\log(s)}{DV_e} \tag{3}$$

and

$$s = -2.35 + 0.45 \cdot T - 0.016 \cdot T^2, \tag{4}$$

where s is the survival fraction through the egg stage.

Yolk Sac Larvae

Beginning with yolk sac larvae, new model individuals were created and followed for the rest of their lives. New individuals were created from all those that hatched in each box on each day, and they were distinguished by whether they came from a first or second spawning event. Length (L; mm) at hatch depended on the temperature on the day of hatching (Bennett 2005),

$$L = 5.92 - 0.05 \cdot T. \tag{5}$$

Weight (g wet weight) at hatch was determined from a field-based length–weight relationship (Kimmerer et al. 2005):

$$W = 0.005 \cdot L^3. \tag{6}$$

Similar to the method used for eggs, the duration of the yolk sac larval stage was determined by accumulating the daily fractional development (DV_y) of each model individual based on the temperature in its box (Bennett 2005) until the cumulative development exceeded 1.0:

$$DV_y = \frac{1}{7.53 - 0.08 \cdot T}. \tag{7}$$

Daily mortality rate of yolk sac larvae was assumed constant (0.035 d^{-1}) and was a key parameter adjusted as part of model calibration.

Feeding Life Stages: Development and Bioenergetics

Larvae became postlarvae at 15 mm, and postlarvae became juveniles at 25 mm; juveniles then became age-1 adults and age-1 adults from the previous year advanced to age 2 on January 1 (Bennett 2005). Age-2 adults were removed from the model just before attaining age 3. Larval to postlarval development coincided with the development of a swim bladder, and the juvenile stage marked the appearance of fin folds and an association with the low-salinity zone.

The daily growth of each feeding individual was represented by a difference form of the Wisconsin bioenergetics model (Ney 1993; Hanson et al. 1997),

$$\begin{aligned} W_t = W_{t-1} &+ (C - R - F - U - SDA) \\ &\cdot W_{t-1} \cdot \frac{e_p}{e_s} - Sp \cdot W_{t-1}, \end{aligned} \tag{8}$$

where W is the weight of each individual, C is the realized consumption rate, R is the total metabolic rate, F is egestion, U is excretion, SDA is specific dynamic action, and Sp is loss due to spawning. All rates except Sp were in units of grams of prey per gram of Delta Smelt per day (g prey·g smelt^{-1}·d^{-1} in wet weight); Sp was the fraction of weight lost (0.15) and occurred only on the day of spawning. The e_p and e_s terms (J/g) were used to convert grams of prey per gram of Delta Smelt to grams of smelt per gram of smelt, which was then multiplied by weight (W) to yield the weight change in grams of Delta Smelt per individual per day. The value of e_s was fixed at 4,814 J/g, while e_p was computed each day based on the fraction of *Limnoithona* in the diet. All zooplankton groups had an energy density of 2,590 J/g; the exception was *Limnoithona*, for which energy density was assumed to be 30% lower (1,823 J/g) because Delta Smelt grow more slowly when fed *Limnoithona* (Lindsay Sullivan, San Francisco State University, personal communication).

Total length (L; mm) was obtained from weight by using equation (6). Length was partially uncoupled from weight because length was allowed only to increase, whereas fish could lose weight. On days of weight gain, length was increased only after the individual's weight equaled that expected from its length. Thus, fish were allowed to become skinny but not fat.

Maximum consumption (C_{max}) depended on an individual's weight (W) and the water temperature (T):

$$C_{max} = a_c W^{b_c} f(T). \tag{9}$$

The temperature adjustment to maximum consumption ($f[T]$) increased from a value of CK_1 at temperature CQ to 0.98 at temperature T_O and then stayed at 0.98 until temperature reached T_M, after which the adjustment declined to CK_4 as temperature approached T_L (Table 1).

Realized consumption by the ith fish (C_i) was a functional response that depended on C_{max} and the densities of each zooplankton group j (prey density, PD_j) in the same channel as the fish:

$$C_{ij} = \frac{C_{max} W_i \left(\frac{PD_j \cdot V_{ij}}{K_{ij}}\right)}{1 + \sum_{k=1}^{6} \left(\frac{PD_k \cdot V_k}{K_{ik}}\right)} \tag{10}$$

and

$$C_i = \sum_{j=1}^{6} C_{ij}, \tag{11}$$

where C_{ij} is the daily rate of consumption of the jth prey type (six zooplankton groups) by individual fish i; V_{ij} is the vulnerability of prey type j to fish i; and K_{ik} is the half-saturation constant for fish i feeding on each prey type k. Equations (10) and (11) allowed an individual fish to consume multiple prey types without exceeding its maximum consumption. Vulnerabilities (V_{ij}) were set to 1.0 for all life stages eating all zooplankton types; the exception was Delta Smelt larvae, for which V_{ij} values of zero were used for all adult prey groups other than *Limnoithona* spp. The K-values were calibrated outside of the model to obtain diet and consumption rates that appeared realistic (Supplement B in the online version of this article).

The total metabolic rate (R) was an allometric function of weight and used an exponential relationship ($g[T]$) to adjust metabolism for temperature:

$$R = a_r W^{b_r} \cdot g(T), \tag{12}$$

where

$$g(T) = e^{(R_Q \cdot T)}. \tag{13}$$

Egestion (F) was a constant fraction of consumption, while *SDA* and excretion (U) were fractions of net assimilated energy

TABLE 1. Parameter values for each Delta Smelt life stage in the bioenergetics model.

Parameter	Description	Larvae	Postlarvae	Juveniles and adults
	Maximum consumption (C_{max})			
a_c	Weight multiplier	0.18	0.18	0.1
b_c	Weight exponent	−0.275	−0.275	−0.54
CQ (°C)	Temperature at CK_1 of maximum	7	10	10
T_O (°C)	Temperature at 0.98 of maximum	17	20	20
T_M (°C)	Temperature at 0.98 of maximum	20	23	23
T_L (°C)	Temperature at CK_4 of maximum	28	27	27
CK_1	Effect at temperature CQ	0.4	0.4	0.4
CK_4	Effect at temperature T_L	0.01	0.01	0.01
	Metabolism (R)			
a_r	Weight multiplier	0.0027	0.0027	0.0027
b_r	Weight exponent	−0.216	−0.216	−0.216
R_Q	Exponent for temperature effect	0.036	0.036	0.036
S_d	Fraction of assimilated food lost to *SDA*	0.175	0.175	0.175
	Egestion (F) and excretion (U)			
F_a	Fraction of consumed food lost to egestion	0.16	0.16	0.16
U_a	Fraction of assimilated food lost to excretion	0.1	0.1	0.1

($C - F$; Table 1):

$$F = F_a \cdot C, \tag{14}$$

$$SDA = S_d \cdot (C - F), \tag{15}$$

and

$$U = U_a \cdot (C - F). \tag{16}$$

During calibration, we adjusted the bioenergetics parameter values developed for Rainbow Smelt *Osmerus mordax* (Lantry and Stewart 1993) until we obtained growth that was realistic for Delta Smelt. We adjusted the allometric and temperature-related parameter values of maximum consumption (a_c, b_c, CQ, T_O, T_M, and T_L in Table 1) and the temperature parameter that affected respiration (R_Q in Table 1). We determined parameter values that satisfied two conditions: (1) realistic daily growth rates and optimal temperatures for growth for mid-stage-sized larvae, juveniles, and adults; and (2) realistic weights and lengths for an individual that had grown from first feeding through age 2 under daily average temperatures and a consumption rate (C) that was equal to 0.8 of the maximum (i.e., proportion of maximum consumption [p-value] = 0.8; $C = p\text{-value} \times C_{max}$). The final bioenergetics rates for the mid-stage-sized larvae, postlarvae, juveniles, and adults are shown in Supplement B.

Mortality

Mortality occurred from stage-specific mortality rates (M), starvation, entrainment losses at the two water export pumping facilities, and old age. Stage-specific mortality rates represented predation and other causes of mortality not explicitly calculated from starvation or entrainment. Daily instantaneous mortality was temperature dependent for eggs (equations 3 and 4); M was set at 0.035 for yolk sac larvae (calibrated), 0.05 for larvae, 0.03 for postlarvae, 0.015 for juveniles, and 0.006 for adults. Starvation occurred if the weight of an individual fell below 50% of the weight expected from its length. Upon reaching age 3 (i.e., the individual's third January 1), the individual died from old age and was removed from the population.

Entrainment mortality for all life stages except eggs occurred when an individual entered Clifton Court Forebay (reservoir number 4; SWP) or arrived at node 181 (CVP; Figure 1). Yolk sac larvae, larvae, and postlarvae were transported there by the PTM, whereas juveniles and adults were unaffected by hydrodynamic conditions except through salinity. Use of only those individual juveniles and adults that arrived at the SWP and CVP by behavioral movements based on salinity resulted in underestimation of the numbers entrained by the pumping facilities. Delta Smelt are recovered at the south Delta fish facilities at higher rates when daily net flow in the southern Delta (Middle and Old rivers) is southwards toward the SWP and CVP (Grimaldo et al. 2009; Kimmerer 2011). Therefore, juveniles and adults that were located in the south Delta box (box 3) of the model were exposed to additional entrainment mortality of 0.02 d^{-1} whenever the daily averaged flow in Middle River (downstream end of channel 90; Figure 1) was southward. The value of the added mortality (0.02 d^{-1}) was determined as part of model calibration.

Movement

Yolk sac larvae, larvae, and postlarvae were transported by water velocities on the spatial grid hourly by using a particle tracking approach, whereas juveniles and adults were moved every 12 h by using a kinesis approach to behavioral movement.

The PTM was a recoded version of the CDWR's PTM and used the same formulations (Wilbur 2000; Miller 2002). The CDWR's PTM has been used to examine entrainment impacts (e.g., Kimmerer and Nobriga 2008) and has been compared with other PTMs (Gross et al. 2010). Our recoded version used as input the hourly values of velocity at each end of each channel and the water level at each node that was generated by the DSM2 hydrodynamic model. The PTM kept track of the hourly positions of particles (the three larval stages) in three dimensions: along-channel (x = distance [m] from the upstream end of a channel), lateral (y = distance [m] from the center line of the channel), and vertical (z = distance [m] from the bottom of the channel). The y and z positions within a channel were altered by random perturbations and were used to adjust the x-direction velocity (Supplement C in the online version of this article).

Day-to-day movements and seasonal migrations of juveniles and adults were based on a kinesis approach (Humston et al. 2000, 2004), with salinity used as the cue. Salinity was used to simulate reasonable distributions of individuals within the system, but salinity did not directly affect growth or mortality. Rather, salinity was used to distribute individuals realistically, and individuals then experienced the local conditions (temperature and prey densities) in the channels.

Only the along-channel (x) position was tracked for juveniles and adults. At each 12-h time step, each individual's x position was updated, and its channel or reservoir location was determined. Kinesis represents the distance moved by each individual as the sum of an inertial component (IC) and a random component (RC), with the inertial component dominating when conditions (salinity) are good and the random component dominating when conditions are poor. The position in the x dimension (m from the upstream end of the channel) was updated every 12 h as

$$x_{t+1} = x_t + \Delta x_t \tag{17}$$

and

$$\Delta x_t = IC + RC, \tag{18}$$

where IC is the inertial component that depends on the movement velocity at the last time step (Δx_{t-1}), and RC is the random component based on fish swimming speed.

To compute *IC* and *RC*, we first computed the functions (f and g) that defined the degree to which salinity (S) in the box deviated from optimal salinity,

$$f(S) = H_1 \cdot e^{-0.5 \cdot \left(\frac{S - S_O}{\sigma_S}\right)^2} \quad (19)$$

and

$$g(S) = 1 - H_2 \cdot e^{-0.5 \cdot \left(\frac{S - S_O}{\sigma_S}\right)^2}, \quad (20)$$

where S_O is the optimal value of salinity (2.0 psu); σ_S ($= 3.0$) determines how quickly the function decreases as salinity deviates from its optimal value; and the H-values are constants (0.75 and 0.90) that define the maximum values of the functions. Inertial velocity (*IC*) was then computed using the distance moved in the last time step (Δx_{t-1}) and $f(S)$:

$$IC = \Delta x_{t-1} \cdot f(S), \quad (21)$$

Equation (21) results in the individual moving at the same total velocity (inertial and random combined) as in the last time step to the degree that conditions (salinity) are favorable; $f(S)$ is larger when salinity is near the optimal value (equation 19).

The random component of distance moved (*RC*) was computed based on $g(S)$ and a random component (r):

$$RC = r \cdot g(S). \quad (22)$$

The random component r was calculated as

$$r = N(0,1) \cdot \frac{d}{2} + d \quad (23)$$

with

$$d = \sqrt{\frac{(0.001 \cdot L \cdot \Delta t \cdot 60 \cdot 60)^2}{2}}, \quad (24)$$

where r is a normal deviate with a mean of d and an SD of $d/2$. The numerator in equation (24) represents the distance (m) moved during one 12-h time step, assuming a swimming speed of 1.0 body length/s. The parameter d computed by equation (24) is typically about 70% of the distance to account for fish not swimming in a straight line. The probability of up-estuary movement (P_{up}) was specified as 0.50; for each individual and each time step, a random uniform number was compared with P_{up} to determine the x direction of movement (seaward or up-estuary) in a channel. The distance moved in that direction was determined by the computed velocity of the individual (Δx_t; equation 18).

If individuals moved past the end of a channel, they then entered a node where they either continued into a new channel or entered a reservoir. The new channel or reservoir was randomly selected from all those connected to the node, regardless of flow (Supplement C). Individuals were simply started at the beginning of a new channel. Supplement D (in the online version of this article) shows the results of testing the behavioral movement with simplified salinity patterns on the model grid.

Up-estuary migrations of adults and seaward migrations of juveniles were simulated using the above kinesis approach by changing S_O (equations 19 and 20) and P_{up}. On December 15 of each year, the spawning migration to freshwater began by changing S_O from 2 to 0 psu and by setting P_{up} to 0.85 (rather than 0.50) so that more moves were in the up-estuary direction. On May 1, the migration of adults and juveniles back to low-salinity water was simulated by setting S_O back to 2 psu and setting P_{up} to 0.15. Once individuals reached their new optimal salinity, P_{up} was switched back to 0.50.

Numerics

We used a super-individual approach (Scheffer et al. 1995) in order to accurately simulate the addition of new yolk sac larvae each year while ensuring that we did not exceed computer limitations (Supplement E in the online version of this article). Each super-individual represented some number of identical individuals in the population, which we term its "worth." Each year during spawning, the same number of super-individuals was added, but with their initial worth adjusted to reflect the yolk sac larvae produced. Mortality acted to decrement the worth of an individual, with the worth then being used to determine population-level numbers of eggs spawned and Delta Smelt densities and abundances. We used a complicated algorithm for determining how to allocate the fixed number of super-individuals each year among hatch dates and boxes (Supplement E). In all simulations, we used 150,000 super-individuals per age-class (450,000 super-individuals total) because this was sufficient for convergence (i.e., almost identical results were obtained when we followed more super-individuals). The model was coded in FORTRAN90.

Computation of Population Growth Rate

We used the individual-based model output to estimate a simple Leslie age-based matrix model for each year, which allowed us to summarize the multidimensional individual-based model results with a single variable of annual finite population growth rate (λ). The value of λ was based on the detailed dynamics of the individual-based model but allowed for easier comparison among years. A 2×2 matrix model was estimated for each year by computing the average maturity, fecundity, and age-specific survival rates (Supplement F in the online version of this article); eigenvalue analysis was then used to determine λ. The value of λ for a specific year is a measure of the conditions for Delta Smelt during that year. The λ value is also a reflection of conditions from the previous year by indicating how growth in the fall prior to spawning affected the elements related to maturity and fecundity in the matrix.

TABLE 2. Calculation of the major model output variables examined in Delta Smelt model simulations and the calculations for the data when model–data comparisons were performed. The corresponding figures for the results are noted; "text" means the results are described in the text.

Variable	Model calculations	Data calculations
(a) January adult abundance (Figure 5)	Summed worth of all individuals on January 1; includes young of the year that just became age 1 and age-1 fish that just became age 2 but does not include age-2 fish that were just removed as they became age 3.	Catch per trawl from the spring Kodiak trawl survey for 2002–2006 was averaged for January and February (first two trawls) and expanded to population size using volume sampled, 100% efficiency, and volume of Sacramento–San Joaquin Delta and Suisun Bay less than 4 m deep. November and December midwater trawl (MWT) abundance was computed the same way but by using volume of Delta and Suisun Bay less than 4 m deep. Log(Kodiak trawl abundance) was then regressed against log(MWT abundance), and the MWT values were used to estimate Kodiak trawl values for 1995–2001.
(b) Mean length of young-of-the-year, age-1, and age-2 fish (Figure 6)	Computed the weighted mean lengths on January 1 (just before their birthdays) using worth as the weighting factor in the averaging.	Mean length of fish in the December MWT samples, excluding fish greater than 100 mm, which were assumed to be age 1 or older.
(c) Annual number of adults entrained in diversion facilities (Figure 7)	Summed worth of individuals that were killed by arrival at reservoir 4 (State Water Project) or node 181 (Central Valley Project), plus the worth associated with the added mortality of all individuals in box 3 (South Delta) when Middle River flow is negative. The amount of worth (w) attributable to Middle River-related mortality (R) versus natural mortality (M) is $w(\frac{R}{M+R})(1-e^{-M+R})$.	Methods are described by Kimmerer (2008), and results used here are shown in Figure 12a of that paper.
(d) Fraction of adults on January 1 subsequently entrained during that year	Ratio of numbers entrained (see variable c) divided by the January adult abundance (see variable a)	Methods are described by Kimmerer (2008), and results used here are shown in Figure 12c of that paper.
(e) Fraction of age-1 individuals that were mature and the number of eggs per entering age-1 individual (Figure 8)	Fraction mature was computed as the summed worth of age-1 individuals greater than 60 mm at the time of projected spawning divided by the summed worth of all age-1 individuals on the same day. The ratio of eggs to entering age-1 fish was computed as the cumulative number of eggs produced by age-1 individuals divided by the summed worth of age-1 fish on January 1 prior to spawning.	No data.
(f) Salinity weighted by densities of larvae, juveniles, and adults (Figure 9)	First, the worth of larvae (including postlarvae) was summed for each box on each day and then divided by the volume of the box to obtain number per m^3 by box on each day. Salinity in each box on each day was used to compute average salinity across boxes, weighted by the larval densities in each box. This process was repeated for juveniles and for adults. This was done for calendar years to better match following a year-class from the early spring spawning.	Number per trawl in each sample of the 20-mm, summer townet, fall MWT, and spring Kodiak trawl surveys was used to weight the salinity value measured with the trawls. Data values include a mix of larvae, juveniles, and adults that varied throughout the year depending on the survey.
(g) Proportion of individuals in and seaward of the confluence box for adults on December 14 and April 30, for postlarvae on June 24, and for juveniles and adults on September 1 (Figure 10)	For each stage and day, we summed the worth of individuals in each box and then divided the sum of worth in the confluence box and seaward boxes by the total summed worth over all boxes.	All of the fall MWT data from all stations during September–December were aggregated for each year, assigned to up-estuary of the confluence box (47 stations) or in or seaward of the confluence box (39 stations). The proportion in Figure 10f was computed from these two totals.

TABLE 2. Continued.

Variable	Model calculations	Data calculations
(h) Daily fraction of larvae plus postlarvae entrained in diversion facilities (Figure 11)	Summed worth of larval and postlarval individuals reaching reservoir 4 and node 181 divided by the summed worth of larvae and postlarvae at the end of the day plus the numbers lost to pumping plant entrainment during that day.	Methods are described by Kimmerer (2008), who used the 20-mm survey data, and the results are shown in Figure 14 of that paper. Note: Kimmerer's (2008) estimates included some juveniles as well as larvae and postlarvae. Also see recent papers about the estimation by Kimmerer (2011) and Miller (2011).
(i) Diets (text)	Computed averaged diets for each life stage using the biomass of zooplankton types eaten by every 500th individual on every 30th day. We first computed the proportions for each individual and then averaged the proportions over individuals. This resulted in individuals covering all life stages for the time periods during which the stages were present.	Diets reported by Lott (1998), Nobriga (2002), and Baxter et al. (2010), who summarized unpublished data from Steven Slater (California Department of Fish and Game); data were only sufficient for qualitative and general comparison.
(j) Annual finite population growth rate (λ; Figure 12)	The λ value was computed from a 2×2 Leslie matrix model with parameter values determined from the individual-based model output each year (see Supplement F).	No data.
(k) Stage-specific survival rates (Figure 13)	Summed worth of individuals entering each life stage during the year divided by the summed worth of individuals entering the next life stage.	No data.
(l) Averaged temperature and proportion of maximum consumption (*p*-values; text)	Computed average temperature and average *p*-value for all individuals (weighted by their worth) each day and then computed seasonal averages weighting the daily values for total daily worth of age-1 individuals during February 27–June 7 (spawning) and total daily worth of juveniles during April 18–October 1 (growing season) and October 1–December 30 (fall).	

MODEL SIMULATIONS

Calibration

The model was calibrated in three steps. We first tested the movement of juveniles and adults on test grids with fixed salinity patterns to understand movement in contrived situations where we knew the correct movement patterns (Supplement D). Once the entire model had been calibrated, we again evaluated the movement patterns among years to confirm that simulated movement was realistic under dynamic salinity conditions. The results using the full model are presented below as part of the 1995–2005 historical simulation.

The second step was to determine the *K*-values (equation 10) for each Delta Smelt life stage and each zooplankton prey group (Supplement B). We averaged daily temperature and the biomass of each zooplankton group in each box over the periods when each life stage would be in the system. We assumed that larvae, juveniles, and adults remained in each of the 11 boxes, and we then iteratively adjusted the *K*-values so that the average consumption rate (i.e., with p-value $= 0.8$) and diets were reasonably close to the available observations.

The third and final step was to put the above two calibrated components (movement and growth) into the full model and then to simulate the period 1995–2005 by adjusting only the yolk sac larval mortality rate and the entrainment mortality multiplier based on Middle River flow. The mortality rate of yolk sac larvae was adjusted because this mortality was relatively simple (i.e., only temperature dependent and of short duration). The entrainment mortality multiplier was adjusted because the role of Middle River flow in affecting entrainment is well documented (Grimaldo et al. 2009), although the magnitude is uncertain, and we had data on adult entrainment mortality (Kimmerer 2011). We adjusted the yolk sac larval mortality rate until the predicted average January abundance for 1995–2005 was close to the data average of 2.7×10^6; we then adjusted the entrainment mortality multiplier until the average annual fraction of adults removed by diversions was close to the data average of 10%. We did not try to fit to individual years or to the pattern in the time series of annual abundances. Thus, any interannual differences in model output were generated by differences in temperature, salinity, entrainment, and zooplankton densities.

Historical Simulation

We report the results from the last step of the calibration: the 1995–2005 historical simulation. The calculations that were performed to obtain all reported model outputs and to summarize the field data used for model–data comparisons are shown in Table 2. The field data for Delta Smelt originate mostly from four surveys that are conducted annually by the California Department of Fish and Game (www.dfg.ca.gov/delta/): (1) the fall midwater trawl (MWT) survey began in 1967 and samples juveniles and adults monthly during September–December at 116 stations; (2) the spring Kodiak trawl survey began in 2002 and samples adults every 2–4 weeks during winter and spring at 39 stations; (3) the 20-mm survey (larval net) began in 1995 and samples larvae at 48 stations between March and July; and (4) the summer townet survey began in 1959 and samples mostly juveniles at up to 32 stations during June–August. These field data have been described and used extensively in previous analyses (e.g., Bennett 2005; Kimmerer et al. 2009; Sommer et al. 2011; Miller et al. 2012).

The model outputs and the model–data comparisons in Table 2 confirmed various aspects of the calibration or served to assess the realism of model behavior. None of the model–data comparisons can be considered as true model validation because no data were kept aside for independent comparison. Comparisons a–d in Table 2 were related to the three steps in model calibration as described above. Maturity of age-1 individuals and the number of eggs per entering age-1 individual (Table 2, comparison e) integrated the effects of growth differences (due to temperature and prey biomass) from the previous year on reproduction. Movement patterns were confirmed by using averaged salinities weighted by Delta Smelt density (comparison f) and the proportions of individuals in and seaward of the Sacramento River–San Joaquin River confluence box (comparison g). We used monthly Delta outflows (m^3/s) from DAYFLOW (www.water.ca.gov/dayflow/) to help interpret the spatial distributions in comparison g. Comparison h, the daily fraction of larvae lost to entrainment, confirmed the realism of the pumping-related mortality determined by the PTM. Overall average diets (comparison i) were examined to confirm reasonable shifts in diet from larvae to juveniles to adults. The λ values (comparison j) and stage survival rates (comparison k) provided condensed summaries of the differences among years. Finally, comparison l identified the between-year differences in temperature and food as actually experienced by the simulated fish.

MODEL RESULTS

Dynamics within the Historical Simulation

For the simulated period 1995–2005, calibration resulted in an average January adult abundance of 2.7×10^6 (compared to the data target of 2.3×10^6) and an average fraction of adults lost to the pumps of 11% (the target was 10%). The final calibrated mortality rates were 0.035 d^{-1} for yolk sac larvae and 0.02 d^{-1} for Middle River-related pumping mortality. Annual January abundances varied from year to year in a pattern similar to that of data-based estimates, with a peak in 2000, a decline in 2001, and then low abundances in 2002–2005 (Figure 5). One exception was that the January adult abundance in 1996 had the highest data-based estimate but a relatively low simulated value.

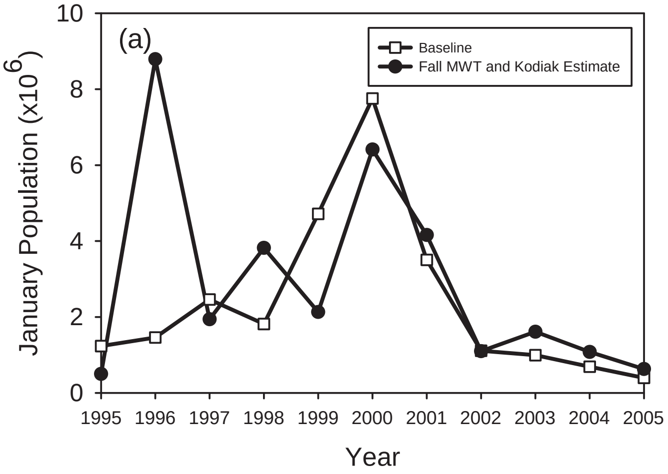

FIGURE 5. Annual abundance of adult Delta Smelt in January for 1995–2005 from the baseline simulation and as estimated from the fall midwater trawl (MWT) and spring Kodiak trawl sampling.

Simulated lengths at age on January 1 were similar to data values for young of the year about to become age 1, with both model and data values varying between 55 and 65 mm (Figure 6). Faster growth was predicted for the summer and fall of 1995 (shown as the January 1996 value), 1997 (the January 1998 value), and 2001–2004. Simulated growth was slow in 1996, 1999, and 2000, resulting in shorter fish recorded during the

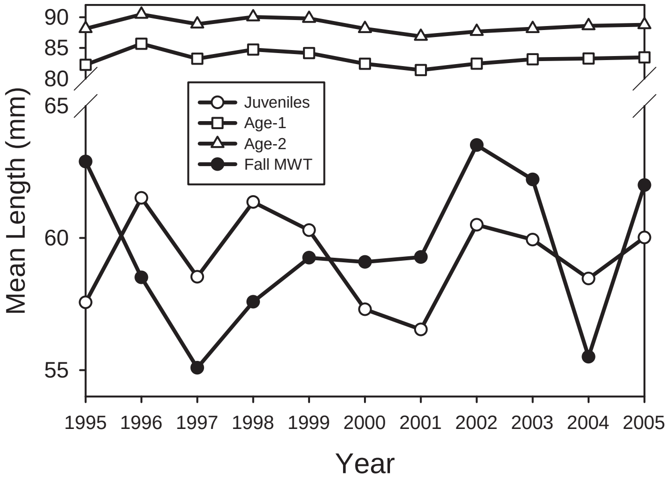

FIGURE 6. Mean total length of juvenile, age-1, and age-2 Delta Smelt on January 1 in each year (just prior to birthdays) of the 1995–2005 baseline simulation. Also included are the mean lengths of young-of-the-year fish from fall midwater trawl (MWT) sampling.

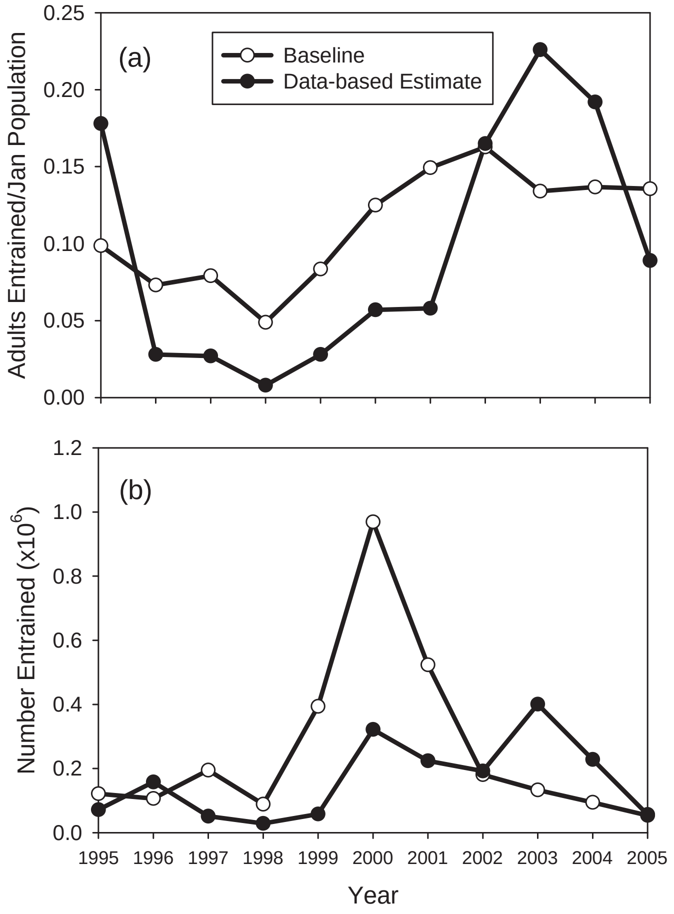

FIGURE 7. Predicted and observed annual values in 1995–2005 for **(a)** the fraction of adult Delta Smelt present in January that were entrained in pumping plants during the next few months (i.e., winter) and **(b)** the number of adults that were entrained during the same time period.

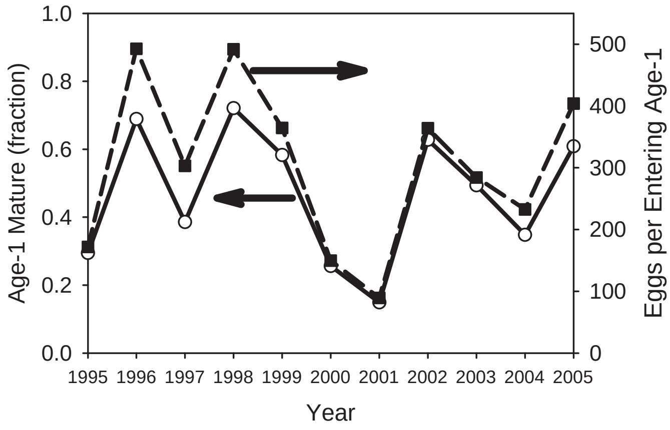

FIGURE 8. Annual fraction of age-1 individual Delta Smelt that were mature (solid line, open circles) and the number of eggs produced per entering age-1 individual (dashed line, black shaded squares) for the 1995–2005 baseline simulation.

next January. Mean lengths of about 82 mm for age-1 fish (about to become age 2) and 90 mm for age-2 fish (about to become age 3) were consistent with the results of Bennett (2005).

The predicted annual fraction of adults entrained showed less interannual variation than the data-based values (Figure 7a), and the predicted numbers entrained were as much as two times the data values for 1999–2001 (Figure 7b). Predicted and estimated annual fractions entrained were low ($<10\%$) for 1996–1999 and then increased to 15–20% for 2002–2004. Predicted fractions showed less variation and were higher than estimated values during the earlier, low-entrainment-loss years and were lower than estimated values during the latter, high-entrainment-loss years (i.e., in Figure 7a, the line connected by open circles is flatter than the line connected by black shaded circles). Substantially more model adults were entrained during 1999–2001 than were shown by the data (Figure 7b) because the fraction entrained was higher, and in two of those years the population estimate (Figure 5a) was higher than that in the data. Overestimation of the fraction entrained in early years and underestimation of the fraction entrained in later years suggested inaccuracies in the simulated adult spatial distributions or in the use of a single value for the pumping mortality at any southward Middle River flow.

Even though the variation in mean length of age-1 adults was small (± 5 mm; Figure 6), interannual differences had large effects on maturity (Figure 8, solid line) and subsequent egg production (Figure 8, dashed line) by age-1 individuals. Age-1 individuals at the beginning of the spawning season (about 3 months into age 1) varied above and below 60 mm from year to year. This hovering around 60 mm caused the fraction of age-1 fish that were mature to range from 0.15 (in 2001) to 0.60–0.70 (in 1996, 1998, and 2002; Figure 8), tracking the slow and fast age-0 growth from the previous year (Figure 6). A greater fraction of individuals becoming mature and a higher weight of these individuals (equation 1) resulted in a fivefold difference among years in the number of eggs produced per entering age-1 individual (Figure 8). Egg production per entering age-1 fish was highest in 1998 (491.8) due to the fast growth of juveniles in 1997 and the high proportion (72%) of age-1 fish being mature at spawning; egg production per entering age-1 individual was lowest in 2001 (89.3; 15% maturity) due to slow juvenile growth in 2000. Such large variation in the fraction mature and eggs produced per entering age-1 fish seems extreme and may partially reflect the all-or-none maturity rule (100% mature if longer than 60 mm) we used. We further investigate the maturity rule in our companion paper (Rose et al. 2013).

Simulated Delta Smelt density-weighted salinities showed the up-estuary spawning migration of adults and the subsequent larval and juvenile movement seaward (Figure 9). Note that the years in Figure 9 are calendar years (i.e., they start on January 1) in order to follow a year-class. Salinity slowly rose for larvae and postlarvae during June–September as they were transported seaward (Figure 9a). Salinity also rose for juveniles during June–October (Figure 9b) after the S_O for juveniles was changed from 0 to 2 psu on May 1. Salinity for adults went from near zero in January–May to approaching 2–6 psu beginning in June

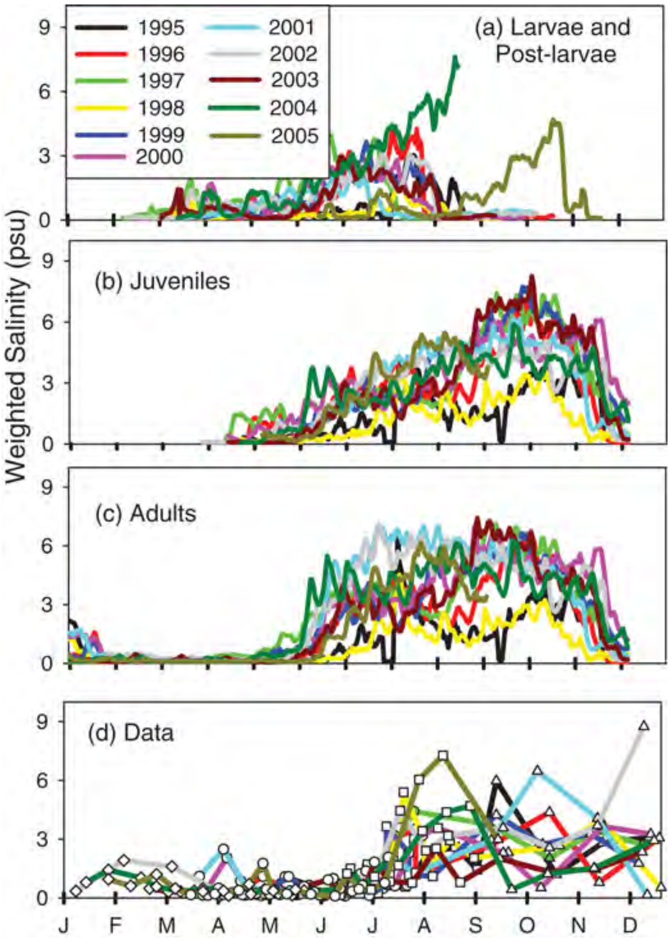

FIGURE 9. Average salinity (psu) weighted by Delta Smelt density computed daily during calendar years 1995–2005 for **(a)** larvae and postlarvae combined, **(b)** juveniles, and **(c)** adults in the baseline simulation. Panel **(d)** shows the weighted salinity values obtained by merging catch per unit effort data from the 20-mm, summer townet, fall midwater trawl (MWT), and spring Kodiak trawl surveys for 1995–2005. Years are calendar years rather than water years (e.g., 1997 refers to January–December). [Figure available online in color.]

(Figure 9c), triggered by a change in the adults' S_O back to 2 psu on May 1. During most years, the density-weighted salinity values for juveniles and adults caused their seaward migration to occur earlier than was shown in the data (June in Figure 9c versus 9d), and they occupied water during the late summer and fall with salinities of 2–6 psu, whereas the data suggested somewhat lower-salinity waters of 1–4 psu during the late summer and fall (August–October in Figure 9c versus 9d).

The interannual influence of Delta outflow on the proportion of individuals in each spatial box is shown in Supplement G (in the online version of this article) and is summarized here by using a single metric: the proportion of fish that were within or seaward of the confluence box (Figure 10). In December, prior to their up-estuary spawning migration, adults were distributed based on salinity, which was roughly correlated with average October outflow (Figure 10a). During the high-outflow years of 1996 and 1999, more than 80% of adults were in or seaward of the confluence box, whereas during the remaining years fewer than 60% were in or seaward of the confluence box.

Spawning migration (including young-of-the-year fish that became age 1 on January 1) began in January and ended by April 30, with almost all individuals located up-estuary of the confluence box (Figure 10b). Once hatched, larvae were transported by the PTM; by June 24, when postlarvae were about to become juveniles, proportions again roughly reflected outflow conditions (Figure 10c). During 1995 and 1998, which were years of high May outflow, over 80% of postlarvae were in or seaward of the confluence box, whereas during relatively low-outflow years (2001, 2002, and 2004) only 20–30% of postlarvae were located in or seaward of the confluence box. Data for 1997 appear anomalous relative to May outflow because that year had a low May outflow but the highest June outflow over the simulation time period (2,033 m^3/s versus less than 1,327 m^3/s). Juvenile and adult distributions on September 1 (Figure 10d, e) resembled each other because both reflected behavioral movement towards 2-psu water. Juveniles and adults were farthest seaward during the high outflow of August 1998 and were situated up-estuary during the low-outflow years of 2001, 2002, and 2004.

Finally, the predicted and observed proportions of adults that were in or seaward of the confluence during the fall showed moderately good agreement for extremely low- and high-outflow years but not for years of intermediate flow (Figure 10f). Predicted and observed proportions showed relatively more fish in and seaward of the confluence during 1996 and 1999 and more fish being relatively up-estuary during 1995, 2004, and 2005. October outflow was highest in 1996 and 1999 and was low in 1995 and 2004 (Figure 10a); October outflow for 2005 was not low, but the summed October–December outflow in 2005 was relatively low. However, predicted proportions were flatter than observed proportions (proportions under low outflow were above the 1-to-1 line, and proportions under high outflow were below the 1-to-1 line in Figure 10f), indicating that simulated adults were generally too far seaward under low outflow and too far up-estuary under high outflow.

The simulated daily proportion of larvae and postlarvae entrained, which results from transport by the PTM, generally agreed with the data-based estimates (Figure 11). Model predictions showed less interannual variation than the data-based values. A few extreme model values of 0.2–0.3 were predicted, whereas data values never exceeded 0.1. In both the simulation and in the data, entrainment was relatively low during 1995, 1996, and 1998 and was high during 2002 and 2003. Model-predicted entrainment was also high during 2000, 2001, and 2005, which were intermediate entrainment years in the data.

Simulated diets were reasonable and consistent among years, even between the most extreme years (not shown). Larvae consumed *Limnoithona* spp. (20% of consumed biomass) and calanoid copepodids (80%) because other prey had vulnerabilities of zero. As Delta Smelt increased in size, they consumed

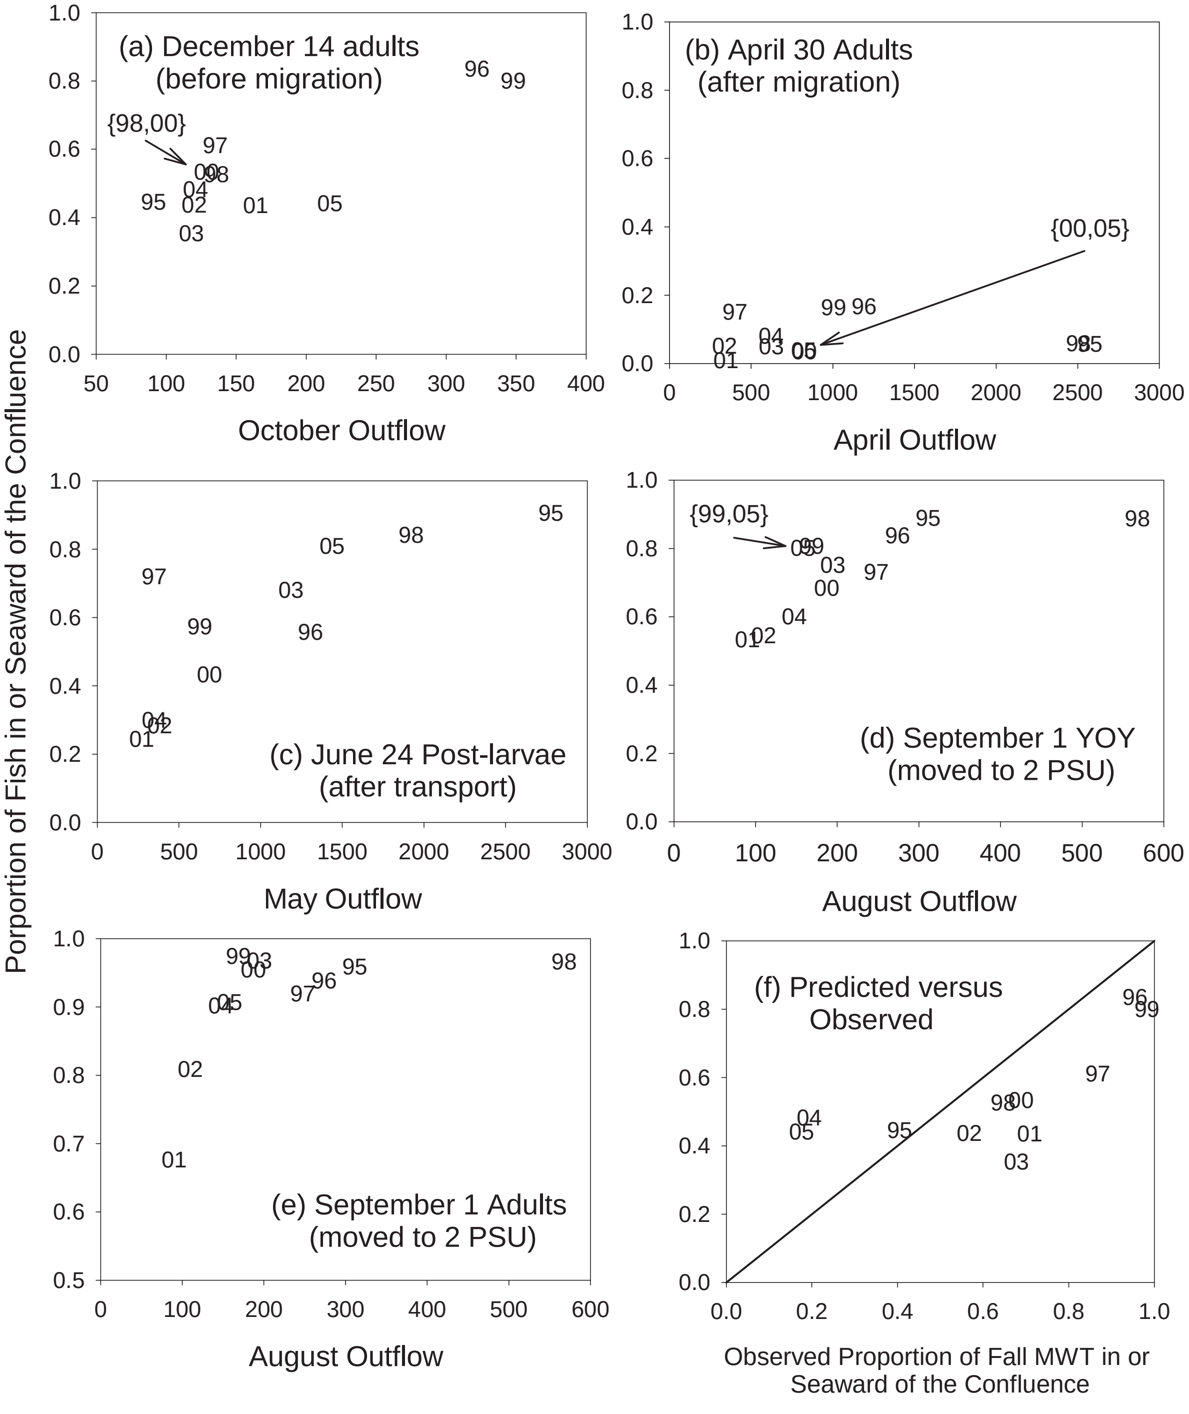

FIGURE 10. Predicted proportion of Delta Smelt individuals in the confluence and seaward boxes (see Figure 1) versus monthly Sacramento–San Joaquin Delta outflow (m^3/s) in the immediately preceding months for 1995–2005 of the baseline simulation: **(a)** adults on December 14 (before the spawning migration), **(b)** adults on April 30 (after the spawning migration), **(c)** postlarvae on June 24 (after particle tracking model transport), **(d)** juveniles (young of the year) on September 1, and **(e)** adults on September 1. Two-digit numbers indicate water years (e.g., 96 = 1996; 02 = 2002). Panel **(f)** is a comparison of the predicted proportion of Delta Smelt in and seaward of the confluence box from December 14 versus the proportion estimated from the fall midwater trawl (MWT) survey. Panel (a) uses outflow from October of the previous year (e.g., October 2001 outflow for the year 2002).

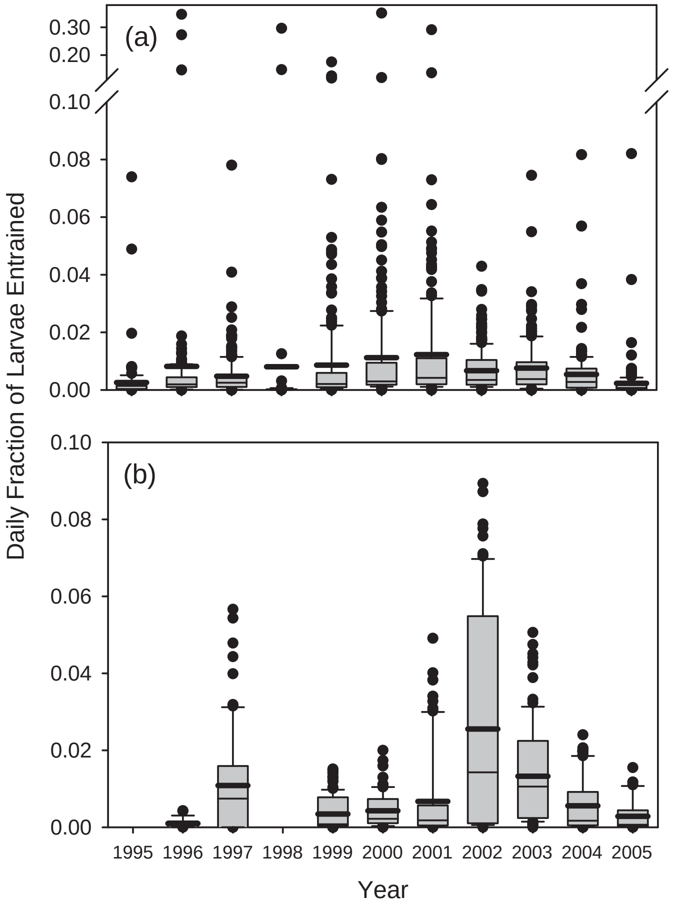

FIGURE 11. Daily entrained fraction of **(a)** Delta Smelt larvae and postlarvae combined as determined by the particle tracking model for 1995–2005 of the baseline simulation and **(b)** larvae (and some juveniles) as estimated by Kimmerer (2008). The thin line within each box is the median, the thick line is the mean, the ends of the box represent the 25th and 75th percentiles, the ends of the whiskers represent the 10th and 90th percentiles, and the black circles are points outside of the 10th and 90th percentiles.

less *Limnoithona* spp. and calanoid copepodids and more of the other four adult zooplankton types (50% [*Limnoithona* spp. and calanoid copepodids] and 50% [other types] for postlarvae; 79% and 21% for juveniles; 92% and 8% for adults). *Pseudodiaptomus* increased in the diet as fish transitioned from postlarvae to juveniles, but the *Pseudodiaptomus* contribution then decreased slightly between juvenile diets and adult diets as the biomass of this zooplankton type decreased in the fall. These results qualitatively agreed with several diet studies of Delta Smelt (Table 2), but more rigorous comparison was not attempted because of the difficulties in interpreting field diets involving rapidly digested zooplankton and without simultaneous measurement of zooplankton densities.

Best versus Worst Years in the Historical Simulation

Population growth rate (λ) from the Leslie matrix model showed that water year 1998 was the best year and water year 2001 was the worst year for the simulated Delta Smelt population (Figure 12). The λ in each year resulted from a combination of (1) growth in the prior year affecting subsequent reproduction and (2) higher stage-specific survival rates in the current year for most of the life stages. Thus, water year 1998 extended from October 1997 to September 1998 and included the fall of 1997, which led up to spawning in spring 1998. Fast growth in fall 1997 resulted in large new adults at the beginning of 1998 (Figure 6) and therefore a high fraction of mature age-1 fish and a high number of eggs per entering age-1 individual (Figure 8). The year 1998 also had moderately high growth during summer (Figure 6), the lowest entrainment losses (Figure 7a, 11), and the highest stage-specific survival rates for all life stages (Figure 13). The bad year, 2001, had the second slowest growth in the prior year (2000; Figure 6) and consequently had the lowest number of eggs per entering age-1 fish (Figure 8). In addition, 2001 had moderately high entrainment losses (Figure 7) and low survival of eggs (Figure 13a), juveniles (Figure 13e), and adults (Figure 13g, h).

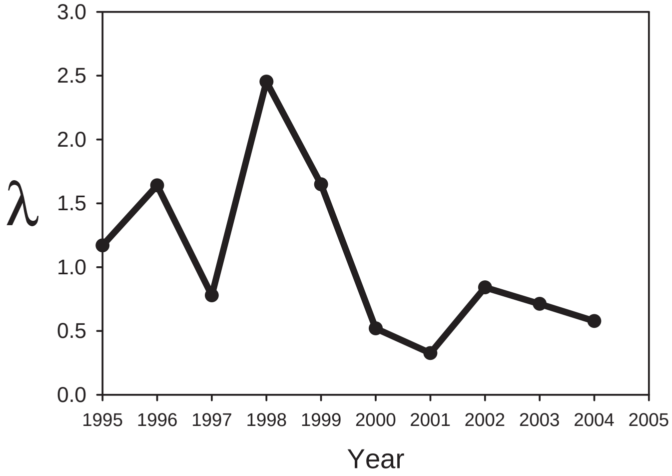

FIGURE 12. Population growth rate (λ; fraction per year) of Delta Smelt as determined by the age-based Leslie matrix model applied to individual-based model output for each year of the 1995–2005 baseline simulation. No value for 2005 was possible because the simulations ended on September 30, 2005; information through December 31, 2005, would be needed to estimate the matrix model for 2005.

Compared with 2001, water year 1998 had a relatively cool and delayed warming in spring that benefited Delta Smelt larvae, but both years had similar growth conditions for juveniles during summer. Mean temperature experienced by age-1 individuals during February 27–June 7 (spawning) was 14.8°C in 1998 versus 16.4°C in 2001. Average day of spawning was April 28 in 1998 versus April 6 in 2001, and average duration of the larval stage (inversely related to growth rate) was 25.2 d (1998) versus 28.6 d (2001). Although juveniles also experienced cooler temperatures during the early summer (16.7°C versus 22.2°C for April 18–June 7), differences became smaller when viewed over the entire growing season. Average temperature experienced by juveniles during April 18–October 1 was slightly cooler during 1998 than during 2001 (20.9°C versus

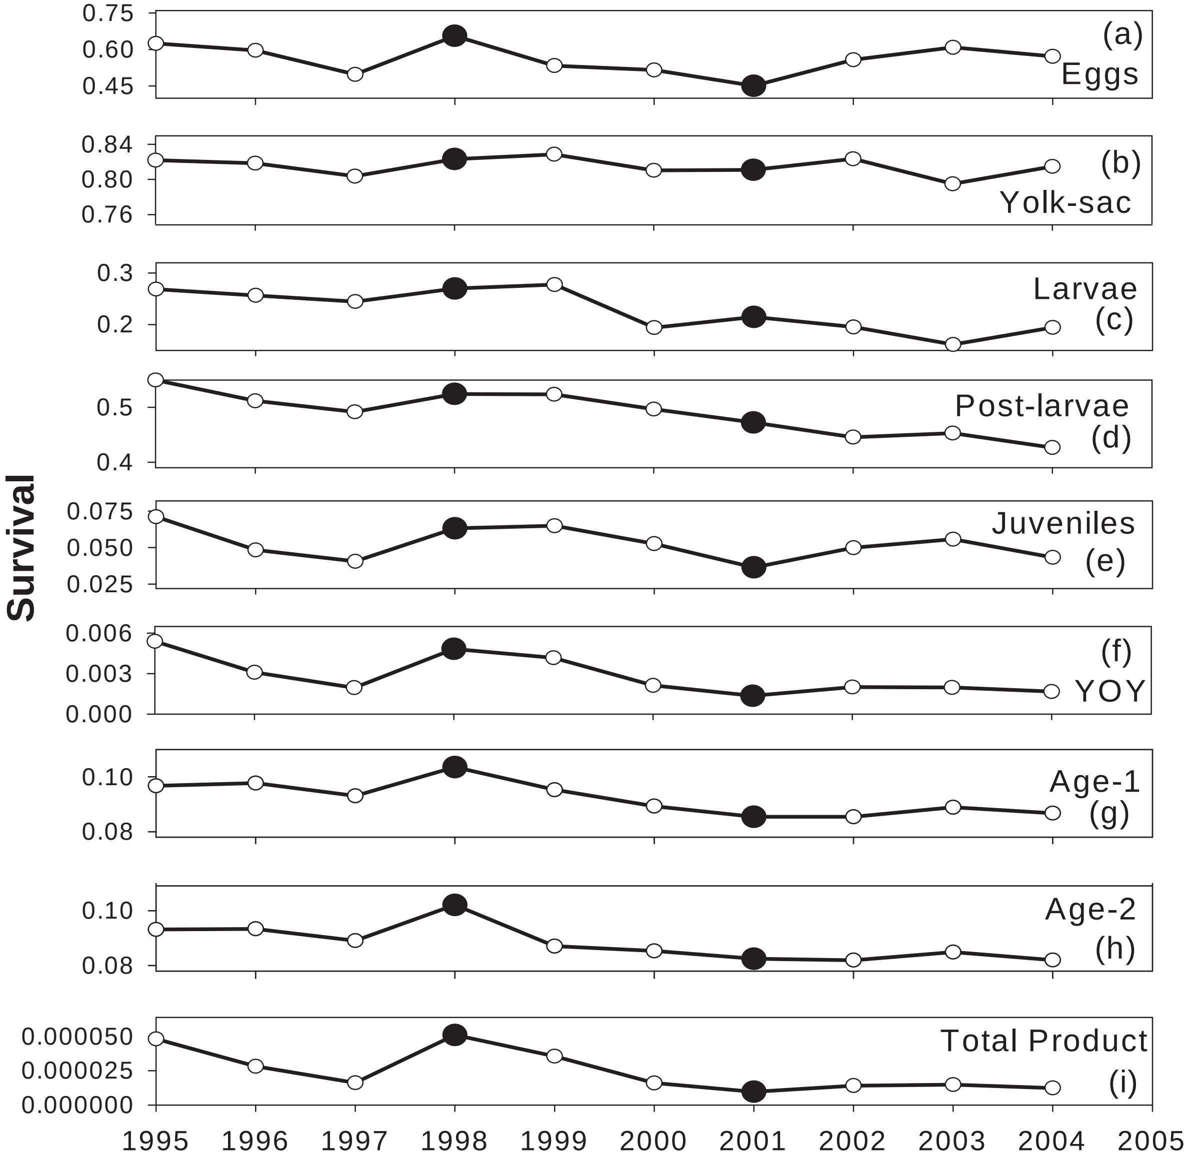

FIGURE 13. Delta Smelt stage-specific survival (fraction) from the 1995–2005 baseline simulation for **(a)** eggs, **(b)** yolk sac larvae, **(c)** larvae, **(d)** postlarvae, **(e)** juveniles, **(f)** total young of the year (product of a–e), **(g)** age 1, **(h)** age 2, and **(i)** total (product of f–h).

22.1°C), and the average *p*-value was higher in 1998 (0.89 versus 0.84). However, mean lengths of juveniles were similar between 1998 and 2001 (60.3 mm in 1999 versus 60.5 mm in 2002; Figure 6), so the difference in summer growth of juveniles between 1998 and 2001 was not a major factor.

The higher number of eggs per age-1 individual in 1998 compared with 2001 was due to faster growth during fall 1997 compared to fall 2000. Mean length of juveniles on January 1 (just before their birthday to age 1) was 61.4 mm for 1998 versus 56.5 mm for 2001. The mean *p*-value for October 1–December 30 was 0.76 in 1997 versus 0.68 in 2000; 1997 was also warmer than 2000 (15.9°C versus 15.0°C).

Delta outflow was generally higher in 1998 than in 2001 (Figure 10), so individuals were farther seaward, resulting in lower entrainment mortality during 1998. The PTM put 84% of postlarvae in or seaward of the confluence box on June 24 in 1998 compared with 24% on June 24 in 2001 (Figure 10c). Similarly, behavioral movement of juveniles resulted in about 88% of them occurring in or seaward of the confluence box on September 1, 1998, versus 53% on September 1, 2001 (Figure 10d). Almost no larvae were predicted to be entrained during 1998, whereas a daily average loss of 1.2% was predicted for 2001 (Figure 11a); the fraction of January adults entrained was 0.05 in 1998 versus 0.14 in 2001 (Figure 7a).

DISCUSSION

We used a detailed, individual-based approach to model the population dynamics of Delta Smelt during a time period that included a major population decline. The model was completely density independent; a density-dependent version is analyzed by Rose et al. (2013). The Delta Smelt has been declining since the 1980s and was one of four species to show a step decline around 2002 (Sommer et al. 2007). The choice of a detailed individual-based model may seem odd because of the extensive data demands of this general approach. Survey data-based modeling approaches are easier to justify in terms of calibration and in testing the degree of fit (e.g., Thomson et al. 2010; Miller et al. 2012); however, unlike our process-based approach, survey data-based approaches do not provide a means of assessing cause-and-effect relationships and so far have not helped to settle the controversy over the causes of the decline.

We opted for a spatially explicit, individual-based approach to explore the potential causes for the Delta Smelt's decline and the conditions that result in good versus bad years for Delta Smelt. The term "spatially explicit" refers to multiple, linked spatial boxes with different conditions among them. The individual-based approach allows for relatively easy simulation of movement and for local experiences to accumulate as each individual moves among the spatial boxes. A spatially explicit approach was required to enable a model that could (1) represent feeding, growth, reproduction, and movement in some detail; and (2) simulate how interannual variation in spatial distributions by life stage interacted with dynamic habitat. The chief disadvantage of such a complicated mechanistic model is that describing how it works can be difficult (Grimm et al. 2006), and many of the assumptions and parameter values must be based on judgment; thus, replication of the modeling by others is a challenge (Wilensky and Rand 2007). Indeed, the output of our model was sufficiently complicated that we chose to fit an age-structured matrix model to its output to provide a more straightforward summary of each year's condition. Our model is designed for exploring hypotheses about some of the factors affecting Delta Smelt population dynamics but is not designed for forecasting future Delta Smelt population abundances. Hypotheses about future conditions can be explored with our model but in a relative way, whereby simulated values are compared with some simulated baseline condition.

Maunder and Deriso (2011) also fitted a stage-based model of Delta Smelt by using the same extensive long-term monitoring data used here. By including covariates such as annual entrainment rate in their model, Maunder and Deriso (2011) were able to evaluate the relative importance of different factors. Their data-based modeling approach is relatively easy to describe (mathematically compact) and can be easily judged for its performance and skill (fit to data), but the approach also inherits problems with the monitoring data in terms of bias and process versus observation errors and is heavily correlation based. Clearly, the data-based approach of Maunder and Deriso (2011) and the detailed, process-based approach used here can complement each other, and detailed comparison between the two approaches would likely allow for more insights than either approach alone can provide.

Calibration of complicated individual-based models is always a challenge. Our approach was first to adjust the movement and feeding algorithms externally under simplified conditions and then calibrate by adjusting two mortality-related parameters for the 1995–2005 historical simulation to get the averaged population abundance and averaged fraction entrained to match the data. None of the calibration steps involved adjustments to fit the model to specific years.

Model results were generally consistent with the available data and information (Table 2) about Delta Smelt. The model reasonably matched a variety of measures related to growth, mortality, and movement. Predicted growth resulted in realistic lengths at age (Figure 6). The PTM produced reasonable larval entrainment rates (Figure 11), and a simple function of Middle River flow yielded annual adult entrainment fractions that mimicked the observed values (Figure 7). Movement was confirmed both based on salinity experienced by individuals (Figure 9) and geographically (Figure 10). The fraction of individuals in the confluence box and seaward boxes during the fall agreed with estimates from fall MWT sampling. Thus, the calibrated model is a good descriptor of the 1995–2005 conditions and is useful for comparing Delta Smelt dynamics among those years. We caution that our bioenergetics model was sufficient for relating prey and temperature to growth, but it must be re-evaluated for other purposes.

There were several major discrepancies between model results and observed values. First, the model underestimated the January abundance in 1996 (Figure 5), and the reason for this is unclear. Second, the model overestimated the degree of adult entrainment in early years and underestimated the degree of adult entrainment in later years (Figure 7). This lack of sufficient interannual variation in simulated adult entrainment may be attributable to the simulated movement of adults being too similar among years (Figure 10f); the center of distribution for simulated adults was less variable across years than the center of distribution for fish caught by the fall MWT. Another possible explanation is that adult entrainment mortality was switched on or off depending on the sign of Middle River flow, whereas analyses showed that the actual entrainment rate probably increases with the magnitude of southward flow toward the diversion facilities (Kimmerer 2011).

A third discrepancy between the model and the data was that movement in the model tended to put juveniles and adults in water that was too saline during late summer to winter (Figure 9). This could reflect a conceptual difference between the data-based and modeled density-weighted salinities. Because the model tracks each individual, an individual-weighted salinity is unbiased by any sampling error. In contrast, the sampling programs catch relatively few fish and do not sample all salinities equally. However, even with the sampling issues, the results suggest that the model is contributing to this discrepancy. Two possibilities are that (1) behavioral movement of juveniles in the model may be too slow to react to local salinity changes (Supplement D) and (2) the starting locations from the PTM were too far seaward. Some of the movement of late larval Delta Smelt in nature likely is a result of both transport (which we assumed) and behavior as the fish gain competence to direct their movements.

Finally, the model showed wide fluctuations in the fraction of age-1 individuals that were mature and the number of eggs per entering age-1 individual (Figure 8) from small changes in mean length (Figure 6). Although we lack data with which to compare these results, these differences among years seemed larger than what we would expect to see in the real population. We partially address this in Rose et al. (2013) by including length-dependent maturation as one of the alternative baselines.

We performed many comparisons of model results with the available data (Table 2), but we did not perform the classical model calibration and validation comparisons and we did not compare model predictions with commonly used abundance indices from the monitoring programs. We focused on using most of the data for calibration and often in a pattern-matching mode (Grimm et al. 2005) rather than a more traditional comparison of predicted values versus observed data (Stow et al. 2009); thus, some of the consistency between the model and the data was a result of calibration. While Delta Smelt abundance indices from the various monitoring programs have been used extensively as indicators of population abundance and survival (Bennett 2005; Maunder and Deriso 2011; Miller et al. 2012), we found the model–data comparisons using the indices to be uninformative due to the sensitivity of the indices to calculation details, such as the months included and the gear selectivity (e.g., Newman 2008).

Our analysis of model results and data for 1995–2005 clearly illustrated why it has been difficult to ascribe the Delta Smelt's decline to a single causative factor, either over the long term or as part of the recent 2002 decline. Interannual variation in λ (Figure 12) was due to a combination of the effects of temperature, salinity, larval growth, hydrodynamics, and growth of juveniles in the prior year affecting the movement, growth, mortality, and reproduction in various combinations of life stages. Small changes in mean length of young-of-the-year fish from the previous year (Figure 6) were amplified into large effects on egg production (Figure 8), and temperature affected the timing of spawning and the subsequent growth of larvae.

We did not include an explicit representation of turbidity in the final version of our model. Turbidity affects spatial distributions (Feyrer et al. 2007; Nobriga et al. 2008) and larval growth (Baskerville-Bridges et al. 2004) of Delta Smelt. We initially included turbidity (estimated from extensive Secchi depth measurements) in the same way that we included salinity and temperature (Supplement A). Turbidity showed the expected decrease during the modeled time period, which is part of a longer-term downward trend (Kimmerer 2004; Wright and Schoellhamer 2004; Nobriga et al. 2008). However, we had no basis upon which to determine relationships between turbidity and growth rate or mortality rate, and thus we could have simulated a decline in the Delta Smelt population based solely on the lower turbidity in the later years. Because we predicted the decrease in Delta Smelt without turbidity (i.e., based on hydrodynamics, temperature, salinity, and zooplankton), a turbidity effect was not included.

In the companion paper (Rose et al. 2013), we further explore Delta Smelt dynamics using the individual-based model. We configure alternative baseline simulations and perform a simulation experiment to further refine our understanding of bad versus good years for Delta Smelt. We vary salinity, temperature, zooplankton, hydrodynamics, and eggs per entering age-1 individual between the best year (1998) and the worst year (2001) to systematically quantify the effects of each factor and their combined effects on λ. We then show that these results are robust to alternative baseline configurations.

ACKNOWLEDGMENTS

This project was funded by a grant from the CALFED Science Program (SCI-05-C106). We acknowledge the many people who discussed various aspects of the model and their willingness to discuss and provide information. Stephen Monismith helped with the PTM. Rachael Miller Neilan derived the Leslie model formulation. Erik Loboschefsky provided the DSM2 output files. Lindsay Sullivan shared data on Delta Smelt feeding, and Steve Slater provided diet data. We also had discussions during model development with Rick Sitts, Joan Lindberg, and Kevin Fleming; in addition, we held a workshop in Santa Cruz, where many people provided information and advice on the modeling in its early stages. The comments of two reviewers and the Associate Editor greatly improved the clarity of the paper.

Abstract

We used a previously described individual-based population model to further explore the population dynamics of Delta Smelt *Hypomesus transpacificus* in the upper San Francisco Estuary. We formulated four alternative baseline configurations of the model and used a factorial design to systematically isolate the effects of factors that determined a good versus bad year. The alternative baseline conditions were obtained by substituting different assumptions about growth, maturity, and mortality into the original baseline configuration. In the simulation experiment, we varied five factors by setting each value to its 1998 (best year) or 2001 (worst year) value: salinity, temperature, zooplankton densities, hydrodynamics, and eggs per age-1 individual at spawning. Although some of the alternative baselines resulted in lower January abundances, estimated finite population growth rates were very similar for all versions. The simulation experiment showed that juvenile growth in the winter prior to spawning (i.e., eggs per age-1 individual) was the most important single factor in making 2001 a bad year, although no single factor alone was sufficient to fully account for the poor conditions in 2001 relative to 1998. Temperature played an important secondary role, and hydrodynamics played a more minor role. The results of the simulation experiment were robust, as similar results were obtained under the four alternative baselines. We compare our results with previous modeling and statistical analyses of the long-term monitoring data; we also discuss some implications of our results for Delta Smelt management and suggest future directions for analyses.

The Delta Smelt *Hypomesus transpacificus* resides only in the San Francisco Estuary and is listed as threatened under the U.S. Endangered Species Act and as endangered under the California Endangered Species Act. Abundance of Delta Smelt started to decline in the 1980s, and a sharp decrease starting in 2001 led to a series of management actions that were intended to benefit the species but that also involved reducing the water available to be diverted for irrigation and water supply (NRC

2012). The State Water Project and the Central Valley Project have exported an average of 30% of the freshwater flowing into the estuary during 1960–2000, with the percentage generally increasing through time and exceeding 60% in some years and seasons (Kimmerer 2004). The State Water Project facility provides drinking water for over 23 million Californians; combined, the two diversion facilities fuel an estimated $\$25 \times 10^9$ annual agricultural economy (Grimaldo et al. 2009).

A suite of factors has been identified as important in contributing to the decline of Delta Smelt. These factors include entrainment by water diversion facilities (Kimmerer 2008, 2011; Miller 2011), contaminant effects (Kuivila and Moon 2004; Connon et al. 2009; Brooks et al. 2012), shifts in the zooplankton (prey) community (Nobriga 2002; Feyrer et al. 2003; Winder and Jassby 2011), and changes in physical habitat (Feyrer et al. 2007; Nobriga et al. 2008; Kimmerer et al. 2009). The role of these factors in contributing to the Delta Smelt's decline has been examined by using statistical analysis of long-term field data (Mac Nally et al. 2010; Thomson et al. 2010; Miller et al. 2012) and population dynamics modeling (Maunder and Deriso 2011). These analyses have led to what many consider to be contradictory conclusions about the relative importance of various factors in affecting Delta Smelt population dynamics (NRC 2010; Kimmerer 2011; Miller 2011).

Determining the factors that affect Delta Smelt population dynamics is critical for formulating effective remediation actions. Remediation actions under the federal Endangered Species Act are termed "reasonable and prudent alternatives" (RPAs), and specific actions were proposed as part of the recent biological opinion for Delta Smelt (USFWS 2008) and were subsequently argued in court (NRC 2010). One RPA restricts water diversions during the winter to limit losses of Delta Smelt at the diversion facilities (Grimaldo et al. 2009; Kimmerer 2011). Another controversial RPA was designed to protect fall habitat by using reservoir releases to maintain the estuarine salinity field in certain spatial regions (NRC 2010). The high economic costs of these various management actions, coupled with uncertainty about how they may affect Delta Smelt population dynamics, have led to controversy (NRC 2012).

In a companion paper (Rose et al. 2013, this issue), we described an individual-based population model of Delta Smelt and used a historical baseline simulation for 1995–2005 to identify the factors leading to good and bad years for Delta Smelt. In the present paper, we extend the analysis of Rose et al. (2013) by formulating alternative baseline configurations of the model and by using a factorial design to systematically isolate the effects of factors that determined a good year versus a bad year. We formulated four alternative baseline conditions by substituting different assumptions about growth, maturity, and mortality into the baseline configuration. The four alternative baselines were (1) fixed larval growth instead of food-dependent larval growth, (2) size-dependent mortality instead of stage-dependent mortality, (3) density-dependent mortality instead of density-independent mortality, and (4) length-dependent maturity rather than a length threshold for maturity. Each of these assumptions was important to baseline dynamics, and each was uncertain. Our earlier identification of good and bad years was from the historical simulation, and the effects of some factors can be confounded by the autocorrelation that is inherent in a historical simulation. Here, we follow up with a designed simulation experiment in which we systematically varied the factors that are potentially important in determining good and bad years, and we further show the robustness of the simulation experiment results by repeating the experiment for each of the four alternative baseline conditions. We demonstrate that the results obtained under the original baseline conditions were similar under the four alternative baseline conditions (i.e., robust), and we further refine the role of various factors in determining good and bad years.

MODEL DESCRIPTION

Overview

The individual-based model followed the reproduction, growth, mortality, and movement of super-individuals over their entire life cycle (from eggs to age 3) on the same spatial grid as the Delta Simulation Model (DSM2) hydrodynamics model that was developed by and is widely used by the California Department of Water Resources (baydeltaoffice.water.ca.gov/modeling/deltamodeling/models/dsm2/dsm2.cfm). A model year was defined as a water year: October 1 of the previous year to September 30 (e.g., model year 2001 extends from October 1, 2000, to September 30, 2001). The model is described in detail by Rose et al. (2013) and is briefly summarized here.

The spatial grid was one-dimensional, with 517 channels and 5 reservoirs (Figure 1 in Rose et al. 2013). The DSM2 hydrodynamics model provided hourly values of water velocities and flows into and out of channels and reservoirs, which were used as inputs to a particle tracking model (PTM) that was embedded in the Delta Smelt individual-based model. A second grid of 11 coarser boxes was overlaid onto the channel grid, and values of daily temperature, salinity, and biomass densities of six zooplankton groups in each box were used to assign values to each channel.

For each super-individual, we tracked a suite of traits, including life stage, growth rate, weight, length, age, diet, location on the grid, maturity status, fecundity, and worth. Worth was the number of identical population individuals represented by the super-individual. Rather than following every individual and removing them upon death, we followed a fixed number of super-individuals and decreased their worth in each time step to account for mortality (Scheffer et al. 1995). All computations were scaled from the super-individuals to the population by multiplying by the worth of the super-individuals. Individuals were assigned to five life stages: egg, yolk sac larva, postlarva, juvenile, and adult. Advancement to the next life stage (development) was based on (1) temperature for egg to yolk sac larva

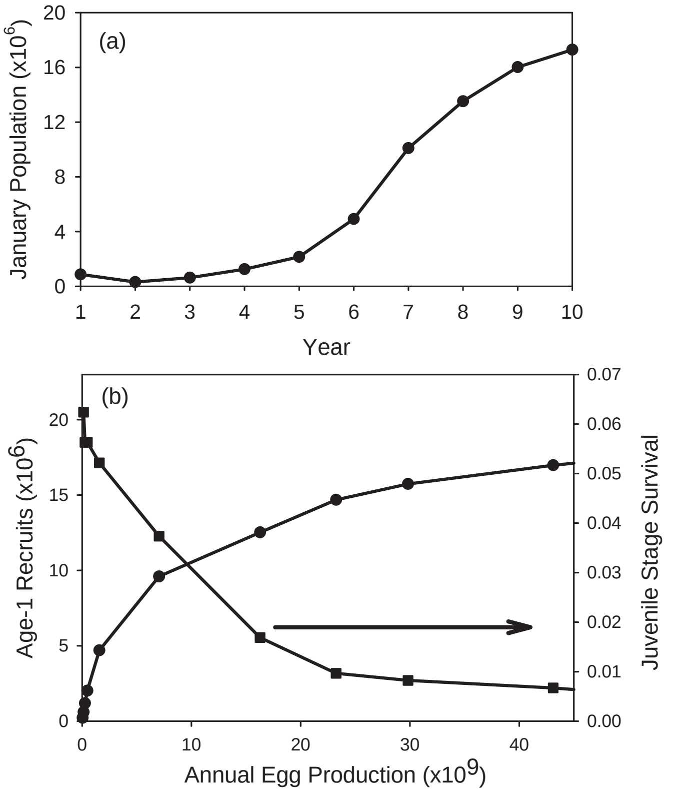

FIGURE 1. Simulated adult Delta Smelt abundance over time and juvenile survival from each year in a 15-year model run with artificially increasing egg production every year and density-dependent juvenile mortality: **(a)** adult abundance in January of each year and **(b)** age-1 recruits (circles, primary *y*-axis) and juvenile-stage survival (squares, secondary *y*-axis) versus annual egg production for each year.

to larva; (2) length for larva to postlarva to juvenile; and (3) date (January 1) for juvenile to age 1 and for age 1 to age 2.

Growth increments at each time step were determined from body weight, temperature, and the biomass densities of the six zooplankton groups (adult *Limnoithona* spp.; calanoid copepodids; other calanoid adults; adult *Eurytemora*; adult *Acanthocyclops vernalis*; and adult *Pseudodiaptomus*). Length was then increased if fish weight had increased sufficiently. Mortality was a stage-specific, fixed rate plus starvation (if the weight of an individual fell below 50% of the weight expected for its length) and entrainment by the two water diversion facilities. Movement on the spatial grid was by physical transport using a PTM for yolk sac larvae, larvae, and postlarvae; movement was behavioral (in response to salinity) for juveniles and adults. Development, reproduction, growth, and mortality were updated daily, whereas movement of eggs and all larval stages was updated hourly and movement of juveniles and adults was updated every 12 h.

Model Outputs

In our companion paper (Rose et al. 2013), we presented a detailed comparison between individual-based model outputs and data. We focus here on model predictions involving a small subset of those output variables. The major outputs presented for all simulations in this paper are the annual adult abundance in January and the annual finite population growth rate (λ). Annual adult abundance in January was computed as the summed worth of all individuals on January 1, including the young of the year that just became age 1 and the age-1 fish that just became age 2; it did not include age-2 fish that were just removed as they became age 3. We used the individual-based model output to estimate a Leslie age-based matrix model for each year to summarize the complicated individual-based model results with a single variable, λ. The value of λ was based on the detailed dynamics of the individual-based model but allowed for easier comparison among years. A 2×2 matrix model was estimated each year by computing the average maturity, fecundity, and age-specific survival rates and by using eigenvalue analysis to determine λ (see Supplement F in the online version of Rose et al. 2013).

Additional model outputs were used selectively to configure or confirm the alternative baselines and to provide some explanation for how the factors in the simulation experiment (described below) affected Delta Smelt. These outputs were defined and their calculations were described by Rose et al. (2013): stage-specific survival rates, recruitment (number of entering age-1 individuals on January 1), fraction of entering age-1 fish that were mature at the time of spawning, number of eggs per entering age-1 individual, percentage of individuals in and seaward of the Sacramento River–San Joaquin River confluence box at various times during the year (together with monthly average Sacramento–San Joaquin River Delta [hereafter, "Delta"] outflows), average daily fraction of larvae that were entrained in water diversions during a year, and annual fraction of adults that were entrained. Finally, we used a Lagrangian approach and reported the averaged values of *p* (proportion of maximum consumption) and temperature experienced by individuals for selected time periods in the simulations.

MODEL SIMULATIONS

Alternative Baselines

We configured four additional versions of the baseline model: fixed larval growth, size-dependent mortality, density-dependent mortality, and length-dependent maturity. We used the historical baseline simulation of 1995–2005 to help configure and calibrate the alternative baselines.

Fixed larval growth.—Model predictions of Delta Smelt abundance in the historical simulation were sensitive to larval growth rates, and we were uncertain about our formulation of larval feeding and bioenergetics. Use of a fixed duration for the larval stage eliminated variation in larval growth as a factor in year-to-year differences. Larval growth was fixed by specifying the larval duration in days rather than letting the transition from larva to juvenile be determined by length. We used the average larval duration over years from the baseline simulation (26 d) for all simulations with the fixed larval growth rate.

Size-dependent mortality.—Mortality in the original baseline version was constant within each stage but decreased with successive stages, so penalties in survival for slow growth occurred only through the delay in transition from larvae to postlarvae and from postlarvae to juveniles. Making mortality length dependent reflected the idea that vulnerability to predation mortality decreases with increasing size (Sogard 1997; Bailey and Duffy-Anderson 2010; Gislason et al. 2010), so that faster growth would increase cumulative survival regardless of how stage transitions were triggered. We assumed that mortality rate was a function of length (M_L; d^{-1}) for larvae through adults; we then fit the function to the constant stage-specific mortality rates from the baseline simulation, associating the rate with the midpoint length of each stage:

$$M_L = -0.034 + 0.165 \cdot L^{-0.322}. \tag{1}$$

We re-ran the 1995–2005 simulation and compared averaged annual stage-specific fractional survival rates between the baseline and the alternative with size-dependent mortality (Table 1) to confirm that this alternative produced mortality rates that were generally similar to those from the original baseline. Survival from yolk sac larva through age 2 was similar (4.4×10^{-5} in the baseline versus 3.5×10^{-5} under size-dependent mortality); juvenile survival increased (0.054 in the baseline; 0.073 under size-dependent mortality), and age-1 survival was approximately halved (0.092 in the baseline; 0.044 under size-dependent mortality).

Density-dependent mortality.—The original baseline version was set up as density independent because the recent Delta Smelt population is at such a low level that density-dependent effects seem unlikely. To allow for subsequent simulations at higher Delta Smelt densities, we included an alternative baseline with density-dependent mortality. The juvenile stage is the likely stage for density dependence based on general theory (Rothschild 1986; Cowan et al. 2000). Bennett (2005) and Maunder and Deriso (2011) found evidence for a density-dependent relationship between summer and fall Delta Smelt indices, and this relationship occurs in our simulation for the juvenile life stage. We assumed a multiplier of the juvenile daily mortality rate based on the normalized density of juveniles in each box on each day,

$$M' = M \cdot e^{3.0\left(\frac{D_t}{0.005}\right)}, \tag{2}$$

where D_t is the density of juveniles (number/m^3) and 0.005 is an average juvenile density (number/m^3).

We calibrated the value of 3.0 in equation (2) to obtain realistic maximum January adult abundances of about 20–25 million; the highest abundance estimate from the spring Kodiak trawl and fall midwater trawl (MWT) data during 1968–2006 was 24.3 million in 1981. We ran the model by repeating 1995 conditions from the historical simulation (high Delta Smelt survival) but with artificially increased egg production each year to generate a spawner–recruit curve under ever-increasing January adult abundances. We adjusted the multiplier in the exponent within equation (2) (final value = 3.0) until it generated a leveling off at high egg production that occurred roughly with about 20–25 million adults in January (Figure 1a). Juvenile-stage survival decreased with increasing population abundance from 0.06 to less than 0.01, resulting in a leveling off of age-1 recruits at about 20 million (Figure 1b). Abundance of age-1 recruits was similar to January adult abundance because most of the adults were age-1 individuals.

Length-dependent maturity.—The simple maturity rule (fish > 60 mm TL are mature) in the original baseline was substituted with a smoother, length-dependent maturity relationship (Figure 2). Model results were potentially sensitive to small

TABLE 1. Stage-specific durations (d) and survival (fraction) of Delta Smelt averaged over the 1995–2005 simulations for the original baseline and the alternative baseline that used size-dependent mortality.

	Duration (d)		Survival (fraction)	
Stage	Baseline	Size dependent	Baseline	Size dependent
Eggs	10.5	10.4	0.56	0.57
Yolk sac larvae	4.88	4.87	0.82	0.71
Larvae	26.3	26.0	0.23	0.25
Postlarvae	21.7	22.2	0.49	0.50
Juveniles	186	187	0.054	0.073
Age 1	365	365	0.092	0.044
Age 2	365	365	0.088	0.11

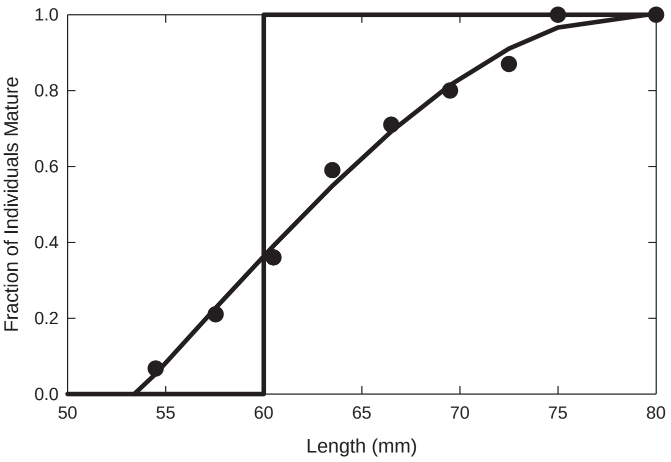

FIGURE 2. Fraction of Delta Smelt individuals that were mature as function of length for the baseline (60-mm cutoff) and the length-dependent maturity alternative. The points (circles) represent the fractions mature by length, estimated by assigning females (from the spring Kodiak trawl survey for 2002–2010) to 3-mm length bins and using ripe or spent individuals (condition codes 4–6) as mature.

changes in length of young of the year causing large changes in the mature fraction of individuals because typical lengths varied around 60 mm when maturity was determined. The relationship between fraction mature and fish length was fitted by allocating females that were sampled in the spring Kodiak trawl survey during 2002–2010 into 3-mm length bins and using ripe or spent individuals (codes 4–6) as mature. This resulted in an asymmetric relationship of fraction mature at around 60 mm (Figure 2). Use of other definitions for maturity resulted in relationships that were more symmetric at around 55–65 mm. We used the asymmetric relationship because it was justifiable based on the data and it provided a better test of model robustness.

Simulations under alternative baselines.—The 1995–2005 historical simulation with the original baseline (analyzed by Rose et al. 2013) was repeated with each of the four alternative baselines. We compared simulated January adult abundances and λ values among the original baseline and the four alternative versions. Results from a single simulation are presented. The individual-based model has stochastic aspects in assigning zooplankton biomass densities to channels and spawning temperatures to females, the *y* and *z* movements of the PTM, and the random component of behavioral movement. Because of the summing and averaging over many individuals and over time, population-level outputs (e.g., mean length at age, spatial distributions, and λ) varied by less than 5%—and often by less than 2%—among replicate simulations.

Good versus Bad Years

In this paper, we further explore the factors affecting the good year (1998) and bad year (2001) for Delta Smelt recruitment as identified in the analysis of the historical simulation (Rose et al. 2013). We performed a factorial simulation experiment to identify the conditions that caused the differences between water year 1998, which had the largest λ (2.45) within the baseline historical simulation, and water year 2001, which had the smallest λ (0.33) in the simulation. We varied five factors: salinity (*S*), temperature (*T*), zooplankton densities (*Z*), hydrodynamics (*H*), and eggs per entering age-1 individual (i.e., recruit) on January 1 (*E*). Each of these five factors was set to either its 1998 value or its 2001 value, resulting in a total of 32 (2^5) combinations.

Salinity.—Salinity affected the movement patterns of juveniles and adults and thus affected their spatial distribution and vulnerability to entrainment. The year 1998 was a high-outflow year, and salinities were very low for the modeled area from roughly March to August, after which salinity increased but remained below 5 psu (Figure 2b in Rose et al. 2013). Salinity in boxes down-estuary from the confluence was higher during the low-outflow year, 2001, than during 1998; this higher salinity occurred throughout 2001 except for a short period in March (Figure 2d in Rose et al. 2013). In the original baseline historical simulation, adults were located farther seaward with the salinity distribution in 1998. Average August outflow was 568 m^3/s in 1998 versus 90 m^3/s in 2001, and the percentage of adults that were in or seaward of the confluence box on September 1 was 97% during 1998 versus 67% during 2001 of the original baseline simulation (Figure 10e in Rose et al. 2013). The fraction of January adults that were entrained was 0.05 in 1998 versus 0.14 in 2001.

Temperature.—Temperature affected the initial date and duration of the spawning period; the egg and yolk sac development and mortality rates; and the bioenergetics (growth) of larvae, postlarvae, juveniles, and adults. When viewed systemwide, differences in temperature between 1998 and 2001 were not obvious (Figure 2a, c in Rose et al. 2013). More detailed analysis of the historical simulation using the average temperature experienced by model individuals showed two major differences between 1998 and 2001: (1) warmer fall and winter at the beginning of the water year and (2) cooler and delayed warming in the spring. Fall 1997 and winter 1998 were warmer than fall 2000 and winter 2001. During October 1–December 30, juveniles experienced an average temperature of 15.9°C in 1997 versus 15.0°C in 2000. Mean temperature experienced by these individuals (which became adults after January 1) during February 27–June 7 (the spawning period) was 14.8°C in 1998 versus 16.4°C in 2001. The warming in the spring also occurred later in 1998, and the average day of spawning was April 28 in 1998 versus April 6 in 2001.

Zooplankton.—The effect of switching 1998 and 2001 zooplankton densities would seem to be the simplest to interpret because this factor only affected feeding rate and therefore growth rate; however, the use of multiple prey groups made interpretation difficult. Dominant prey groups in the annual diets of postlarval, juvenile, and adult Delta Smelt in the baseline simulation were other calanoid adults and adult *Pseudodiaptomus*. The differences between 1998 and 2001 in the biomass densities of these two key prey groups were complicated (see Figure 3c versus 4c and Figure 3f versus 4f in Rose et al. 2013). Although adult *Pseudodiaptomus* biomasses were generally higher during summer and fall in 1998 than in 2001, biomasses of other calanoid adults during summer and fall were higher in 2001 and biomass in the southwest Suisun Bay box during winter and spring was much higher in 2001. Biomass densities of the other zooplankton groups also showed complicated differences. For example, the biomass density of adult *A. vernalis* was higher (and occurred at high levels for a longer period) in the Suisun Marsh box during 1998, but adult *Eurytemora* biomass density was higher in the southern Delta and eastern Delta boxes during 2001 (see Figure 3d versus 4d and Figure 3e versus 4e in Rose et al. 2013).

We relied on the *p*-value from the bioenergetics model to infer prey availability. The *p*-value reflects prey availability scaled for maximum consumption rate, which also depends on temperature. The historical simulation using the original baseline version showed that average *p*-values experienced by juveniles during the faster fall–winter growth (October 1–December 30) was 0.76 in 1997–1998 versus 0.68 in 2000–2001. This difference, in combination with warmer temperatures, led to longer recruits

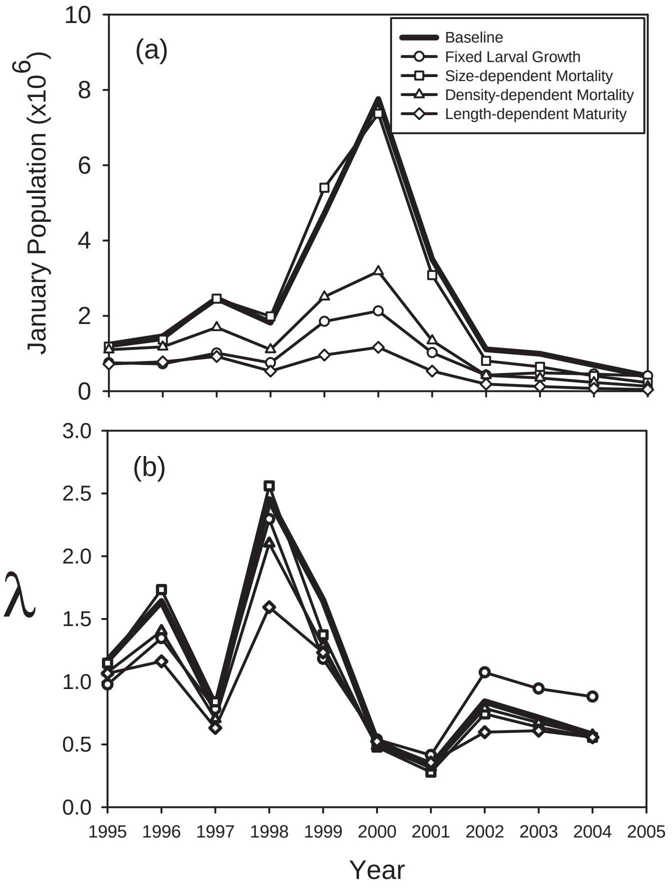

FIGURE 3. Simulated **(a)** annual adult Delta Smelt abundance in January and **(b)** finite population growth rate (λ; fraction per year), 1995–2005, for the original baseline simulation and the four alternative baseline simulations. The values of λ were determined by using an age-based Leslie matrix model applied to individual-based model output for each year. No value for 2005 is possible because the simulations ended on September 30, 2005; information through December 31, 2005, would be needed to estimate the matrix model for 2005.

on January 1 in 1998 than in 2001 (mean TL = 61.4 mm versus 56.5 mm). Averaged *p*-values in 1998 were also somewhat higher during the summer growth period (April 18–October 1) for young of the year (0.89 in 1998 versus 0.84 in 2001), although by October the mean lengths of young of the year were only slightly greater in 1998 than in 2001 (54 mm versus 52 mm).

Hydrodynamics.—Hydrodynamics affected the entrainment of yolk sac larvae, larvae, and postlarvae via the PTM; the entrainment of juveniles and adults; and the starting locations of new juveniles by determining the transport of larval life stages. Average May outflow was 1,922 m^3/s in 1998 versus 273 m^3/s in 2001, and the percentage of postlarvae that were in or seaward of the confluence box after transport (June 24) was 84% in 1998 versus 24% in 2001. Almost no larvae were predicted to be entrained during 1998, whereas the daily average entrainment loss was 1.2% in 2001.

Eggs per age-1 individual.—Unlike the other factors, which had readily available values for 1998 and 2001, the number of eggs per age-1 individual required additional calculations in the model to achieve 1998 or 2001 values in the factorial simulation experiment. The number of eggs per age-1 fish reflected growth that occurred in the fall and winter leading up to spawning. In the original historical simulation, the mean length of young of the year on October 1 was somewhat greater in 1997 (starting value for 1998) than in 2000 (54.0 mm versus 52.0 mm) due to the more favorable summer conditions in 1997 than in 2000. This small difference was amplified by warmer temperature and higher prey densities in the fall and winter of 1997, resulting in a mean length of 61.4 mm on January 1, 1998, versus 56.5 mm on January 1, 2001. These lengths straddled the 60-mm maturity cutoff, and whereas 72% of entering age-1 individuals were mature in 1998, only 15% of entering age-1 fish were mature in 2001 of the historical baseline simulation. Thus, although there were fewer recruits on January 1, 1998, than on January 1, 2001 (0.159×10^7 versus 0.258×10^7), the number of mature age-1 female spawners was greater in 1998 (0.287×10^6 versus 0.1105×10^6) and egg production was about 1.5 times higher in 1998 (0.942×10^9 versus 0.641×10^9).

In the historical baseline simulation, the average number of eggs per age-1 individual was 491.8 for 1998 versus 89.3 for 2001. We did not explicitly simulate the previous year's conditions for the simulation experiment, in which either 1998 or 2001 conditions were repeated year after year. Rather, we adjusted the fecundity of entering age-1 individuals each year when we projected spawning so that the total projected number of eggs divided by the number of simulated entering age-1 individuals would be either 491.8 or 89.3.

Simulations in the good year versus bad year experiment.—Simulations were for 15 years, with 4 years of spin-up using 1999 conditions as in the baseline simulations, followed by 11 years of 1 of the 32 combinations of 1998 or 2001 conditions repeated every year. We used the two extreme years because they provided the best contrast for separating out the effects of multiple factors and thus for identifying which factors were most important in determining year-class strength. Eleven years of repeated conditions were simulated in order to ensure that we had the long-term (equilibrium) population responses to the specified conditions; shorter simulations could be affected by initial conditions and still reflect aspects of the transient solutions. We refer to the 32 combinations by using the letters of the factors that were set to 2001 values (i.e., *S* for salinity, *T* for temperature, *Z* for zooplankton, *H* for hydrodynamics, and *E* for eggs per entering age-1 individual). For example, in the simulation labeled "*EH*," eggs per age-1 fish and hydrodynamics were set at 2001 values, while salinity, temperature, and zooplankton were set at 1998 values. We report λ averaged over years 10–14 of each 15-year simulation. As with the baseline simulations, results from a single simulation are presented because replicate simulations differed by less than 5% in their population-level outputs. Values of λ that were 25% and 50% higher than the

2001 value are shown for reference to aid in judging how close the other λ values were to the 2001 value.

Robustness

To confirm the robustness of results based on the original baseline, we also repeated all of the 32 simulation combinations under each of the four alternative baseline conditions. We only report the averaged λ for years 10–14 for four combinations (*ET*, *EH*, *ETH*, and *ETHS*) that resulted in low λ values to illustrate that the full set of combinations was robust to the alternative baselines. We focused on these four combinations because they resulted in low λ values near the 2001 value and because their robustness is particularly important, as they form the basis for identifying which factors determine how a good year differs from a bad year.

RESULTS

Alternative Baselines

The use of size-dependent mortality resulted in January adult abundances similar to those in the original baseline, while the alternative baselines with fixed larval growth, density-dependent mortality, and length-dependent maturity resulted in January abundances that were lower than those in the original baseline (Figure 3a). Lower peak abundances were expected for the density-dependent mortality version because juvenile survival was specified to decrease under high abundances. Larval growth (and therefore larval-stage survival) had an important influence on both good and bad years. Lower abundances under length-dependent maturity occurred because the maturity relationship was not symmetric around 60 mm (Figure 2) and thus would, on average, result in a lower fraction of young of the year becoming mature than was observed with the simple 60-mm rule in the original baseline.

Despite these differences in January abundances, λ values were very similar for all versions of the baseline, with the length-dependent maturity alternative differing the most from the original baseline (Figure 3b). Relatively high January adult abundance occurred in 2001 (Figure 3a), despite the lowest λ being observed in that year, because January abundance was related to conditions in the previous summer and fall and was not reflective of the spring and summer conditions in 2001. The high λ values during years prior to 2001 led to high January adult abundance in 2001. The temporal pattern in λ values for length-dependent maturity was the same as that for the original baseline, but values in all years were lower than baseline values, with the largest difference occurring in 1998 ($\lambda = 1.59$ for length-dependent maturity versus 2.45 for the original baseline). The original baseline and the four alternatives all identified 1998 as the best model year and 2001 as the worst model year for Delta Smelt.

Systematic Comparison of Best versus Worst Years

The intersimulation variability in λ values decreased and more combinations approached the 2001 value as the number of factors set to 2001 values increased (Figure 4). The percentage of combinations that resulted in λ values within 50% of the 2001 λ value increased from 0% when one factor was set to the 2001 value to 10% for two factors at 2001 values, 50% for three factors at 2001 values, and 60% for four factors at 2001 values. All but one of the combinations that generated a λ value within 50% of the 2001 value involved either eggs per age-1 individual or temperature being set at the 2001 value.

Juvenile growth in the fall prior to spawning (i.e., as reflected by the number of eggs per age-1 fish) was the most important single factor in making 2001 a bad year, although no single factor alone was sufficient to fully account for the poor conditions in 2001 relative to 1998 (Figure 4). Temperature (*T*) played an important secondary role (Figure 4, shaded circles), and hydrodynamics (*H*) played a more minor role; salinity (*S*) and zooplankton (*Z*) as single factors were unimportant. When one factor at a time was switched from 1998 to 2001 values (Figure 4, leftmost section), only eggs per age-1 fish (*E*) resulted in a λ value less than 1.0. The single factors *T* and *H* (each at the 2001 value) generated the second- and third-lowest λ values (1.1 and 1.5). As a single factor, *Z* (which determined

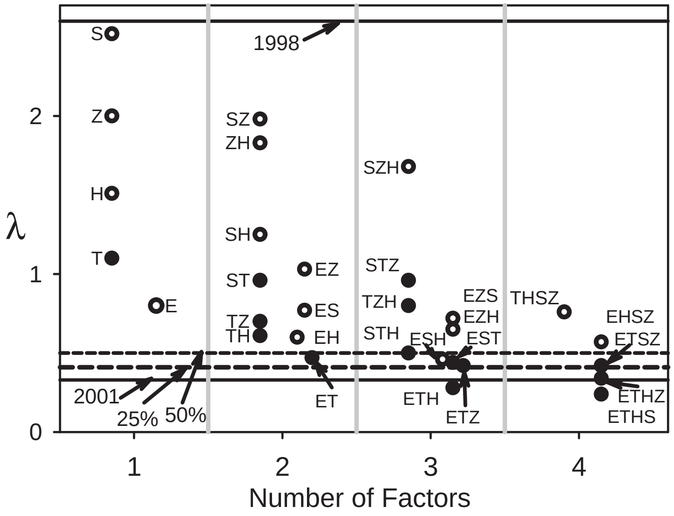

FIGURE 4. Contributions of five factors to differences between the best year (1998) and worst year (2001) for Delta Smelt. Each circle represents the mean finite population growth rate (λ) for years 10–14 of a 15-year simulation of repeated conditions for each factor (salinity [*S*], temperature [*T*], zooplankton [*Z*], hydrodynamics [*H*], and number of eggs per age-1 individual [*E*]) at either 1998 or 2001 values. Results are organized by the number of factors that were set to 2001 values (i.e., 1–4 factors; each combination code [e.g., "*STZ*"] lists the factors set at 2001 values); within each section, results with the number of eggs per age-1 individual at its 1998 value are shown on the left and results with that factor at its 2001 value are shown on the right. Shaded circles denote all combinations that included the 2001 temperature. The 1998 and 2001 values of λ are indicated by solid horizontal lines; the dotted horizontal lines represent λ values that are 25% and 50% higher than the 2001 value.

growth) generated a λ of 2.0, which was lower than the value for 1998 ($\lambda = 2.6$) but still much higher than the value for 2001 ($\lambda = 0.33$). When only *S* was set to the 2001 value, there was almost no effect on λ (2.52 versus 2.60).

All combinations of two factors set at 2001 values with eggs per age-1 individual at its higher 1998 value (left-side points in Figure 4, second section) generated λ values above 0.6; among these two-factor combinations, temperature and hydrodynamics at 2001 values together (*TH*) resulted in the lowest λ (0.61). The three lowest λ values all included 2001 temperature (Figure 4, shaded circles). The two-factor combinations that included the 2001 value for eggs per age-1 fish (right-side points in Figure 4, second section) resulted in λ values less than 1.0, and the *ET* and *EH* combinations produced λ values less than 0.6. Again, the lowest of these λ values was from the combination *ET* (Figure 4, shaded circle) and approached the λ value predicted for 2001 (0.47 versus 0.33).

Among the three-factor combinations set at 2001 values with eggs per age-1 individual set at the 1998 value (left-side points in Figure 4, third section), temperature and hydrodynamics were important. The highest λ (1.68) was predicted for the one combination that did not include 2001 temperature (*SZH*). The combinations with the three lowest λ values included the 2001 value for temperature (*STZ*, *TZH*, and *STH*; Figure 4, shaded circles); the two lowest of these λ values were from combinations that also included 2001 hydrodynamics ($\lambda = 0.8$ for *TZH* and 0.5 for *STH*).

When the number of eggs per age-1 fish was included as one of the three factors set at 2001 values (right-side points in Figure 4, third section), all λ values were less than 1.0. The combinations also including 2001 temperature (*ETH*, *ETZ*, and *EST*) generated the lowest λ values (0.28, 0.42, and 0.44, respectively), which were close to the λ value for 2001. The combinations that did not include 2001 temperature (Figure 4, open circles) generally had higher λ values (0.72 for *EZS* and 0.65 for *EZH*); the exception was *ESH*, which yielded a λ value (0.46) similar to those from the three combinations that included the 2001 temperature.

The number of eggs per age-1 individual and temperature continued to be very important in four-factor combinations. All four-factor combinations that included the 2001 value for eggs per age-1 fish (right-side points in Figure 4, fourth section) resulted in λ values less than 0.5, and those combinations that also included 2001 temperature (Figure 4, shaded circles) generated λ values that were close to the 2001 value. Of the four combinations that included the 2001 value for eggs per age-1 fish, the three combinations that also included 2001 temperature (*ETSZ*, *ETHZ*, and *ETHS*) all generated λ values less than 0.45, whereas the combination without temperature (*EHSZ*) generated the highest λ value (0.60). The remaining four-factor combination (*THSZ*; left-side point in Figure 4, fourth section), in which the number of eggs per age-1 individual was set at the 1998 value, generated the highest λ (0.85) observed for any four-factor combination.

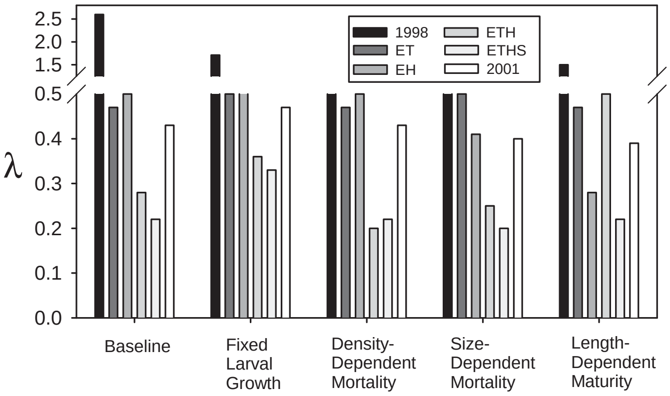

FIGURE 5. Averaged finite population growth rate (λ; years 10–14) of Delta Smelt under the four alternative baselines and the four factor combinations that resulted in low λ values near the value for 2001. Factors are salinity (*S*), temperature (*T*), zooplankton (*Z*), hydrodynamics (*H*), and number of eggs per age-1 individual (*E*); each combination code (e.g., "*ETH*") lists the factors that were set at 2001 values, and the remaining factors (i.e., with letters not shown) were set at 1998 values.

Robustness

The conditions leading to the good year (1998) were more sensitive to alternative baselines than the poor conditions leading to the bad year (2001; Figure 5). The four combinations (i.e., selected from Figure 4) that produced low λ values when set to their 2001 values under the original baseline generated similarly low λ values under the four alternative baselines. In contrast, the λ values varied more among the 1998 simulations. The alternative of density-dependent mortality produced the greatest reduction in λ for 1998 (λ decreased from 2.45 to 1.00). Larval growth and length-dependent maturity were also important in attaining the high λ predicted for 1998 in the original baseline. When larval growth was fixed at the overall average value (fixed duration), λ was reduced from 2.45 in the original baseline to 1.7; under length-based maturity, λ was reduced to 1.5. Size-dependent mortality was associated with the smallest reduction in the λ value for 1998 (λ decreased from 2.45 to 2.13).

DISCUSSION

Our analysis using a simulation experiment approach further clarified the relative influence of factors affecting Delta Smelt recruitment and population dynamics. In our companion paper (Rose et al. 2013), we compared conditions in 1998 with those in 2001 by using the 1995–2005 historical simulation. The five factors analyzed were inferred to be important in the historical simulation because their values differed, at least in some ways, between the best year and the worst year. In this paper, we systematically varied the five factors in a factorial simulation experiment to look for main and interaction effects. We moved away from the historical sequence of years and performed 15-year simulations with either 1998 or 2001 values repeated every year to allow the simulated population to reach a quasi-steady-state response. We also showed that our results, when viewed in a comparative mode, were generally robust to alternative versions of the baseline model.

Our results demonstrated that among the factors we examined, no single factor completely accounted for the difference between the high λ in the best year (1998) and the low λ in the worst year (2001). Growth of juveniles in the fall–winter, temperature, and hydrodynamics clearly had the strongest effects, but λ could not be brought down from its 1998 value to near its 2001 value without some combination of factors. Thus, our results support the growing consensus that no single factor explains the Delta Smelt decline that occurred during 1995–2005 (Bennett and Moyle 1996; Bennett 2005; Baxter et al. 2010; Thomson et al. 2010).

Although we have shown that growth conditions in fall–winter were an important factor, there are many ways to achieve the faster growth that was predicted for 1998 relative to 2001. The growth conditions in winter affected the lengths of entering age-1 fish on January 1, with a 1998 value of 60.2 mm versus a 2001 value of 58.8 mm, and consequently affected the fraction mature (0.55 versus 0.41) and the egg production per entering age-1 fish (502.6 versus 107.6). These values for 1998 and 2001 differ from those reported in Rose et al. (2013) because the present values are averaged from the repeated years in the simulation experiment, whereas in our other paper (Rose et al. 2013) we reported values for 1998 and 2001 within the historical simulation. The difference in predicted mean lengths between 1998 and 2001 was well within the range of observed interannual values (see Figure 6 in Rose et al. 2013). Our analysis did not, however, distinguish how juveniles attained greater lengths prior to becoming age 1 and spawning. We used 1998 and 2001 conditions, but other years can also generate similar differences in growth based on combinations of zooplankton conditions and temperature; essentially, any mechanism that allows new age-1 recruits to have a greater length prior to spawning would result in a high number of eggs per age-1 fish and would set the stage for a good year. This can be achieved via warmer winter temperature (as in 1998) or by higher zooplankton densities causing faster growth at any time from the previous summer through early spring. If zooplankton conditions are better at higher salinity (seaward), then hydrodynamics (via its effect on transport) or salinity could also produce faster growth by putting individuals in boxes with higher prey biomass densities. We did not systematically examine how temperature, zooplankton, hydrodynamics, and salinity during the growing season of the year before or during the winter–spring period could potentially combine to promote faster growth and larger spawners in the spring. Rather, we used the suite of conditions for 1998 and 2001 to contrast a good year with a bad year.

A second way to increase egg production without faster growth of spawners would be to increase young-of-the-year survival prior to spawning. Total egg production was calculated as the number of eggs per entering age-1 fish times the number of age-1 fish. Our results were robust to the size-dependent mortality and length-based maturity versions of the baseline, so the growth of adults affected the number of eggs per age-1 individual but not the abundance of age-1 fish. Higher Delta outflow at key times resulted in reduced entrainment, and hydrodynamics were consistently an important factor. Further analysis should explore spatial (box-scale) differences in mortality, which, if sufficient, could benefit the Delta Smelt via management manipulation of hydrodynamics and salinity, generating differences in starting age-1 abundances for spawning. We assumed that except for entrainment losses, mortality was stage dependent but not spatially variable.

Our results for the importance of food (zooplankton) are similar to those of Maunder and Deriso (2011), but we disagree about the roles of entrainment and density dependence. Maunder and Deriso (2011) used a stage-based life cycle model, and by introducing covariates into life stage survival (spawner–recruit) relationships, they determined that food abundance, temperature, predator abundance, and density dependence were the most important factors controlling the population dynamics of Delta Smelt. They further stated that there was some support for negative effects of water clarity and adult entrainment.

Our simulation experiment contrasting the best year versus the worst year agrees with the important role of temperature and zooplankton, but we did not examine the effects of predator abundance or water clarity. Maunder and Deriso (2011) used spring and summer zooplankton conditions: minimum *Eurytemora* and *Pseudodiaptomus* densities for April–June; average *Eurytemora* density for July; and average *Pseudodiaptomus* density for July–August. We found that fall, winter, and early spring growth was potentially important, at least for the comparison between 1998 and 2001. Maunder and Deriso (2011) examined a longer time period (1970–2006) that covered larger changes in the zooplankton community, and this could emphasize the importance of spring and summertime zooplankton relative to other factors, such as winter growth and its consequences for spring reproduction. We recommend that conditions in the winter and early spring and conditions from the year before be further evaluated for their potential to benefit Delta Smelt.

We disagree to some extent with Maunder and Deriso (2011) about the role of entrainment and density dependence. Examination of Figure 8 of Maunder and Deriso (2011) to assess the role of entrainment showed more agreement with our analysis than did their general statement of "some support for a negative relationship with . . . adult entrainment." They showed an approximately twofold increase in adults during 2002–2006 by eliminating entrainment. This agrees with our analysis, showing higher entrainment mortality during the same years as in our simulation; however, we would term their Figure 8 results as providing more than "some" support for a negative effect of adult entrainment. The Maunder and Deriso (2011) analysis covered a longer time period (1970–2006) than our analysis (1995–2005); thus, the role of covariates can differ and density dependence likely played a larger role at the earlier, higher abundance levels (see Bennett 2005). In addition, direct comparisons between the models are somewhat confounded because our analysis and the

Maunder and Deriso (2011) analysis shared some information, such as the entrainment estimates from Kimmerer (2008) and the spawner–recruit information from long-term monitoring.

Several statistical analyses of similar monitoring and covariate data as used by Maunder and Deriso (2011) also implicated various indicators of spring and summer zooplankton food availability as being important. Thomson et al. (2010) used Bayesian change point analysis to examine variation in the fall MWT index; Mac Nally et al. (2010) used multivariate autoregressive modeling to analyze the fall MWT index in a multispecies approach; and Miller et al. (2012) used Ricker spawner–recruit relationships to analyze the ratio of indices as survival indicators. These analyses all inferred that various combinations of water temperature, water clarity, zooplankton indicators, and entrainment were correlated to various degrees with the historical pattern in the Delta Smelt abundance indices.

Other assumptions that are inherent in our modeling merit further analyses as possible alternative versions of baseline conditions. The representation of predation on Delta Smelt was partially explored by using size-dependent mortality, but there are also temporal trends and spatial patterns to the key predators of Delta Smelt that could be important. Striped Bass *Morone saxatilis* and Largemouth Bass *Micropterus salmoides* show distinct spatial distributions within the San Francisco Estuary and have also exhibited recent temporal trends, with young Striped Bass declining and Largemouth Bass increasing (Nobriga and Feyrer 2007). Furthermore, exotic Mississippi Silversides *Menidia audens* are known to readily consume larval Delta Smelt and have increased substantially in recent years (Baerwald et al. 2012).

Another assumption worthy of investigation is that the Delta Smelt population in the individual-based model consisted of individuals that all exhibit the same migratory behavior. Limited field data indicate that there is partial or divergent migration (Secor 1999; Chapman et al. 2012) within the Delta Smelt population, with some individuals possibly remaining year-round in the Cache Slough region, which is located in the southwestern portion of our Sacramento River model box (Merz et al. 2011; Sommer et al. 2011). An alternative version of the baseline individual-based model could include some proportion of individuals that remain resident in some areas. Resident individuals, or individuals with reduced or altered migrations, could exhibit different growth because of spatial variation in temperature, zooplankton, and susceptibility to entrainment.

Our detailed individual-based approach is not commonly used to simulate the population dynamics of endangered fish species, although it can be adapted for use in the more traditional population viability analysis (PVA) and risk framework. The individual-based approach is increasingly being used to simulate fish population and community dynamics for purposes of answering ecological and fisheries management questions (DeAngelis and Mooij 2005). However, although the individual-based approach is usually mentioned in reviews of PVA approaches (e.g., Akçakaya and Sjögren-Gulve 2000; Morris et al. 2002; Petersen et al. 2008), the number of examples of its use specifically for PVA remains quite limited. Some commonly used general models apply an individual-based approach, but they employ a very simple representation of processes (e.g., Jarić et al. 2010). Examples in which a more mechanistic individual-based model approach was used include models of endangered birds (Letcher et al. 1998), turtles (Mazaris et al. 2005), and recruitment of Colorado Pikeminnow *Ptychocheilus lucius*. Using an individual-based approach very similar to our Delta Smelt modeling, Jager et al. (2001) analyzed the effects of habitat fragmentation by dams on the White Sturgeon *Acipenser transmontanus*, which is a species of concern and has been listed as endangered elsewhere. Population viability analysis usually involves many realizations of a modeled population trajectory to generate risk values. Our individual-based model cannot easily be used to perform thousands of simulations. A possible link to a PVA-type analysis of Delta Smelt would be to (1) use the individual-based model in a systematic way to create crude probability distributions for the elements of the Leslie matrix model (which can generate λ values with Monte Carlo simulation) or (2) use the coupled individual-based model and Leslie model to directly generate distributions of λ values. Once sets of λ values are obtained for a variety of environmental and biological conditions, they can be used in more traditional PVA projections of long-term persistence (see Morris et al. 2002).

Our analysis addresses several ongoing methodological issues in fish population dynamics: spatial dynamics in complex habitats, coupled biological–physical modeling, and recruitment and population dynamics at low abundances. The need for studies of long-term population dynamics to deal with spatial dynamics has recently been discussed (Giske et al. 1998; Struve et al. 2010), and approaches that deal with spatial variation explicitly are receiving greater attention (e.g., Kerr et al. 2010). Increasingly, fish-related management issues require an integrated approach that combines the physics of water with the biology of the fish and other biota (Shenton et al. 2012), and one method is the direct coupling of fine-scale hydrodynamics with long-term fish population dynamics (Buckley and Buckley 2010; Rose et al. 2010; Hinrichsen et al. 2011; Stock et al. 2011).

Our model expands on the classical particle tracking approach by simulating detailed biological processes, relatively complicated behavioral movement, and multiple generations. Our Delta Smelt model simulated growth, survival, reproduction, and movement of individual fish on the same spatial grid as the hydrodynamics, and the super-individual method allowed for 15-year simulations. Although PTMs are commonly embedded within hydrodynamics models (North et al. 2009; Hinrichsen et al. 2011), the PTMs typically do not include detailed descriptions of growth and reproduction. Rather, these studies usually invoke, at most, simple movement behavior as an addition to passive transport and are mostly used for short-term (<1 year) simulations (Miller 2007; Lett et al. 2009; Gallego 2011). However, a consequence of full life cycle modeling that includes juveniles and adults within a detailed spatial grid is that now we must simulate behavioral movement on relatively fine scales. Modeling behavioral movement is critical to ensure that individuals experience the appropriate conditions over time, but this remains a challenge (Watkins and Rose 2013). Delta Smelt movement patterns in our simulations were generally realistic but require further refinement.

Finally, much fish population modeling has focused on the effects of harvesting from high-number populations, whereas there is an increasing need to examine dynamics of fish populations at low abundances due to overharvest and in support of recovery plans for listed species (Keith and Hutchings 2012). The focus on harvesting leads to an emphasis on density-dependent mortality, often via the spawner–recruit relationship (Rose et al. 2001). Our approach differs from this by focusing on Delta Smelt population dynamics under density-independent conditions. We emphasized how individuals were transported through or navigated through their spatially complex and temporally varying habitat. Our analysis can be viewed as part of the broader idea of multiple factors within the match–mismatch theory of controls on young-of-the-year survival and therefore recruitment (Peck et al. 2012), coupled with the idea that adult bioenergetics are important for determining maturity and annual egg production (Neil et al. 1994; Rose et al. 2001). Because our model was density independent, all of the predicted variation in stage-specific survival rates was due to variation in how spatial distributions interacted with dynamic environmental conditions. Our results showed how the spatial and temporal positioning of all life stages each year (based on physical transport and salinity), combined with the pattern in daily water temperature and the amount of Delta outflow, affected the magnitude and location of egg production and the subsequent dynamic matching of larval and juveniles with their prey types, thus affecting recruitment success. However, even our modeling results were not simple to interpret, and therefore they also illustrate how spatially and temporally dynamic habitat can create complicated match–mismatch situations.

Delta Smelt have been at the center of escalating controversy in the San Francisco Estuary region for several decades (NRC 2010; Kimmerer 2011; Miller 2011). What initially arose as a conflict between water demands for export versus for the environment (including Delta Smelt) has metastasized as the number of ostensible factors behind the decline of Delta Smelt has grown (e.g., Mac Nally et al. 2010; Maunder and Deriso 2011; Miller et al. 2012). The conflict has now evolved into a complicated situation in which multiple factors operate in interactive ways and are continually being argued over in court (Delta Smelt Consolidated Cases 2010). Our results contribute to the growing number of examples showing that multiple factors affect aquatic ecosystems (Breitburg and Riedel 2005; Ormerod et al. 2010; Cloern and Jassby 2012) and that the search for a single factor controlling fish population dynamics is unlikely to be successful (e.g., Rose 2000; Krebs 2002; Hecky et al. 2010; Lindegren et al. 2011).

Our results to date suggest that management actions to benefit Delta Smelt must deal with multiple stressors that occur at different points in the life cycle. An increase in prey would induce relatively large responses in reproduction but may not be feasible. We showed that growth leading up to spawning was important for subsequent population growth; it remains to be seen whether it is possible to promote growth of Delta Smelt or higher young-of-the-year survival prior to spawning (fall–spring) via management actions. We also showed that no single factor can alone account for the differences between good and bad years and that promoting growth should be done in combination with other actions (if feasible) to (1) ensure good temperatures for summer growth and delayed spawning and (2) ensure sufficient outflow and avoidance of high entrainment (see results in Rose et al. 2013). Our results also demonstrate that expectations should be clearly stated, as most management actions are unlikely to generate large, immediate responses because the influence of stressors varies from year to year and because the reduction in a single stressor during any one year may be moderated by the conditions in other, non-manipulated stressors occurring in that year.

We envision two other areas for future analyses using the individual-based model. First, extending the model simulations for the periods before 1995 and after 2005 would allow for more comparisons and contrasts of good versus bad years to determine other combinations of factors that may be important; climate change scenarios should be included in these simulations to allow for future-looking comparisons. This would require use of the DSM2 hydrodynamic model or another hydrodynamic model and the development of synthetic temperature, salinity, and zooplankton data. Second, a more rigorous side-by-side comparison of the Maunder and Deriso (2011) model and our individual-based model would facilitate an understanding of the relative effects of key stressors on Delta Smelt population dynamics. The population dynamics and reasons for the decline of Delta Smelt are complex. However, complexity is not a reason to avoid rigorous quantitative analyses—indeed, it is perhaps the best reason to develop and compare alternative modeling approaches.

Abstract.— Fall, late-fall, spring, and winter-run Chinook salmon (*Oncorhynchus tshawytscha*) and Steelhead/Rainbow trout (*Oncorhynchus mykiss*) spawn in the Sacramento River and tributaries in California's Central Valley upstream of Red Bluff Diversion Dam (RBDD) throughout the year. Sampling of juvenile anadromous fish at RBDD allows for year-round quantitative production and passage estimates of all runs of Chinook and *O. mykiss*. Incidental capture of Green Sturgeon (*Acipenser medirostris*) and various Lamprey species (*Lampetra spp. and Entosphenus tridentatus)* has occurred throughout juvenile Chinook monitoring activities since 1995. This compendium report addresses, in detail, juvenile anadromous fish monitoring activities at RBDD for the period April 4, 2002 through September 30, 2013.

Sampling was conducted along a transect using four 8-foot diameter rotary-screw traps attached via aircraft cables directly to RBDD. Trap efficiency (i.e., the proportion of the juvenile salmonid population passing RBDD captured by traps) was modeled with percent of river discharge sampled (%*Q*) to develop a simple least-squares regression equation. Chinook and *O. mykiss* passage were estimated by employing the trap efficiency model. The ratio of fry to pre-smolt/smolts passing RBDD was variable among years. Therefore, juvenile passage was standardized to determine juvenile production by estimating a fry-equivalent Juvenile Production Index (JPI) for among-year comparisons. Catch per unit volume (CPUV) was used as an index of relative abundance for Green Sturgeon and Lamprey species. Abiotic data collected or calculated throughout sample efforts included: water temperature, flow, turbidity, and moon illuminosity (fraction of moon illuminated). The abiotic variables were analyzed to determine if relationships existed throughout the migration periods of the anadromous species.

A trap efficiency model developed in 2000 to estimate fish passage demonstrated improved correlation between 2002 and 2013 with the addition of 85 mark-recapture trials. The model's *r*-squared value improved greatly with the addition of numerous mark-recapture trials that used wild fry size-class salmon over a variety of river discharge levels. Total passage estimates including annual effort values with 90% confidence intervals (CI) are presented, by brood year, for each run of Chinook. Fry and pre-smolt/smolt Chinook passage estimates with 90% CI's are summarized annually by run in Appendix 1. Comparisons of relative variation within and between runs of Chinook were performed by calculating Coefficients of Variation (CV). Fall Chinook annual total passage estimates ranged between 6,627,261 and 27,736,868 juveniles for brood years 2002-2012 ($\bar{y}$ = 14,774,923, CV = 46.2%). On average, fall Chinook passage was composed of 74% fry and 26% pre-smolt/smolt size-class fish (SD = 10.3). Late-fall

Chinook annual total passage estimates ranged between 91,995 and 2,559,519 juveniles for brood years 2002-2012 (ȳ = 447,711, CV = 159.9%). On average, late-fall Chinook passage was composed of 38% fry and 62% pre-smolt/smolt size-class fish (SD = 22.5). Winter Chinook annual total passage estimates ranged between 848,976 and 8,363,106 juveniles for brood years 2002-2012 (ȳ = 3,763,362, CV = 73.2%). On average, winter Chinook passage was composed of 80% fry and 20% pre-smolt/smolt size-class fish (SD = 11.2). Spring Chinook annual total passage estimates for spring Chinook ranged between 158,966 and 626,925 juveniles for brood years 2002-2012 (ȳ = 364,508, CV = 45.0%). On average, spring Chinook passage was composed of 54% fry and 46% pre-smolt/smolt size-class fish (SD = 20.0). Annual total passage estimates for *O. mykiss* ranged between 56,798 and 151,694 juveniles for calendar years 2002-2012 (ȳ = 116,272, CV = 25.7).

A significant relationship between the estimated number of adult females and fry-equivalent fall Chinook production estimates was detected ($r^2 = 0.53$, df = 10, $P = 0.01$). Recruits per female were calculated and ranged from 89 to 1,515 (ȳ = 749). Egg-to-fry survival estimates averaged 13.9% for fall Chinook. A significant relationship between estimated number of females and fry-equivalent late-fall Chinook production estimates was detected ($r^2 = 0.67$, df = 10, $P = 0.002$). Recruits per female were calculated and ranged from 47 to 243 (ȳ = 131). Egg-to-fry survival estimates averaged 2.8% for late-fall Chinook. A significant relationship between estimated number of females and fry-equivalent winter Chinook production estimates was detected ($r^2 = 0.90$, df = 10, $P < 0.001$). Recruits per female were calculated and ranged from 846 to 2,351 (ȳ = 1,349). Egg-to-fry survival estimates averaged 26.4% for winter Chinook. No significant relationship between estimated number of females and fry-equivalent spring Chinook production estimates was detected ($r^2 = 0.00$, df = 10, $P = 0.971$). Recruits per female were calculated and ranged from 1,112 to 8,592 (ȳ = 3,122). Egg-to-fry survival estimates averaged 61.5% for spring Chinook. Spring Chinook juvenile to adult correlation values appear unreasonable and well outside those found for other runs and from other studies.

Catch of Green Sturgeon was highly variable, not normally distributed and ranged between 0 and 3,701 per year (median = 193). Catch was primarily composed of recently emerged, post-exogenous feeding larvae. The 10-year median capture total length averaged 27.3 mm (SD = 0.8). Green Sturgeon annual CPUV was typically very low and ranged from 0.0 to 20.1 fish/ac-ft (ȳ = 2.5 fish/ac-ft, SD = 5.9). Data were positively skewed and median annual CPUV was 0.8 fish/ac-ft.

Lamprey species sampled included adult and juvenile Pacific Lamprey (*Entosphenus tridentatus*) and to a much lesser extent River Lamprey (*Lampetra ayresi*) and Pacific Brook Lamprey (*Lampetra pacifica*). Unidentified lamprey ammocoetes and Pacific Lamprey composed 99.8% of all captures, 24% and 75%, respectively. River Lamprey and Pacific Brook Lamprey composed the remaining 0.2%, combined. Lamprey captures occurred throughout the year between October and September. Lamprey ammocoete annual relative abundance ranged from 3.6 to 11.7 fish/ac-ft (ȳ = 6.8 fish/ac-ft, SD = 2.6). Overall, these data were normally distributed as median annual CPUV was 6.5 fish/ac-ft, similar to the mean value. Pacific Lamprey macropthalmia annual relative abundance was generally higher than ammocoete relative abundance and ranged from 2.1 to 112.8 fish/ac-ft ($\bar{y}$ = 41.0 fish/ac-ft, SD = 34.7). Overall, Pacific Lamprey data was slightly positively skewed and median CPUV was 34.1 fish/ac-ft.

Tabular summaries of the abiotic conditions encountered during each annual capture period were summarized for each run of salmon, *O. mykiss*, Green Sturgeon and Lamprey species. The range of temperatures experienced by Chinook fry and pre-smolt/smolts in the last 11 years of passage at RBDD have been within the optimal range of temperature tolerances for juvenile Chinook survival. Green Sturgeon have likely benefitted from temperature management efforts aimed at winter Chinook spawning and production, albeit less comprehensively. Lamprey species have also likely benefitted from temperature management as temperatures for early life stages of Lamprey in the mainstem Sacramento River appear to have been, on average, optimal in the last 11 years.

The relationship between river discharge, turbidity, and fish passage are complex in the Upper Sacramento River where ocean and stream-type Chinook of various size-classes (i.e., runs, life stages and ages) migrate daily throughout the year. Fish passage increases often coincided with an increase in turbidity which were sampled more effectively than increases in river discharge. A positive bias of fish passage estimates may result if the peak turbidity event was sampled following an un-sampled peak flow event. The importance of the first storm event of the fall or winter period cannot be overstated. Smolt passage and juvenile Lamprey passage increase exponentially and fry passage can be significant during fall storm events.

Rotary trap passage data indicated fry size-class winter Chinook exhibit decreased nocturnal passage levels during and around the full moon phase in the fall. Pre-smolt/smolt winter Chinook appeared less influenced by nighttime light levels and much more influenced by changes in discharge levels. Spring, fall and late-fall Chinook fry exhibited varying degrees of decreased passage during full moon periods, albeit storms and related hydrologic influx dominated peak migration periods.

Introduction

The United States Fish and Wildlife Service (USFWS) has conducted direct monitoring of juvenile Chinook salmon (*Oncorhynchus tshawytscha)* passage at Red Bluff Diversion Dam (RBDD; RM 243) on the Sacramento River, CA since 1994 (Johnson and Martin 1997). Martin et al. (2001) developed quantitative methodologies for indexing juvenile Chinook passage using rotary-screw traps to assess the impacts of the RBDD Research Pumping Plant. Absolute abundance (production and passage) estimates were needed to determine the level of impact from the entrainment of salmonids and other fish community populations through experimental 'fish friendly' Archimedes and internal helical pumps (Borthwick and Corwin 2001). The original project objectives were met by 2000 and funding of the project was discontinued.

In 2001, funding was secured through a CALFED Bay-Delta Program grant for three years of annual monitoring operations to determine the effects of restoration activities in the Upper Sacramento River aimed primarily at winter Chinook[1] salmon. Through various amendments, extensions, and grant approvals by the CALFED Ecosystem Restoration Program, the State of California based funding source lasted until 2008. At this point, the State of California defaulted on their funding agreement and internal USFWS funding sources through the Central Valley Project Improvement Act (CVPIA) bridged the gap for a period of time until State funding was restored. The US Bureau of Reclamation, the primary proponent of the Central Valley Project (CVP) of which this project provides monitoring and abundance trend information, has funded this project since 2010 due to regulatory requirements contained within the Biological Opinion for the Operations and Criteria Plan for the CVP (NMFS 2009).

Protection, restoration, and enhancement of anadromous fish populations in the Sacramento River and its tributaries is an important element of the CVPIA Section 3402. The CVPIA has a specific goal to double populations of anadromous fishes in the Central Valley of California. Juvenile salmonid production monitoring is an important component authorized under Section 3406 (b)(16) of CVPIA and has funded many anadromous fish restoration actions which were outlined in the CVPIA Anadromous Fisheries Restoration Program (AFRP) Working Paper (USFWS 1995), and Draft Restoration Plan (USFWS 1997; finalized in 2001).

---

[1] The National Marine Fisheries Service first listed Winter-run Chinook salmon as threatened under the emergency listing procedures for the ESA (16 U.S.C.R. 1531-1543) on August 4, 1989 (54 FR 32085). A proposed rule to add winter Chinook salmon to the list of threatened species beyond expiration of the emergency rule was published by the NMFS on March 20, 1990 (55 FR 10260). Winter Chinook salmon were formally added to the list of federally threatened species by final rule on November 5, 1990 (55 FR 46515), and they were listed as a federally endangered species on January 4, 1994 (59 FR 440). Critical habitat for winter Chinook salmon has been designated from Keswick Dam (RM 302) to the Golden Gate Bridge (58 FR 33212; June 16, 1993). Winter Chinook salmon have been listed as endangered under the CESA since September 22, 1989 (California Code of Regulations, Title XIV, Section 670.5). Their federal endangered status was reaffirmed in June 2005 (70 FR 37160).

Since 2002, the USFWS rotary trap winter Chinook juvenile production indices (JPI's) have primarily been used in support of production estimates generated from carcass survey derived adult escapement data using the National Oceanic and Atmospheric Administration's (NOAA) Juvenile Production Estimate Model. Martin et al. (2001) stated that RBDD was an ideal location to monitor juvenile winter Chinook production because (1) the spawning grounds occur almost exclusively above RBDD (Vogel and Marine 1991; Snider et al. 1997, USFWS 2011), (2) multiple traps could be attached to the dam and sample simultaneously across a transect, and (3) operation of the dam could control channel morphology and hydrological characteristics of the sampling area providing for consistent sampling conditions for purposes of measuring juvenile fish passage.

Fall, late-fall, spring, and winter-run Chinook salmon and Steelhead/Rainbow Trout (*Oncorhynchus mykiss*) spawn in the Sacramento River and tributaries upstream of RBDD throughout the year resulting in year-round juvenile salmonid passage (Moyle 2002). Sampling of juvenile anadromous fish at RBDD allows for year-round quantitative production and passage estimates of all runs of Chinook and Steelhead/Rainbow trout. Timing and abundance data have been provided in real-time for fishery and water operations management purposes of the CVP since 2004[2]. Since 2009, confidence intervals, indicating uncertainty in weekly passage estimates, have been included in real-time bi-weekly reports to allow better management of available water resources and to reduce impact of CVP operations on both federal Endangered Species Act (ESA) listed and non-listed salmonid stocks. Currently, Sacramento River winter Chinook are ESA listed as endangered. Central Valley spring Chinook and Central Valley Steelhead (hereafter *O. mykiss)* are listed as threatened within the Central Valley Endangered Species Unit.

Incidental capture of Green Sturgeon (*Acipenser medirostris*) and various Lamprey species (*Lampetra spp. and Entosphenus sp.)* has occurred throughout juvenile Chinook monitoring activities at RBDD since 1995 (Gaines and Martin 2002). Although rotary traps were designed to capture outmigrating salmonid smolts, data from the incidental capture of sturgeon and lamprey species has become increasingly relied upon for basic life-history information and as a measure of relative abundance and species trend data. The Southern distinct population segment of the North American Green Sturgeon was proposed for listing as threatened under the Federal ESA on April 7, 2006 (FR 17757) which then took effect June 6, 2006. Pacific Lamprey (*Entosphenus tridentatus*) are thought to be extirpated from at least 55% of their historical habitat and have been recognized by the USFWS as a species needing a comprehensive plan to conserve and restore these fish (Goodman and Reid 2012).

The objectives of this compendium report are to: (1) summarize the estimated abundance of all four runs of Chinook salmon and *O. mykiss* passing RBDD for brood

---

[2] Real-time biweekly reports located for download at: http://www.fws.gov/redbluff/rbdd_biweekly_final.html

years (BY) 2002 through 2012, (2) estimate annual relative abundance of Green Sturgeon and Lamprey species production for eleven consecutive years, (3) define temporal patterns of abundance for all anadromous species passing RBDD, (4) correlate juvenile salmon production with adult salmon escapement estimates, (5) perform exploratory data analyses of potential environmental covariates driving juvenile fish migration trends, and (6) describe various life-history attributes of anadromous juvenile fish produced in the Upper Sacramento River as determined through long-term monitoring efforts at RBDD.

This compendium report addresses, in detail, our juvenile anadromous fish monitoring activities at RBDD for the period April 4, 2002 through September 30, 2013. This report includes JPI's and relative abundance estimates for the 2002-2012 brood year emigration periods and will be submitted to the California Department of Fish and Wildlife to comply with contractual reporting requirements for Ecosystem Restoration Program Grant Agreement Number P0685507 and to the US Bureau of Reclamation who funded in part or in full the surveys from years 2008 through 2013 (Interagency Agreement No. R10PG20172).

Study Area

The Sacramento River originates in Northern California near Mt. Shasta from the springs of Mt. Eddy (Hallock et al. 1961). It flows south through 370 miles of the state draining numerous slopes of the coast, Klamath, Cascade, and Sierra Nevada ranges and eventually reaches the Pacific Ocean via San Francisco Bay (Figure 1). Shasta Dam and its associated downstream flow regulating structure, Keswick Dam, have formed a complete barrier to upstream anadromous fish passage since 1943 (Moffett 1949). The 59-river mile (RM) reach between Keswick Dam (RM 302) and RBDD (RM 243) supports areas of intact riparian vegetation and largely remains unobstructed. Within this reach, several major tributaries to the Sacramento upstream of RBDD support various Chinook salmon spawning populations. These include Clear Creek and Cottonwood Creek (including Beegum Creek) on the west side of the Sacramento River and Cow, Bear, Battle and Payne's Creek on the east side (Figure 1). Below RBDD, the river encounters greater anthropogenic impacts as it flows south to the Sacramento-San Joaquin Delta. Impacts include, but are not limited to, channelization, water diversion, agricultural and municipal run-off, and loss of associated riparian vegetation.

RBDD is located approximately 1.8 miles southeast of the city of Red Bluff, California (Figure 1). The dam is 740-feet (ft) wide and composed of eleven, 60-ft wide fixed-wheel gates. Between gates are concrete piers 8-ft in width. The USBR's dam operators were able to raise the RBDD gates allowing for run-of-the-river conditions or lower them to impound and divert river flows into the Tehama-Colusa and Corning canals. USBR operators generally raised the RBDD gates from September 16 through May 14 and lowered them May 15 through September 15 during the years 2002-2008. As of the spring of 2009, the RBDD gates were no longer lowered prior to June 15 and were raised by the end of August or earlier (NMFS 2009) in an effort to reduce the impact to spring Chinook salmon and Green Sturgeon. Since the fall of 2011, the RBDD gates have been left in the raised position allowing unobstructed upstream and downstream passage of adult and juvenile anadromous fish. The RBDD has been replaced by a permanent pumping plant upstream of the RBDD and the facilities have been relinquished to the Tehama Colusa Canal Authority as of spring 2012. Mothballing of the RBDD infrastructure was scheduled to occur in 2014.

Methods

Sampling Gear.—Sampling was conducted along a transect using four 8-ft diameter rotary-screw traps (E.G. Solutions® Corvallis, Oregon) attached via aircraft cables directly to RBDD. The horizontal placement of rotary traps across the transect varied throughout the study but generally sampled in the river-margin (east and west river-margins) and mid-channel habitats simultaneously (Figure 2). Rotary traps were positioned within these *spatial zones* unless sampling equipment failed, river depths were insufficient (< 4-ft), or river hydrology restricted our ability to sample with all traps (water velocity < 2.0 ft/s).

Sampling Regimes.—In general, rotary traps sampled continuously throughout 24-hour periods and samples were processed once daily. During periods of high fish abundance, elevated river flows, or heavy debris loads, traps were sampled multiple times per day, continuously, or at randomly pre-selected periods to reduce incidental mortality. When abundance of Chinook was very high, sub-sampling protocols were implemented to reduce listed species take and incidental mortality in accordance with National Marine Fisheries Service (NMFS) Section 10(a)(1)(A) research permit terms and conditions. The specific sub-sampling protocol implemented was contingent upon the number of Chinook captured or the probability of successfully sampling various river conditions. Initially, rotary trap cones were structurally modified to only sample one-half of the normal volume of water entering the cones (Gaines and Poytress 2004). If further reductions in capture were needed, the number of traps sampled was reduced from four to three. During storm events and associated elevated river discharge levels, each 24-hour sampling period was divided into four or six non-overlapping strata and one or two strata was randomly selected for sampling (Martin et al 2001). Estimates were extrapolated to un-sampled strata by dividing catch by the strata-selection probability (i.e., $P = 0.25$ or 0.17). If further reductions in effort were needed or river conditions were intolerable, sampling was discontinued or not conducted. When days or weeks were unable to be sampled, mean daily passage estimates were imputed for missed days based on weekly or monthly mean daily estimates (i.e., interpolated).

Data Collection.—All fish captured were anesthetized, identified to species, and enumerated with fork lengths (FL) measured to the nearest millimeter (mm). When capture of Chinook juveniles exceeded approximately 200 fish/trap, a random sub-sample of the catch to include approximately 100 individuals was measured, with all additional fish being enumerated and recorded. Chinook salmon race was assigned using length-at-date criteria developed by Greene[3] (1992). Juvenile salmon were assigned to a fry or pre-smolt/smolt life stage based on their fork length. Individuals ≤ 45 mm were classified as fry, and individuals ≥ 46 mm were classified as pre-smolt/smolts.

O. mykiss between 80 and 200-mm fork length were weighed to the nearest gram using a digital scale with a stated accuracy of +/- 0.5 grams. This size range was selected to reduce the influence of measurement error for fish lengths <80 mm (Pope and Kruse 2007). Additionally, state and federal permit regulations restricted the use of anesthetizing agents for fish that may be consumed by the public (i.e., fish >200mm). *O. mykiss* were visually assessed and assigned a life-stage rating based on morphological features following protocols developed by the Comprehensive Assessment and Monitoring Program (CAMP; USFWS 1997). Furthermore, *O. mykiss* annual weight-length regression coefficients were generated by transforming (Log_{10}) the weight and fork length data to create a linear regression equation:

$$\mathrm{Log}_{10}(\text{Total Weight}) = b(\mathrm{Log}_{10}\text{Fork Length}) + a$$

Confidence interval overlap between the annual slope coefficients was used to test if the annual *O. mykiss* growth rates between years were significantly different (Pope and Kruse 2007). If the 95% confidence intervals around any two slope coefficients did not overlap they were considered significantly different.

Green Sturgeon and Lamprey species were measured for total length (TL) to the nearest mm. Identification of Green Sturgeon larvae was possible based on meristics for individuals > 46 mm TL and assumed for all individuals <46 mm[4]. Lamprey species were identified to the genus level during the ammocoete stage and described as ammocoetes. Adult and macropthalmia (eyed juveniles) were identified to the genus and species level using dentition patterns, specifically by the number of inner lateral horny plates on the sucking disk (Moyle 2002).

Trap Effort. Data quantifying effort by each rotary trap were collected at each trap sampling and included the length of time each trap sampled (expressed as sample weight with 1440 minutes equal to 1.0 for 24-hour samples), water velocity immediately in front of the cone at a depth of 2-ft, and depth of cone “opening” submerged. Water velocity was measured using a General Oceanic® Model 2030 flowmeter. These data collectively were used to calculate the estimated volume of water sampled by traps (X_i)

---

[3] Generated by Sheila Greene, California Department of Water Resources, Environmental Services Office, Sacramento (May 8, 1992) from a table developed by Frank Fisher, California Department of Fish and Game, Inland Fisheries Branch, Red Bluff (revised February 2, 1992). Fork lengths with overlapping run assignments were placed with the latter spawning run.

[4] To confirm the identification of larval sturgeon, samples were transferred to UC Davis to be grown-out between 1996 and 1997 (Gaines and Martin 2002) and annual subsamples of larvae were sent to UC Davis for genetic analyses between 2003 and 2012 (Israel et al 2004, Israel and May 2010). To date, all samples have been confirmed to be Green Sturgeon.

in acre-feet (ac-ft). Trap effort data were then standardized to a sample weight of 1.0 for within- and between-day comparisons. Individual (X_i) data were summed for the number of traps operating within a 24-hour sample period to estimate daily water volume sampled (X_d). The percent river volume sampled by traps (%Q_d) was estimated as the ratio of river volume sampled (X_d) to total river volume passing RBDD in acre-feet. River volume (Q_d) was obtained from the United States Geological Survey gauging station at Bend Bridge at RM 258 (USGS site no. 11377100, http://waterdata.usgs.gov/usa/nwis/uv?site_no=11377100). Daily river volume at RBDD was adjusted from Bend Bridge river flows by subtracting daily RBDD diversions, when applicable.

Sampling Effort.— Annual rotary trap sampling effort was quantified by assigning a value of 1.00 to a sample consisting of four, 8-ft diameter rotary-screw traps sampling 24 hours daily, three hundred and sixty-five days a year. Annual values <1.00 represent occasions where less than four traps were sampling, traps were structurally modified to sample only one-half the normal volume of water, or when less than the entire year were sampled. Annual passage estimate effort was calculated by summing the total number of days passage was estimated, based on 3 or 4 traps sampling (minimum required to generate passage estimate; Martin et al. 2001), and divided by the sum of the annual total number of days sampled plus the number of days unsampled.

Mark-Recapture Trials.— Chinook collected as part of daily samples were marked with bismark brown staining solution (Mundie and Traber 1983) prepared at a concentration of 21.0 mg/L of water. Fish were stained for a period of 45-50 minutes, removed, and allowed to recover in fresh water. Marked fish were held for 6-24 hours before being released 2.5-miles upstream from RBDD after official sunset. Recapture of marked fish was recorded for up to five days after release. Trap efficiency was calculated based on the proportion of recaptures to total fish released (i.e., mark-recapture trials). Trials were conducted as fish numbers and staffing levels allowed under a variety of river discharge levels and trap effort combinations.

Trap Efficiency Modeling.— To develop a trap efficiency model, mark-recapture trials were conducted as noted above. Estimated trap efficiency (i.e., the proportion of the juvenile population passing RBDD captured by traps; $\hat{T}_d$) was modeled with %Q to develop a simple least-squares regression equation (eq. 5). The equation (slope and intercept) was then used to calculate daily trap efficiencies based on daily estimated river volume sampled. Each successive year of mark-recapture trials were added annually to the original trap efficiency model developed by Martin et al. (2001) on July 1 of each year.

Daily Passage Estimates ($\hat{P}_d$).—The following procedures and formulae were used to derive daily and weekly estimates of total numbers of unmarked Chinook and *O. mykiss* passing RBDD. We defined C_{di} as catch at trap i (i = 1,…,t) on day d (d = 1,…,n), and X_{di} as volume sampled at trap *i* (*i* = 1,…*t*) on day *d* (*d* = 1,…*n*). Daily salmonid catch and water volume sampled were expressed as:

1. $$C_d = \sum_{i=1}^{t} C_{di}$$

and,

2. $$X_d = \sum_{i=1}^{t} X_{di}$$

The *%Q* was estimated from the ratio of water volume sampled (X_d) to river discharge (Q_d) on day *d*.

3. $$\%\hat{Q}_d = \frac{X_d}{Q_d}$$

Total salmonid passage was estimated on day *d* (*d* = 1,…,*n*) by

4. $$\hat{P}_d = \frac{C_d}{\hat{T}_d}$$

where,

5. $$\hat{T}_d = (a)(\%\hat{Q}_d) + b$$

and, $\hat{T}_d =$ estimated trap efficiency on day *d*.

Weekly Passage ($\hat{P}$).—Population totals for numbers of Chinook and *O. mykiss* passing RBDD each week were derived from $\hat{P}_d$ where there are *N* days within the week:

6. $$\hat{P} = \frac{N}{n} \sum_{d=1}^{n} \hat{P}_d$$

Estimated Variance.—

7. $$Var(\hat{P}) = (1 - \frac{n}{N}) \frac{N^2}{n} s^2_{\hat{p}_d} + \frac{N}{n} \left[\sum_{d=1}^{n} Var(\hat{P}_d) + 2 \sum_{i \neq j}^{n} Cov(\hat{P}_i, \hat{P}_j) \right]$$

The first term in eq. 7 is associated with sampling of days within the week.

8. $$s^2_{\hat{P}_d} = \frac{\sum_{d=1}^{n}(\hat{P}_d - \hat{\bar{P}})^2}{n-1}$$

The second term in eq. 7 is associated with estimating $\hat{P}_d$ within the day.

9. $$Var(\hat{P}_d) = \frac{\hat{P}_d(1-\hat{T}_d)}{\hat{T}_d} + Var(\hat{T}_d)\frac{\hat{P}_d(1-\hat{T}_d) + \hat{P}_d{}^2\hat{T}_d}{\hat{T}_d^3}$$

where,

10. $Var(\hat{T}_d) =$ error variance of the trap efficiency model

The third term in eq. 7 is associated with estimating both $\hat{P}_i$ and $\hat{P}_j$ with the same trap efficiency model.

11. $$Cov(\hat{P}_i, \hat{P}_j) = \frac{Cov(\hat{T}_i, \hat{T}_j)\hat{P}_i\hat{P}_j}{\hat{T}_i\hat{T}_j}$$

where,

12. $$Cov(\hat{T}_i, \hat{T}_j) = Var(\hat{\alpha}) + x_i Cov(\hat{\alpha}, \hat{\beta}) + x_j Cov(\hat{\alpha}, \hat{\beta}) + x_i x_j Var(\hat{\beta})$$

for some $\hat{T}_i = \hat{\alpha} + \hat{\beta}x_i$

Confidence intervals (CI) were constructed around $\hat{P}$ using eq. 13.

13. $$P \pm t_{\alpha/2, n-1}\sqrt{Var(\hat{P})}$$

Annual JPI's were estimated by summing $\hat{P}$ across weeks.

14. $$JPI = \sum_{week=1}^{52}\hat{P}$$

Fry-Equivalent Chinook Production Estimates.—The ratio of Chinook fry (<46 mm FL) to pre-smolt/smolts (>45 mm FL) passing RBDD was variable among years. Therefore, we standardized juvenile production by estimating a fry-equivalent JPI for among-year comparisons. Fry-equivalent JPI's were estimated by the summation of fry JPI and a weighted (1.7:1) pre-smolt/smolt JPI (inverse value of 59% fry-to-presmolt/smolt survival; Hallock undated). Rotary trap JPI's could then be directly compared to determine variability in production between years.

Relative Abundance.—Catch per unit volume (CPUV; Gaines and Martin 2002) was used as an index of relative abundance (RA) for Green Sturgeon and Lamprey species at RBDD.

15. $$RA_{dt} = \frac{C_{dt}}{V_{dt}}$$

RA_{dt} = relative abundance on day *d* by trap *t* (catch/acre-foot),
C_{dt} = number of fish captured on day *d* by trap *t*, and
V_{dt} = volume of water sampled on day *d* by trap *t*.

The volume of water sampled (V_{dt}) was estimated for each trap as the product of one-half the cross sectional area (wetted portion) of the cone, water velocity (ft/s) directly in front of the cone at a depth of 2-feet, cone modified (multiplied by 0.5) or not (multiplied by 1.0), and duration of sampling.

Exploratory Data Analyses.—The sampling of four runs of Chinook, *O. mykiss*, Green Sturgeon, and Lamprey occurred over 11 years and a variety of environmental conditions. Abiotic data collected or calculated throughout sample efforts included water temperature, flow, turbidity, and moon illuminosity (fraction of moon illuminated). The abiotic factors were analyzed to determine if patterns or trends existed throughout the migration periods of the various species. Additional statistical analyses were performed, when applicable, and additional methods are noted within the results section for species-specific data trends analyzed.

Results

Sampling Effort.—Annual sampling effort varied throughout the 11-year period of reporting. The reasons for less than 100% effort varied by time of year and run sampled due to numerous factors. These factors can be categorized as either intentional or unintentional decreases in effort. Intentional decreases in effort were primarily due to ESA Section 10(a)1(A) take and incidental mortality limits, the desire to decrease potential impacts to ESA listed fish or hatchery released production groups, or when staffing levels were not appropriate for the conditions encountered. Unintentional decreases in effort were due primarily to storm activity and related debris flows or conditions considered too dangerous to sample. Additionally, during the years RBDD was in operation (2002-2011), many days were not sampled due to operational requirements imposed by USBR operators (e.g., lowering or raising of the dam gates).

Annual sample effort was assigned a value of 1.0 based on sampling four traps 365 days a year. Annual sample effort values by salmonid species and run are described in Table 1. Overall, annual sample effort for all salmonids combined ranged from 0.53 to

0.91 (ȳ = 0.80, SD = 0.10) following annual juvenile salmonid brood year cycles. The lowest values corresponded to the year 2002 when sampling did not begin until mid-April of the year. The highest value corresponded to the year 2007 when flow events were mild, staffing levels were optimal, and permit restrictions did not dictate major sampling effort reductions (Table 1).

Mark-Recapture Trials.—Trap efficiency estimates were calculated by conducting mark-recapture trials (Volkhardt et al. 2007) using unmarked salmon collected from daily trap samples. Trials were conducted when trap catch values allowed the release of 1,000 fish per trial, generally, as well as when staffing and river conditions would allow. Mark-recapture trials were also employed to validate daily trap efficiency estimates by comparing actual with predicted (modeled) estimates. This was especially important during peak salmon outmigration periods.

The number of trials conducted each calendar year ranged from 0 in 2010 to 21 in 2004 (ȳ = 7.7) and totaled 85 trials between 2002 and 2013 (Table 2). Trials were conducted with four rotary traps (*N* = 74) or three traps (*N* = 11). Some trials were conducted with cones modified to sample half the volume of water (*N* = 25) or mixed (*N* = 1), but primarily unmodified and sampling full effort (*N* = 59). Trap efficiencies were tested with the RBDD gates raised (*N* = 72) and lowered (*N* = 13) during the years when RBDD was in operation (Table 2).

Trials were conducted through a variety of flow and trap effort conditions representing actual sampling conditions detected throughout various fish migration periods (Table 2). Estimates of the percentage of river water volume sampled by traps (*%Q*) ranged from 0.72 to 6.87% (ȳ = 3.10, SD = 1.32). Efficiency estimates for the 85 trials ranged from 0.34 to 5.48% (ȳ = 2.37%, SD = 0.01).

Released fish groups ranged from 340 to 5,143 individuals (ȳ = 1,598) and recaptured fish numbers ranged from 7 to 119 (ȳ = 36) per trial. Trials were conducted predominantly with fry size-class (<46 mm fork length), naturally produced fall Chinook (67%) and to a lesser extent winter Chinook (22%). Trials were conducted in some years using unmarked pre-smolt/smolts (11%) following annual Coleman National Fish Hatchery Fall Chinook production releases[5] during spring, as conditions and staffing levels allowed (Table 2).

Average fork lengths of release groups in the fry size-class had fork lengths ranging from 35.5 to 57.1 mm (ȳ = 37.2 mm). Recaptured fork lengths ranged from 34.6 to 62.4 mm (ȳ = 37.3 mm). Average fork lengths of fish released in the pre-smolt/smolt size-class ranged from 68.7 to 81.2 mm (ȳ = 75.3 mm). Recaptured fork lengths ranged from 61.3 to 80.2 mm (ȳ = 75.3 mm; Table 2). A paired t-test was performed on the average

---

[5] Coleman National Fish Hatchery is located upstream of RBDD on Battle Creek a tributary to the Sacramento. Fall Chinook production fish (~12 million per year) were adipose clipped (i.e., marked) in varying proportions over the years of study between 0 and 25%. Unmarked fish were included in some efficiency trials as they could not be distinguished from naturally produced fish.

release and recaptured fish lengths for all trials and indicated no significant difference between the released and recaptured fish sizes ($P = 0.759, df = 83, t = -0.308$).

Trap Efficiency Modeling.—Between 1998 and 2000, Martin et al. (2001) developed a trap efficiency model for the RBDD rotary trapping operation by conducting 58 mark-recapture trials (one trial excluded due to zero efficiency value). These data were used as the basis of the trap efficiency model to calculate daily passage estimates. The model was further developed between 2002 and 2013 with the addition of 85 mark-recapture trials. Trap efficiency was positively correlated to (*%Q)*, with higher efficiencies occurring as the relative percentage of discharge volume sampled by rotary traps increased. Trap efficiency was inversely related to river discharge (*Q*), as river discharge increased, trap efficiency decreased.

As mark-recapture trials were conducted, the trap efficiency model was typically updated one time each year. The newest model was applied on July 1 of each year, the beginning of the annual winter Chinook juvenile brood year period. Between 2002 and 2013 nine different models were utilized. The specific dates and model parameters with *P*-values used throughout the reporting period are listed chronologically below the groups of mark-recapture trials incorporated into the models in Table 2. The net result over the 11-year period was stabilization and improvement of the trap efficiency model with the addition of 85 mark-recapture trials. Overall, the *P*-values indicated a high level of significance for the parameter *%Q* in all years ($P< 0.001$). The model's *r*-squared value dropped in the first few years and then improved greatly with the addition of numerous naturally produced fry size-class mark-recapture trials over a variety of river discharge levels (Table 2; Figure 3).

Over the 11 years' data was collected a wide range of *%Q* values were sampled (0.44 to 6.86%, $\bar{y}$ = 2.90, SD = 0.01). On 10 occasions, extremely low *%Q* values (<0.72%) were sampled outside of the range of values tested through efficiency trials (Figure 3). The net result was that trap efficiency values were extrapolated outside the range of the model on a mere 10 of 3,315 days sampled (0.3%).

Chinook Capture Fork Length Analyses.—Chinook run assignment based on length-at-date (LAD) criteria was originally developed from growth data in the Upper Sacramento River at the Tehama Colusa Fish Facility using fall Chinook production records from 1972 through 1981 (Fisher 1992). An estimate of apparent growth rate was originally developed from fall Chinook < 90 mm FL as fish migrated or were depleted from the spawning channels by this size (Fisher 1992). Johnson et al. (1992) further developed (extrapolated) the data to predict run for fish ≥ 90 mm and ≤ 250 mm FL. The data was further refined by Frank Fisher of the California Department of Fish and Game, whereby estimated growth curves were produced for all runs based on adult timing, water temperatures, and juvenile emergence timing and growth (Brown and Greene 1992). The growth curves were fitted to a table of daily growth increments (i.e., fork length at age in days) by the California Department of Water Resources in the early

1990's (Brown and Greene 1992; Greene 1992). The following fork length data encompassed fish sampled by rotary traps using the LAD tables up to 180 mm FL, as fish were rarely captured above this length (i.e., extreme outliers).

Fall Chinook sampled from brood years 2002-2012 were heavily weighted to the fry size-class category (<46mm). On average, 75.7% of all fish sampled as fall could be described as fry (SD = 6.9) with 71.0% of the fry measuring less than 40 mm FL (Figure 4a). The remaining 24.3% (SD = 6.9) were attributed to the pre-smolt/smolt category (>45 mm) with fish between 70 and 89 mm composing 71.0% of that value. Overall, fall Chinook were sampled between 30 and 134 mm annually, with trivial numbers below or above this range (Figure 4b). Fall Chinook showed little growth, on average, between December and March, followed by a significant increase in length in April, followed by more moderate and variable growth through November (Figure 4c). The growth pattern exhibited by fall Chinook appears strongly influenced by the duration of the fall Chinook spawning period and the LAD criteria. Beginning on April 1, newly emerged fry were classified as late-fall Chinook instead of fall Chinook thereby significantly increasing the median fork length of fall Chinook during the first two weeks of April.

Late-fall Chinook sampled from brood years 2002-2012 were not heavily weighted to the fry size-class category (<46mm). On average, 24.9% of all fish sampled as late-fall could be described as fry (SD = 12.8) with 96.3% of the fry measuring less than 40 mm FL (Figure 5a). The remaining 75.1% (SD = 12.8) were attributed to the pre-smolt/smolt category (>45 mm) with fish between 70 and 89 mm composing 48.3% of that value. Overall, late-fall Chinook were sampled between 26 and 180 mm annually (Figure 5b). Late-fall Chinook showed little growth, on average, between April and May, followed by a significant increase in length in June and July, followed by more moderate and variable growth between late-September and February (Figure 5c). The growth pattern exhibited by late-fall Chinook appears modestly influenced by the LAD criteria. Beginning on July 1, newly emerged fry were classified as winter Chinook instead of late-fall Chinook slightly increasing the median fork length of late-fall Chinook during the first few weeks of July. In mid-September and to a lesser extent in late-December, the overall fork length distribution for late-fall Chinook increases from one week to the next and was likely a result of decreased sampling effort due to RBDD gate operations and initial winter storms.

Winter Chinook sampled from brood years 2002-2012 were heavily weighted to the fry size-class category (<46mm). On average, 77.9% of all fish sampled as winter could be described as fry (SD = 8.8) with 92.8% of the fry measuring less than 40 mm FL (Figure 6a). The remaining 22.1% (SD = 8.8) were attributed to the pre-smolt/smolt category (>45 mm) with fish between 46 and 69 mm composing 85.3% of that value. Overall, winter Chinook were sampled between 27 and 162 mm annually (Figure 6b). Winter Chinook showed little growth, on average, between July and October, followed by a significant increase in length in mid-October, followed by more moderate growth through December. The growth pattern was then highly variable between January and

April (Figure 6c). The growth pattern exhibited by winter Chinook appears moderately influenced by the LAD criteria. Beginning on October 16, newly emerged fry were classified as spring Chinook instead of winter Chinook thereby significantly increasing the median fork length of winter Chinook during the last two weeks of October.

Spring Chinook sampled from brood years 2002-2012 were slightly weighted to the fry size-class category (<46mm). On average, 58.6% of all fish sampled as spring could be described as fry (SD = 19.6) with 90.0% of the fry measuring less than 40 mm FL (Figure 7a). The remaining 41.4% (SD = 19.6) were attributed to the pre-smolt/smolt category (>45 mm) with fish between 70 and 89 mm composing 69.2% of that value. Overall, spring Chinook were sampled between 28 and 143 mm annually (Figure 7b). Spring Chinook showed moderate growth, on average, between October and mid-December, followed by more consistent increasing growth through May (Figure 7c). Spring Chinook disappear from the catch typically by June with sporadic capture of large smolts in July of some years. The growth pattern exhibited by spring Chinook appears moderately influenced by the LAD criteria. Beginning on December 1, newly emerged fry were classified as fall Chinook instead of spring Chinook likely resulting in positive size-class bias for spring Chinook.

O. mykiss Capture Size Analyses.—Following the conventions used by Gaines and Martin (2002) size categorization for *O. mykiss* followed a slightly different pattern than Chinook and was organized by fork length as fry (<41 mm), sub-yearling (41–138 mm), and yearling (>138 mm). Moyle (2002) described Sacramento River *O. mykiss* populations as highly variable, but typically reaching 140-150 mm FL in their first year. The focus of our data reporting is age-0 and the focus of our size-class analyses was primarily < 139mm and secondarily < 200 mm for length-weight analyses.

O. mykiss sampled from calendar years 2002-2012 were heavily weighted towards the 41-80 mm size-class (79.2%; Figure 8a) which fell into the sub-yearling category (Figure 8b). On average, a modest 8.2% could be categorized as fry (Table 3). Overall, *O. mykiss* yearling and estimated age-2 fish were annually sampled at rates of 2.4% and 0.6%, respectively (Table 3). There was little variation detected within any size-class between categories, yet variance in weekly captures was high throughout the year (Figure 8c). The variable life-history strategies of *O. mykiss* resident and anadromous forms was evident from our size-class capture data. In general, newly emerged fry occurred in early-April and increased in size to early July. Thereafter, a second cohort of either resident trout or summer steelhead[6] was sampled which demonstrated a secondary growth pattern through December (Figure 8c).

O. mykiss CAMP Program Life-Stage Comparisons.— *O. mykiss* capture patterns appeared to be different than that of Chinook salmon as relatively few *O. mykiss* were captured as fry ($\bar{y}$ = 8.3%) and the majority were sampled as sub-yearlings ($\bar{y}$ = 88.7%;

---

[6] Summer steelhead are believed to be extirpated since the construction of dams blocked access to headwater habitat (Moyle 2002).

Table 3; Figure 8b). Fry capture was highest in 2002 and 2006 (11.2% and 17.5%) although these years sampled the first and third fewest *O. mykiss* of the 11 years, respectively. Yearling and age-2 capture was generally low averaging only 3.0%.

Life stage classification of fry was uniform throughout all years ($\bar{y}$ = 6.8%, SD = 2.6%) and did not vary greatly in 2002 and 2006 in contrast to age classification. Parr and silvery-parr accounted for 91.5% of the *O. mykiss* handled at RBDD although there was a large difference between the two categories, 74.0% and 17.5% respectively. Annual variability in parr and silvery-parr classifications (SD = 15.5 and 16.8) seemed to change after 2005 and was likely due to a protocol change or interpretation of morphological characteristics by field staff. Juveniles showing signs of anadromy (i.e., smolts) made up only 1.6% of individuals sampled.

O. mykiss Weight-Length Analysis.—Log $_{10}$ transformed *O. mykiss* weight-length data showed a strong overall relationship between the two variables (r^2 = 0.942, Table 4). The annual slope coefficients for the 11-year period varied slightly, ranging from 2.858 to 3.052. The variability in growth was not considered significant as the 95% CI annual slope coefficients encompassed the slope coefficient of the overall mean (Table 4). Typical of most weight-length models (Pope and Kruse 2007), the variability about the regression increased with the overall length of the fish (Figure 9).

Salmonid Passage.—Passage estimates for the four runs of Chinook were calculated weekly as fry and pre-smolt/smolt passage. The sum of the weekly fry and pre-smolt/smolt passage values equal the weekly *total* passage values. Confidence intervals (CI) were calculated at the 90% level for all runs for weekly passage estimates. Weekly CI values were summed to obtain the annual CI's around the annual passage estimate (i.e., summed weekly passage estimates). Negative CI values were set to zero and result in some years CI's being asymmetrical around the annual passage estimate. Annual passage estimates (i.e., total passage estimates), by brood year, with CI's and annual effort values are presented for Chinook within Tables 5a-5d and graphically in Figures 10, 12, 14, and 16. Fry and pre-smolt/smolt Chinook passage estimates with 90% CI's summarized annually by run can be found in Appendix 1 (Tables A1-A8). Comparisons of relative variation within and between runs of Chinook were performed by calculating Coefficients of Variation (Sokal and Rohlf 1995) of passage estimates.

Fall Chinook annual passage estimates ranged between 6,627,261 and 27,736,868 juveniles for brood years 2002-2012 ($\bar{y}$ = 14,774,923, CV = 46.2%; Table 5a). On average, fall Chinook passage was composed of 74% fry and 26% pre-smolt/smolt size-class fish (SD = 10.3). Proportions as low as 56% and as high as 87% fry were detected (Table 5a). Annual effort values resulted in interpolations of between 9 and 60% of annual passage estimates ($\bar{y}$ = 28%). In general, the effect of annual effort on CI width indicated greater spread of CI's with decreasing effort (Figure 10).

On average, weekly fall passage equated to 5% of total annual fall Chinook passage between mid-January and early March (Figure 11a). Weekly passage varied considerably during this period with some weeks' passage totals accounting for >25% of annual passage values. Between BY 2002 and 2012, 75% of average annual passage occurred by the end of March, signifying January through March as the greatest period of migration. A second, albeit much diminished, mode of passage occurred between late April and May of each year due to the release of unmarked fall Chinook production fish from Coleman National Fish Hatchery. These fish could not be distinguished from wild fish due to fractional marking processes that varied over the 11-year period from 0 to 25%. Overall, fall passage was complete by the end of July each year with sporadic small pulses of smolts through November (Figure 11b).

Late-fall Chinook annual passage estimates ranged between 91,995 and 2,559,519 juveniles for brood years 2002-2012 ($\bar{y}$ = 447,711, CV = 159.9%; Table 5b). On average, late-fall Chinook passage was composed of 38% fry and 62% pre-smolt/smolt size-class fish (SD = 22.5). Proportions as low as 11% and as high as 72% fry were detected (Table 5b). Annual effort values resulted in interpolations of between 9 and 56% of annual passage estimates ($\bar{y}$ = 31%). The effect of annual effort on CI width indicated greater spread of CI's with decreasing effort due to hatchery fish releases, in general (Figure 12).

On average, weekly late-fall passage started abruptly and held at ≤ 5% of total annual passage between April and May (Figure 13a). Weekly passage varied considerably during this period with some weeks' passage totals accounting for >35% of annual passage values. A second, similar magnitude mode of passage occurred between July and August in most years. A third, albeit diminished, mode occurred during October and November with passage accounting for up to 35% of the annual run in some years. Between BY 2002 and 2012, 75% of average annual passage occurred by mid-September, signifying April through September as the greatest period of migration. Overall, late-fall passage was complete by the end of December each year with sporadic small pulses of smolts through February (Figure 13b).

Winter Chinook annual passage estimates ranged between 848,976 and 8,363,106 juveniles for brood years 2002-2012 ($\bar{y}$ = 3,763,362, CV = 73.2%; Table 5c). On average, winter Chinook passage was composed of 80% fry and 20% pre-smolt/smolt size-class fish (SD = 11.2). Proportions as low as 53% and as high as 90% fry were detected (Table 5c). Annual effort values resulted in interpolations of between 8 and 42% of annual passage estimates ($\bar{y}$ = 18%). The effect of annual effort on CI width indicated greater spread of CI's with decreasing effort due to subsampling measures during peak migration periods (i.e., take or impact reduction), in general (Figure 14).

On average, weekly winter passage increased consistently through September to a peak into early October. Weekly passage varied considerably during August through December with some weeks' passage totals accounting for >20% of annual passage values. Between BY 2002 and 2012, 75% of average annual passage occurred by mid-

October. Weekly passage between October and December indicated wide variability over the 11-year period, yet the trend showed steady decreases followed by a second increase or mode of winter passage in November and December (Figure 15a). Overall, winter passage was 99% complete by the end of December each year with sporadic pulses of smolts through March that contributed minimally to the annual total winter passage estimate (Figure 15b).

Spring Chinook annual passage estimates ranged between 158,966 and 626,925 juveniles for brood years 2002-2012 ($\bar{y}$ = 364,508, CV = 45.0%; Table 5d). On average, spring Chinook passage was composed of 54% fry and 46% pre-smolt/smolt size-class fish (SD = 20.0). Proportions as low as 24% and as high as 91% fry were detected (Table 5d). Annual effort values resulted in interpolations of between 1 and 49% of annual passage estimates ($\bar{y}$ = 29%). The effect of annual effort on CI width indicated a slightly greater spread of CI's with decreasing effort due to subsampling during winter storm events, in general (Figure 16).

On average, weekly spring passage started abruptly and held at roughly 5% of total annual passage between mid-October and mid-November (Figure 17a). Weekly passage varied somewhat during this period with some weeks' passage totals accounting for up to 20% of annual passage values. A second, increased magnitude mode of passage occurred during December in most years with a single week accounting for nearly 50% of the annual passage estimate. Between BY 2002 and 2012, 75% of average annual passage occurred by mid-April, signifying October through April as the greatest period of migration. A third mode of similar magnitude to the second mode occurred during April and May with passage accounting for up to 45% of the annual run in some years. This could be characterized as an erroneous increase in spring passage. Unmarked fall production fish exceeded the size-class for fall run and therefore fell within the spring run category using LAD criteria. Between 2007 and 2012, on average, 4.3% of the marked fall production fish fell within the spring-run size-class using LAD criteria. Assumedly, a similar proportion of the unmarked fish were added into the spring-run passage estimates as they could not be distinguished from naturally produced fish. Overall, spring Chinook passage was complete by the end of May each year (Figure 17b).

O. mykiss passage estimates were generated using trap efficiency estimates calculated using the Chinook-based trap efficiency model. Caution should be exercised when interpreting the following results as Chinook and *O. mykiss* trap efficiency values likely differ, perhaps greatly. Irrespective of the accuracy of the magnitude of passage estimates based on Chinook efficiency trials, the trends in abundance remain plausible due to the standardization of effort and catch. Unlike Chinook, *O. mykiss* were not attributed to a fry or pre-smolt/smolt category and passage estimates with 90% CI's were calculated that included all size-classes and life-stages combined.

Annual passage estimates for *O. mykiss* ranged between 56,798 and 151,694 juveniles for calendar years 2002-2012 ($\bar{y}$ = 116,272, CV = 25.7%; Table 5e). Annual effort values resulted in interpolations of between 4 and 56% of annual passage estimates ($\bar{y}$ = 22%). The effect of annual effort on CI width indicated a slightly greater spread of CI's with decreasing effort, in general (Figure 18).

On average, weekly *O. mykiss* passage was low (<5% on average) from April through July of each year with some variability. In 11 years of sampling only once did passage exceed 10% of annual passage during these months. Weekly passage between July and August increased to peak values ranging from 5% to nearly 25% (Figure 19a). Between 2002 and 2012, 75% of average annual passage occurred by mid-August. Weekly passage generally declined between September and October. Overall, *O. mykiss* passage was negligible between December and the following February each year (Figure 19b).

Fry-Equivalent Chinook Production Estimates.—Juvenile Chinook passage values were standardized to *fry-equivalent* production estimates for within- and between-year comparisons. As noted above, the various runs were sampled with oftentimes considerable variability in fry to pre-smolt/smolt ratios over the 11–year sample period (Table 5a-5d). By multiplying 1.7 to all fish sampled in the pre-smolt/smolt category (>45mm) within each run, annual Chinook production above the RBDD transect could be estimated. These standardized production estimates could then be compared to adult escapement estimates calculated from the California Central Valley Chinook Population Report (Azat 2013) or carcass survey data in the case of winter Chinook (USFWS 2006-2011 and 2013). Moreover, by comparing production to the number of adult Chinook females each year (by run) and estimating fecundity data from CNFH and Livingston Stone National Fish Hatchery (LSNFH) hatchery production records, estimated recruits per female and egg-to-fry survival estimates were generated.

Fall Chinook fry-equivalent production estimates between 2002 and 2012 ranged from 7,554,574 to 30,624,209 ($\bar{y}$ = 17,262,473, CV = 43.2%). Lower and upper 90% CI's were generated for each week, summed annually, and averaged between 6,670,475 and 30,707,529 (Table 6a).

Adult fall Chinook escapement estimates above RBDD (mainstem Sacramento River plus tributaries reported) estimated escapement between 12,908 and 458,772 ($\bar{y}$ = 93,661) for the same years. Fall Chinook carcass survey data collected by California Department of Fish and Wildlife (CDFW) provided annual female:male sex ratio estimates averaging 0.46:0.54 (D. Killam, unpublished data). A significant relationship between estimated number of females and fry-equivalent fall Chinook production estimates was detected (r^2 = 0.53, df = 10, P = 0.01; Figure 20a). Recruits per female were calculated ranging from 89 to 1,515 ($\bar{y}$ = 749). Assuming an average female fecundity value of 5,407, based on fall Chinook spawning records from CNFH between 2008 and 2012 (K. Brown, unpublished data), resulted in an egg-to-fry survival estimate averaging 13.9% for fall Chinook (Table 6a).

Late-fall Chinook fry-equivalent production estimates between 2002 and 2012 ranged from 116,188 to 4,041,505 ($\bar{y}$ = 669,939, CV = 169.8%). Lower and upper 90% CI's were generated for each week, summed annually, and averaged between 222,044 and 1,236,432 (Table 6b).

Adult late-fall Chinook escapement estimates above RBDD estimated escapement between 2,931 and 36,220 ($\bar{y}$ = 9,108) for the same years. Late-fall Chinook annual female:male sex ratio estimates relied on an assumption of the average ratio found for fall Chinook (i.e., 0.46:0.54). A significant relationship between estimated number of females and fry-equivalent late-fall Chinook production estimates was detected ($r^2 = 0.67$, df = 10, $P = 0.002$; Figure 20b). Recruits per female were calculated ranging from 47 to 243 ($\bar{y}$ = 131). Assuming an average female fecundity value of 4,662 based on late-fall Chinook spawning records from CNFH between 2008 and 2012 (K. Brown, unpublished data) resulted in an egg-to-fry survival estimate averaging 2.8% for late-fall Chinook (Table 6b).

Winter Chinook fry-equivalent production estimates between 2002 and 2012 ranged from 996,621 to 8,943,194 ($\bar{y}$ = 4,152,547, CV = 70.1%). Lower and upper 90% CI's were generated for each week, summed annually, and averaged between 2,265,220 and 6,124,494 (Table 6c).

Adult winter Chinook escapement estimates above RBDD (USFWS/CDFW carcass survey data; available at http://www.fws.gov/redbluff/he_reports.aspx) estimated escapement between 824 and 17,205 ($\bar{y}$ = 6,532) for the same years. Winter Chinook annual female:male sex ratio estimates were estimated during the annual carcass surveys (Table 6c). A highly significant relationship between estimated number of females and fry- equivalent winter Chinook production estimates was detected ($r^2 = 0.90$, df = 10, $P < 0.001$; Figure 20c). Recruits per female were calculated ranging from 846 to 2,351 ($\bar{y}$ = 1,349). Annual female fecundity values were estimated based on winter Chinook spawning records from LSNFH between 2008 and 2012 (USFWS Annual Propagation Reports; available at http://www.fws.gov/redbluff/he_reports.aspx) and resulted in an egg-to-fry survival estimate averaging 26.4% for winter Chinook (Table 6c).

Spring Chinook fry-equivalent production estimates between 2002 and 2012 ranged from 207,793 to 747,026 ($\bar{y}$ = 471,527, CV = 40.9%). Lower and upper 90% CI's were generated for each week, summed annually, and averaged between 199,365 and 792,668 (Table 6d).

Adult spring Chinook escapement estimates above RBDD (mainstem Sacramento River plus tributaries reported) estimated escapement between 77 and 399 ($\bar{y}$ = 195) for the same years. Spring Chinook annual female:male sex ratio estimates relied on an assumption of the average ratio found for fall Chinook (i.e., 0.46:0.54). No significant relationship between estimated number of females and fry-equivalent spring Chinook production estimates was detected ($r^2 = 0.00$, df = 10, $P = 0.971$; Figure 20d). Recruits per female were calculated ranging from 1,112 to 8,592 (ȳ = 3,122). Assuming an average female fecundity value of 5,078, based on averaging of 5 years of fall and late-fall Chinook spawning records from CNFH and 10 years of winter Chinook spawning records from LSNFH, resulted in an egg-to-fry survival estimate averaging 61.5% for spring Chinook (Table 6d).

Green Sturgeon Data.—Capture of young of the year sturgeon occurred annually between calendar years 2002 and 2012, except in 2008. Catch was highly variable, not normally distributed, and ranged between 0 and 3,701 per year (median = 193; Table 7). Sturgeon sampled by rotary traps could be positively identified as Green Sturgeon in the field *above* total length of 46 mm. At this size, lateral scutes were fully developed and could be counted to distinguish between White (*Acipenser transmontanus*) and Green Sturgeon (Moyle 2002). Of 2,912 sturgeon measured in the field, 99.14% were less than 46 mm. In all years, except 2007 and 2008, sub-samples of larval and/or juvenile sturgeon rotary trap catch (up to 50% in some years) were supplied to UC Davis for genetic research and all were determined to be Green Sturgeon (See Israel et al. 2004; Israel and May 2010). We therefore assumed all sturgeon captured in rotary traps were Green Sturgeon based on the results of genetic analyses. Moreover, Green Sturgeon were the only confirmed spawning Acipenserids sampled at or above the RBDD transect between 2008 and 2012 during sturgeon spawning surveys (Poytress et al. 2009-2013).

Green Sturgeon catch was primarily composed of recently emerged, post-exogenous feeding larvae with a 10-year median capture total length averaging 27.3 mm (SD = 0.8; Table 7). Sturgeon were sampled between 18 and 188 mm, but those sampled above 40 mm were considered outliers (N = 51; Table 7; Figure 21a).

The temporal pattern of Green Sturgeon captures occurred, on average, between May 1 and August 28 of each year. Green Sturgeon capture trends indicated annual variability, but on average 50% were sampled by the end of June each year and nearly 100% by the end of July (Figure 21b), with outliers (i.e., juveniles) captured in August, September and as late as November (e.g., 188 mm TL) in some years.

Relative abundance of Green Sturgeon was measured as catch per estimated water volume sampled (CPUV in ac-ft) through rotary trap cones and summed daily. Daily values were summed annually to produce each year’s annual index of abundance. Absolute abundance estimates, via trap efficiency trials, could not be calculated due to low numbers of sturgeon sampled on a daily basis and the fragile nature of newly emerged exogenous feeding larvae.

Green Sturgeon annual CPUV was typically low and ranged from 0.0 to 20.1 fish/ac-ft (ȳ = 2.5 fish/ac-ft, SD = 5.9). Data were positively skewed and median annual CPUV was 0.8 fish/ac-ft. Relative abundance distribution data were highly influenced by samples collected in 2011 that equated to two orders of magnitude higher than any other year's index (Figure 21c). Overall, variability in CPUV between years was relatively high as the CV was 236% for the eleven-year period (Table 7).

Lamprey Species Data.—Capture of multiple lamprey species occurred between water year (WY; October - September) 2003 and 2013. WY 2002 was excluded from analyses as less than 50% of the entire year was sampled. Lamprey species sampled included adult and juvenile Pacific Lamprey and to a much lesser extent River Lamprey (*Lampetra ayresi*), and Pacific Brook Lamprey (*Lampetra pacifica)*. Unidentified lamprey ammocoetes and Pacific Lamprey (PL) composed 99.8% of all captures, 24% and 75%, respectively. River Lamprey and Pacific Brook Lamprey combined, composed the remaining 0.2% of all captures. Annual catch, length, and relative abundance information for River and Pacific Brook Lamprey can be found in Appendix 1 (Tables A9 and A10) and are not discussed further due to very low capture rates.

Annual catch of ammocoetes was relatively stable and ranged between 385 and 1,415 individuals per year ($\bar{y}$ = 757, median = 657; Table 8a). The catch coefficient of variation for ammocoetes was 38.5%. Minimum TL of lamprey ammocoetes was 14 mm and maximum TL was 191. Over the eleven complete years sampled, the average minimum and maximum TL's were 32 and 164 mm, respectively ($\bar{y}$ =105, SD = 4.7; Figure 22a).

Annual catch of PL macropthalmia and a small fraction of adults was variable and ranged between 204 and 5,252 individuals per year ($\bar{y}$ = 2,335, median = 2,747; Table 8b). The catch coefficient of variation for PL was 75.3%. Minimum TL of PL was 72 mm and maximum TL was 834. Over the eleven years sampled, the average minimum and maximum TL's were 88 and 665 mm, respectively ($\bar{y}$ = 150, SD = 37.3; Figure 23a).

Lamprey captures occurred throughout the year between October and September. Ammocoete capture trends indicated annual variability, but on average 25% were sampled by the end of January, 50% were sampled by the end of March, 75% were sampled by the end of May and 100% by the end of September (Figure 22b). Transformed PL (macropthalmia and adult) capture trends indicated a different pattern of capture and annual variability compared to ammocoetes. On average, 5% were sampled through October, 50% were sampled through December, 75% were sampled through February, 90% by the beginning of April with a 100% by the end of September (Figure 23b).

Relative abundance of ammocoetes and PL were measured as CPUV through individual rotary trap cones and summed daily. Daily values were summed annually to produce each year's annual index of abundance. Absolute abundance estimates employing mark-recapture methods could not be calculated due to the sporadic capture of adequate numbers of juveniles (e.g., > 1,000 individuals) that would be needed for mark-recapture trials. Moreover, emphasis was placed on conducting Chinook mark-recapture trials at times of pronounced lamprey abundance.

Ammocoete annual relative abundance ranged from 3.6 to 11.7 fish/ac-ft (ȳ = 6.8 fish/ac-ft, SD = 2.6; Figure 22c). Overall, ammocoete data were normally distributed as median CPUV was 6.5 fish/ac-ft, similar to the mean value. Variability in CPUV between years was modest and the coefficient of variation was 39% for the eleven-year period (Table 8a).

PL annual relative abundance was generally higher than ammocoete relative abundance and ranged from 2.1 to 112.8 fish/ac-ft (ȳ = 41.0 fish/ac-ft, SD = 34.7; Figure 23c). Overall, PL data was slightly positively skewed and median CPUV was 34.1 fish/ac-ft. Variability in CPUV between years was moderate and the coefficient of variation was 85% for the eleven-year period (Table 8b).

Abiotic Conditions.—Tabular summaries of the abiotic conditions that were encountered during each annual capture period were summarized for each run of salmon, *O. mykiss*, Green Sturgeon and Lamprey species. Tabular summaries associated with each species annual captures are located in Tables 9a-9f and include: dates of capture, peak daily water temperature, peak daily river discharge levels and mean daily turbidity values. A series of exploratory plots comparing the above daily environmental data variables plus an index of moon illuminosity were generated for fry and pre-smolt Chinook daily passage estimates for visual analyses. Winter Chinook fry and pre-smolt/smolt plots are included in Appendix 2 (Figures A1-A23) for reference.

Annual environmental covariate data for fall Chinook salmon can be found in Table 9a. Results presented below describe data averaged over 11 brood years. Fall Chinook were sampled over a period of 250 to 273 days per year (ȳ = 264 days, SD = 7). Water temperatures ranged from 45 to 62 °F (ȳ = 55°F, SD = 0.8). Sacramento River discharge ranged from 5,605 to 72,027 CFS (ȳ = 14,844 CFS, SD = 5,442). Turbidity values ranged from 1.5 to 298.7 NTU (ȳ = 14.4 NTU, SD = 6.3).

Annual environmental covariate data for late-fall Chinook salmon can be found in Table 9b. Results presented below describe data averaged over 11 brood years. Late-fall Chinook were sampled over a period of 270 to 338 days per year (ȳ = 300 days, SD = 24). Water temperatures ranged from 46 to 62 °F (ȳ = 56°F, SD = 0.7). Sacramento River discharge ranged from 5,536 to 67,520 CFS (ȳ = 12,580 CFS, SD = 2,829). Turbidity values ranged from 1.4 to 272.0 NTU (ȳ = 11.3 NTU, SD = 6.2).

Annual environmental covariate data for winter Chinook salmon can be found in Table 9c. Results presented below describe data averaged over 11 brood years. Winter Chinook were sampled over a period of 207 to 278 days per year (ȳ = 250 days, SD = 20). Water temperatures ranged from 46 to 61 °F (ȳ = 55°F, SD = 0.8). Sacramento River discharge ranged from 5,349 to 66,800 CFS (ȳ = 11,952 CFS, SD = 3,767). Turbidity values ranged from 1.3 to 290.2 NTU (ȳ = 12.5 NTU, SD = 5.1).

Annual environmental covariate data for spring Chinook salmon can be found in Table 9d. Results presented below describe data averaged over 11 brood years. Spring Chinook were sampled over a period of 221 to 250 days per year ($\bar{y}$ = 232 days, SD = 9). Water temperatures ranged from 46 to 62 °F ($\bar{y}$ = 53°F, SD = 0.6). Sacramento River discharge ranged from 5,349 to 68,720 CFS ($\bar{y}$ = 13,370 CFS, SD = 6,116). Turbidity values ranged from 1.4 to 305.9 NTU ($\bar{y}$ = 16.0 NTU, SD = 7.0).

Annual environmental covariate data for *O. mykiss* can be found in Table 9e. Results presented below describe data averaged over 10 calendar years. *O. mykiss* were sampled over a period of 331 to 363 days per year ($\bar{y}$ = 349 days, SD = 12). Water temperatures ranged from 46 to 63 °F ($\bar{y}$ = 56°F, SD = 0.8). Sacramento River discharge ranged from 5,333 to 67,610 CFS ($\bar{y}$ = 12,519 CFS, SD = 3,551). Turbidity values ranged from 1.4 to 263.7 NTU ($\bar{y}$ = 11.4 NTU, SD = 4.1).

Annual environmental covariate data for Green Sturgeon can be found in Table 9f. Results presented below describe data averaged over 11 calendar years. Green Sturgeon were sampled over a period of 56 to 151 days per year ($\bar{y}$ = 88 days, SD = 27). Water temperatures ranged from 55 to 61 °F ($\bar{y}$ = 58°F, SD = 0.9). Sacramento River discharge ranged from 9,639 to 23,538 CFS ($\bar{y}$ = 13,483 CFS, SD = 2,181). Turbidity values ranged from 2.4 to 93.9 NTU ($\bar{y}$ = 8.5 NTU, SD = 6.9).

Due to the large amount of variability and lack of a normal distribution, all environmental covariate CPUV data analyses for Green Sturgeon were performed using natural log transformed data (Sokal and Rohlf 1995). Environmental covariates were regressed against the natural log of daily CPUV estimates for Green Sturgeon in a linear regression setting (Figure 24). Maximum daily water temperature was the only variable found to be significantly related to Green Sturgeon relative abundance, albeit the relationship explained ~5% of the variability around daily relative abundance (r^2= 0.045, df = 315, $P < 0.001$).

Annual environmental covariate data for Lamprey *spp.* can be found in Table 9g. Results presented below describe data averaged over 11 water years. Lamprey were sampled over a period of 358 to 364 days per year ($\bar{y}$ = 362 days, SD = 2). Water temperatures ranged from 46 to 63 °F ($\bar{y}$ = 56°F, SD = 0.7). Sacramento River discharge ranged from 5,347 to 68,873 CFS ($\bar{y}$ = 12,595 CFS, SD = 4,177). Turbidity values ranged from 1.2 to 306.8 NTU ($\bar{y}$ = 11.9 NTU, SD = 4.4).

Due to the variability and lack of a normal distribution, all environmental covariate CPUV data analyses for Lamprey *spp.* were performed using natural log transformed data. Environmental covariates were regressed against the natural log of daily CPUV data for Lamprey *spp.* in a linear and multiple regression setting. All four independent variables appear to contribute to predicting Lamprey *spp*. relative abundance and were significantly related to abundance levels (r^2= 0.223, df = 1999, $P < 0.001$). Individual variable linear regression analyses indicated turbidity, water temperature, discharge, and full moon illuminosity were correlated in descending order of magnitude (Figure 25). None of the covariates tested explained more than ~16% of the variability associated with daily CPUV data.

Discussion

Trap Efficiency Modeling.—Over the past 11 years, annual mark-recapture trials added 85 data points to the RBDD rotary trap efficiency linear regression model (Figure 3). Explanation of the variability associated with trap efficiency and *%Q*, in terms of the associated r-squared value, was reduced for the first few years and then steadily increased in more recent years. The reduction was due, in part, to more precise *%Q* calculations over the initial model when diversions from RBDD were not subtracted from daily river discharge values. Diversions were able to be removed from the total discharge (*Q*) passing the transect as these data became available in real-time starting in 2002.

The addition of a multitude of fry size-class trials over a variety of discharge levels greatly increased the accuracy of trap efficiency estimates. Fry size-class fish are the predominant size-class sampled at RBDD (i.e., fall and winter Chinook) thereby making them the best representatives for use in mark-recapture trials. The original trap efficiency model developed by Martin et al. (2001) employed primarily hatchery-raised smolts, as these fish were all that were available in large quantities and permitted for use in experiments to develop the initial model. However, hatchery fish weakly represented the primary fish size-class sampled by RBDD rotary traps. Roper and Scarnecchia (1996) and Whitton et al. (2008) found significant differences in trap efficiency when conducting paired mark-recapture trials using hatchery and wild caught fish. The most recent years of RBDD data support this concept.

While a simple linear regression model has worked well over the years for our real-time data output needs, analysis of the data within the model, other possible covariates, and other more advanced modeling techniques has been warranted. Analysis incorporating additional potential explanatory variables was conducted using a generalized additive model technique (GAM; Hastie and Tibshirani 1990). From this analysis, variables including turbidity, fish size and run, water temperature, weather condition, lunar phase, and river depth were explored in addition to *%Q*. The result was that only *%Q* and weather were found to be significant model explanatory variables ($r^2 = 0.68$; df = 141, $P < 0.01$). The weather variable needs focused testing by conducting more mark-recapture trials under a variety of weather conditions to determine the applicability or mechanism of this variable. The GAM modeling technique may be employed in the future as an improved statistical format to interpolate missed sample days.

At minimum, an update to the 142 trial linear trap efficiency model (Figure 3) needs to be implemented for future passage estimate calculations. The update will include the removal of hatchery fish trials (*N*=23) used as surrogates for natural stocks. Removal of all RBDD "gates in" mark-recapture trials (*N*=31) due to the cessation of RBDD dam operations since 2011 (NMFS 2009) is also warranted.

The loss of annual maintenance and RBDD gate lowering operations at the rotary trap sample site (Figure 1) will allow the river channel's geometry to change more frequently due to natural flow driven substrate transport mechanisms. RBDD operations of the past virtually "reset" the sample site to facilitate pumping during the gates-out period and improve fish passage at the fish ladders during the gates-in period. As the sample site's channel configuration is allowed to fluctuate in the absence of dam operations, the overall effect could be differing trap efficiency values in relation to flow compared to previous years' data. Annual mark-recapture trials will be needed to evaluate this phenomenon, which has been observed in other uncontrolled channel sampling locations (e.g., Clear Creek; Greenwald et. al. 2003). The use of a GAM model may also be of benefit in this situation as it could be constructed and employed annually to account for wide variation in annual trap efficiency values; albeit at the expense of being able to produce real-time data summaries.

A linear model that also removed the remaining pre-2002 trials (*N*=16) which estimated *%Q* in a less precise manner, would result in the most representative trap efficiency model. A post-RBDD wild Chinook model of this type would incorporate 72 mark-recapture trials with a high degree of significance (*N*=72, $r^2 = 0.669$, F = 141.5, $P < 0.001$) and be most representative of current sampling conditions in terms of fish size-class and environmental conditions.

Chinook Capture Size Analyses.—Overall capture of Chinook salmon by RBDD rotary traps was heavily weighted towards fry size-class less than 40mm in fork length. All four runs' greatest proportion of fish were found in this size-class, albeit in a range of proportions from 24% for late-fall (Figure 5b) to over 72% for winter run (Figure 6b). The capture size-class results fit well with the migratory strategies of 'stream' and 'ocean type' as noted in Moyle (2002) for late-fall/spring and fall/winter Chinook, respectively. The question of size selectivity or capture bias of rotary traps, a passive sampling gear (Hubert 1996), comes into question when dealing with two very different migration strategies.

A two sample t-test was performed to evaluate the potential for size-class bias by comparing fry (fall and winter Chinook) size-class trap efficiency values (*N*=43) to pre-smolt/smolt (fall) trap efficiency values (*N*=10) between similar river discharge conditions. The t-test results did not indicate any significant difference between the mean efficiency values (t = -0.398, df = 51, $P = 0.624$). Interestingly, the mean efficiency and standard deviation of the values were identical ($\bar{y} = 2.1\%$, SD = 0.01) between groups. We recommend further study of the relationship between pre-smolt/smolt size-class and trap efficiency to determine if differences or bias may exist between or among Chinook runs. Additional sampling effort would be needed to capture substantially more pre-smolts in the numbers required for efficiency trials in the Sacramento River to further test this potential bias. Smolting salmonids also appear to succumb to stress induced mortality at a much greater rate than fry, particularly in warmer water conditions due to relatively high respiration levels, adding to the difficulty in testing this potential bias.

O. mykiss Life-Stage and Growth.— Catch of *O. mykiss* was scattered throughout the year with multiple modes in abundance of predominately sub-yearling parr and silvery-parr occurring in early May and August. *O. mykiss* fry (<41 mm) made up 17.5% of the total *O. mykiss* catch in 2006 and was 2.4 standard deviations from the 11-year mean. In contrast, yolk-sac fry, made up only 9.4% of the *O. mykiss* catch in 2006 and varied less than 1 standard deviation from the 11-year mean (Table 3). Elevated spring discharge resulted in poor sampling conditions which reduced sampling effort, possibly scoured redds, and ultimately resulted in low overall *O. mykiss* catch in 2006. Regardless of the cause of low catch rates, it is unlikely the migration patterns of *O. mykiss* changed in 2006 and the variability in age-class distribution was likely due to our sampling effort in that year.

The small percentage of *O. mykiss* smolts that showed signs of anadromy were generally migrating during March through June which was consistent with outmigrating smolts found in Battle, Mill, and Deer Creeks (Johnson and Merrick 2012; Colby and Brown 2013). Interpretation of *O. mykiss* data collected at the RBDD was complicated as a robust resident (non-anadromous) population exists throughout the Upper Sacramento River and its' tributaries. Populations of anadromous and resident *O. mykiss* life history forms are often sympatric and may inter-breed (Zimmerman and Reeves 2000; Docker and Heath 2003), thereby reducing our abilities to separate the anadromous and non-anadromous components of this species. Donahue and Null (2013) conducted research using otolith Strontium/Calcium ratios to determine whether *O. mykiss* returning to a hatchery were progeny of anadromous or resident females. A similar analysis could be conducted using juvenile *O. mykiss* collected at the RBDD. Data from juveniles might provide incite as to whether temporal separation in spawn timing exists between anadromous and resident forms of O. mykiss coexisting within the Upper Sacramento River basin.

Linear regression equations developed using weight-length data obtained from *O. mykiss* showed a strong correlation between the two variables (r^2= 0.942). The annual slope coefficient varied slightly between 2.858 and 3.052. Carlander (1969) suggested that slopes less than 3.0 might indicate a crowded or stunted population. However, permit restrictions may have introduced bias into our results as we were unable to anesthetize and weigh fish >200 mm thereby reducing the slope of the regression compared to that of a complete analysis of the population.

Sample Effort Influence on Passage Estimates.—Sampling effort had profound effects on the precision of passage estimates and confidence intervals (Figures 10, 12, 14, 16, and 18). In general, as sampling effort decreased, variance within weekly passage estimates increased and the width of confidence intervals subsequently increased. This effect was most prominent when effort was reduced during peak periods of outmigration or for long periods of time (> 1 week) when sharp increases or decreases in fish abundance occurred. Unfortunately, sampling of outmigrant Chinook on a large river system such as the Sacramento River is invariably subject to discharge events that are insurmountable for variable periods of time.

Logistical factors including staffing and permitting restrictions can also have significant effects on the precision of estimates. For example, a comparison of BY 2002 and BY 2005 winter Chinook passage with equivalent effort values (0.64) shows less precision of BY 2002 passage estimates over BY 2005 (Table 5c). The basis of the relatively low effort in 2002 was capture restrictions prompted by ESA Section 10(a)(1)(A) NMFS permits for endangered winter Chinook. Moreover, staff levels were initially low as the program was reinstated after a nearly two-year hiatus and substantial sub-sampling measures (i.e., standardized sub-sampling of repeated weeks) had to be taken during record abundance levels. The net effect was that sampling of fry, the predominant size-class of ocean type Chinook (Moyle 2002; Figure 6a/b), was reduced in terms of the number of days each week and hours of each night sampled during the peak emigration period. The overall net effect was 20% wider CI's about the 2002 estimate (i.e., less precision) compared to BY 2005. This was due to interpolation of 45% of the fry data which comprised 90% of the 2002 annual estimate. In contrast, BY 2005 sampled 90% of the fry data which comprised 90% of the annual estimate. Effort was reduced 36% in 2005 as a result of winter storms whereby sampling ceased for 3 straight weeks due to high river discharge levels. The effect of that lost sampling time in January did little to reduce the precision of the BY 2005 estimate as it was during a period when a mere fraction of a percent of total passage for winter Chinook typically occurs (Figure 15). The impact to the BY 2005 *fall Chinook* passage estimate, on the other hand, was very wide CI's about the estimate due to the lowest effort of all 11 years during a critical time period for that run's outmigration (Table 5a, Figure 11).

In summary, the precision of passage estimates can vary widely for numerous reasons within runs and among years. Inter-annual variability in environmental conditions will always be a factor when attempting to sample a riverine environment. Making good sampling decisions with knowledge of the species of interest and riverine conditions coupled with tenacity to sample critical periods of outmigration (Volkhardt et al. 2007) are key to generating passage estimates with an acceptable level of precision. Applying effort throughout each period of interest needs to be balanced between the value of data collected, an acceptable level of precision required of the data, the cost to attain the required precision, the impact sampling may have to a particular species, and the feasibility to appropriately sample the species of interest.

Chinook Passage Variability.—Juvenile Chinook passage by one to four runs occurs every single day of the year in varying proportions at RBDD. The sources and degree of variability of juvenile Chinook passage are as diverse as the life-history and migration strategies of the runs they encompass. The magnitude of run-specific adult spawners appears to have the greatest influence on the overall magnitude of juvenile Chinook passage and associated variability.

In recent decades, fall Chinook adults consistently dominated the Upper Sacramento River spawning salmon populations (Williams 2006, Azat 2013). Throughout the past decade, we witnessed a 'collapse' of the Sacramento River fall Chinook adult population and accordingly tracked declines in juvenile passage (Figure 10). Lindley et al. (2009) analyzed the freshwater and marine components of fall Chinook outmigrants from BY 2004 and 2005 through their return as adults in 2007 and 2008. They indicated BY 2004 and 2005 juveniles encountered poor marine conditions upon ocean entry in the spring of 2005 and 2006 which resulted in the marked decline in fall Chinook adult abundance starting in 2007.

Juvenile fall Chinook had the greatest mean annual passage value (14,774,923) of the four runs sampled at RBDD (Table 5a). Fall Chinook passage also exhibited the second smallest degree of variability with a CV of 46.2%. Notably, fall Chinook annual production by the CNFH averages 12 million juveniles, a similar value to the mean passage value of unmarked fall Chinook[7]. Fall Chinook production fish from CNFH contributed heavily to the relative stability of the annual returning fall Chinook adult population (Williams 2006) and, consequently, juvenile passage estimates over the past eleven years (i.e., basis of fall Chinook population).

Temporal abundance patterns of fall Chinook indicate the primary passage of juveniles occurs between late December and March (Figure 11a/b). Over half the run passed RBDD by mid-February, yet this varied over the 11-year period by +/- one month. Fall run passage on the American River (Williams 2006), Clear Creek (Earley et al. 2013a) and Stanislaus River (Pyper and Justice 2006) in California generally subsides to low values by the end of March. This would be consistent with the ocean type migration strategy as noted by Moyle (2002). The remaining fall run smolts and subsequent 'jump' in abundance in April to May was a result of the unmarked proportion of the CNFH production releases. Reduced variability in weekly passage was observed in the final 20% of annual fall Chinook passage (Figure 11b).

Spring Chinook had the lowest average passage value of 364,000 juveniles and the lowest CV of 45% (Table 5d). The low value of spring Chinook passage at RBDD can be attributed to a relatively small number of adults spawning primarily in Battle and Clear Creeks (Figure 1). Some extant populations appear to inhabit Beegum Creek, a tributary to Cottonwood Creek (CDFG 2001), and in the mainstem Sacramento River (Killam 2009, Azat 2013). Of particular interest with respect to the accuracy of spring Chinook

---

[7] Fall Chinook passages estimates do not include the marked proportion (0-25%) of CNFH production fish. Unmarked fish of hatchery origin are included in annual passage estimates and their occurrence is evidenced by increased passage values primarily in May through June of each calendar year (Figure 11b).

juvenile passage at RBDD is the annual spawn timing of adult spring Chinook and expected juvenile emergence timing. USFWS rotary trapping operations on Battle and Clear Creeks between 2003 and 2012 have not predicted emergence (i.e., through temperature unit analyses; Beacham and Murray 1990) nor sampled juvenile spring Chinook prior to November of each year. On average, the first spring Chinook juvenile migrants from Battle and Clear Creeks were sampled during the week of November 26th each year (USFWS, unpublished data). As a result, LAD criteria used to identify juvenile spring Chinook at RBDD are noticeably inaccurate as fish sampled prior to late November were not sampled upstream in primary production areas at that time of year.

Simulating a removal of all LAD spring run between October 16 and November 25 of each year sampled would result in *decreased* spring run passage estimates by 19%, on average (range 2.6 to 44.2%). The effects of removing incorrectly assigned fry annually did not indicate a statistically significant difference between annual estimates (paired *t*-test, $N = 11$, $P < 0.001$). When incorrectly assigned fry are removed, the slightly more accurate simulated spring Chinook annual passage values remain within the 90% CI of standard estimates.

Furthering the simulation by adding the weekly October through November spring Chinook estimated passage to the winter Chinook passage estimates (i.e., late spawning or emerging winter run most likely candidate; see USFWS 2013), had minimal effect on the magnitude of winter Chinook passage. The average *increase* to winter Chinook passage was a mere 2.6% (range 0.6 to 8.8%) and simulated passage remained within the 90% CI of the annual winter Chinook estimates in all years.

Winter Chinook average annual juvenile passage was the second highest of the four runs estimated at 3,763,362 (Table 5c). The CV of the annual estimates was 73.2%; higher than fall or spring, but moderately dispersed. Overall, passage in years 2002, 2003, 2005, and 2006 surpassed the highest previous value of winter Chinook passage since juvenile monitoring began in 1995 (Gaines and Martin 2002). Similar to fall Chinook, winter Chinook adult escapement and subsequent juvenile passage began a marked decline in 2007 (Figure 16). Juvenile winter Chinook have been determined to enter the ocean during March and April of each spring (Pyper et al. 2013). Overall, it is believed that juvenile winter Chinook suffered the same fate as juvenile fall Chinook with poor marine conditions upon ocean entry in the spring of 2005 and 2006. Winter Chinook juvenile cohort replacement rates dropped below 1.0 starting with BY 2007, similar to adult fall run as noted in Lindley et al. (2009). The lowest passage estimate between 2002 and 2012 for winter Chinook occurred in 2011 at 848,976. Not until 2014 will we know if adult or juvenile cohort replacement rates will improve to a value of 1.0 or greater. Winter Chinook passage estimates between BY 1999 to BY 2002 (Gaines and Poytress 2003) indicate that replacement rates can vary substantially and replacement rates of 3.0 or greater have been estimated between juvenile cohorts.

Late-fall Chinook passage averaged 447,711 juveniles for the 11-year period and exhibited the greatest amount of variability with a CV of 159.9%. Late-fall Chinook juvenile passage estimates are likely affected by LAD criteria similar to spring Chinook in terms of potential for overestimation. The variability associated with weekly late-fall passage shows a decrease in median abundance by the beginning of June each year which may be more representative of actual late-fall emergence. Additionally, as demonstrated by Figures 13 a/b, the late-fall migration starts abruptly unlike for fall and winter Chinook which follow a more bell-shaped pattern in abundance (See Figures 11a/b and 15 a/b). It was highly likely that early emergent late-fall fry were, in fact, late emerging fall Chinook. Run specific genetic monitoring (Banks et al. 2000, Banks and Jacobsen 2004) could assist in determining the magnitude of the error in run assignment.

Sampling effort during mid-April to mid-May, the early late-fall run emergent period, was also typically low in an effort to reduce impacts to CNFH fall Chinook production fish caught in rotary traps. Within trap predation of fry by CNFH production smolts could also negatively bias late-fall juvenile production estimates. Sub-sampling of portions of the day and night (≤25% of each period) were only feasible with full staffing in some years which can reduce potential bias. During all other years, multiple sample days were typically sacrificed to allow peaks in CNFH production fish to recede ultimately reducing the accuracy of late-fall passage estimates.

Fry-Equivalent Chinook Production Estimates.—Estimation and analyses of the productivity of salmon runs in the Upper Sacramento River basin can provide valuable information to a variety of interests. Management of California’s complex water resources for agriculture, municipal, commercial, and ecological uses is an increasingly controversial and complex endeavor. Knowledge of the effects of manipulating water storage and river processes on the productivity of the Sacramento River fish populations can only benefit fishery and water operations managers in an attempt to balance the competing demands on the system. Reducing uncertainty associated with threatened and/or endangered fish population dynamics by employing knowledge of the abundance, migration timing, and variability of those populations over time can then inform the decision making processes guiding management of water and fishery resources into the future.

Fall Chinook fry-equivalent juvenile production indices (FEJPI; Table 6a) indicate a significant and moderate correlation with fall Chinook escapement estimates (Figure 20a). Approximately 53% of the variation associated with fall FEJPI’s was attributed to the estimated number of females in the system above RBDD each year (Figure 20a). The CV of estimated fall run females was greater than 132% indicating wide dispersion of contributors to the juvenile population over the eleven-year period. Conversely, the CV of FEJPI’s was relatively low valued at 43%. Furthermore, recruits per female and similarly egg-to-fry survival demonstrated moderately low average values of 749 and

13.9%, respectively, when compared to the estimated values for winter Chinook (Table 6a).

As noted in Kocik and Taylor (1987), factors limiting production are typically a combination of biotic and abiotic factors. The sources of variability relating to fall FEJPIs are directly and indirectly related to adult abundance, but abundance alone does not explain the low CV in fall run juvenile production. A simple, albeit incorrect, conclusion might be that adult escapement of fall Chinook in some years exceeds the useable spawning area of the system (Bovee 1982, Connor et al. 2001) or optimal spawning efficiency (Wales and Coots 1955). Upon closer examination of the likely origin(s) of juvenile production, the data indicate substantial variability in the distribution of fall run adults between the mainstem Sacramento River and tributaries, including Clear Creek and Battle Creek, between years. Proportions of returning adults within the mainstem and Battle Creek have demonstrated high degrees of variability (Figure 26). The overwhelming return of fall run to Battle Creek in 2002 resulted in the lowest value of fall Chinook recruits per female (*N* = 89) which was outside two standard deviations of the average (Table 6a). The number of adults returning to the CNFH clearly overwhelmed the capacity of Battle Creek to produce juveniles. Sub-optimal wetted useable spawning area (Bovee 1982), red superimposition (McNeil 1968, Heard 1978), and female stress resulting in egg retention (Neave 1953, Foerster 1968) were likely just some of the factors that reduced the overall productivity of the 2002 fall Chinook adults returning to the Upper Sacramento River.

In years when estimates of fall Chinook production were at their highest in terms of recruits/females (Table 6a), the proportions spawning in the mainstem and combined tributaries were closest to 50:50. Further examination indicates that when contributions from the Battle and Clear Creeks accounted for equal proportions (i.e., 25% each), peak values of ~1,500 recruits/females were estimated to have been produced resulting in the highest net spawning efficiency (Wales and Coots 1955). Optimal natural juvenile fall Chinook production values in the Upper Sacramento River system could result under some conditions if integration of restoration projects on Battle and Clear Creeks integrate with mitigation projects (e.g., CNFH production) for the mainstem Sacramento River. The effect of consistent hatchery fall Chinook production on Battle Creek irrespective of natural fish production in the Sacramento and Chinook-bearing tributaries should be considered for further evaluation as was noted in Williams (2006). The effects of restoration of Clear Creek appear to be providing production benefits on stream and basin wide scales. Management prerogatives and actions related to the CVP affect both factors, to varying degrees, and decisions should be prioritized to attain optimal results for both fisheries and water operations.

Late-fall Chinook FEJPIs indicated high variability (CV = 170%; Table 6b), but a strong correlation with escapement estimates (r^2=0.67; Figure 20b). The magnitude of late-fall FEJPIs were consistently an order of magnitude less than FEJPIs of fall Chinook. One exception was 2002, which increased the CV for the eleven-year period by 100%

(Table 6b). The fall and late-fall adult Chinook escapement values of 2001 and 2002 were high compared to the other 10 years of data (Azat 2013). A large run of late spawning fall run may also have contributed to the large number of juvenile fish falling within the late-fall size-class according to LAD criteria, but the adult estimate could have suffered similar inaccuracies in run assignment. Variability in CV values of anadromous fish was described by Rothchild and Dinardo (1987) as being inversely related to the number of years included within the time series analyses. While 2002 appears to be an outlier in this data set, it is likely with more years of data collection and analyses the CV associated with late-fall production would be more commensurate with other runs of Chinook.

The stream-type migration strategy noted by Moyle (2002) and our size classification method categorized the majority of late-fall outmigrants as smolts ($\bar{y}$ = 62%) which inflated the late-fall FEJPIs greatly at times (Table 5b, Table 6b). Recruits per female and similarly egg-to-fry survival had low CVs and the lowest average values of 131 and 2.8%, respectively, in comparison to other runs (Table 6b). This was unexpected as this metric does not appear to apply well to a run that was sampled primarily as smolts ($\bar{y}$ = 62%) over eleven years. Moreover, fry-equivalent calculations based on a static fry-to-smolt survival estimate of 59% (Hallock undated) was unlikely to be an accurate constant for late-fall Chinook as it was calculated from hatchery-based fall Chinook survival data. The fact that correlations with adult escapement were determined to be significant and moderately strong was unexpected given the vagaries of sampling late-fall Chinook smolts and the use of the static 59% survival estimate inversely applied to the majority of the run sampled. Additionally, difficulties with performing carcass surveys for late-fall Chinook due to low visibility, winter flow events or logistical issues (Killam 2009 and 2012) typically result in sub-optimal sampling conditions and, assumedly, would reduce the accuracy of the adult estimate.

Overall, production of late-fall Chinook appears low and the run has been characterized by some as vulnerable to extinction (Moyle et al. 2008, Katz et al. 2012). Greater attention to the relatively low abundance levels and juvenile rearing habitat needs of this genetically distinct run (Banks et al. 2000, Garza et al. 2007, Smith et al. 2009) with its unique over-summering, relatively long freshwater residency (Randall et al. 1987) and large size-at-outmigration strategy (Zabel and Achord 2004) should be afforded. The life-history strategies of late-fall Chinook have likely allowed them to persist in the Upper Sacramento River system as they occupy a distinct ecological niche. Juvenile monitoring of this run could benefit greatly if confidence in the accuracy of run assignment of juveniles was examined using non-lethal genetic techniques (Harvey and Stroble 2013).

Comparisons between winter Chinook adults and juvenile production began early using data generated by this monitoring project. Martin et al. (2001) demonstrated a strong relationship with only 5 years of data. The annual analyses of the winter FEJPI and adult estimates continually indicated a strong relationship with the addition of each year’s data (See Gaines and Poytress 2003, Poytress and Carrillo 2008, Poytress and Carrillo 2012). The analysis of the most recent 11 years of data continues to indicate a strong relationship between the two variables even as adult escapement values have varied an order of magnitude.

Winter Chinook FEJPIs indicated mild variability (CV = 67%; Table 6c) and a very strong level of significance and correlation with female adult escapement estimates (r^2 =0.90; Figure 20c). Intensive adult and juvenile monitoring for this ESA listed endangered species coupled with superlative sampling conditions, in most years, appears to have resulted in very high quality information regarding the status and trends in adult and juvenile population abundance.

Egg-to-fry survival estimates generated from annual winter Chinook data indicate a range of values between 15 and 49% (Table 6c). At first glance, this appeared counterintuitive based on the highly regulated Sacramento River system (e.g., flow and water temperatures) that typically exists during the winter Chinook spawning period. The average egg-to-fry survival estimate of 26% is considerably higher than that determined from other studies on Pacific salmonids ($\bar{y}$ = 15%; e.g., Wales and Coots 1955) but was consistent with highly regulated aquatic systems (Groot and Margolis 1991). A very low CV of 38% also appeared consistent with a regulated system. Recruits per female, similarly, indicated a low CV of 36% and the second highest average value of 1,349 (Table 6c).

Natural log transformed adult female estimates influenced juvenile production and a significant relationship was determined accounting for roughly half of the variability associated with egg-to-fry survival rates (r^2 = 0.51, *df* = 10, *P* = 0.012). Densities of winter Chinook spawners are much lower currently than in the years estimated following the completion of Shasta Dam (USFWS 2001). Completion of the re-engineered Anderson-Cottonwood Irrigation District fish ladders in 2001 resulted in greater access and subsequently a greater concentration of spawners in the uppermost reaches accessible to anadromous fish (USFWS 2006-2011). Competition for optimal spawning habitat can result in lower juvenile production if sub-optimal wetted useable spawning area (Bovee 1982), red superimposition (McNeil 1968, Heard 1978), and female stress resulting in egg retention (Neave 1953, Foerster 1968) occur to varying degrees. Low resolution carcass recovery data (e.g., reach specific) indicate an abundance of spawners utilizing the uppermost 6 river miles of the Sacramento River (USFWS 2006-2011) even as seemingly suitable habitat has been made available for approximately 20+ river miles downstream of the terminus at Keswick Dam (RM 302). Geist et al. (2002) studied physiochemical characteristics affecting redd site selection preferences by Chinook and different growth and development rates have been attributed to different segments within the same river (Wells and McNeil 1970). High resolution redd surveys or spawning area mapping employing a GIS spatial analytical framework (Earley et al. 2013b) may shed light on the variability associated with winter Chinook spawning habitat over a variety of adult abundance levels. Analyses of these types of data could result in less uncertainty over the annual specific density dependent mechanisms affecting juvenile production and provide direction for future restoration activities for winter Chinook.

Spring run Chinook FEJPIs were the lowest of all four runs monitored and indicated the lowest variability (CV = 41%; Table 6d). No relationship with female adult escapement estimates was detected (r^2 =0.00; Figure 20d) and may be attributed substantially to measurement error (Sokal and Rohlf 1995). Estimates of recruits per female averaged 3,122 and the egg-to-fry survival value averaged 61.5%. These values appear unreasonable outside of a hatchery environment and well above those found for other runs (this report) and other studies (e.g., Wales and Coots 1955, Groot and Margolis 1991). Individual annual estimates varied moderately (CV= 70.8%) and nearly half appeared highly unlikely, with some values exceeding the number of eggs deposited by spawners (Table 6d).

Spring Chinook juvenile fish production estimates at RBDD were the least accurate and currently constitute 2.1%, on average, of total annual Chinook production above RBDD. Mainstem Sacramento River spawner estimates ranged from a low of 0 to a high of 370 between 2002 and 2012. Annual indexes of spring Chinook adult abundance above RBDD during the same years constitute 2.7% of the total escapement estimated in the Sacramento River system (Azat 2013). Given the relatively sporadic and low adult abundance levels, vagaries of using LAD criteria and annual CNFH fall Chinook production releases with fractional mark rates, no relationship could be found between adult escapement and spring Chinook FEJPIs when attempting to use methods to correct for these inaccuracies. The effects of inaccurate spring run assignment did not appear to affect the FEJPIs of other runs (e.g., winter or fall run) and therefore were not considered biologically significant. Genetic monitoring of fry in the fall after emergence from tributaries where emergence and migration data is collected (e.g., Earley et al. 2013a) may allow for more accurate estimation of the contributions of this run to the Upper Sacramento River outmigrant population.

Green Sturgeon Capture Dynamics.—Rotary traps were originally constructed to sample outmigrating salmonid smolts, but have been effective in sampling a variety of downstream migrating fish (Volkhardt et al. 2007). Rotary traps sampling at RBDD have been effective at monitoring temporal and spatial trends in relative abundance of Green Sturgeon since 1995 (Gaines and Martin 2002).

Annual adult Green Sturgeon aggregations were observed behind the RBDD when gates were lowered each spring (Brown 2007). Green sturgeon larvae were captured in 2012 (Table 7), the first year the RBDD gates were not lowered as it was replaced by a permanent pumping plant (NMFS 2009). Spawning was determined to have occurred in multiple locations as far as 20 river miles upstream of RBDD (Poytress et al. 2009-2013). The location of the RBDD rotary traps has been confirmed to be within the Green

Sturgeon spawning grounds as eggs were sampled directly below the RBDD and upstream of the RBDD traps in multiple years (Poytress et al. 2009, 2010, 2012).

Total length distribution data from Green Sturgeon collections at RBDD indicate a narrow and consistent size-class of larvae (Figure 21a). These data are consistent with laboratory-based studies conducted by Kynard et al. (2005) on the behavior of early life intervals of Klamath River Green Sturgeon. Their study determined that larvae migrated during two distinct periods (i.e., two-step migration). The first migration of newly exogenous feeding larvae was determined to be an initial dispersion from production areas. The second migration (of juveniles) to overwintering areas occurred in the fall some 180 days after hatching, on average. Our rotary trap data suggest we are sampling exclusively the initial redistribution of larvae from egg incubation and hatching areas.

Benthic D-net sampling conducted by Poytress et al. (2010-2011) targeted the lowest portion of the water column (inverse of rotary traps) and consistently captured Green Sturgeon larvae of the same size-class and temporal distribution pattern as rotary traps. D-net samples were collected between May and early-August (See Figure 21b for corresponding RST data only) downstream of spawning areas in years 2008-2011; even as no larvae were collected by rotary traps in 2008. Larvae were sampled by both methods primarily in the thalweg and in river velocities >/= 1.3 ft/sec[8]. Conversely, zero *juveniles* were collected with benthic D-nets in a pilot study (Poytress et al. 2013) targeting this life-stage and habitat type in the benthos during the fall period. Rotary traps have collected a few sporadic juveniles (e.g., outliers; Figure 21a) over the entire sample record of the project. These data indicate that Green Sturgeon juveniles are no longer utilizing our sampling region or more likely using a different habitat type (Hayes et al. 1996). Accordingly, rotary traps appear to be a relatively ineffective gear type for sampling the secondary juvenile sturgeon migration.

Protections afforded to ESA listed southern distinct population segment of Green Sturgeon (since 2006), limited quantities of larvae, and the small size at capture have not allowed their drift distances (Auer and Baker 2002), rates (Braaten et al. 2008), or rotary trap efficiencies to be calculated for the initial dispersion migration of Sacramento River Green Sturgeon at RBDD. Relative abundance indices for Green Sturgeon were highly variable, typically low valued at <1.0 fish/ac-ft sampled (Table 7), and contained one extraordinarily strong year-class (Figure 21c). As noted by Allen and Hightower (2010), variations in recruitment by orders of magnitude between years is common among fish stocks. Moreover, strong and weak year classes greatly influence adult fish populations. Green sturgeon relative abundance indices should not be interpreted as recruitment to the adult population, but should be viewed as a production metric influencing recruitment (e.g., age-0 year class strength). Alternately,

---

[8] Rotary traps generally require a minimum water velocity of 1.2 ft/sec to operate properly. D-nets sampled velocities ranging from 1.3 – 6.6 ft/sec. RST' sampled velocities ranging from 1.3 – 6.3 ft/sec.

Green Sturgeon larvae relative abundance indices could be viewed as an indirect metric for adult spawning population densities *upstream* of RBDD if genetic monitoring were conducted consistently (Israel and May 2010).

Lamprey Capture Dynamics.— Similar to Green Sturgeon, rotary trap sampling for Chinook salmon has provided the additional benefit of capturing out-migrating lamprey ammocoetes and juveniles. Greater attention to this ancestor of the earliest vertebrates (Moyle 2002) has recently been paid by the USFWS since it was petitioned for listing under the ESA in 2003 (Nawa et al. 2003). Although not listed due to inadequate data on the species' range and threats, the USFWS has engaged in a strategy to collaboratively conserve and restore Pacific Lamprey throughout their native range. Through the formation and development of the Pacific Lamprey Conservation Initiative, an assessment of Lamprey populations in California has recently been completed (Goodman and Reid 2012). The assessment noted that Lamprey species had been extirpated from at least 55% of their historical habitat north of Point Conception, CA by 1985. Long-term monitoring data sets including the RBDD rotary trap data, utilizing temporal and spatial distribution patterns as well as size-class and relative abundance levels of lamprey, can aid in the assessment and conservation of this ecologically vital species (Close et al. 2002).

Variability in annual size-class total length distributions was typically minor for both lamprey life stages sampled (Figure 22a and Figure 23a). Ammocoetes were slightly smaller than macropthalmia and slightly more variable in their annual average length distributions valued at 110 mm TL (CV= 4.6%; Table 8a). Pacific Lamprey macropthalmia were the dominant life stage sampled and the median size at capture was consistently near 125 mm TL (CV= 1.6%; Table 8b). Adults, typically noted as outliers, were encountered in much lower frequencies and were considered upstream migrants inadvertently captured when the RBDD gates were lowered as they sought upstream passage around the partial migration barrier.

Temporal distribution patterns indicated that ammocoetes and macropthalmia migrate past RBDD year-round. Ammocoetes, on average, were sampled regularly throughout the year (Figure 22b), whereas macropthalmia moved, en masse, episodically between November and March (Figure 23b). These data are consistent with studies of macropthalmia in the Columbia River system as noted by Close et al. (1995) and Kostow (2002).

Relative abundance indices of ammocoetes (Figure 22c) varied little between years and little overall when compared with macropthalmia (Figure 23c). Macropthalmia abundance indices varied considerably between years (Table 8b). On average, macropthalmia relative abundance was six times that of ammocoetes indicating metamorphosis and redistribution to different habitats from those used for rearing by ammocoetes (Goodman and Reid 2012). Differences in the relative abundance CV's of the two life stages likely indicates differences in catchability (Hubert and Fabrizio 2007) or habitat use (Hayes et al. 1996), variable migration trigger effects, or variability in sampling effort that often occurred during periods of macropthalmia migration.

Water Temperature and Juvenile Fish Dynamics.—Slight variation within and among salmonid runs (including *O. mykiss*) and years was noted for water temperatures found at RBDD (Tables 9a-e). Nonetheless, Upper Sacramento River salmonids were subjected to a relatively wide 20 degree range of water temperatures. Temperatures were recorded between 44 and 64 degrees with the average being 55 degrees each year. As summarized in Vogel and Marine (1991), the range of temperatures experienced by Chinook fry and pre-smolt/smolts in the last 11 years of passage at RBDD have been within the optimal range of thermal tolerances for survival.

Sacramento River water temperatures below Shasta/Keswick dams can be managed at certain times of the year under some conditions through discharge management to provide selective withdrawal at submerged intakes (USBR 1991 & 1994, Vermeyen 1997). Ambient air temperatures typically regulate river water temperatures during winter and early spring periods while storage and flood control operations are preeminent. The water temperatures recorded during the last 11 years appear to have been favorable for extant spring run spawners, and more so for fall and late-fall run Chinook and *O. mykiss* spawner and outmigrant populations.

The most vulnerable Chinook run to temperature management operations conducted by the USBR is winter Chinook (NMFS 2009). Temperature management of the Sacramento River via Shasta/Keswick releases by the USBR for winter Chinook appeared to be effective during the last 11 years as evidenced by the relatively favorable and stable egg-to-fry survival estimates (Table 6c). Moreover, temperature management of the upper 50 river miles of the Sacramento River aimed at winter Chinook resulted in benefits to over-summering late-fall Chinook pre-smolts and a relatively small proportion of fall Chinook smolts.

Temperature management during the summertime aimed at winter Chinook may have indirectly favored the resident form of *O. mykiss*. As noted by Lieberman et al. (2001), altering the thermal regime and food web structure by way of temperature management likely affects the proportion of anadromous to resident forms in large rivers. Lamprey species have likely benefitted from temperature management as temperatures for early life stages of lamprey in the mainstem Sacramento River appear to have been, on average, optimal (Meeuwig et al. 2005) in the last 11 years (Table 9g).

Green Sturgeon have likely benefitted from temperature management efforts aimed at winter Chinook spawning and production, albeit less comprehensively. Van Ennennaam et al. (2005) determined Green Sturgeon egg development temperatures to be optimal between 57.0 and 63.5° F. Mayfield and Cech (2004) determined optimal temperatures for larval development to be between 59.0 and 66.2°F. Temperatures recorded at RBDD during larval capture periods averaged 58.3°F and were generally within sub-optimal (lower end) to optimal ranges (Table 9f). A weak negative relationship between Green Sturgeon CPUV and water temperatures was detected in our analysis indicating greater capture rates at lower water temperatures (Figure 24d). The slightly sub-optimal temperatures might result in larvae migrating from incubation areas prematurely. Conversely, the optimal thermal environment of the lab-based migration data from Kynard et al. (2005) resulted in very similar migration timing between the lab and larval captures in rotary traps in terms of days post hatch (Poytress et al. 2013). Sacramento River Green Sturgeon larvae appear to be following their natural life-history migration patterns as opposed to being coerced from their incubation areas due to sub-optimal water temperatures at RBDD. This may not be true for larvae migrating some 20 miles upstream where the effects of temperature management may have a more pronounced negative effect on Green Sturgeon larvae (Poytress et al. 2013). Temperature management for Chinook may also have the indirect negative effect of redirecting the spawning habitat of Green Sturgeon adults by 20 river miles. A habitat comparison study on the relative value of the upper 20 river miles of the Sacramento River versus 20 lower river miles of habitat currently benefitting Green Sturgeon adult spawners and eggs from temperature management efforts should be conducted.

River Discharge, Turbidity, and Juvenile Fish Dynamics.—Volkhardt et al. (2007) stated that “flow” (i.e., discharge) was a dominant factor in juvenile trapping operations. Trapping efficiency and migration rates are affected by flow and the RBDD rotary trap passage data reflect these statements well. Exploratory plots demonstrating fry (Appendix 2, Figures A1-A11) and pre-smolt/smolt winter Chinook passage (Appendix 2, Figures A12-A23) were produced to illustrate the effects of environmental variables on fish migration. Turbidity was plotted, but not included in the final plots presented as the effects could not be deciphered from discharge at the daily scale of analyses.

The effects of river discharge on turbidity and resultant fish passage are complex in the Upper Sacramento River where ocean and stream-type Chinook of various size-classes (i.e., runs, life stages and ages) migrate daily throughout the year. Decreases in discharge in the Shasta/Keswick dam regulated Sacramento River, typical of late summer to early winter periods, appear to coincide with relatively clear water conditions and low turbidity (e.g., ~ 1.5 NTU) at RBDD. Fall or early winter freshets and winter rain-driven storm events result in highly variable increases in discharge levels and turbidity measures in terms of the magnitude and duration depending upon the source(s) of run-off.

A course scale analyses of fish passage and river discharge and turbidity measurements during storm events typically indicates a pattern that fish passage increases with simultaneous increases in both variables. Inspection of Chinook passage on a daily time step typically demonstrate a reduction in fish passage a day prior to a storm or rain-event during periods of stable river discharge. As storms produced increases in run-off or discharge from tributary inputs outside of the Shasta/Keswick dam complex, mean daily turbidity typically increased and fish passage began to increase. When storm related increases in discharge diminished, turbidity diminished, but Chinook passage often increased greatly for 24-72 hours after the peak flow event.

One problem confounding the results of storm and fish passage observations and analyses was that sampling during large storm run-off/discharge events often ceased due to safety concerns, concerns for fish impacts or simply due to the inability to sample the river when woody debris stop rotary traps from operating properly. In some years, storm events resulted in discharge levels too great to sample effectively or damaged traps which resulted in numerous days or weeks un-sampled afterwards. The results are typically negative bias in passage estimates if days following the peak discharge or concurrent turbidity events are un-sampled. Alternately, the direction of bias can be positive depending on time of year, interpolation methods, sample effort during extended storm periods, or fish developmental stage.

A fine scale, hourly analysis of fish passage, river discharge and turbidity during storm events indicated a more intricate relationship between the variables. As a comparison, two separate storm events (December 2005 and November 2012) were analyzed (Figure 27a/b). In 2005, 24-hour samples were conducted prior to and after the peak flow period which was missed due to an inability to sample the river as it more than quintupled in discharge (i.e., 7,000 CFS to ~35,000 CFS). During this storm event, sampling was conducted following the peak of river discharge as river stage decreased, but while turbidity continued to peak (Figure 27a). The planned 24-hour sample had to be cut short due to the huge influx of fry and smolt passage that occurred during the turbidity increase (i.e., from 10’s to 1,000’s per hour) and the need to reduce the potential impact to listed winter Chinook.

During a November 2012 storm event, a different strategy was employed to collect data more effectively throughout the storm period. For this event, we randomly sampled portions of the day and night in an attempt to manage the huge influx of fish anticipated to occur during the year’s first storm event. Between 11/17/12 and 11/23/12, the project was able to collect 7-randomly selected samples that occurred throughout the first major river stage increase (Figure 27b). Samples were collected during increases and decreases in river stage. Samples were also collected prior to, during, and following a substantial increase in turbidity that lagged behind the initial stage increase by nearly 12 hours (Figure 27b). Fry and pre-smolt/smolt Chinook and juvenile lamprey fish passage increased exponentially. The peak period of fish capture occurred following the peak in river stage and during the increase and peak periods of turbidity measurements taken at RBDD. Capture rates subsided in the following days, but then increased greatly during the night-time period at the beginning of the next stage increase (Figure 27b).

Overall, it appears that flow and turbidity are important drivers for fish passage. The RBDD rotary trap data indicate that increased turbidity often results in greater fish passage than increases in river discharge or stage alone which often occur as part of water management operations at Shasta Dam. The two variables generally increase sequentially with discharge increases followed by turbidity increases (Figure 27a/b). Fish passage increases often coincide with the increase in turbidity which can often be sampled more effectively than increases in river discharge and may result in positive bias of juvenile fish passage estimates if the peak turbidity event is sampled compared to the peak flow event.

The importance of the first storm event of the fall or winter period cannot be overstated. Chinook smolt and juvenile lamprey passage increased exponentially and fry passage can be significant if first storms occur as fall Chinook begin to emerge. Fishery and water operations managers should be aware of the importance of the first Sacramento River stage increases following the summer and fall Sacramento River flow regulation period. The redistribution of winter and over-summering fall and late-fall Chinook smolts, or more generally, all anadromous juvenile fish[9] migrating from the Upper Sacramento River to the lower river and Sacramento San-Joaquin Delta with the first storm events of each water year should be incorporated into management plans for Delta operations.

Moon Illuminosity and Juvenile Fish Dynamics.—As noted in Hubert and Fabrizio (2007), species and life stages within species exhibit differing behaviors and therefore catchability in response to light levels. Gaines and Martin (2002) determined that Chinook passage occurred primarily during nocturnal periods except when turbidity levels and discharge increased with storm events. Further analyses of the effects of moon phase and ambient light levels in a statistical framework may be warranted for Chinook salmon as trends were detected based on observations. Rotary trap passage data indicated winter Chinook fry exhibit decreased nocturnal passage levels during and around the full moon phase in the fall (Appendix 3, Figures A1-A11). Pre-smolt/smolt winter Chinook appeared less influenced by night-time light levels and much more influenced by changes in discharge levels (Appendix 3, Figures A12-A23). A similar phenomenon was noted by Reimers (1971) for juvenile fall Chinook in Edson Creek, Oregon. Alternately, more data concerning night time cloud cover may further clarify the behavior associated with moon illuminosity as pre-smolt/smolts were more likely to encounter unclear night time weather between late October and December each year.

Spring, fall and late-fall Chinook fry exhibited varying degrees of decreased passage during full moon periods, albeit storms and related hydrologic influx dominated peak migration periods. *O. mykiss* relative abundance was not analyzed with respect to moon illuminosity. Lamprey CPUV regression analyses indicated a significant, but nearly imperceptible relationship (Figure 25a) likely due to the fact that lamprey are captured throughout the year under nearly all conditions. Green Sturgeon regression analysis

---

[9] Juvenile Green Sturgeon have been captured sporadically during the first flow events along with large numbers of Pacific Lamprey juveniles and ammocoetes.

indicated no significant linear relationship between moon illuminosity and relative abundance (Figure 24a). Migration of age-0 Green Sturgeon larvae has been determined to occur during nocturnal hours (Kynard et al. 2005) primarily between 21:00 and 02:00 using D-nets (Poytress et al. 2011) and was presumed to be similar for rotary traps as periodic diel sampling events have not collected sturgeon during daytime sample periods.

Acknowledgments

The CALFED program and later California Bay-Delta Authority Ecosystem Restoration Program through a Directed Action of the California Department of Fish and Game (Grant # P0685507) provided funding for this project between 2002 and 2009. The U.S Bureau of Reclamation provided additional financial support during periods of fiscal insecurity by the State of California and for years 2010 through 2013 (Interagency Agreement No. R10PG20172). Numerous individuals over the years helped with development and implementation of this project including, but not limited to, Mark Belter, Brian Bissell, Oliver "Towns" Burgess, Michelle Casto-Yerty, David Colby, Nick Demetris, Melissa Dragan, Charles Elliott, Jessica Fischer, Sierra Franks, Phillip Gaines, Jerrad Goodell, Mike Gorman, Andrew Gross, Eric Grosvenor, Aime Gucker, Jeremy Haley, James Hoang, Matt Holt, Jess Johnson, Doug Killam, Tammy Knecht, Edwin Martin, Ryan Mertz, Josh Olsen, Erich Parizek, Andy Popper, Chad Praetorius, Adam Reimer, Ben Reining, Peter Roginski, Marie Schrecengost, Geoffrey Schroeder, Zach Sigler, Jennessy Toribio, David Trachtenbarg, Greg True, Charmayne Walker and Kara Yetifshefksy. Elizabeth Cook, Billie Jo DeMaagd, Valerie and Robert Emge, Tom Kisanuki, Christine Olsen, Harry Ostapenko, Deon Pollett, Jim Smith, Angela Taylor, and Keenan True provided programmatic support. We sincerely appreciate the support provided by the U.S. Bureau of Reclamation and former Red Bluff Diversion Dam staff, especially Jerry Sears and Paul Freeman.

Table 2. Summary of mark-recapture experiments conducted by RBDD rotary trap project between 2002 and 2013. Summaries include trap effort data, fish release and recapture group sizes (*N*) and mean fork lengths (FL), percentage of river discharge sampled (%Q) and estimated trap efficiency for each trial (%TE). Model data below each trial period indicate dates model was employed, total trials incorporated into model and linear regression values of slope, intercept, p-value and coeeficient of determination.

[1] Annual sex ratio values based on annual carcass survey estimates of female recoveries.

[2] Female fecundity estimates based on annual values from LSNFH winter Chinook spawning data collected between 2002 and 2012.

Table 6d. Spring Chinook fry-equivalent production estimates, lower and upper 90% confidence intervals (CI), estimates of adults upstream of RBDD (Adult Estimate), estimated female to male sex ratios, estimated females, estimates of female fecundity, calculated juveniles per estimated female (recruits per female) and egg-to-fry survival estimates (ETF) by brood year (BY) for Chinook sampled at RBDD rotary traps between October 16, 2002 and September 30, 2013.

BY	FRY EQ Passage	Lower 90% CI	Upper 90% CI	Adult Estimate	Sex Ratio (F: M)[1]		Estimated Females	Fecundity[2]	Recruits per Female	ETF

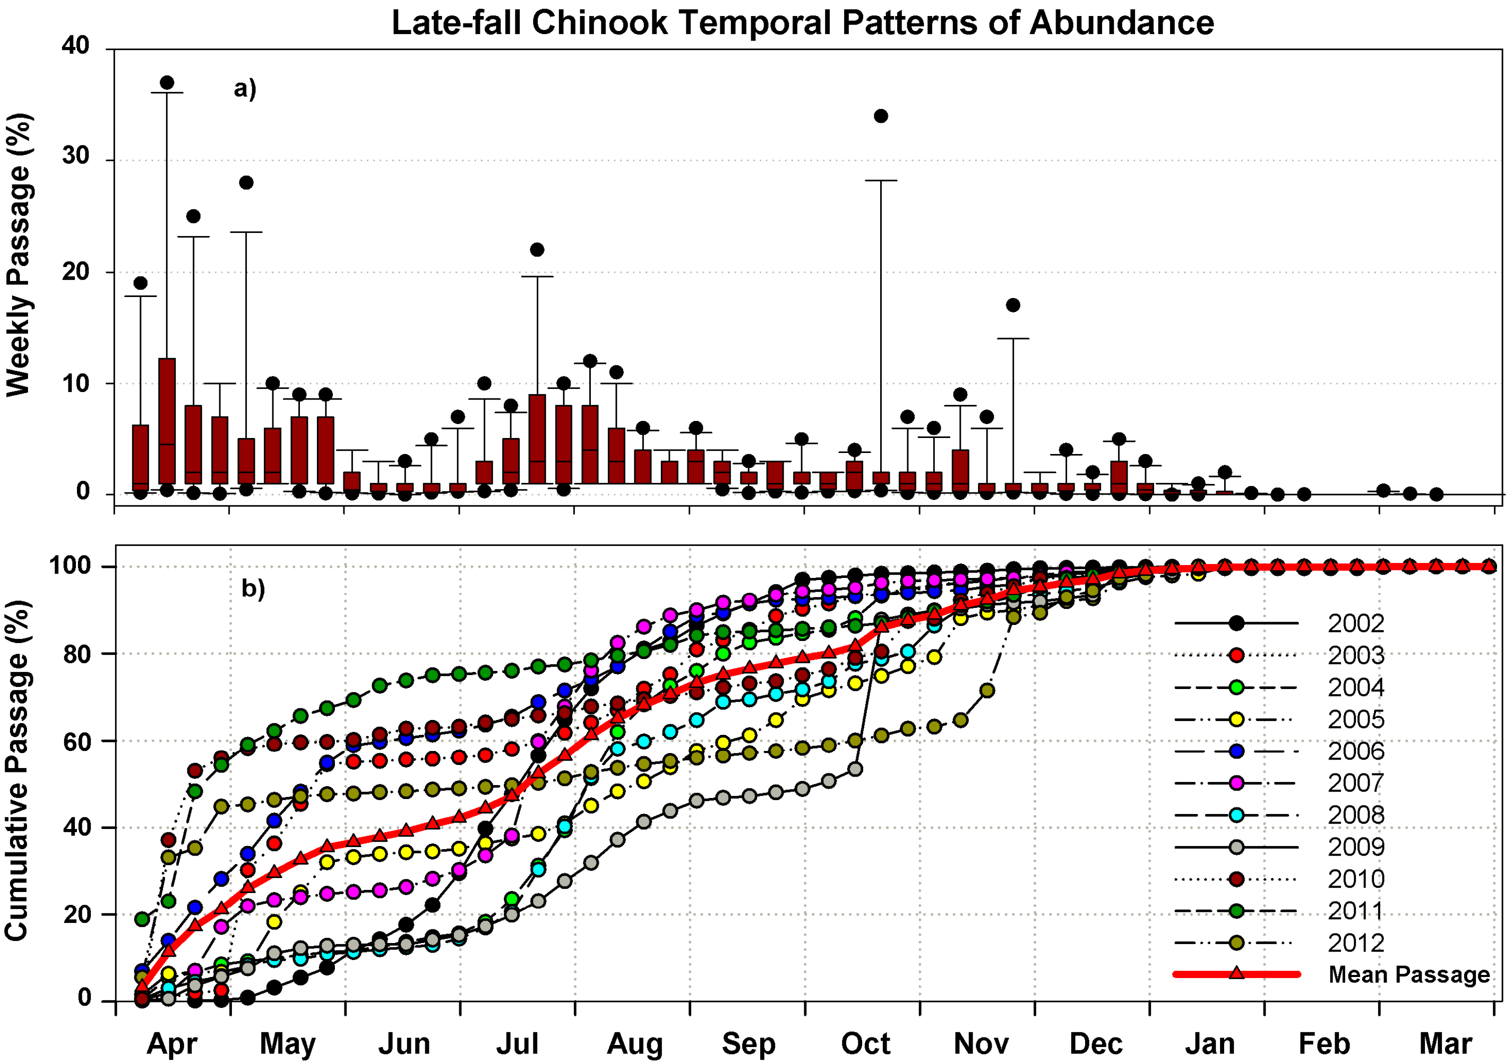

Figure 13. RBDD rotary trap late-fall Chinook (a) boxplots of weekly passage estimates relative to annual total passage estimates and (b) cumulative weekly passage with 11-year mean passage trend line for the period April 2002 through March 2013.

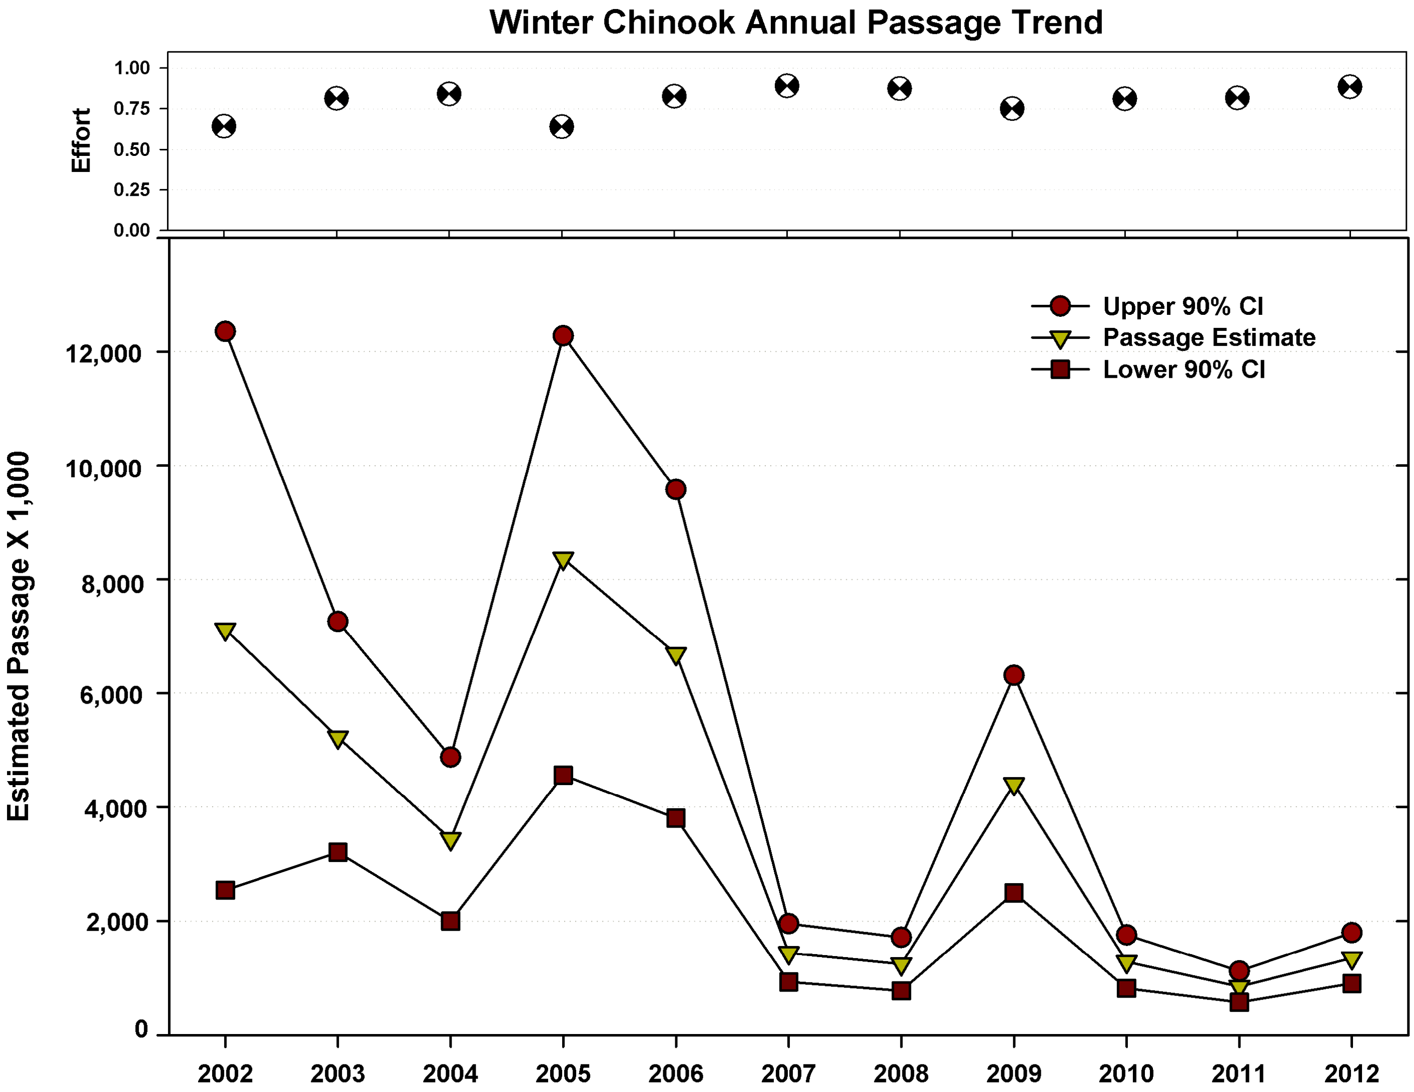

Figure 14. RBDD rotary trap winter Chinook annual sample effort and passage estimates with 90% confidence intervals (CI) for the period July 2002 through June 2013.

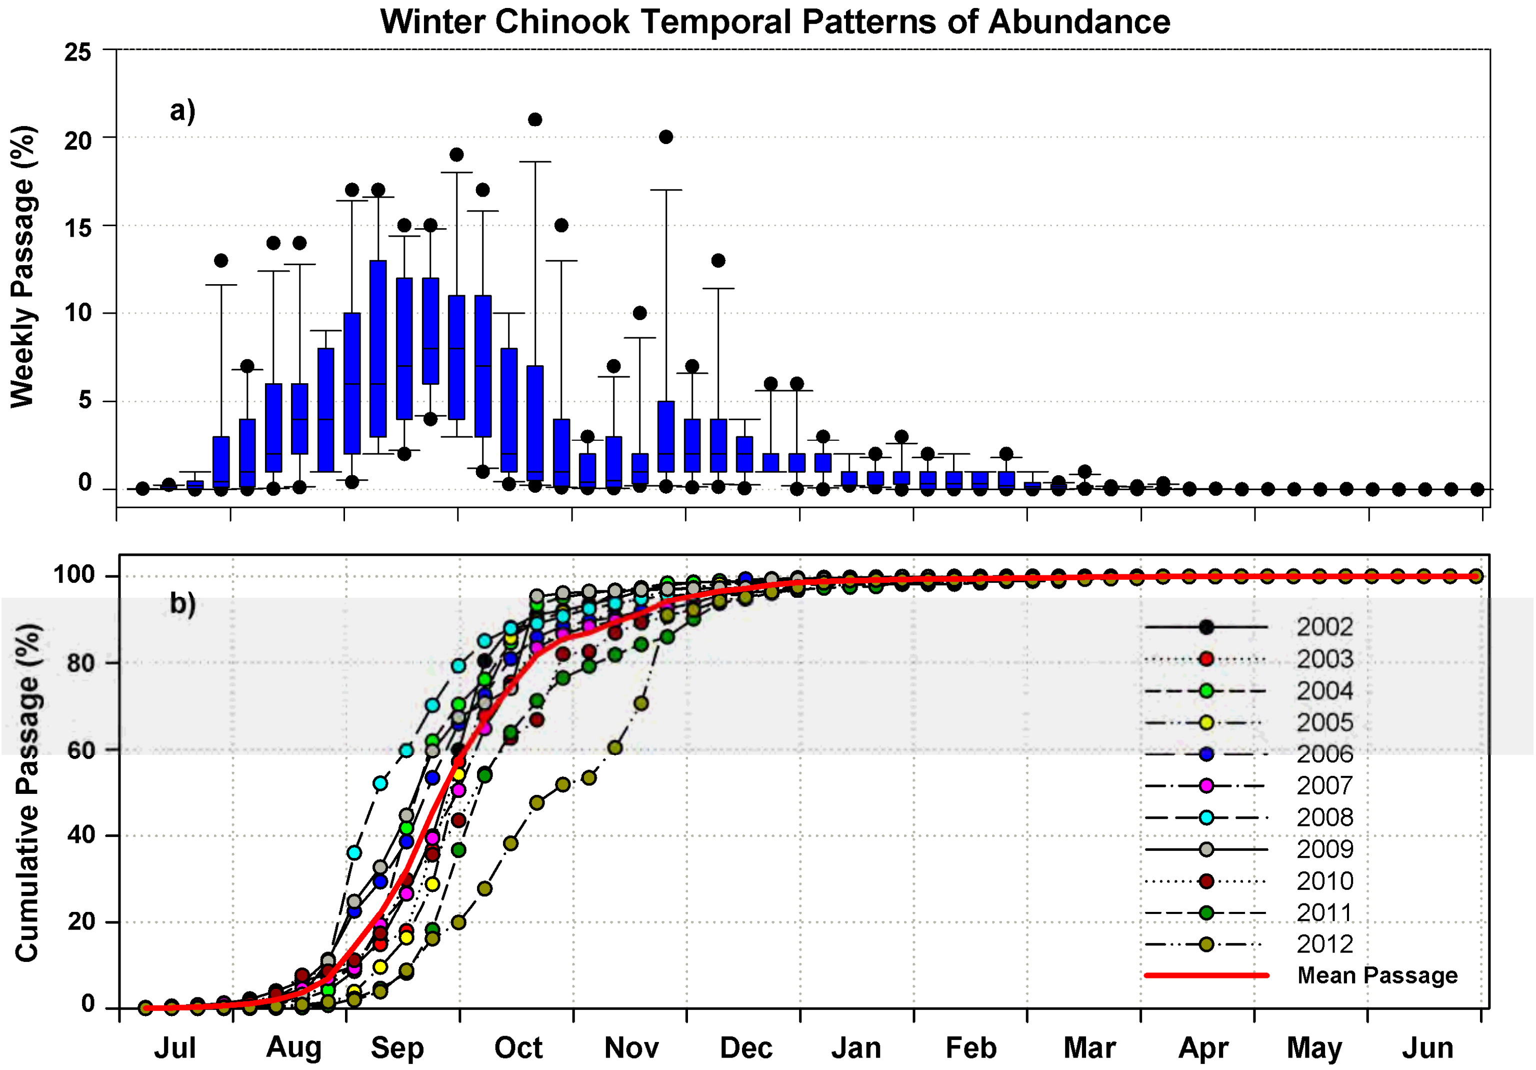

Figure 15. RBDD rotary trap winter Chinook (a) boxplots of weekly passage estimates relative to annual total passage estimates and (b) cumulative weekly passage with 11-year mean passage trend line for the period July 2002 through June 2013.

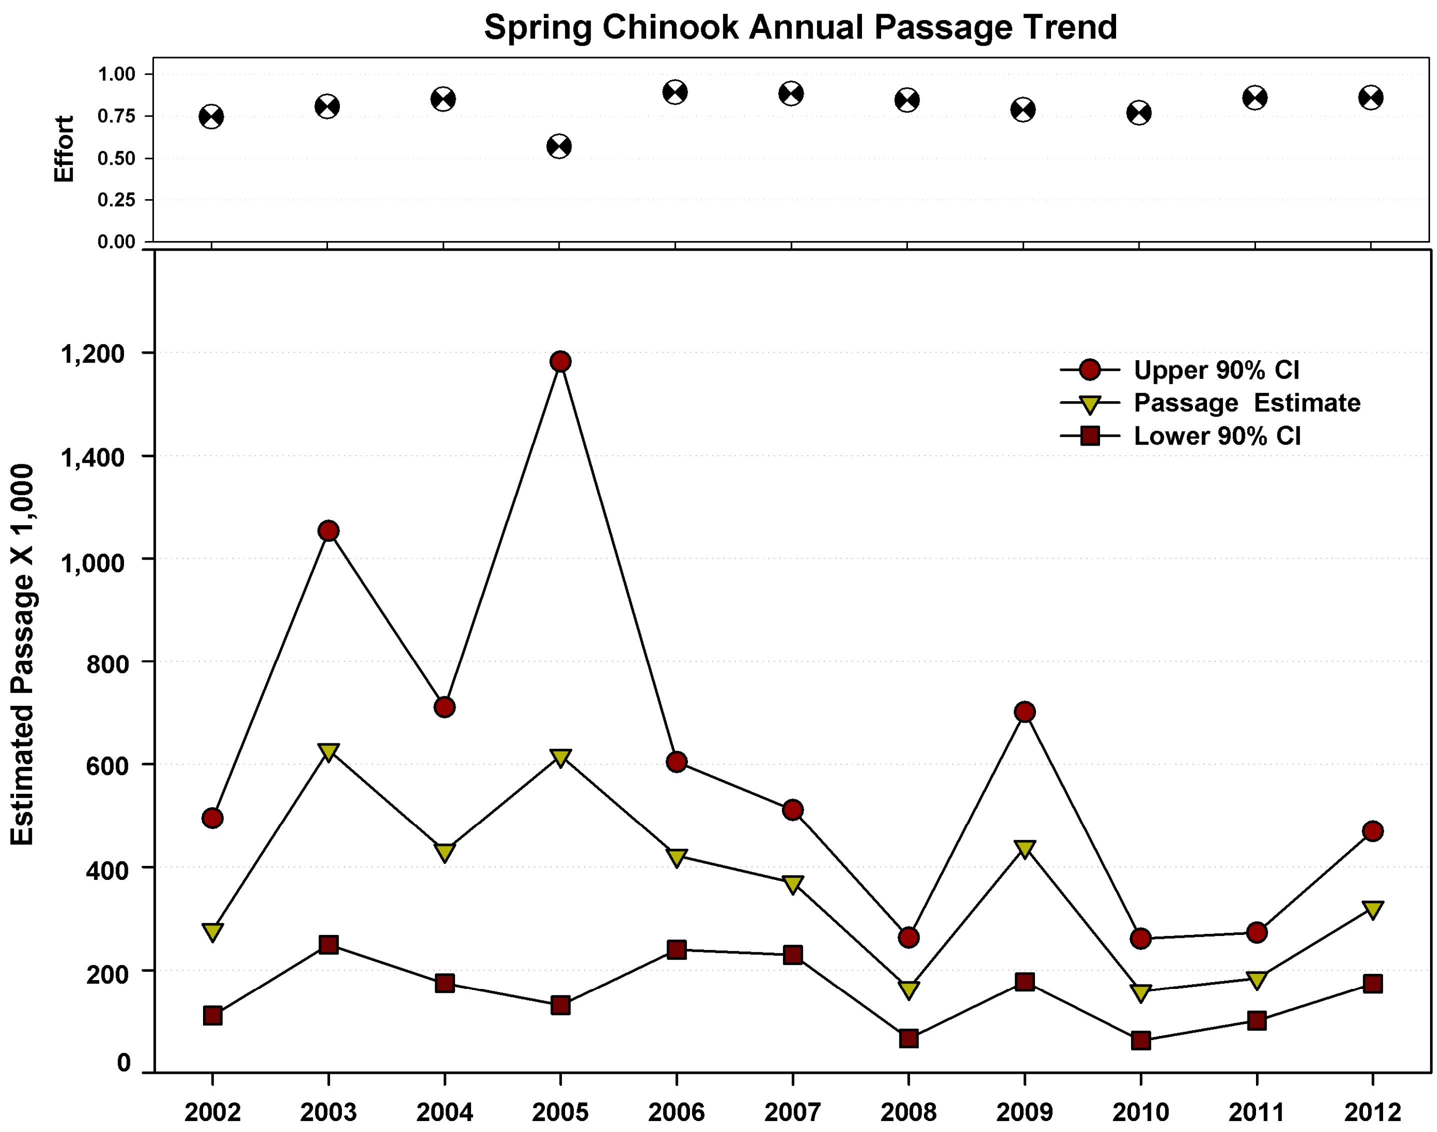

Figure 16. RBDD rotary trap spring Chinook annual sample effort and passage estimates with 90% confidence intervals (CI) for the period October 2002 through September 2013.

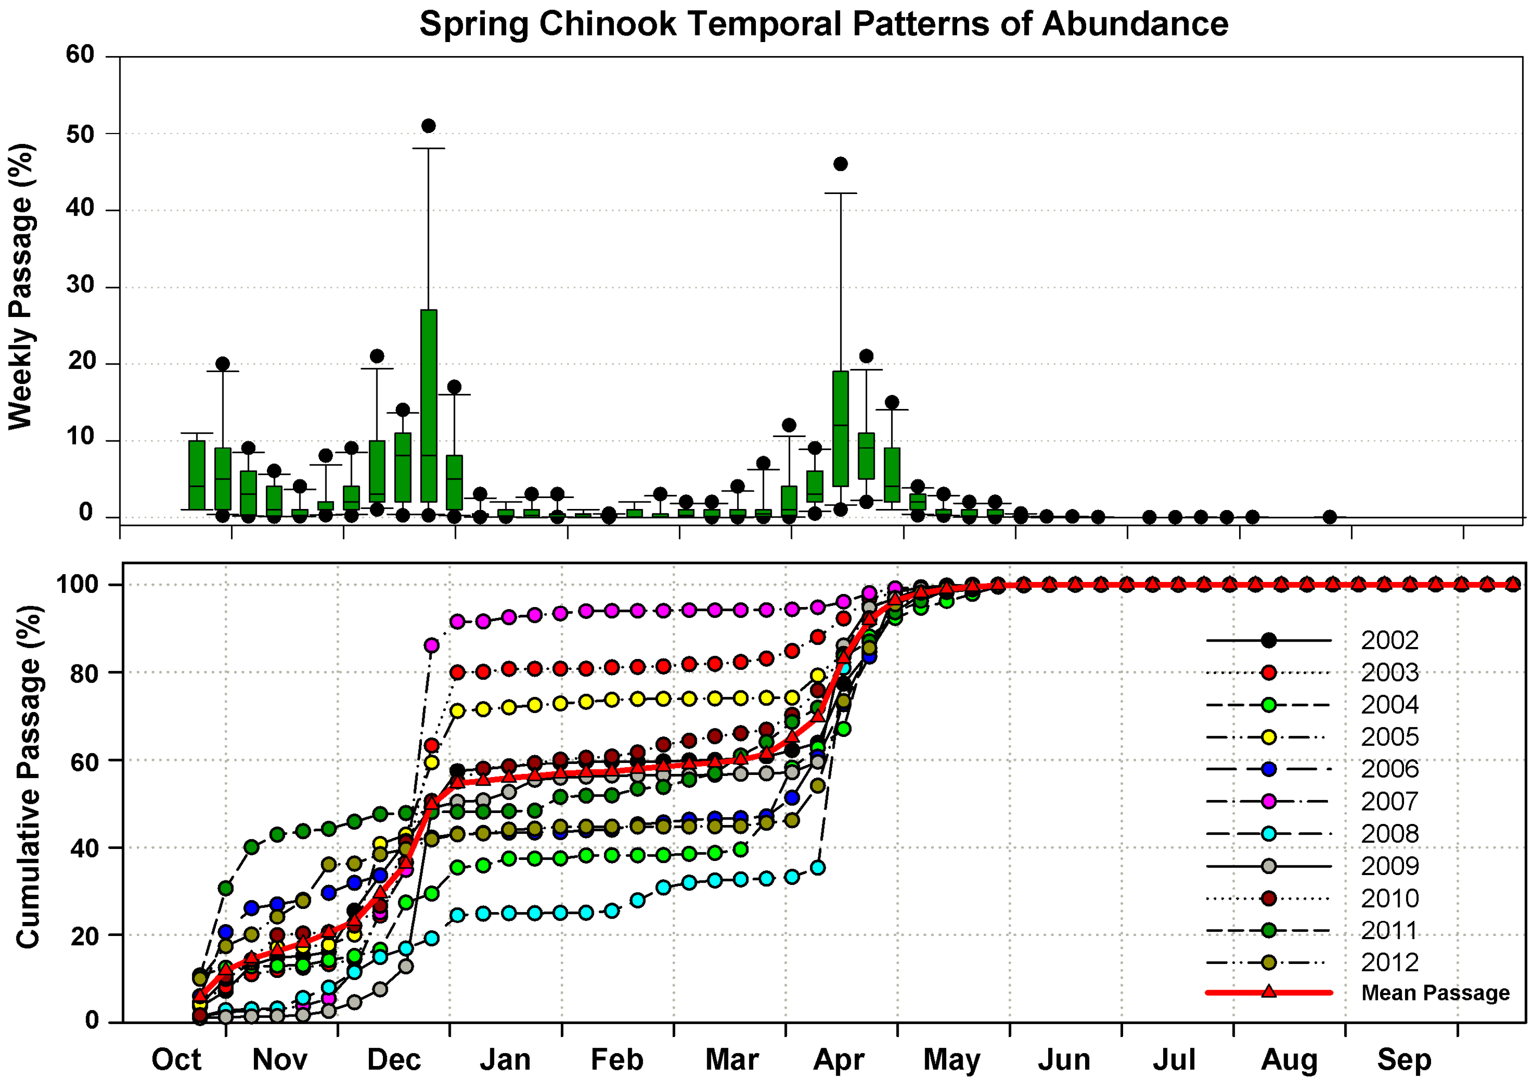

Figure 17. RBDD rotary trap spring Chinook (a) boxplots of weekly passage estimates relative to annual total passage estimates and (b) cumulative weekly passage with 11-year mean passage trend line for the period October 2002 through September 2013.

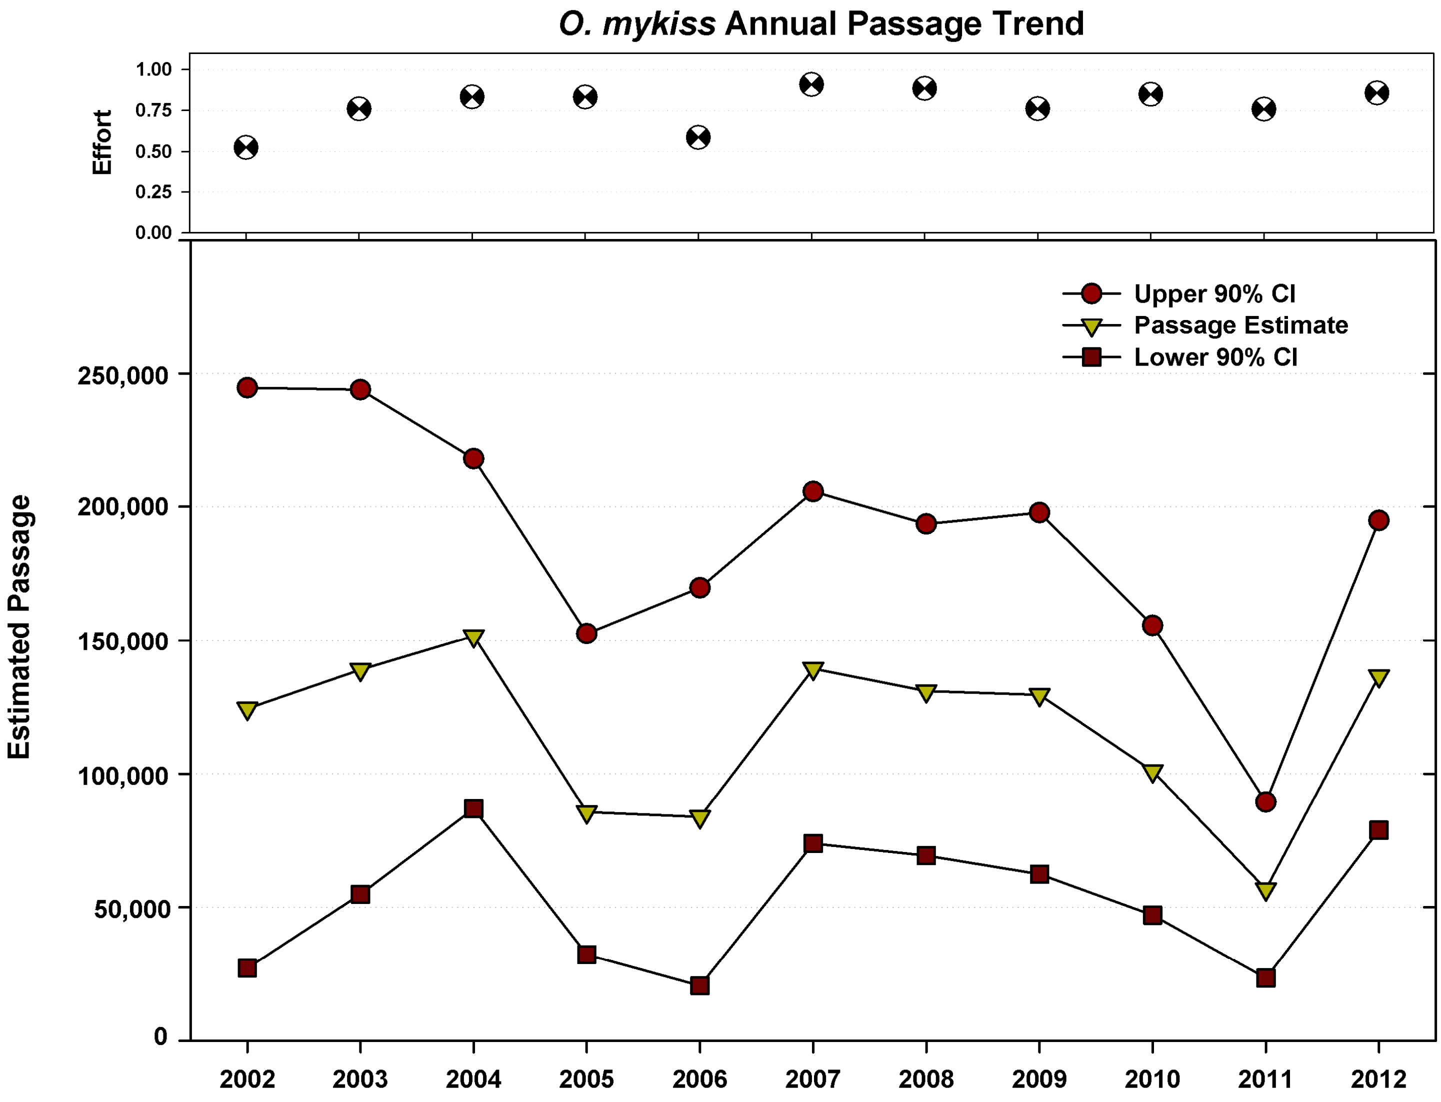

Figure 18. RBDD rotary trap *O. mykiss* annual sample effort and passage estimates with 90% confidence intervals (CI) for the period April 2002 through December 2012.

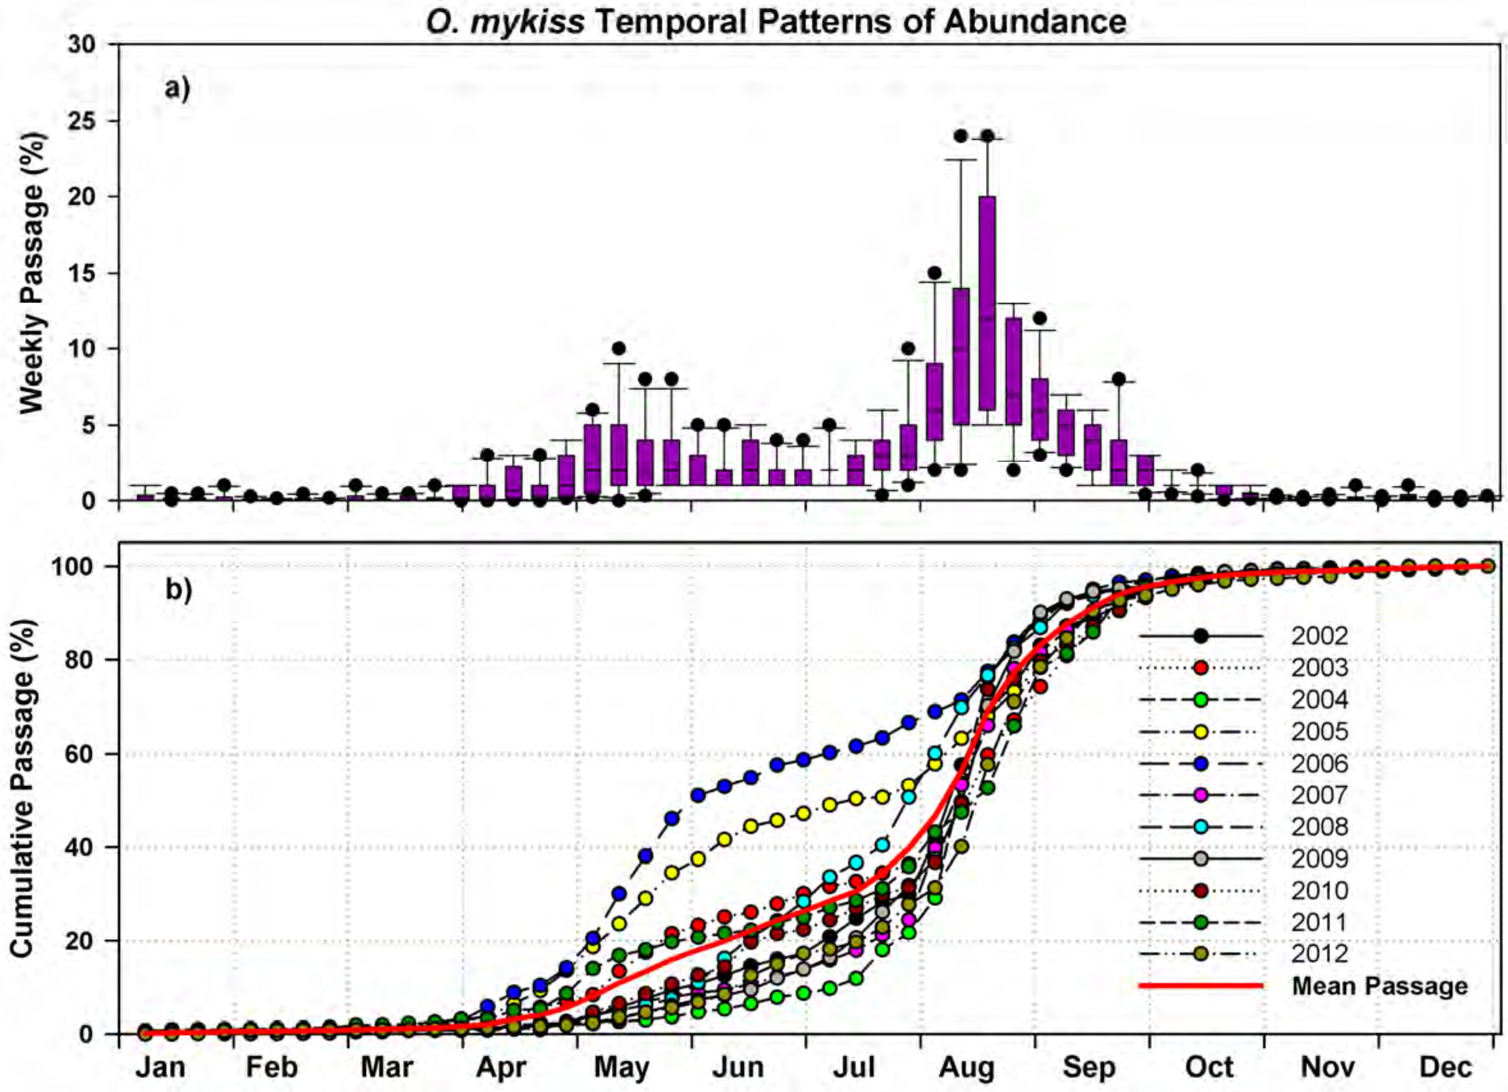

Figure 19. RBDD rotary trap *O. mykiss* (a) boxplots of weekly passage estimates relative to annual total passage estimates and (b) cumulative weekly passage with 11-year mean passage trend line for the period April 2002 through December 2012.

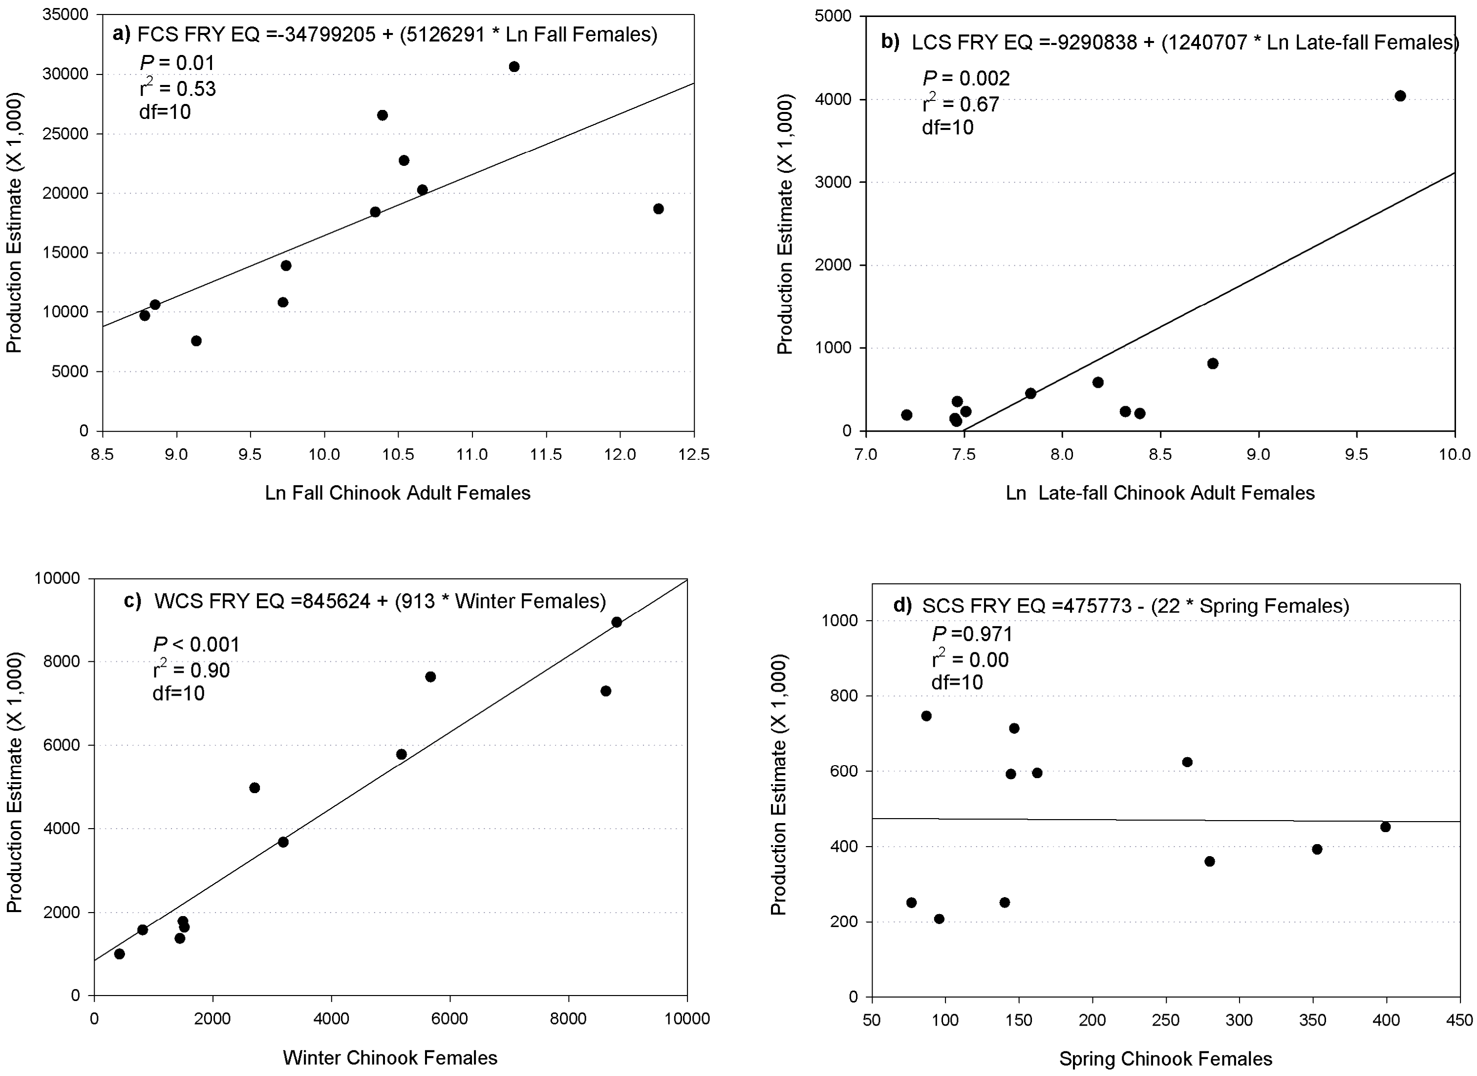

Figure 20. Relationships between a) fall, b) late-fall, c) winter, and d) spring Chinook fry-equivalent production estimates and estimated number of female adult Chinook salmon upstream of RBDD between 2002 and 2012. Note: fall and late-fall adult females were natural log transformed due to extraordinary escapement values estimated for the year 2002.

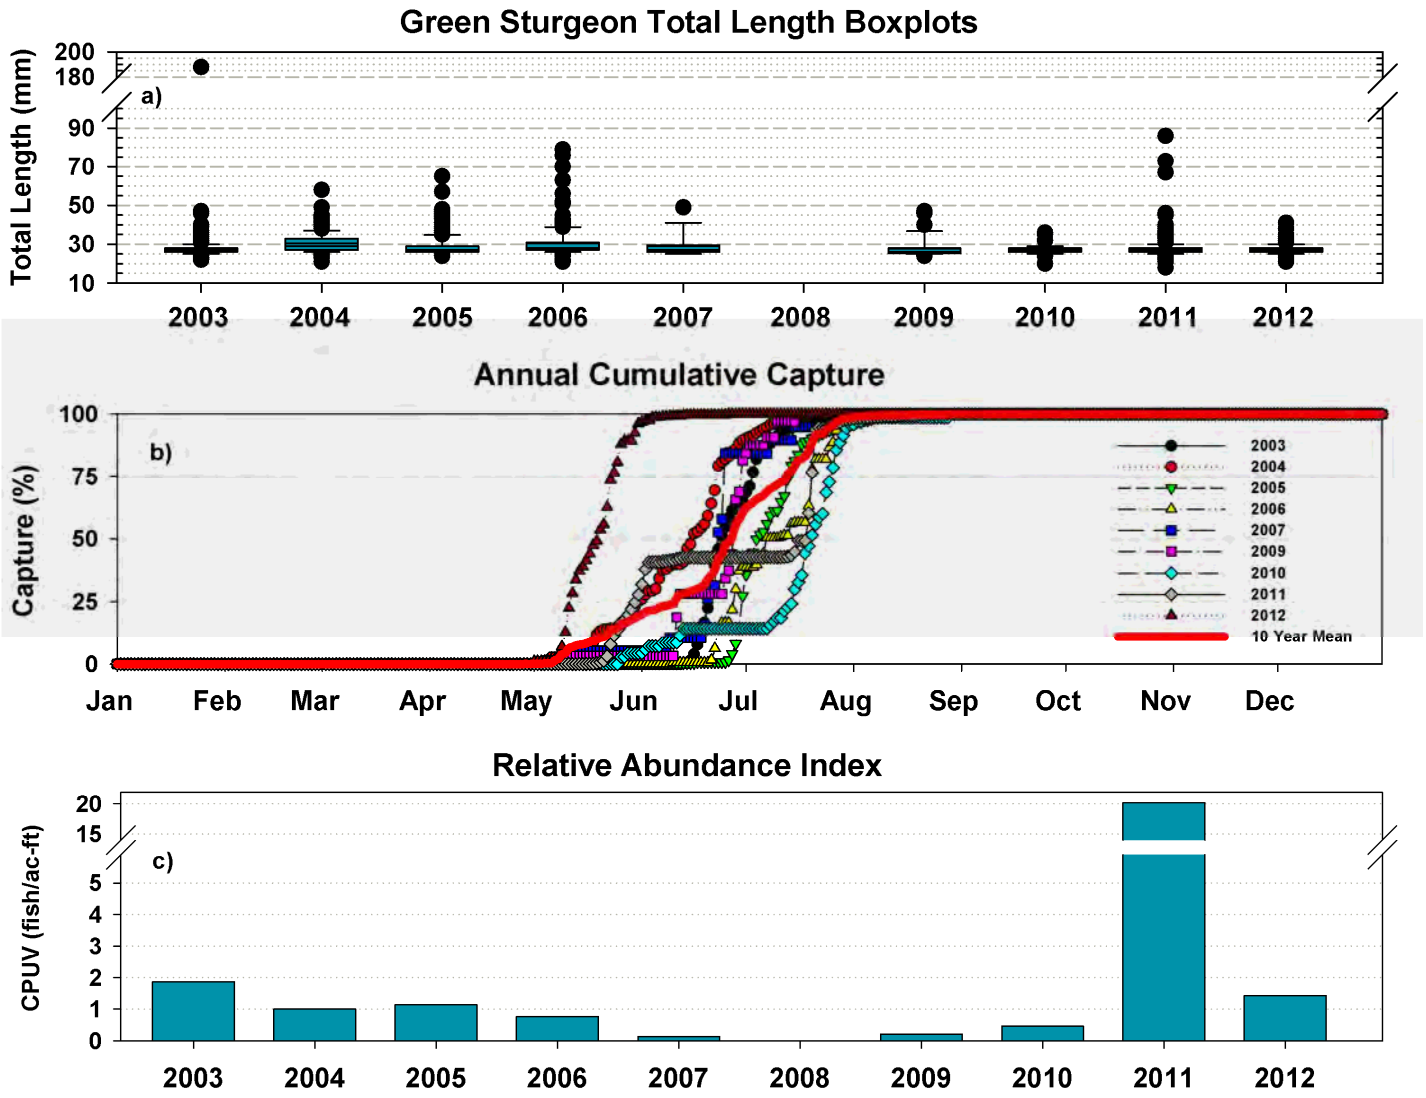

Figure 21. Green sturgeon a) annual total length capture boxplots, b) annual cumulative capture trends with 10-year mean trend line, and c) relative abundance indices. All fish captured by rotary trap at RBDD (RM 243) on the Upper Sacramento River, CA between 2003 and 2012. Data from 2002 excluded from analysis due to limited effort and USBR Crown Flow study resulting in incomparable sampling regimes and results.

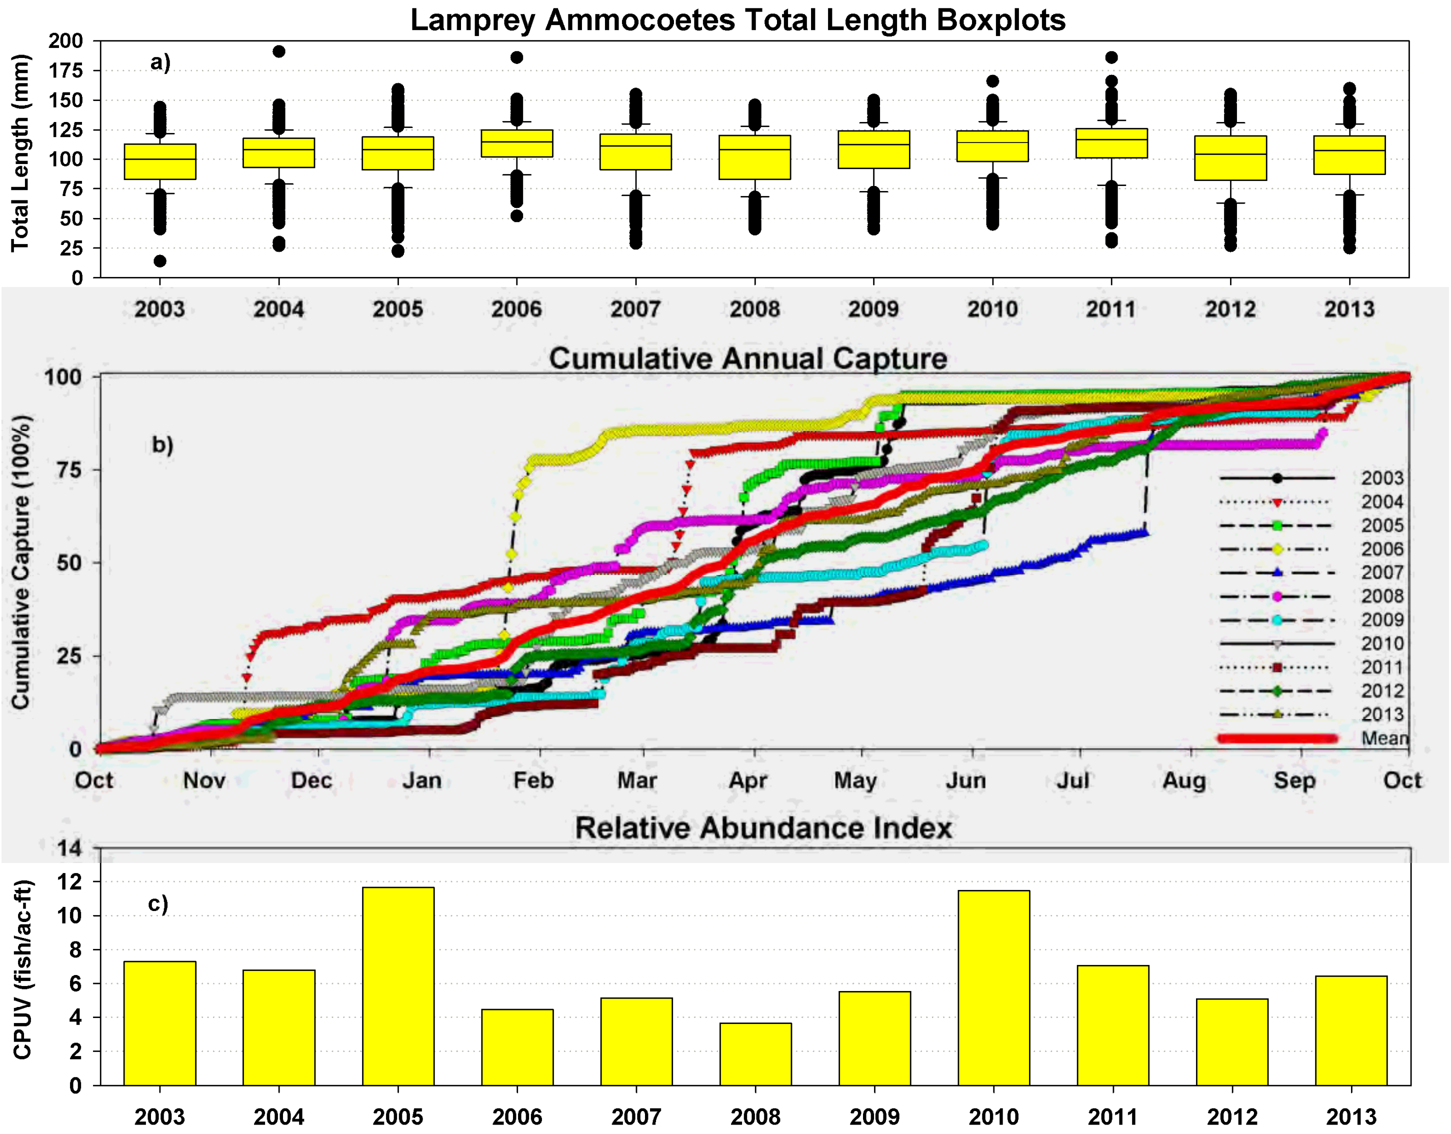

Figure 22. Unidentified lamprey ammocoetes a) total length distribution box plots, b) cumulative annual capture trends, and c) relative abundance indices from rotary trap samples collected between October 1, 2002 and September 30, 2013 by water year from the Sacramento River, CA at the RBDD (RM 243).

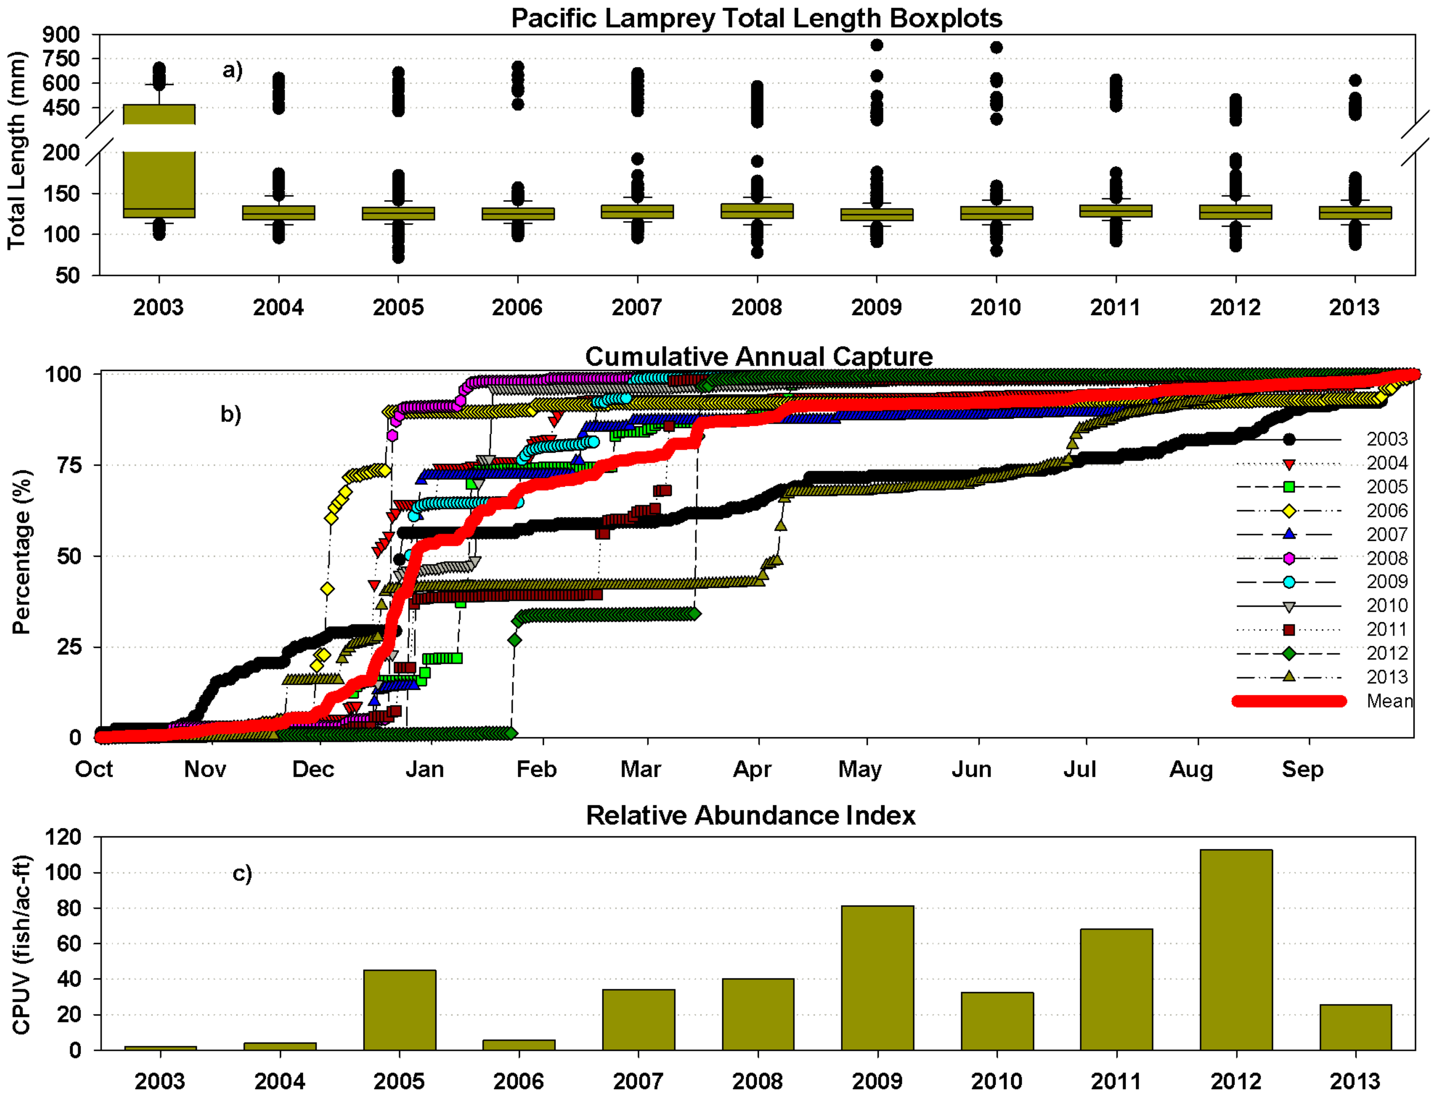

Figure 23. Pacific Lamprey (macropthalmia and adults) a) total length distribution box plots, b) cumulative annual capture trends, and c) relative abundance indices from rotary trap samples collected between October 1, 2002 and September 30, 2013 by water year from the Sacramento River, CA at the RBDD (RM 243).

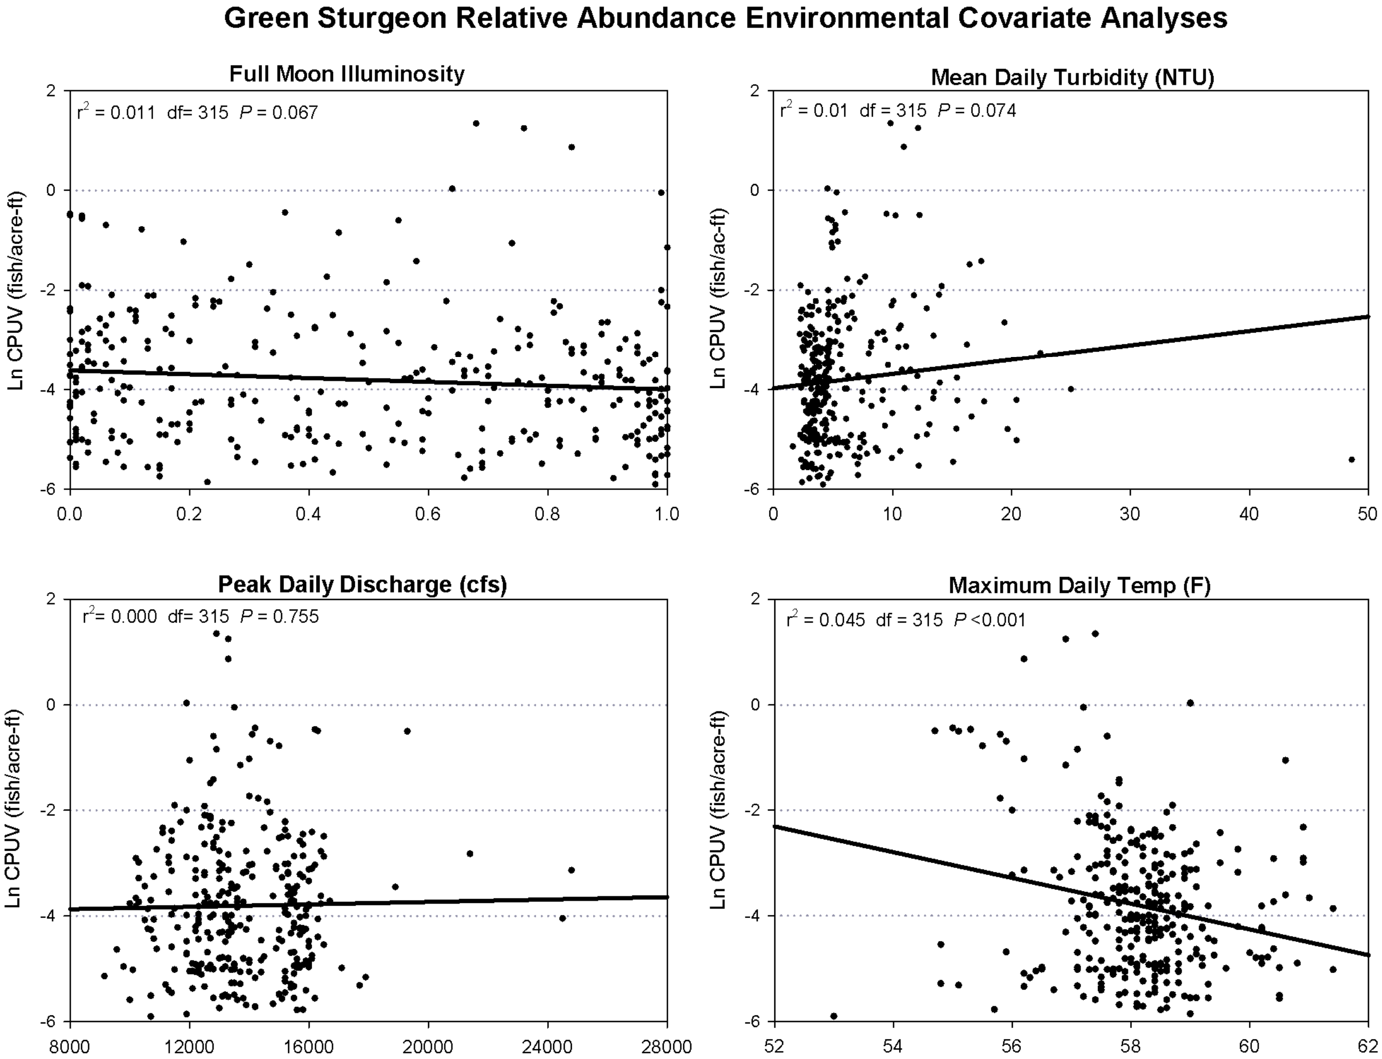

Figure 24. Regression analysis results of natural log (Ln) Green Sturgeon catch per unit volume (CPUV) and a) full moon illuminosity, b) mean daily turbidity, c) peak daily discharge and d) maximum daily temperatures at RBDD. All fish captured by rotary trap at RBDD (RM 243) on the Upper Sacramento River, CA between 2003 and 2012. Data from 2002 excluded from analysis due to limited effort and USBR Crown Flow study resulting in incomparable sampling regimes and results.

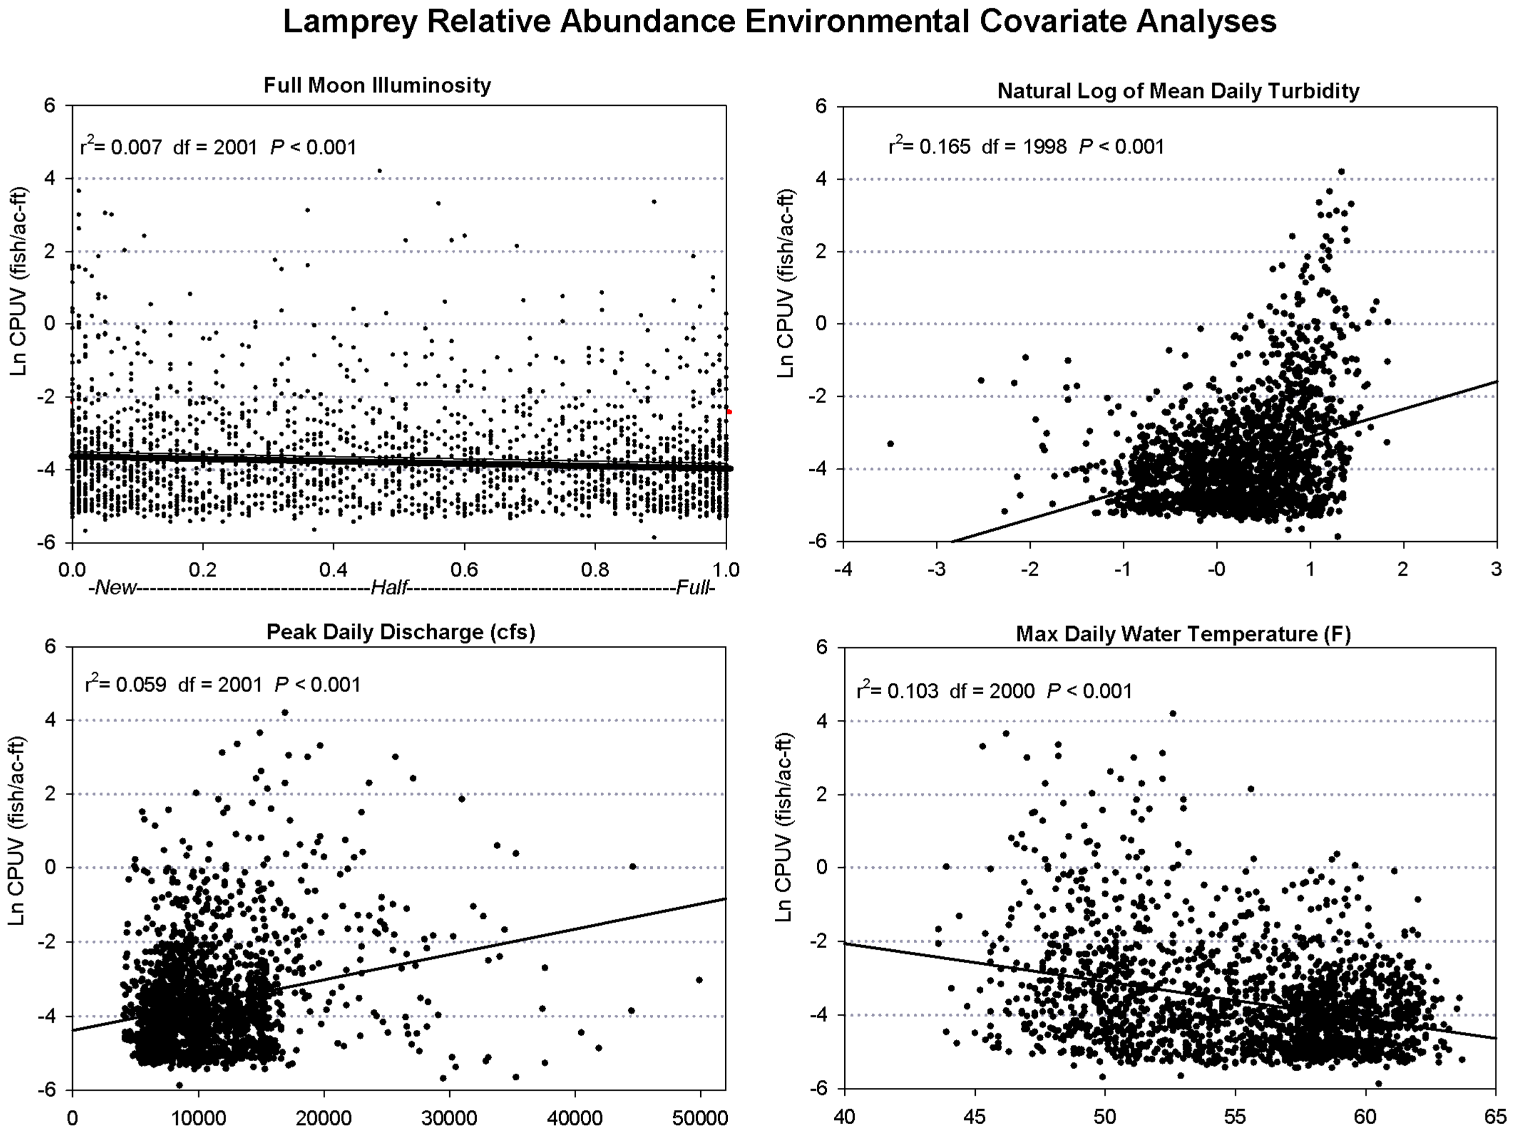

Figure 25. Regression analysis results of natural log (Ln) Lamprey *spp.* catch per unit volume (CPUV) and a) full moon illuminosity, b) Ln mean daily turbidity, c) peak daily discharge and d) maximum daily temperatures at RBDD. All fish captured by rotary trap at RBDD (RM 243) on the Upper Sacramento River, CA between water year 2003 and 2013.

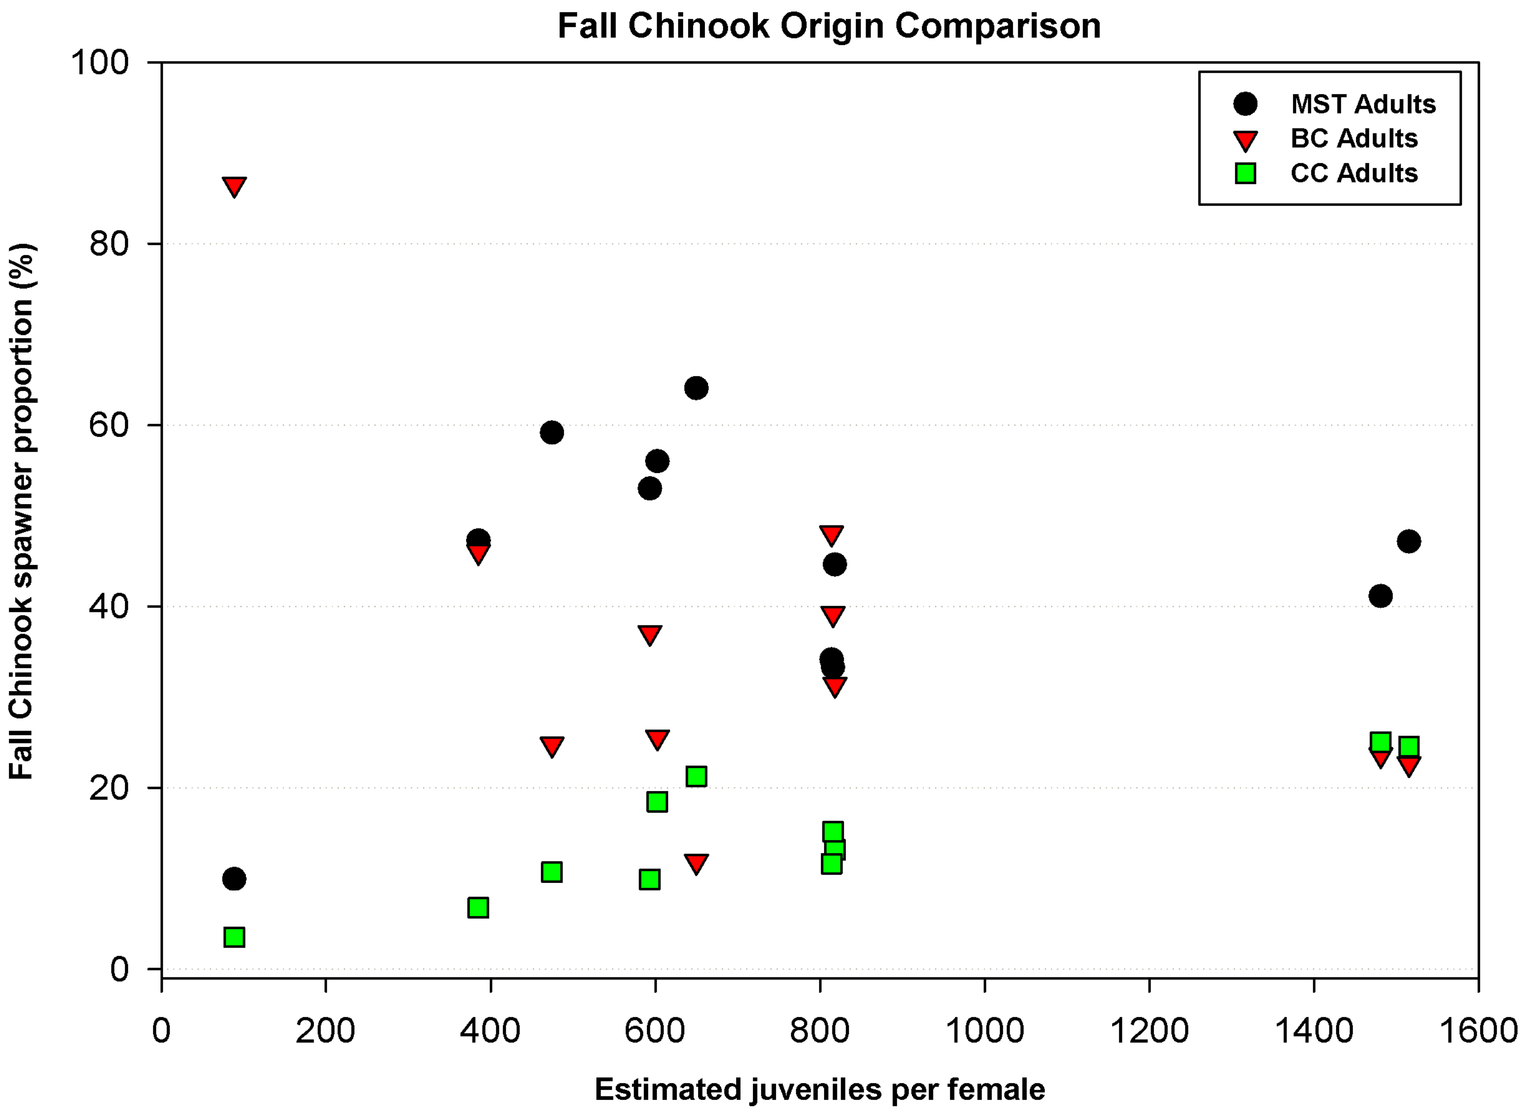

Figure 26. Comparison of estimated juveniles produced per estimated number of females in relation to distribution of fall Chinook spawners in the mainstem Sacramento River (MST), Battle Creek (BC), and Clear Creek (CC) between years 2002 and 2012.

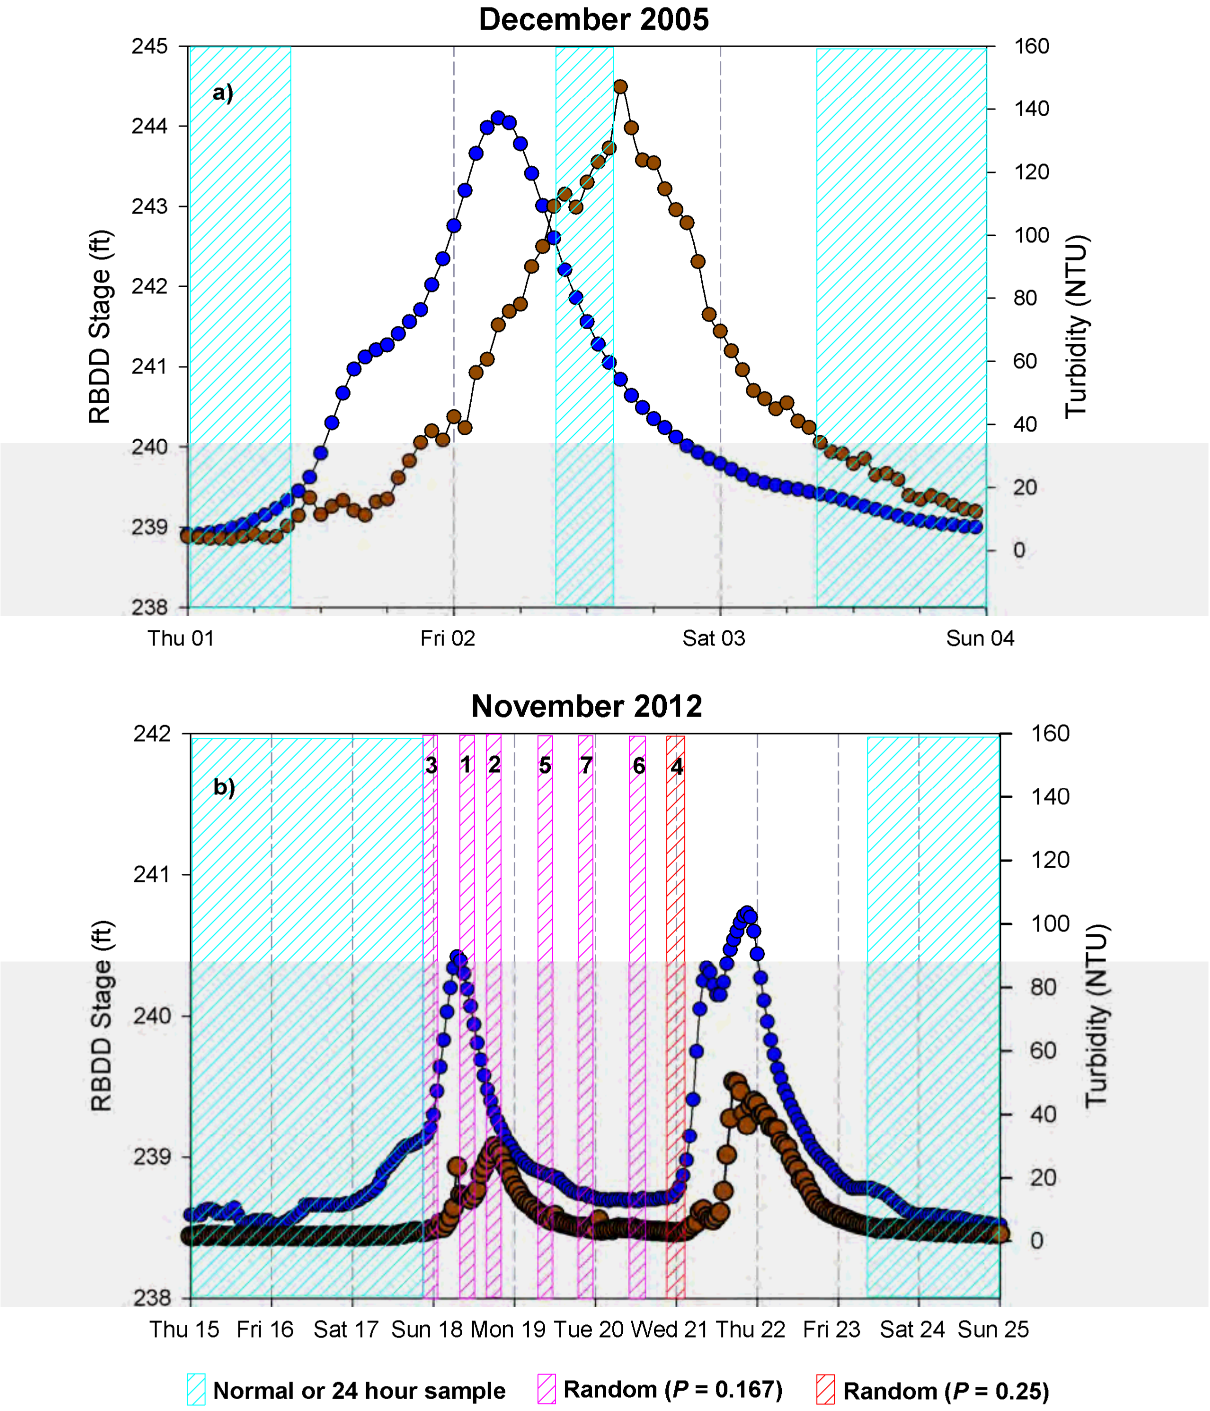

Figure 27. Timing comparison of RBDD stage (i.e., discharge level) and turbidity measurements along with sample collection times for storm events on a) December 1-4, 2005 and b) November 15-25, 2012. Numerals within sample period boxes in figure b indicate rank of standardized Chinook passage totals from greatest (1) to least (7).

APPENDIX 1

Appendix 1: List of Tables

Fall Chinook

Table A1. Summary of RBDD rotary trap annual effort, fall Chinook fry (<46 mm FL) passage estimates and lower and upper 90% confidence intervals (CI), by brood year for the period December 2002 through September 2013.

Brood Year	Effort	Estimated Fry Passage	Low 90% CI	Up 90% CI
2002	0.76	14,687,984	348,386	42,027,818
2003	0.81	23,612,094	6,953,966	44,283,689
2004	0.85	7,946,496	3,449,094	12,447,378
2005	0.56	11,740,225	2,452,034	24,687,255
2006	0.90	10,152,406	3,458,524	17,567,355
2007	0.88	9,594,099	4,834,813	14,353,810
2008	0.79	6,684,332	3,335,617	10,033,164
2009	0.84	6,900,302	2,190,210	11,662,489
2010	0.75	6,302,961	3,432,017	9,502,694
2011	0.87	4,437,956	2,380,436	6,498,878
2012	0.85	21,375,192	14,332,396	28,700,826

Table A2. Summary of RBDD rotary trap annual effort, fall Chinook pre-smolt/smolt (>45 mm FL) passage estimates and lower and upper 90% confidence intervals (CI), by brood year for the period December 2002 through September 2013.

Brood Year	Effort	Estimated Smolt Passage	Low 90% CI	Up 90% CI
2002	0.76	2,350,433	505,837	5,318,021
2003	0.81	4,124,773	1,879,521	6,393,281
2004	0.85	6,161,742	1,626,946	12,527,167
2005	0.56	6,470,030	1,041,939	14,426,210
2006	0.90	5,955,245	3,056,683	8,855,302
2007	0.88	2,537,504	1,291,848	3,821,912
2008	0.79	2,431,215	1,034,851	3,827,754
2009	0.84	1,632,074	868,002	2,396,298
2010	0.75	2,539,519	1,288,830	3,850,851
2011	0.87	1,833,305	1,029,403	2,637,509
2012	0.85	3,054,227	1,692,494	4,416,322

Late-Fall Chinook

Table A3. Summary of RBDD rotary trap annual effort, late-fall Chinook fry (<46 mm FL) passage estimates and lower and upper 90% confidence intervals (CI), by brood year for the period April 2002 through March 2013.

Brood Year	Effort	Estimated Fry Passage	Low 90% CI	Up 90% CI
2002	0.57	442,393	84,832	901,368
2003	0.76	196,271	4,562	683,458

An updated conceptual model of Delta Smelt biology: our evolving understanding of an estuarine fish

By Management, Analysis, and Synthesis Team

Executive Summary

The main purpose of this report is to provide an up-to-date assessment and conceptual model of factors affecting Delta Smelt (*Hypomesus transpacificus*) throughout its primarily annual life cycle and to demonstrate how this conceptual model can be used for scientific and management purposes. The Delta Smelt is a small estuarine fish that only occurs in the San Francisco Estuary. Once abundant, it is now rare and has been protected under the federal and California Endangered Species Acts since 1993. The Delta Smelt listing was related to a step decline in the early 1980s; however, population abundance decreased even further with the onset of the "pelagic organism decline" (POD) around 2002. A substantial, albeit short-lived, increase in abundance of all life stages in 2011 showed that the Delta Smelt population can still rebound when conditions are favorable for spawning, growth, and survival. In this report, we update previous conceptual models for Delta Smelt to reflect new data and information since the release of the last synthesis report about the POD by the Interagency Ecological Program for the San Francisco Estuary (IEP) in 2010. Specific objectives include:

1. Provide decision makers with a practical tool for evaluating difficult trade-offs associated with management and policy decisions.
2. Provide scientists with a framework from which they can formulate and evaluate hypotheses using qualitative or quantitative models.
3. Provide the general public with a new way of learning about Delta Smelt and their habitat.

Our updated conceptual model describes the habitat conditions and ecosystem drivers affecting each Delta Smelt life stage, across seasons and how the seasonal effects contribute to the annual success of the species. The conceptual model consists of two nested and linked levels of increasing specificity. The *general life cycle conceptual model* for four Delta Smelt life stages (adults, eggs and larvae, juveniles, and subadults) includes stationary ecosystem components and dynamic environmental drivers, habitat attributes, and Delta Smelt responses. The more detailed *life stage transition conceptual models* for each of the four Delta Smelt life stages describe relationships between environmental drivers, key habitat attributes, and the responses of Delta Smelt to habitat attributes as they transition from one life stage to the next.

Our analyses and conceptual model show that good larval recruitment is essential for setting the stage for a strong year class; however, increased growth and survival through subsequent life stages are also needed to achieve and sustain higher population abundance. We used our conceptual model to generate 16 hypotheses about the factors that may have contributed to the 2011 increase in Delta Smelt relative abundance. We then evaluated these hypotheses by comparing habitat conditions and Delta Smelt responses in the wet year 2011 to those in the

prior wet year 2006 and in the drier years 2005 and 2010. Larval recruitment was similarly high in both wet years and lower in the drier antecedent years, but juvenile and adult abundance increased only in 2011. In 2005 and 2006, the population was limited by very poor survival from the larval to the juvenile life stage. We found that in 2011, Delta Smelt may have benefitted from a combination of favorable habitat conditions throughout the year, including:

1. Adults and larvae benefitted from prolonged cool spring water temperatures, high 2011 winter and spring outflows which reduced entrainment risk and possibly improved other habitat conditions, and possibly enhanced food availability in late spring.

2. Juveniles benefitted from cool water temperatures in late spring and early summer as well as from improved food availability and low levels of harmful *Microcystis*.

3. Subadults also benefitted from improved food availability and from favorable habitat conditions in the large, low salinity zone (salinity 1-6) located more toward Suisun Bay in 2005-2006 and 2010.

Our comparisons of other habitat attributes either produced inconclusive results or were limited by a lack of suitable data or other necessary information. This was especially true for predation risk and toxicity, and other contaminant effects. Clearly more monitoring and studies are needed on these two topics, but we also found many other data and information gaps. Overall, we did not entirely reject any of our hypotheses. Together with the large amount of published information used to construct our conceptual model, this gives us some confidence that the majority of the elements and linkages of our conceptual model are relevant and (qualitatively) correct. However, the mechanisms they describe are likely variable in the degree to which they drive population outcomes, depending on the conditions in any given year and prior Delta Smelt abundance levels. In addition, the scientific merit of some linkages for which data are sparse (e.g., predation and contaminants effects) is impossible to evaluate without additional information.

Importantly, while this report identifies many data and information gaps that must be filled before some hypotheses can be objectively evaluated, the report includes a very large amount of pertinent data and information that is currently available. The San Francisco Estuary is clearly an intensely monitored and studied ecosystem and Delta Smelt may well be one of the most thoroughly studied endangered fish species in the world. The most critical data for this report came from four long-term Interagency Ecological Program fish monitoring surveys. These surveys provide sound, high-quality data about the annual distribution and relative abundance of Delta Smelt for time periods ranging from one to more than five decades. These four surveys, other monitoring surveys, and numerous research studies provide data about many habitat attributes and ecosystem drivers.

The report ends with key conclusions, a discussion of our hypothesis testing approach, and recommendations for future work and adaptive management applications. The final report Chapter contains many concrete examples of studies, modeling approaches, and management applications that are directly derived from the conceptual model. These examples are not meant to be exhaustive lists. Rather, they are primarily intended to illustrate science and management applications of our conceptual model.

We strongly recommend that analysis, synthesis and modeling efforts, such as this report, be a high priority for the management and science organizations that oversee monitoring and research in the estuary. Without these types of integrative efforts, ongoing and proposed adaptive management processes must conduct such efforts in an *ad hoc* manner, often driven by unrealistic schedules that are unlikely to be fulfilled. Such adaptive management processes in the estuary include the ongoing adaptive management of fall outflow for Delta Smelt, the new "Collaborative Science and Adaptive Management Program," the California Delta Stewardship Council's Delta Plan, and the multi-agency Bay Delta Conservation Plan. On a more basic level, such synthesis efforts identify data gaps that serve to focus research and management efforts on scientifically relevant topics rather than the "crisis of the day."

The 2011 increase in the Delta Smelt abundance index demonstrated that the species still has the ability to rebound to higher abundance levels. Delta Smelt has often been called an indicator – or canary in the coalmine – for overall ecosystem conditions in the estuary. The 2011 increase suggests that the system has not yet irreversibly shifted into an altered state that will no longer support native species. Given the profound habitat alterations in the San Francisco Estuary, continued study of the environmental drivers and habitat attributes and the subsequent responses of the Delta Smelt population seem critical to the wise management of the species. Some possible topics for future synthesis groups include:

1. Reviews and updates to existing conceptual and mathematical models.
2. Further development of mathematical models of Delta Smelt population abundance drawn specifically from the conceptual models described in this report; applications and extensions of recently published models to help make management decisions and guide new modeling efforts; additional modeling efforts and future research projects to improve resolution and understanding of the particular factors identified as critical to reproduction, recruitment, survival, and growth.
3. Review and refinement of new models such as the emerging comprehensive state-space population model (K. Newman, U.S. Fish and Wildlife Service, personal communication); development of additional models or modules of models specifically aimed at estimating effects of inadequately monitored or difficult to measure and evaluate habitat attributes such as predation risk and toxicity; development of new "nested" and/or "linked" mathematical modeling approaches that can accommodate multiple drivers and their interactive effects across temporal and spatial scales.
4. Interdisciplinary collaboration among scientists, managers, and stakeholders to develop and model management scenarios and strategies based on principles of integrative ecosystem and landscape-based management rather than relatively crude distinctions among categorical "water year types."

Continued growth of California's human population, climate change, new species invasions, and other changes will increase management challenges. Science and management have to go hand in hand to constantly identify, implement, evaluate, and refine the best management options for this ever-changing system. We hope that the conceptual model and information in this report will be useful for achieving these goals.

Chapter 1: Introduction

The San Francisco Estuary

Estuarine ecosystems are among the most complex ecosystems on earth (Wilson 1998). They are constantly changing ecosystems that respond to dynamic “drivers” of change (Healey et al. 2008, Baxter et al. 2010). Natural drivers include the geological and geographic setting, climatic and oceanic variability, dynamic hydrological and nutrient regimes, weather and disturbance regimes, biogeochemical processes, species assemblages, and many other biotic and abiotic features. Estuaries also respond to a broad range of human activities. Some of these “human drivers” have negative impacts on ecosystems. These negative human drivers are often called “stressors.” Human stressors on estuarine ecosystems include water and land use, pollutant discharges, species introductions, and fishing (Townend 2004, Lotze et al. 2006, Cloern and Jassby 2012). The interplay of natural and human drivers and their effects on the San Francisco Estuary and in particular on the Delta Smelt (*Hypomesus transpacificus*), an endemic fish species, is the subject of this report.

The San Francisco Estuary (SFE; Fig. 1) is comprised of an upstream region consisting of channels and islands associated with the confluence of the Sacramento and San Joaquin Rivers known as the “Delta” and a series of downstream bays and marshes that are separated from the Pacific Ocean by the “Golden Gate,” the sea passage between the San Francisco and Marin peninsulas. Because of California’s Mediterranean climate, the SFE experiences large interannual and seasonal flow variations, which are modulated by tides and human management of the rivers within the Delta watershed (Moyle et al. 2010). These hydrological variations lead to a dynamic estuarine salinity gradient. In the winter and spring fresh water often extends into San Pablo Bay, while in the summer and fall brackish water can intrude into the western Delta. These seasonal differences are exacerbated by pronounced interannual differences in precipitation in the watershed. Extremely dry years with little precipitation and very wet years with widespread flooding do not occur in predictable patterns (Dettinger 2011).

The SFE has undergone dramatic morphological, hydrological, chemical, and biological alterations since the onset of the California Gold Rush in the middle of the 19th century (Nichols et al. 1986, Arthur et al. 1996, Baxter et al. 2010, Brooks et al. 2012, NRC 2012, Whipple et al. 2012, Cloern and Jassby 2012). These alterations include five human activities that have changed ecological functions and habitats in many riverine and estuarine systems with increasingly dense human populations: diking, draining, dredging, diverting, and discharging. Specifically, diking and draining have reduced the vast wetlands that once covered and surrounded the SFE to small remnants. There has been an 80-fold decrease in the ratio of wetland to open water area in the Delta, from a historical ratio of 14:1 to a current ratio of 1:6 (Whipple et al. 2012, Herbold et al. 2014). Diking and dredging have led to a substantial reconfiguration of the bays, sloughs, and channels, while large-scale water diversions, and discharge of contaminants have altered water quantity and quality. Small water diversions occur throughout the freshwater portion of the estuary, but the largest water diversions are at the pumping facilities of the federal Central Valley Project (CVP) and the State Water Project (SWP) that export water from the southwestern Delta to agricultural and urban areas to the south (Fig. 2). In addition, a wide variety of non-native plants and animals have been introduced and have become established in the SFE (Cohen and Carlton 1998, Light et al. 2005, Winder et al. 2011).

Figure 1. Map of the San Francisco estuary. The inset shows various values of X2, the distance in kilometers from the Golden Gate to the near bottom salinity 2 isohaline.

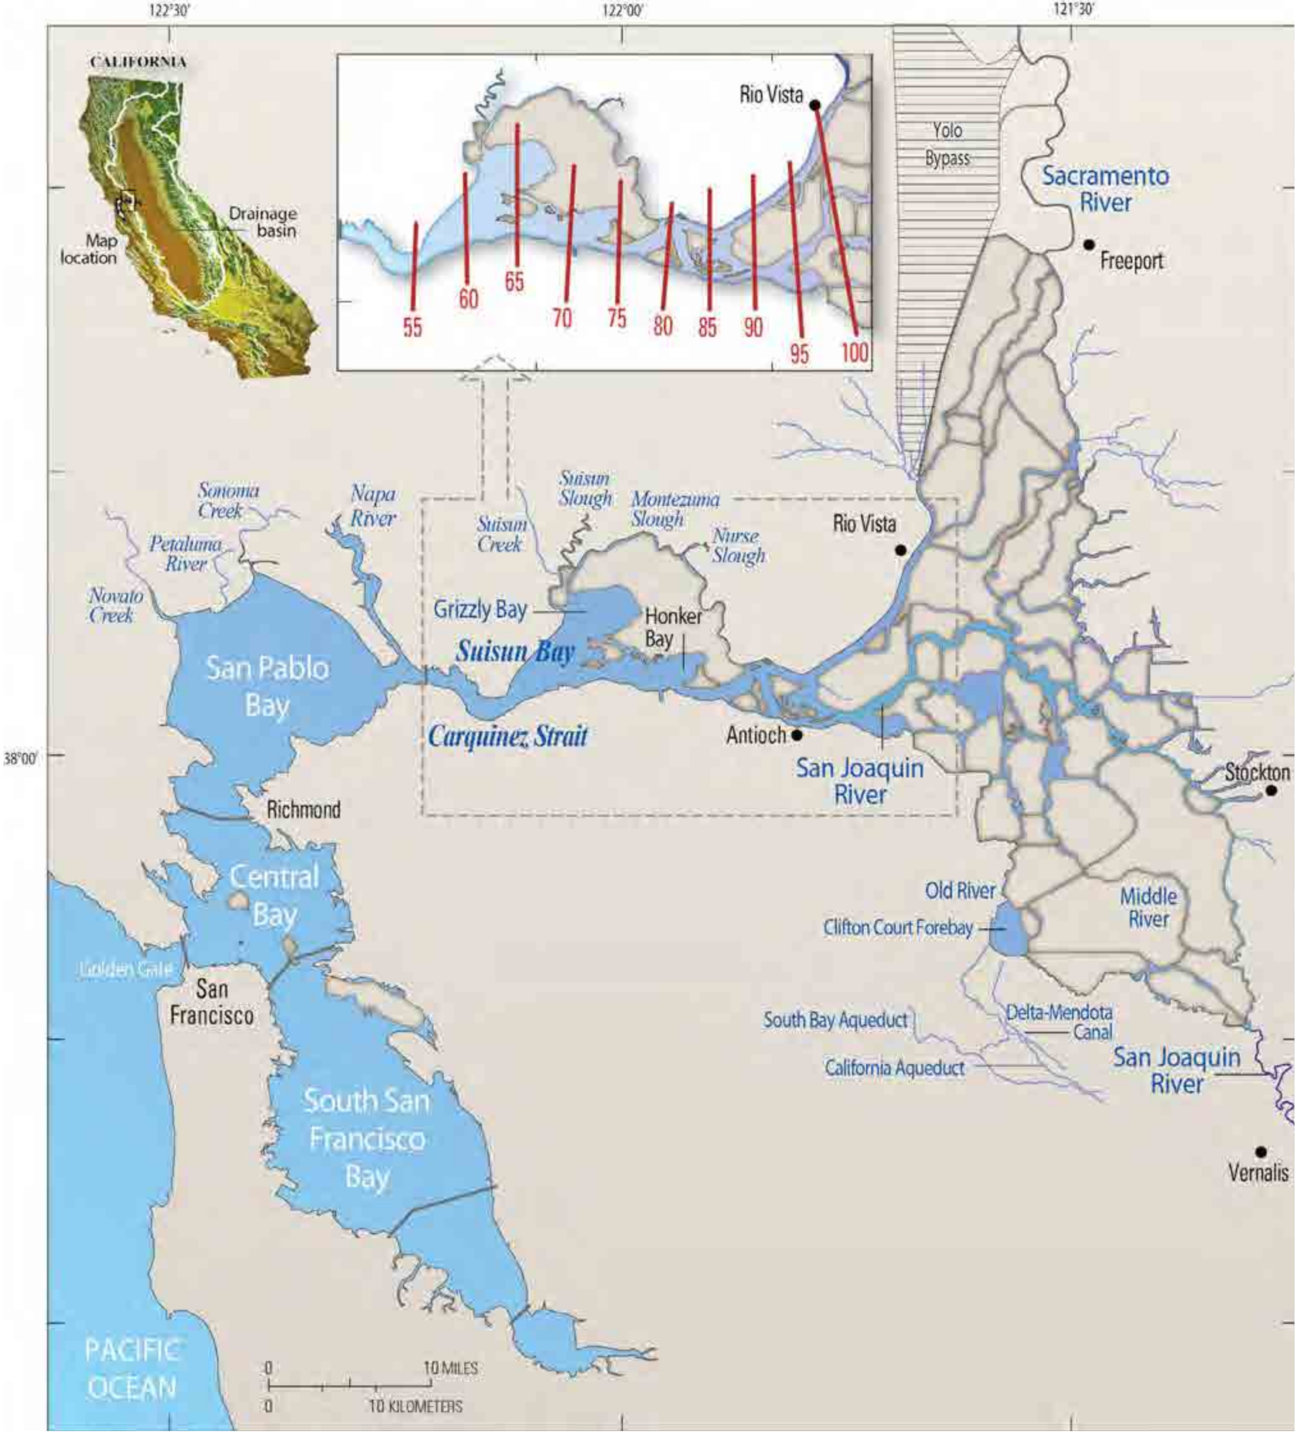

Figure 2. Map of the upper San Francisco estuary. The upper estuary includes the Suisun Bay region and the Sacramento-San Joaquin Delta, which are west and east of Chipps Island respectively. The area from approximately Chipps Island to the west end of Sherman Island is referred to as the "confluence."

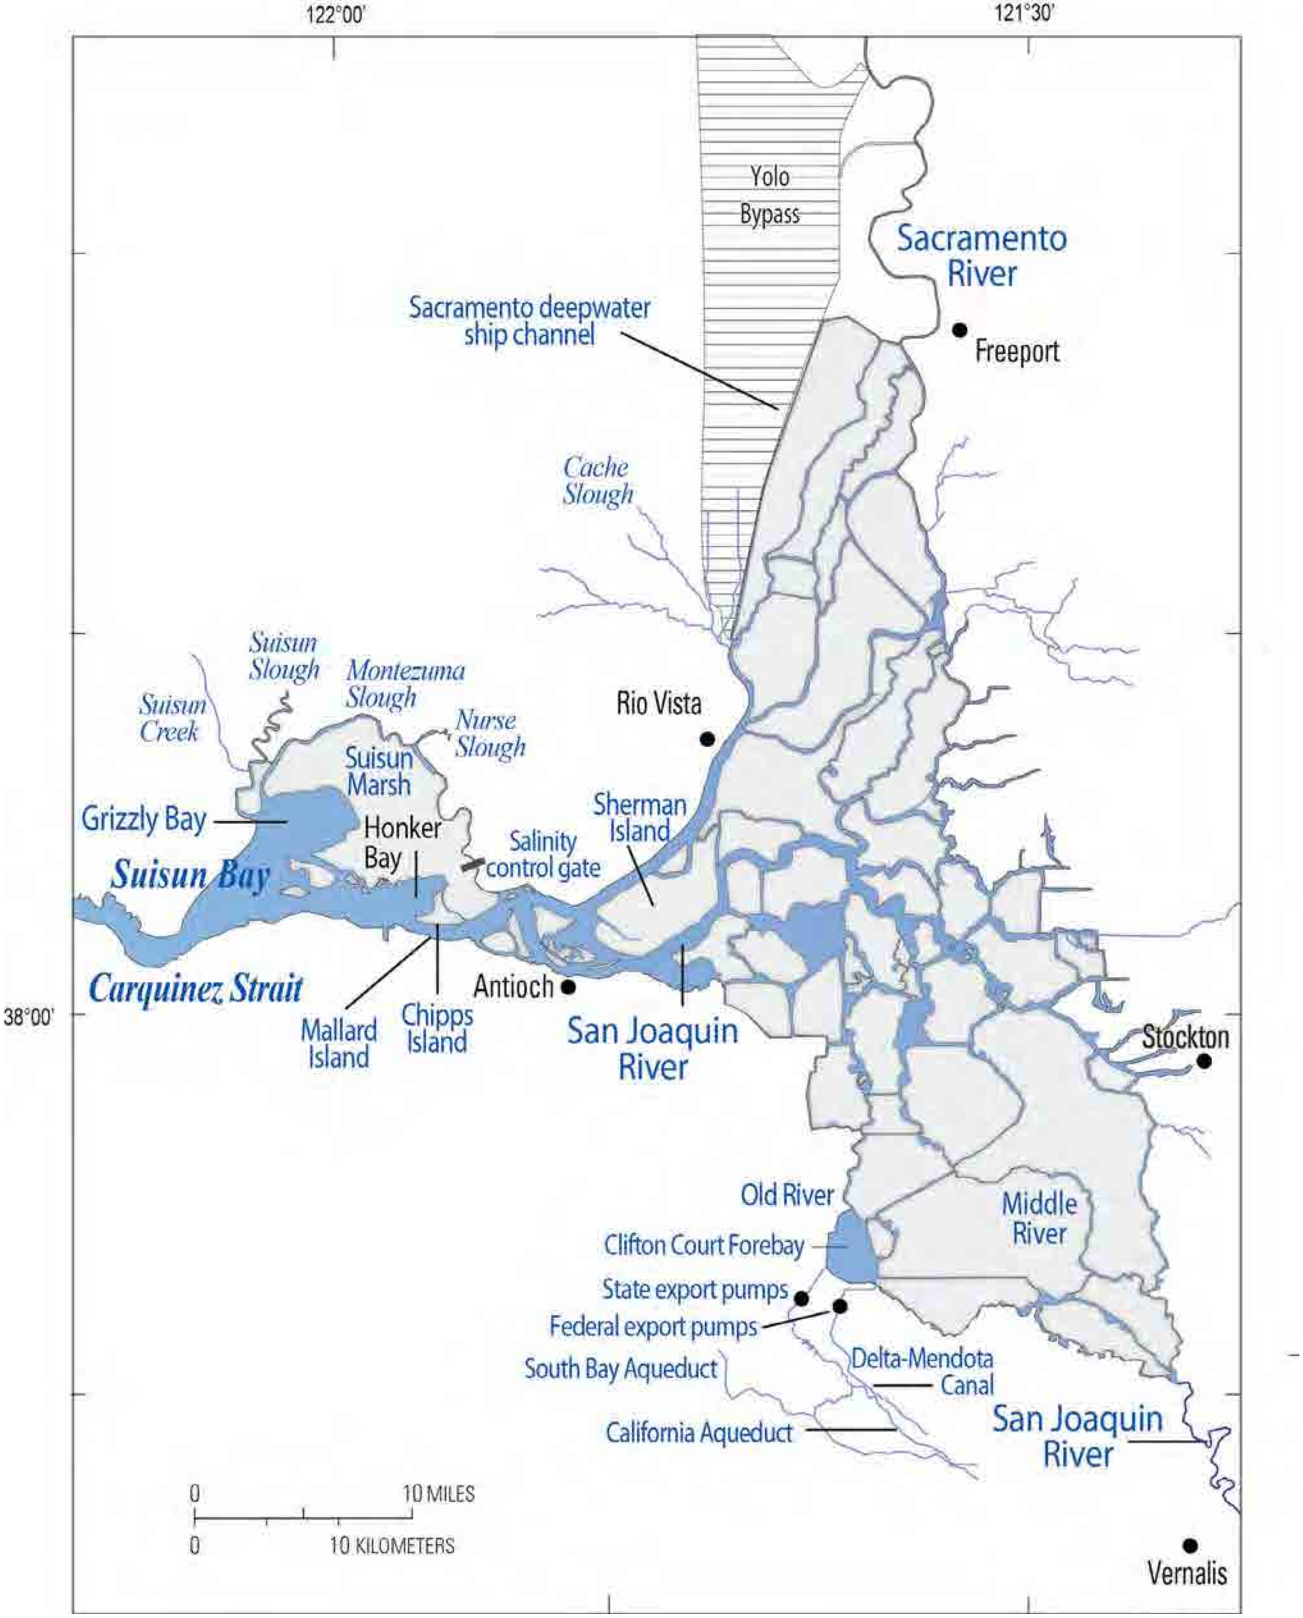

Many of the more recent ecological changes in the SFE have been documented by long-term monitoring surveys. Most of these surveys are conducted under the auspices of the Interagency Ecological Program (IEP), an interagency science consortium with three State and six federal member agencies (http://www.water.ca.gov/iep/). Together with monitoring conducted by others, these monitoring surveys provide one of the longest and most comprehensive environmental and biological data records in a U.S. coastal ecosystem. With each additional year of monitoring, this data record serves as an increasingly valuable tool for observing gradual changes or abrupt shifts in ecological conditions and for identifying their underlying causes (Cloern and Jassby 2012).

The modern SFE continues to be a dynamic and complex ecosystem that supports many important ecosystem services (Millennium Ecosystem Assessment 2005), including the provision of fresh water, agricultural crops, commercial and recreational fisheries, and other recreational opportunities. However, it no longer provides adequate habitat for many of its native species as evidenced by severe declines in several of its native fish populations (e.g., Bennett and Moyle 1996, Brown and Moyle 2005, Sommer et al. 2007).

Pelagic fish declines

Among the native fishes of the upper SFE (Fig. 2), the endemic Delta Smelt is of high management concern because of a decline of its annual abundance indices (see Chapter 3 for details of fish surveys and indices), particularly longer term indices for juveniles and subadults, to persistent low levels (Fig. 3). This decline led to its listing under the federal Endangered Species Act in 1993. The Delta Smelt is a slender-bodied pelagic fish with a maximum size of about 120 mm standard length (length from snout to end of vertebral column) and a maximum age of two years. It is the most estuary-dependent of the native fish species in the SFE (Moyle et al. 1992, Bennett 2005). The continued existence of the species is dependent upon its ability to successfully grow, develop, and survive in the SFE.

Delta Smelt is not the only fish species currently in decline in the Delta. Abundance indices of Longfin Smelt (*Spirinchus thaleichthys*), age-0 Striped Bass (*Morone saxatilis*), and Threadfin Shad (*Dorosoma petenense*) declined simultaneously with those of Delta Smelt in about 2002. This simultaneous decline has become known as the pelagic organism decline (POD) (Sommer et al. 2007, Baxter et al. 2008, 2010) (Fig. 4). Given the very different life histories of these four pelagic species, it is unlikely that a single environmental variable could account for the POD declines. In general, researchers have suggested that the POD declines were likely multi-causal (Sommer et al. 2007, Baxter et al. 2008, 2010, Mac Nally et al. 2010, Cloern and Jassby 2012, NRC 2012). Several researchers have suggested that the SFE has undergone an ecological regime shift (Moyle and Bennett 2008, Baxter et al. 2010, Glibert et al. 2011, Cloern and Jassby 2012). In the present system, an invasive aquatic macrophyte (*Egeria densa*) dominates the littoral zone of many areas of the Delta and provides favorable habitat for many invasive fishes (e.g., Largemouth Bass *Micropterus salmoides*; Brown and Michniuk 2007); invasive clams (*Potamocorbula amurensis* and *Corbicula fluminea*) consume a large portion of the available pelagic phytoplankton (Alpine and Cloern 1992, Lopez et al. 2006, Lucas et al. 2002, Lucas and Thompson 2012); agricultural, industrial, and urban discharges transport large quantities of nutrients and a plethora of contaminants into many regions of the estuary; and current management of water for agricultural, industrial and urban purposes is focused on optimizing the reliability of water exports by the CVP and SWP.

Figure 3. Delta Smelt abundance index for life stages of Delta Smelt including the larvae-juveniles (20 mm Survey), juveniles (Summer Townet Survey), subadults (Fall Midwater Trawl), and adults (Spring Kodiak Trawl). The initiation of each individual survey is indicated by the initial bar with subsequent missing bars indicating when an index could not be calculated. See Chapter 3 for details of sampling programs, including geographic coverage, and Appendix B for details of calculationg abundance indices.

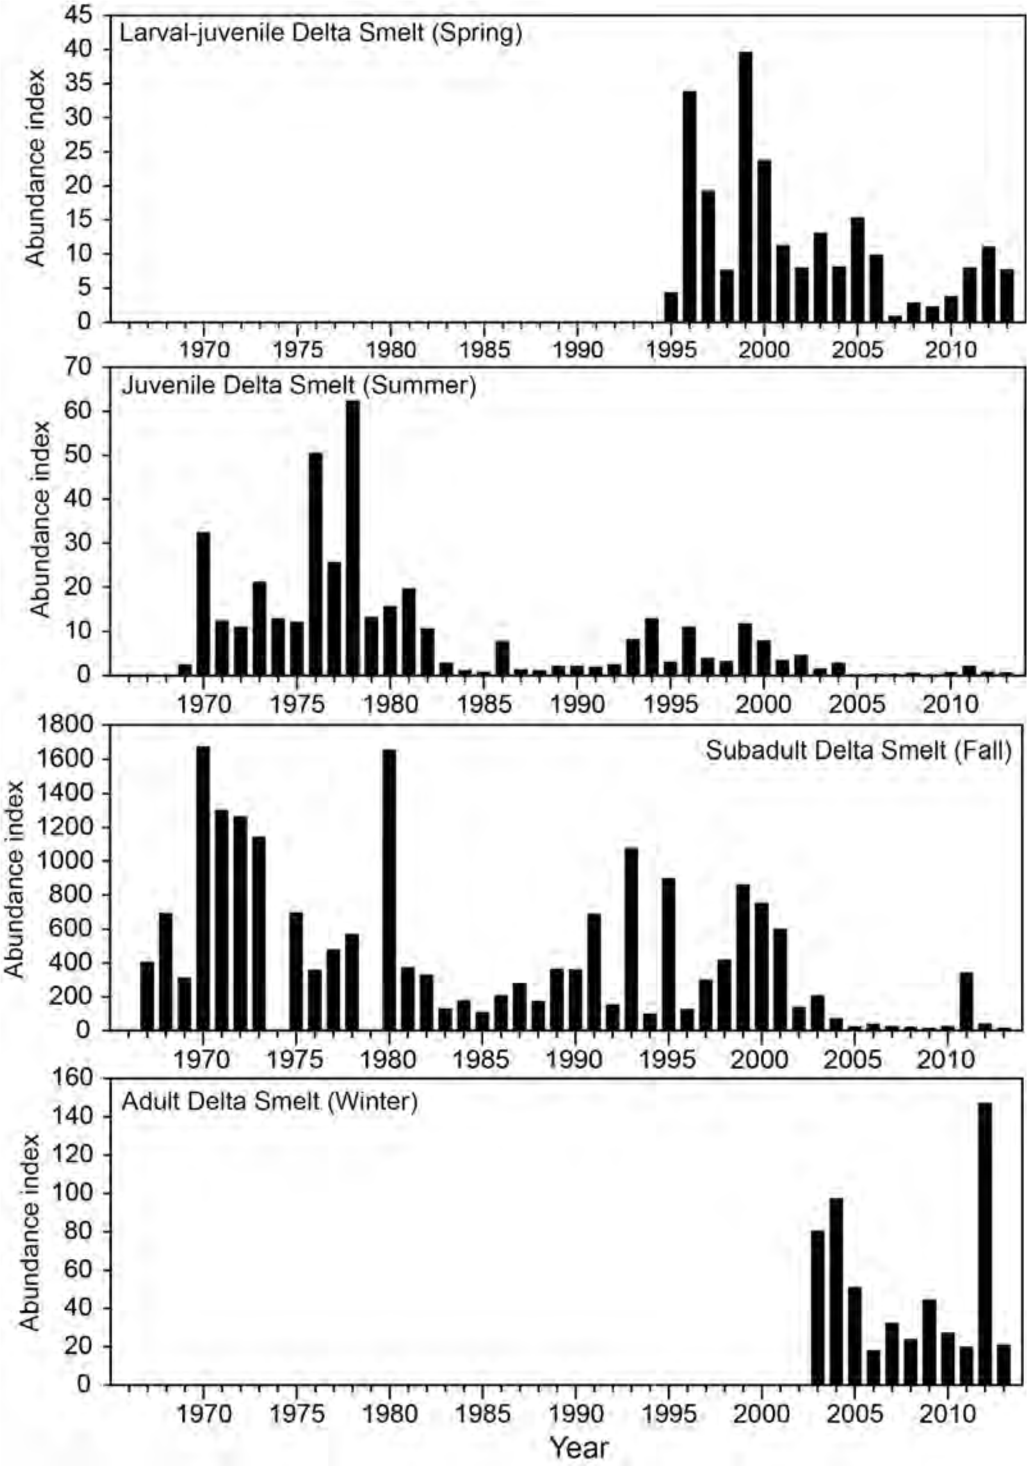

Figure 4. Abundance indices from Fall Midwater Trawl for Delta Smelt, Longfin Smelt, age-0 Striped Bass, and Threadfin Shad. Missing bars indicate when an index could not be calculated. See Chapter 3 for details of sampling programs, including geographic coverage, and Appendix B for details of calculationg abundance indices.

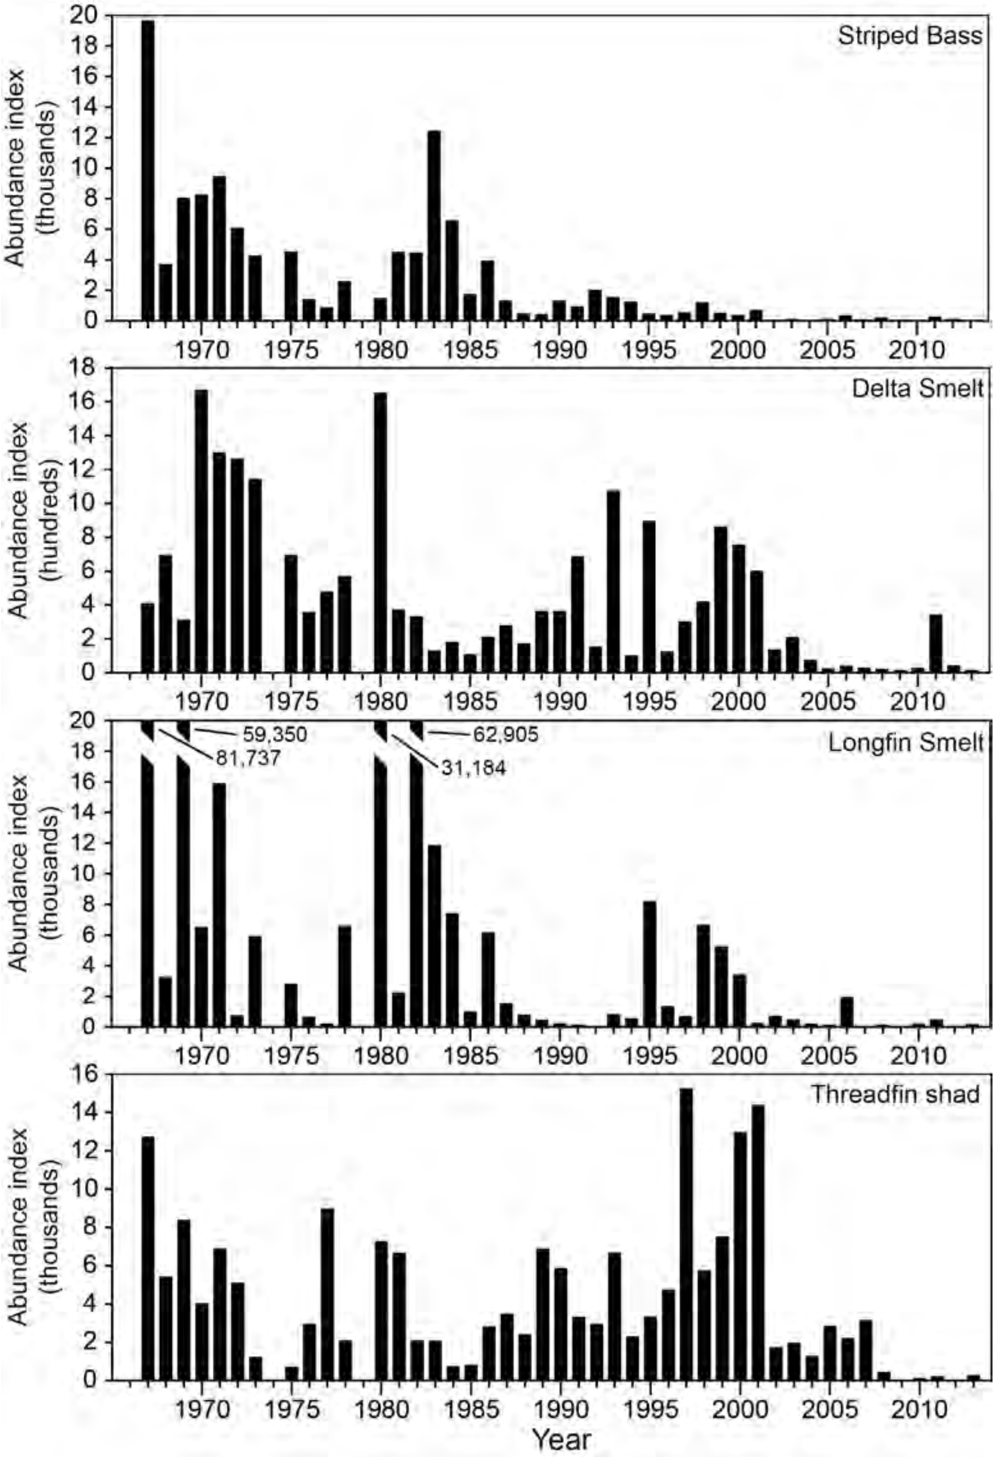


Changes in Delta Smelt distribution and abundance

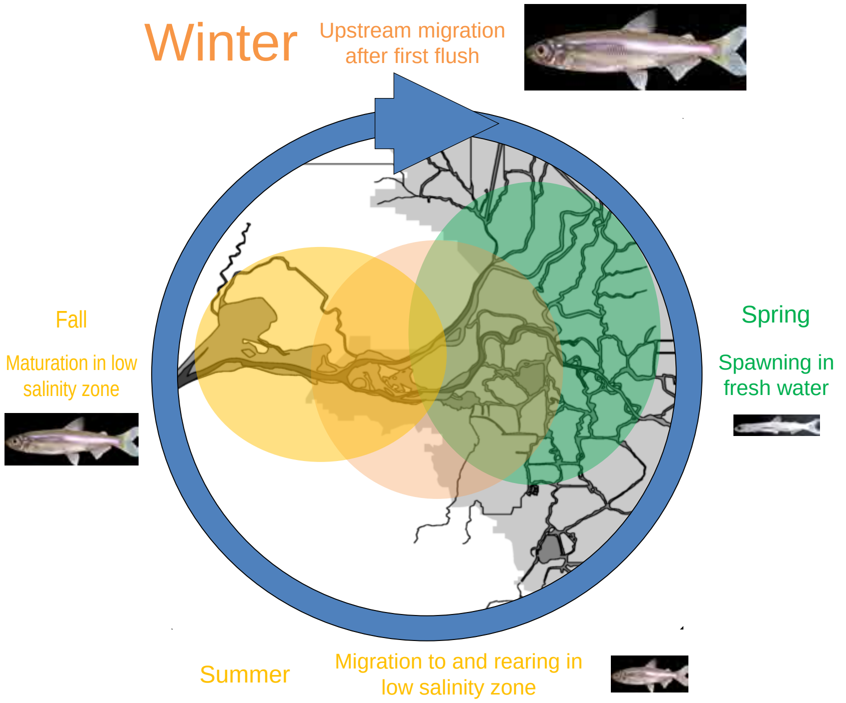
Long-term monitoring surveys conducted by the IEP have documented substantial changes in the distribution and abundance of Delta Smelt in its small native geographic range which extends from the upstream boundaries of tidal influence in the northern, eastern and southern Delta region of the estuary to Suisun and San Pablo Bays in the north-western region of the estuary. The geographic range of Delta Smelt also includes some of the larger tidal sloughs and tributaries adjacent to Suisun and San Pablo Bays, including some Suisun Marsh sloughs and the lower Napa River (Bennett 2005, Hobbs et al. 2007, Sommer et al. 2011, Merz et al. 2011, Sommer and Mejia 2013, Murphy and Hamilton 2013). Delta Smelt are generally considered a pelagic species. While they are commonly found in shallow shoal areas such as Honker and Grizzly Bays in the Suisun Bay region of the estuary and larger marsh sloughs such as Suisun and Montezuma Sloughs in Suisun Marsh and the lower reaches of Cache and Lindsey Sloughs in the northern Delta, they are less commonly encountered in near-shore areas and only rarely in smaller marsh sloughs (Bennett 2005, Merz et al. 2011, Sommer and Mejia 2013).

The Delta Smelt has been characterized as a “semi-anadromous” fish species that spawns in fresh water and rears in fresh to brackish water (Fig. 5; Dege and Brown 2004, Bennett 2005, Sommer et al. 2011, Merz et al. 2011). While Delta Smelt have been documented throughout their geographic range during most months of the year (Sommer et al. 2011, Merz et al. 2011, Murphy and Hamilton 2013), their distribution varies seasonally in response to dynamic abiotic and biotic habitat attributes such as salinity, temperature, turbidity, and presumably food supplies (Bennett et al. 2005, Sommer et al. 2013, Brown et al. 2014). In years with high freshwater discharge in winter and spring, spawning and rearing of larval and early post-larval fish can temporarily extend seaward into San Pablo Bay, while in years with less discharge it usually occurs in the Delta, Suisun Bay and Suisun Marsh. Juveniles and adults are distributed across a broader salinity range (0 to about 18) than larval and post-larval fishes which tend to be most abundant in the low salinity zone (salinity 1-6). Dege and Brown (2004) and Sommer et al. (2011) found that the center of the Delta Smelt distribution is associated with salinities of about 2 during most months and moves with the estuarine salinity gradient as the salinity gradient responds to flow.

Historically, Delta Smelt were commonly observed throughout the fresh and low salinity portions of their geographic range (Erkkila et al. 1950, Radke 1966). Over the last two decades, their geographic distribution has become more constricted during the summer and fall. At present, Delta Smelt are less commonly found in the southern and eastern Delta during the winter and spring and are largely absent from this region in the summer and fall (Nobriga et al. 2008, Sommer et al. 2011). While Delta Smelt continue to be found in the northern Delta year-round and individual catches in this region are sometimes large, particularly during winter and spring, the majority of the population is usually observed in the region near to and west of the Sacramento-San Joaquin River confluence, especially in the summer and fall (Sweetnam 1999, Feyrer et al. 2007, Nobriga et al. 2008, Merz et al. 2011, Sommer et al. 2011, Sommer and Mejia 2013).

In addition to documenting changes in distribution, long-term IEP surveys also reveal that the annual abundance indices of Delta Smelt have greatly declined since the first long-term pelagic fish monitoring survey began in summer 1959 (Fig. 3). Both a gradual, long-term decline and step changes, most recently around 2002, have been described using a variety of qualitative and statistical approaches for subadult Delta Smelt caught in the fall (e.g., Bennett and Moyle 1996, Bennett 2005, Manly and Chotkowski 2006, Thomson et al. 2010). These declines have not been smooth or entirely unidirectional and also include a great deal of interannual variability (Fig. 3).

Figure 5. **Simplified life cycle of Delta Smelt (modified from Bennett 2005). Colors correspond to different seasons with the low salinity zone changing position with season.**



Since the beginning of the POD in 2002, the Delta Smelt abundance indices have often been at record low levels, leading to concerns about declines in effective population size (Fisch et al. 2011) and a loss of population-level resilience, meaning the ability of the population to recover to higher population abundances when conditions are suitable. For example, population sizes might become too small to produce enough eggs or larvae to outpace predation on eggs and larvae.

Delta Smelt had previously rebounded from low population abundances, most recently in the wet years of the late 1990s (Fig. 3). The lack of increase in Delta Smelt in the wet year of 2006 combined with new evidence for genetic bottlenecks and a significant decline in effective population size from 2003 to 2007 (Fisch et al. 2011) were thus a source of great concern. However, during 2011, the next wet year after 2006, the species did increase in abundance (Fig. 3). Unfortunately, the increase in Delta Smelt abundance was short-lived and did not carry over into the following year-class in 2012, a drier year. Nevertheless, the temporary increase gave some cause for renewed optimism about the resilience of the species and its potential recovery. In addition, the contrasts between habitat conditions and Delta Smelt responses in 2006 and 2011 provided an opportunity to gain new insights into the Delta Smelt habitat requirements that might help better manage this species and its habitat.

Protecting Delta Smelt

Delta Smelt are currently protected under both California and federal endangered species legislation. The protection and recovery of Delta Smelt and its estuarine habitat in the SFE will likely require the human population of California to reduce its dependence on some of the natural resources provided by the SFE. This will become even more challenging in the future because of climate change and the continued growth of California's human population. California's population has increased by approximately 38 million people compared to the population when California became a state in 1850 and has increased by about 22.5 million compared to 1959 when Delta Smelt monitoring started 55 years ago (U.S. Census Bureau data). More than three quarters of today's 38 million Californians live south of the SFE, and the majority of these Californians and millions of acres of farmland rely on fresh water diverted from the Delta for all or part of their water supply. The conflicts and trade-offs between species protection measures and actions to provide water and other natural resources to California's growing human population have resulted in repeated attempts to reconcile these seemingly irreconcilable objectives through regulatory requirements, new institutional arrangements, and management plans.

Among the regulatory requirements are the State water right decisions issued by the California State Water Resources Control Board, which grant SWP and CVP water rights permits, but also include requirements to protect fish. State regulations also include increasingly more stringent waste discharge permits. For example, the new permit recently issued to the Sacramento Regional County Wastewater Treatment Plant includes new requirements for major treatment upgrades to better protect downstream water uses and the health of the estuary. Federal regulations include water quality requirements under the Clean Water Act and Biological Opinions (BiOps) issued under the federal Endangered Species Act. Two BiOps assess the effects of the coordinated operations of the SWP and CVP on Delta Smelt, Green Sturgeon, and salmonid fish populations, and their designated critical habitat. These BiOps include "reasonable and prudent alternatives" to lessen negative impacts of SWP and CVP operations and avoid jeopardy to the species, while at the same time trying to avoid major reductions in water exports from the Delta.

Recent institutional reconciliation attempts include the multiagency, State and federal CALFED Bay-Delta Program and Authority (CALFED) and the California Delta Stewardship Council (DSC), a new State agency. From 1994 to 2010, CALFED attempted to reconcile water allocation and ecosystem restoration efforts in the estuary in a way that would allow them to "get better together" (Doremus 2009). After the demise of CALFED, the State of California created the DSC to address what the legislature termed the "co-equal goals" of providing a more reliable water supply for California and protecting, restoring, and enhancing the Delta ecosystem (CA Water Code §85054, http://deltacouncil.ca.gov/).

Among the many management plans aimed at reconciling species protection and human water and land use objectives are plans by the DSC, SWRCB, and new groupings of multiple agencies and stakeholders. The DSC recently completed and is now starting to implement its comprehensive "Delta Plan" (http://deltacouncil.ca.gov/delta-plan-0) to achieve the co-equal goals, while the SWRCB is on track to complete a major update to its "Bay-Delta Plan" which may result in changes to water right permits (http://www.waterboards.ca.gov/waterrights/water_issues/programs/bay_delta/). Three California State agencies recently completed a new California Water Action Plan that includes actions to help achieve the co-equal goals (http://resources.ca.gov/california_water_action_plan/). A multi-agency planning effort that includes State and federal agencies as well as local Public Water Agencies (water contractors) is working to complete the "Bay-Delta Conservation Plan" (BDCP, http://baydeltaconservationplan.com). The BDCP is a proposed Habitat Conservation Plan under the federal Endangered Species Act and a Natural Community Conservation Plan under the California Natural Community Conservation Planning Act. It proposes to implement habitat restoration measures, stressor reduction activities, improved water project operations criteria, and new water conveyance infrastructure. If approved by the regulatory agencies, this plan would provide long-term permits for the various projects and water operations to proceed over a 50-year time frame.

Management actions, regulatory requirements, and institutional arrangements in the SFE have undergone substantial and complex changes over the last 150 years. Hanak et al. (2011) describe a progression from an early disorganized "laissez-faire" era of California and SFE water management followed by increasingly organized and large-scale management schemes, from local water use to state-wide water projects, which led to a current "era of conflict" and the hope for a new "era of reconciliation." A complete review of these changes is outside the scope of this report and the reader is referred to Hanak et al. (2011) and other existing reports on this topic. It is important to note, however, that increasingly, these changes have been "adaptations" based on the results of monitoring, studies, and other scientific activities in the SFE. Many of these scientific activities have been conducted under the auspices of the IEP (Herrgesell 2013). It can be argued that some of the activities preceding and ultimately leading to the creation of the IEP in 1970 ushered in an era of increasingly intense and formalized "adaptive management" before the term itself was coined.

Adaptive management is a formal approach to natural resource management that closely connects science with management to devise, track, and improve management outcomes. This connection started to become an important aspect of fisheries management in the 1950s (e.g., Beverton and Holt 1957), although the term itself was not coined until 1978 when Holling (1978) and Walters and Hilborn (1978) provided a conceptual framework for adaptive resources management. This framework was later refined to distinguish between "passive" and "active" adaptive management. According to Williams (2011), "active adaptive management actively pursues the reduction of uncertainty through management interventions, whereas passive adaptive management focuses on resource objectives, with learning a useful but unintended byproduct of decision making […]. In practice this means that a key difference between passive and active adaptive management is the degree to which the objectives that guide decision making emphasize the reduction of uncertainty." In active adaptive management, management actions are designed as "experimental treatments" with clear hypotheses about outcomes that are tested through rigorous data collection and analyses. This accelerates learning, but can come at the expense of achieving resource objectives because potentially less effective management actions may be included in the experimental design. Moreover, the more intense science efforts needed for active adaptive management can be costly over the short term (Williams 2011). This may explain why passive adaptive management, while not always referred to by this name or implemented in the formal and rigorous way now advocated by the DSC's Delta Plan (DSC 2013), has been and continues to be common in the SFE, but active adaptive management – viewed by some as the only "real" adaptive management – is still rare.

Of all current management actions and requirements affecting Delta Smelt, the actions required in the 2005 and 2008 BiOps issued by the U.S. Fish and Wildlife Service (FWS) are most directly aimed at the protection of Delta Smelt. The 2008 BiOp takes a life cycle approach to protecting Delta Smelt and includes an explicit requirement for adaptive management of fall outflow. After initial steps to design a passive adaptive management program, the U.S. Bureau of Reclamation (Reclamation) decided to take a more active approach aimed at more rapidly reducing uncertainties about the underlying mechanisms and effects of fall outflow management on Delta Smelt (Reclamation 2011, 2012, Brown et al. 2014). The study component of the fall outflow adaptive management plan, also known as the "fall low salinity habitat" (FLaSH) studies, was developed with the help of a new conceptual model (FLaSH conceptual model, Brown et al. 2014) and has been implemented by the IEP starting in 2011. The FLaSH studies provided an opportunity to intensely study the increase in the Delta Smelt abundance index observed in 2011. At this initial stage of the adaptive management program and the FLaSH studies, the 2011 data were compared to data gathered in the previous wet year, 2006, during which fall outflow was lower. The intitial data analysis effort also considered antecedent conditions in 2010 and 2005, resulting in a simple comparative approach focusing on four years (Brown et al. 2014).

Report Purpose and Organization

It is clear that the recovery of Delta Smelt and other listed and unlisted native species will be a key requirement of any plan to manage the resources of the SFE. Understanding the factors driving Delta Smelt population dynamics is a major goal of resource management agencies. The main purpose of this report is to provide an up to date assessment of factors affecting Delta Smelt throughout its primarily annual life cycle. Specific goals are to provide decision makers with scientific information for evaluating difficult trade-offs associated with management and policy decisions, provide scientists with a resource for formulating and testing hypotheses and mathematical models, and provide the general public with a new way for learning about Delta Smelt and their habitat.

We address these goals through a synthesis of scientific information about Delta Smelt with an emphasis on new information since the release of the last POD synthesis report in 2010 (Baxter et al. 2010). As in previous reports, conceptual models play a key role in this report. Conceptual models are useful tools for organizing and synthesizing information, designing research and modeling studies, and for evaluating potential outcomes of management actions. Here, we revisit previously developed conceptual models for Delta Smelt, and synthesize new information about factors affecting Delta Smelt and Delta Smelt responses to those factors. This comprehensive body of information is then used to construct and populate a Delta Smelt conceptual model, within a new framework.

Numerous conceptual models have been developed to describe the relationships and linkages among environmental drivers of ecosystem change, ecosystem and habitat attributes, and Delta Smelt responses. In Chapter 2 of this report, we provide a brief introduction to conceptual models and review some of the conceptual models developed for the SFE and for Delta Smelt. In Chapter 3, we introduce a new conceptual model framework for Delta Smelt and describe our approach to updating the previously developed Delta Smelt conceptual models. We also describe the data sources and analytical approaches used in this report. In Chapter 4, we review and synthesize recent information about drivers and habitat attributes affecting Delta Smelt and Delta Smelt responses to habitat attributes. In Chapter 5, we present an updated conceptual model for Delta Smelt that include key drivers, habitat attributes, interactions between them, and Delta Smelt responses discussed in Chapter 4. In Chapter 6, we review and synthesize recent information about Delta Smelt population dynamics, life history, and population trends. In Chapter 7, we use the updated conceptual model to formulate hypotheses about Delta Smelt responses and changing habitat conditions and test them using a simple comparative approach similar to the FLaSH approach (Brown et al. 2014), but for all life stages of Delta Smelt. The purpose of Chapter 7 is to put the new conceptual model along with the comparative approach to an immediate test that is of high relevance to the management of Delta Smelt. Chapter 8 presents key results and conclusions from the preceding Chapters. In Chapter 9, we discuss next steps for future conceptual, qualitative, and quantitative modeling as well as the science and management implications of the information contained in this report.

Chapter 2: Conceptual Models

Overview

We learn and think about the world we live in through mental models of how the world looks and how it works. Our mental models guide all our conscious decisions and actions. They are never static; we constantly update them with new information gained by observing the world around us and by assessing the outcomes of our decisions and actions. In our minds, we compare the new information against our existing mental models. Observations that agree with our mental models strengthen them, observations that don't agree with our mental models force us to modify, adjust, and update them.

Conceptual models are formalized versions of mental models that are communicated to others verbally and graphically. Ecologists and environmental managers use them to communicate hypotheses about "how ecosystems work" and to explore how human actions and other drivers change ecosystems. They usually use a combination of narrative text and graphical illustrations about ecosystem components and the relationships among them. More informal narrative conceptual models verbally describe cause-effect relationships, while more formal conceptual models may express them through scientific hypotheses or mathematical equations.

Conceptual model illustrations often take the form of pictures, plots, schematic images or diagrams, matrices, or tables (Fischenich 2008). For example, the IEP Estuarine Ecology Team used elaborate matrices to illustrate and assess the likely mechanisms underlying the statistically determined relationships between SFE fishes and "X2," an indicator of estuarine salinity dynamics (Estuarine Ecology Team 1997), while Reclamation (2011, 2012) used a table format to illustrate how fall outflow interacts with other features of Delta Smelt habitat and affects Delta Smelt. Schoellhamer et al. (2012) used a series of conceptual X-Y plots to illustrate a conceptual model of sediment supply reduction and downstream propagation in the SFE. Glibert (2012) and Glibert et al. (2011) used schematic images to conceptualize changes in nutrients, flows, biogeochemical processes, and the food web of the SFE. Many schematic conceptual model diagrams use boxes to depict ecosystem components and arrows to illustrate the relationships, flows, and interactions among them. The conceptual models developed by the IEP for its POD investigations (see below) include examples of schematic conceptual model depictions with few boxes and arrows, while some of the conceptual models developed for the "Delta Regional Ecosystem Restoration Implementation Plan" (DiGennaro et al. 2012, see below) and the "effects hierarchy" of factors affecting Delta Smelt abundance developed by Miller et al. (2012) provide examples of more complex schematics with a large number of boxes and arrows.

Conceptual models have become essential tools for summarizing, synthesizing, and communicating scientific understanding of ecosystem structure and functioning. They are also key to successful planning and implementation of ecological research and mathematical modeling as well as to adaptive management, restoration and recovery of ecosystems, and environmental science education (e.g., Thom 2000, Ogden et al. 2005, Fortuin et al. 2011). Conceptual models are also essential tools for identifying management and science priorities and for the selection of key ecological attributes to be used to evaluate the performance of management actions (i.e., performance measures) and assess the present relative to a desired state of an ecosystem (i.e., indicators) (Washington State Academy of Sciences 2012).

Conceptual models have clear limitations. For example, even the most complex conceptual models are highly simplified descriptions of a small part of an ecosystem – they can never tell the “whole” story. Just like our every-day mental models, they are also never final. To remain relevant, ecological conceptual models must evolve and change with the evolution of our knowledge about ecosystems. Furthermore, conceptual models identify key ecosystem components and relationships, but they do not quantify them and unless they are coupled with mathematical models, conceptual models cannot be used to make quantitative predictions.

Conceptual models can be used to make qualitative predictions about changes in ecosystem components and their relationships. These qualitative predictions can serve as testable hypotheses that help design scientific analyses and studies. The creation or revision of the conceptual models themselves usually forces the formulation of hypotheses and their testing with available data and information, as will be demonstrated in the later Chapters of this report. Qualitative predictions and testable hypotheses are also at the heart of active adaptive management. They are needed to design experimental adaptive management actions and the studies and monitoring needed to assess the outcomes from such actions. The fall outflow adaptive management plan (Reclamation 2011, 2012) provides an example of how a conceptual model was used to make qualitative predictions and design a comprehensive set of studies, the FLaSH studies. Finally, the formulation of conceptual models is usually the essential first step for constructing quantitative models. Mathematical models are sets of mathematical expressions that quantify the components and relationships in the conceptual models and can be used to make quantitative predictions about the state of ecosystem components and linkages under specific circumstances (Jackson et al. 2000). The (few) quantitative predictions in the fall outflow adaptive management plan (Reclamation 2011, 2012) are based on such mathematical models.

Ecological conceptual models generally link ecological “drivers” with ecological effects or “outcomes.” Drivers are physical, chemical, or biological factors of human or natural origin (for example, nutrients from natural soils and applied fertilizers). Outcomes can be physical, chemical or biological responses to the drivers (for example, phytoplankton growth and biomass), but can also be social and economic impacts on human components of the ecosystem (for example, harmful algal blooms that affect recreational use or costs of water treatment for drinking water supply). Drivers and outcomes are the components of the system under consideration. They are linked by mechanistic cause-effect relationships. Conceptual models can also be nested within each other, for example, to accommodate different temporal or spatial scales, or conceptual models can be coupled so that the outcome of one conceptual model becomes a driver in the next one. Drivers are often categorized in various ways, including their causal proximity to specific outcomes, whether they are natural or anthropogenic, and whether they can be altered by human management strategies and actions. Graphically, drivers are often arranged in hierarchical tiers that reflect these categories.

For example, Gentile et al (2001) describe a basic three-tiered approach that links environmental outcomes (tier 1) to proximal anthropogenic drivers termed “stressors” (tier 2) and the natural and anthropogenic drivers that act on these stressors (tier 3). Davis et al. (2010) show how different ecological regimes in Australian lakes (outcomes, tier 1) arise from the interplay of stressors (tier 2) and hydrological changes (tier 3) acting on the original ecological regime (tier 4). Carr et al. (2007) review a widely used five-tiered “Driver–Pressure–State–Impact–Response” (DPSIR) framework that focuses on identifying human-caused environmental problems and solutions. In this framework, the ultimate drivers (D) are social processes that result in specific human activities that manifest as proximal “pressures” (P) that change the “state” (S), or condition, of the environment. This can have “impacts” (I) on human well-being that are recognized as problems. Some impacts are so severe that they require a human response (R), usually in the form of institutional solutions aimed at reducing high-priority impacts. The Puget Sound Partnership Science Panel (2012) recently used the DPSIR framework to develop a conceptual model that links management strategies (i.e., responses; e.g., reduce pollution) to anthropogenic drivers (e.g., human population growth) and pressures (e.g., pollution) that affect the state of ecosystem components (e.g., habitats and species) and impact the provisioning of ecosystem services (e.g., fishing). This model helped identify scientific knowledge gaps and decision-critical issues and questions that needed to be answered in response to management priorities.

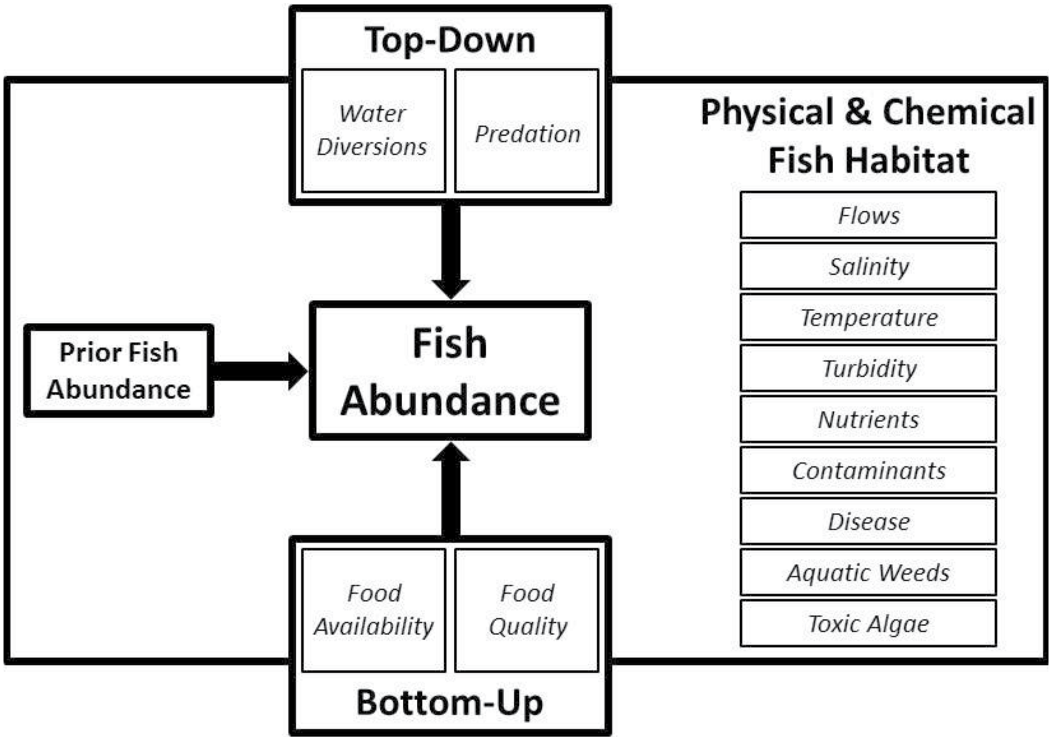
Recent Conceptual Models for the San Francisco Estuary

Over the last decade, two integrated sets of conceptual models have been developed for portions of the SFE. The first conceptual model set was developed by the Ecosystem Restoration Program (http://www.dfg.ca.gov/ERP/) to evaluate restoration actions in the Delta under the "Delta Regional Ecosystem Restoration Implementation Plan" (DRERIP; DiGennaro et al. 2012). DRERIP conceptual models were developed for ecological processes, habitats, specific species, and stressors. The DRERIP conceptual models were built around environmental drivers, their expected effects termed "outcomes," and cause-and-effect relationships between the two shown as one-way arrows termed "linkages." In the graphical depiction of the DRERIP conceptual models, different arrow widths, colors, and styles denote the importance, degree of understanding, and predictability, respectively, of the driver-linkage-outcome relationships, while symbols next to the arrows denote the direction and nature of the effect (positive, negative, or non-linear) (DiGennaro 2012, Opperman 2012). The DRERIP species conceptual models include "transition matrix" diagrams depicting how environmental drivers affect the probability of one life stage successfully transitioning to the next.

The second set of conceptual models was developed by the IEP as a comprehensive conceptual framework intended to guide investigations of the POD and to synthesize and communicate results (Sommer et al. 2007, Baxter et al. 2010). This framework includes a "basic" POD conceptual model about key drivers of change affecting pelagic fish and their habitat (Fig. 6), more narrowly focused "species-specific" conceptual models about drivers affecting the different life stages of each of the four POD fish species (e.g., Fig. 7), and a broader "ecological regime shift" conceptual model that placed the POD decline in a longer-term historical context (not shown; see Baxter et al. 2010). The basic POD conceptual model placed the four fish species in the center of interacting drivers affecting the quantity and quality of their habitat (Fig. 6), while the species-specific models identified key seasonal drivers in red, with proximal causes and effects in yellow (Fig. 7).

The National Research Council Committee on Sustainable Water and Environmental Management in the California Bay-Delta (NRC Committee) (NRC 2012) called the POD conceptual model framework "an important example of supporting science. This framework identifies and links, in the context of both ecosystem structure and functioning, the key stressors that help to explain the decline of pelagic organisms." The NRC Committee further noted that the "drivers of change" identified in the POD conceptual models "are quantifiable" and "suitable for model evaluation" and that the:

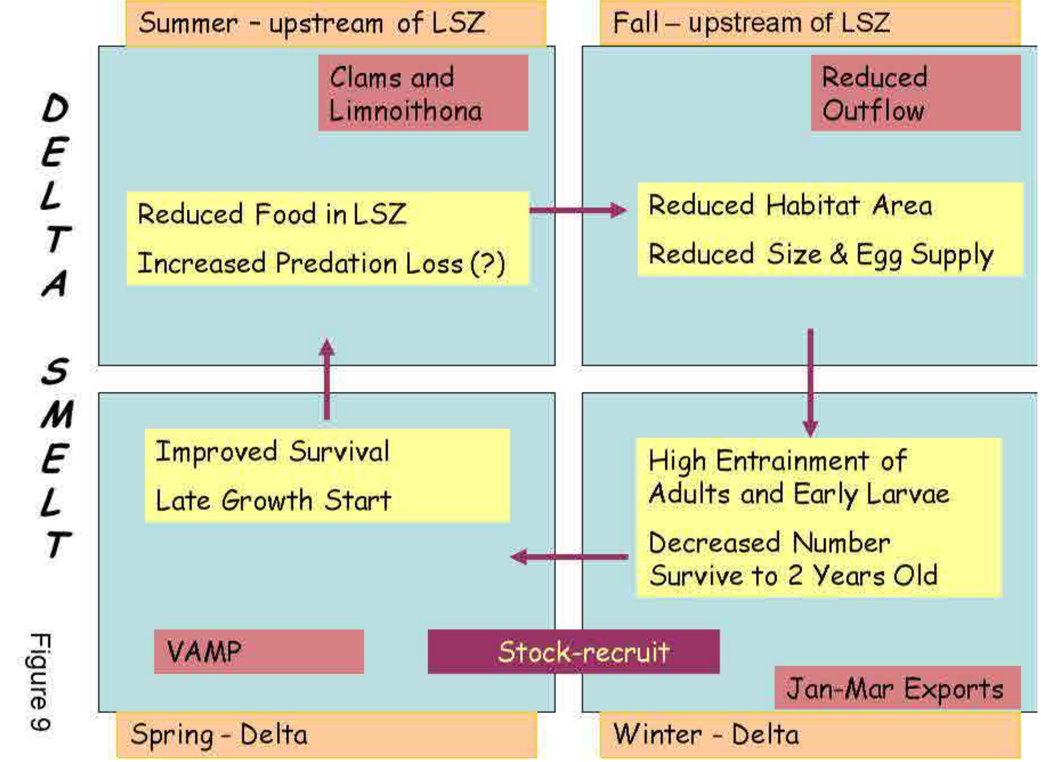
Figure 6. **The basic conceptual model for the pelagic organism decline (Baxter et al. 2010).**



> "types of stressors identified are integrative, reflecting co-occurring physical, chemical, and biotic changes. They also apply to multiple structural (food web structure, biodiversity) and functional (food transfer changes, biogeochemical cycling) changes taking place in the Delta. The framework and associated detail are both comprehensive and useful in terms of linking these drivers to changes taking place at multiple levels of the food web. This type of conceptual approach will also be useful for examining other drivers and impacts of ecological change, including observed changes in fish community structure and production; specifically, how these changes are affected and influenced by changes in physico-chemical factors (e.g., salinity, temperature, turbidity, nutrients/contaminants) and at lower trophic levels (phytoplankton, invertebrate grazers, and prey)" (NRC 2012, p. 34-35).

Since the release of the 2012 NRC report, the POD conceptual model framework has been used as the basis for additional conceptual models developed to aid planning and quantifying the ecological effects of active adaptive management of Delta outflow to improve fall low salinity habitat for Delta Smelt and to guide the associated fall low salinity habitat (FLaSH) studies (Reclamation 2011, 2012). A more complete summary of the POD and FLaSH conceptual models along with additional information about related conceptual and quantitative models in the SFE can be found in the initial FLaSH report (Brown et al. 2014, see also http://deltacouncil.ca.gov/science-program/fall-low-salinity-habitat-flash-studies-and-adaptive-management-plan-review-0).

Figure 7. Species-specific conceptual model for Delta Smelt. This is one of four species-specific conceptual models developed as part of the conceptual framework for the pelagic organism decline (Baxter et al. 2010). The low salinity zone (LSZ) is defined as salinity 1-6. The Vernalis Adaptive Management Plan (VAMP) included reductions in spring exports with possible effects on Delta Smelt.



One important new feature of the conceptual model developed for the fall outflow adaptive management plan and the FLaSH studies was the explicit consideration of interacting dynamic and relatively more stationary (geographically and temporally fixed) habitat components that was based on a conceptual model of environment-habitat-production linkages in tidal river estuaries developed by Peterson (2003). In the FLaSH conceptual model, the interactions among dynamic and stationary habitat components determine the characteristics of Delta Smelt habitat in the fall and lead to varying Delta Smelt outcomes. In essence, the dynamic flow and salinity regimes of the SFE move water, particles, and organisms across the estuary's stationary topography, which has distinct physical features that modulate the dynamic habitat components. Together, these stationary and dynamic habitat components are hypothesized to control the survival, health, growth, fecundity, and, ultimately, the reproductive success of estuarine pelagic species, such as Delta Smelt. The interplay between stationary and dynamic habitat components also helps explain the distribution and movement of Delta Smelt across its range which cannot be understood – or managed – based on geography alone.

Numerous other conceptual and quantitative models have been developed for the SFE. Kimmerer (2004) summarized many of the earlier conceptual models. More recent conceptual model examples include those by Glibert (2012) and Glibert et al. (2011) as well as the five-tiered effects hierarchy by Miller et al. (2012). Recent examples of mathematical models of habitat use and population dynamics of Delta Smelt include models based on statistical approaches (e.g., Manly and Chotkowski 2006, Feyrer et al. 2007, Nobriga et al. 2008, Feyrer et al. 2010, Thomson et al. 2010, Mac Nally et al. 2010, Miller et al. 2012). There is also a rapidly developing body of life cycle models for Delta Smelt and other SFE fish species that use statistical and numerical simulation approaches (e.g. Blumberg et al., 2010, Maunder and Deriso 2011, Massoudieh et al. 2011, Rose et al. 2011, Rose et al. 2013a,b).

Chapter 3: Approach

This report is the result of a team effort by the IEP Management, Analysis, and Synthesis Team (MAST, often referred to as “we” in this report). Appendix A briefly describes the MAST and the report development process and schedule which included a public and independent expert peer review step that led to major revisions to the draft report.

General Approach

Our general approach in this report was to develop a new conceptual model framework for Delta Smelt and to use this framework to synthesize new scientific information and update and integrate existing conceptual models including the “basic” and “species-specific” POD conceptual models, the DRERIP “transition matrix” models, the tabular FLaSH conceptual model and the hierarchical conceptual model in Miller et al. (2012) described in Chapter 2.

The development of the new conceptual model framework was guided by the conceptual model literature (see Chapter 2) and by recommendations from the independent “FLaSH Panel” of national experts convened by the Delta Science Program. The FLaSH Panel recommended to:

> “develop a schematic version of the [FLaSH] conceptual model that matches the revised, written version of the conceptual model in the draft 2012 FLaSH study report. The conceptual model in written and schematic form should continue to emphasize processes and their interactions over simple correlations, should ensure Delta Smelt vital rates remain central to thinking, and should be designed for routine use by scientists as an organizational tool and for testing hypotheses associated with the AMP [adaptive management plan]; it should be as complex as necessary to achieve these purposes. The conceptual model should also be able to encompass processes and interactions that extend before and after Fall Outflow Action periods, including areas both upstream and downstream of the LSZ” (FLaSH Panel 2012, page ii).

The conceptual modeling approach in this report is intended to provide a basis, not a substitute for the development or use of mathematical models. While mathematical models are outside of the scope of this report, we briefly discuss the promise and challenges of mathematical models for Delta Smelt, summarize some of the highlights of existing mathematical modeling efforts for Delta Smelt, and offer a brief description of two additional proposed mathematical modeling efforts — one qualitative and the other quantitative — we think are natural outgrowths of the information in this report (see Chapter 8). Development of a variety of flexible working tools to facilitate discussion of elements of the conceptual model is one intended outcome of the MAST effort. Even simple quantitative and qualitative models based on our revised conceptual model will serve to further organize thinking and characterize weaknesses in current data collection and analysis efforts.

In this Chapter, we introduce the new conceptual model framework for Delta Smelt. This framework consists of a series of nested and tiered conceptual models: a general life cycle conceptual model and more detailed life stage transition conceptual models. It was developed following recommendations by the FLaSH Panel (FLaSH Panel 2012) and extensive reviews of a draft version of this report (see http://www.water.ca.gov/iep/pod/mast.cfm and Appendix A). In Chapter 4 we review and synthesize existing information about drivers, habitat attributes, and Delta Smelt responses with a focus on new information since 2010. We use the drivers in the basic POD conceptual model as the basis for this synthesis. This information is then used to populate the nested conceptual models in the new conceptual model framework with key drivers and their linkages to Delta Smelt responses. The fully populated nested conceptual models are presented in Chapter 5. Chapter 6 focuses on Delta Smelt life history and population dynamics and trends. Chapters 4 and 6 include some new analyses of long-term monitoring data, but are largely based on a review and synthesis of the existing published literature. In Chapter 7, we compare data pertaining to ecosystem drivers (drivers), habitat attributes (drivers or outcomes) and Delta Smelt responses (outcomes) in four recent years with moderate to wet hydrology: the two most recent wet years (2006 and 2011) and the two drier years immediately before them (2005 and 2010). The intent is to assess the utility of the conceptual model for formulating and testing hypotheses that expand the comparative FLaSH approach (Brown et al. 2014) that focused on the fall to a more comprehensive year-round investigation of why Delta Smelt abundance increased in the wet year of 2011, but failed to respond to wet conditions in 2006. In each of the sections in Chapter 7 covering a specific life stage, the hypotheses inherent in the conceptual model are stated and the reasoning for including each hypothesis is explained. Although we attempted to develop independent hypotheses, this was not always possible because many drivers were related and important habitat attributes were influenced by multiple drivers and their interactions, as shown in the conceptual model diagrams and explored in Chapter 4.

Key insights from Chapters 4–7 are summarized in Chapter 8. In Chapter 8, we also discuss limitations of the analytical approaches in this report. In Chapter 9, we describe additional data and analyses needed to test hypotheses that could not be conclusively tested with the available data and our simple comparative analysis approach. We also present some ongoing or possible next steps for future years, including some recommendations for future synthesis and mathematical lifecycle modeling efforts aimed at Delta Smelt and other species and for future adaptive management, including the fall outflow adaptive management and FLaSH studies effort.

Framework for the Delta Smelt Conceptual Model

The updated Delta Smelt conceptual model framework in this report integrates and modifies features of the “basic” and “species specific” POD conceptual models (Baxter et al 2010), the FLaSH conceptual model (Brown et al. 2014), the DRERIP “transition matrix” conceptual models (DiGennaro et al. 2012), and the hierarchical conceptual model in Miller et al. (2012). It consists of two nested and linked conceptual models of increasing specificity:

1. A *general life cycle conceptual model* for the four Delta Smelt life stages (adults, eggs and larvae, juveniles, and subadults) that includes stationary landscape attributes and dynamic environmental drivers, habitat attributes, and Delta Smelt responses; and

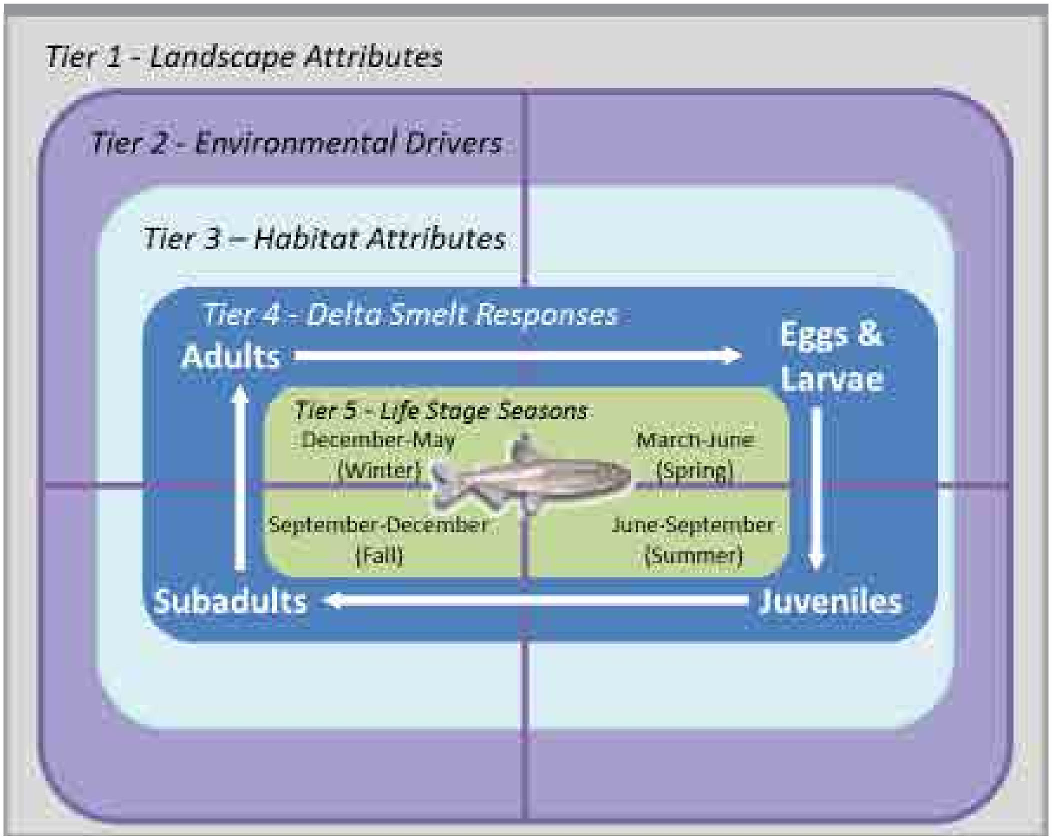
2. More detailed *life stage transition conceptual models* for each of the four Delta Smelt life stages that describe relationships between environmental drivers, key habitat attributes, and the population-level probability of successfully transitioning from one life stage to the next. This probability is dependent on the effects of environmental drivers and habitat attributes on the growth, survival, reproduction, and movements of Delta Smelt but data are currently inadequate to provide causal links for most of these processes individually.

General Life Cycle Conceptual Model

The updated general life cycle conceptual model for Delta Smelt (Fig. 8) follows the FLaSH Panels (2012) recommendation to “ensure Delta Smelt vital rates remain central to thinking” and is structurally similar to the basic POD conceptual model (Fig. 6). The general life cycle conceptual model is divided vertically and horizontally into four sections representing four Delta Smelt life stages from eggs and larvae to adults occurring in four “life stage seasons” indicated in the center of the diagram (Fig. 8; tier 5 box, green shading). This is similar to the four seasonal compartments of the species-specific conceptual model diagram in Baxter et al. (2010). Importantly, these life stage seasons are not exactly the same as calendar-based seasons. Instead, they have somewhat variable duration and overlapping months. This is because life stage transitions from eggs to adults are gradual and different life stages of Delta Smelt often overlap for a period of one to three months. Delta Smelt responses (Fig. 8; tier 4 box with dark blue shading) to important habitat attributes throughout their usually annual life cycle are placed within a box representing habitat attributes important to their growth and survival, which conveys the idea that biotic and abiotic habitat elements drive Delta Smelt responses (Peterson 2003; Fig. 8; tier 3 box with light blue shading). For each life stage season, there are a set of natural and anthropogenic environmental drivers associated with the estuarine environment (Fig. 8; tier 2 box with purple shading) that generate the habitat attributes important to Delta Smelt growth and survival. Surrounding the environmental drivers box is a fourth, outer box that represents the stationary (geographically and temporally fixed) landscape attributes of the estuarine ecosystem associated with its physical geometry and the orientation and connections of its component waterbodies (Fig. 8; tier 1 box with grey shading). In contrast to this outer box, the components and processes described in the inner boxes of this conceptual model are dynamic in space and time. Note that the fixed landscape attributes are considered fixed in the context of Delta Smelt population biology in any particular year rather than across longer time scales. The different spatial and temporal scales for each tier of the conceptual model are shown in Figure 9.

The tiered components of the general life cycle conceptual model for Delta Smelt can vary over a wide range of spatial and temporal scales (Fig. 9). Landscape attributes of the San Francisco Estuary (tier 1) encompass local to estuarine-wide features and change slowly over decades or longer periods. Environmental drivers (tier 2) that affect Delta Smelt habitat attributes vary and manifest over the broadest range of spatial and temporal scales, from local variations over tidal or daily cycles to long-term changes at the watershed or even larger geographic scales. Similar to environmental drivers, habitat attributes of Delta Smelt (tier 3) can be highly dynamic at small spatial and temporal scales or change gradually over many years, but they don’t extend beyond the geographic range of the species, which in the case of Delta Smelt is the SFE. Delta Smelt responses (tier 4) vary in response to changing habitat attributes within subregions of the estuary. In this small fish species with its maximum age of two years and extremely small geographic range, population-level responses can range from rapid (e.g., in response to toxic spills) to more

Figure 8. **A new conceptual model for Delta Smelt showing Delta Smelt responses (dark blue box) to habitat attributes (light blue box), which are influenced by environmental drivers (purple box) in four "life stage seasons" (green box). Environmental drivers are influenced by landscape attributes (grey box).**



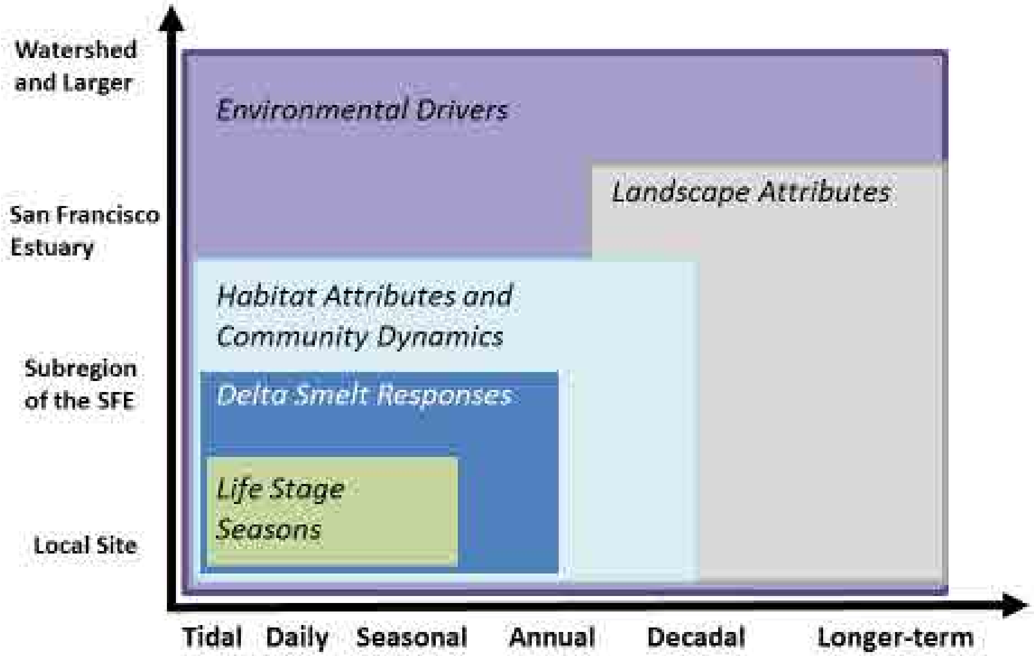
slowly over the course of one or more years. Life stage seasons (tier 5) occur over the course of a year in seasonally occupied areas of the estuary.

Similar to the POD and DRERIP conceptual models, the updated Delta Smelt life cycle conceptual model includes only those landscape attributes and environmental drivers with plausible mechanistic linkages to outcomes, which in this case are changes in habitat attributes and resulting Delta Smelt responses in the four life stage seasons. These mechanistic linkages are depicted as arrows in a series of four new conceptual models for each life stage season (Fig. 10). These life stage season conceptual models are nested components of the general life cycle conceptual model as shown in Fig. 8. They will be described in detail in Chapter 5.

Data Sources

Our examination of environmental drivers in Chapter 4, Delta Smelt life history and population dynamics and trends in Chapter 6, and the evaluation of hypotheses about Delta Smelt responses to changing habitat attributes in Chapter 7 rely largely on results of previously published data and analyses, but in several cases we update these analyses with more recent data. We also include some additional analyses (described below). All these analyses depend largely on environmental monitoring data collected by IEP agencies during routine, long-term monitoring surveys

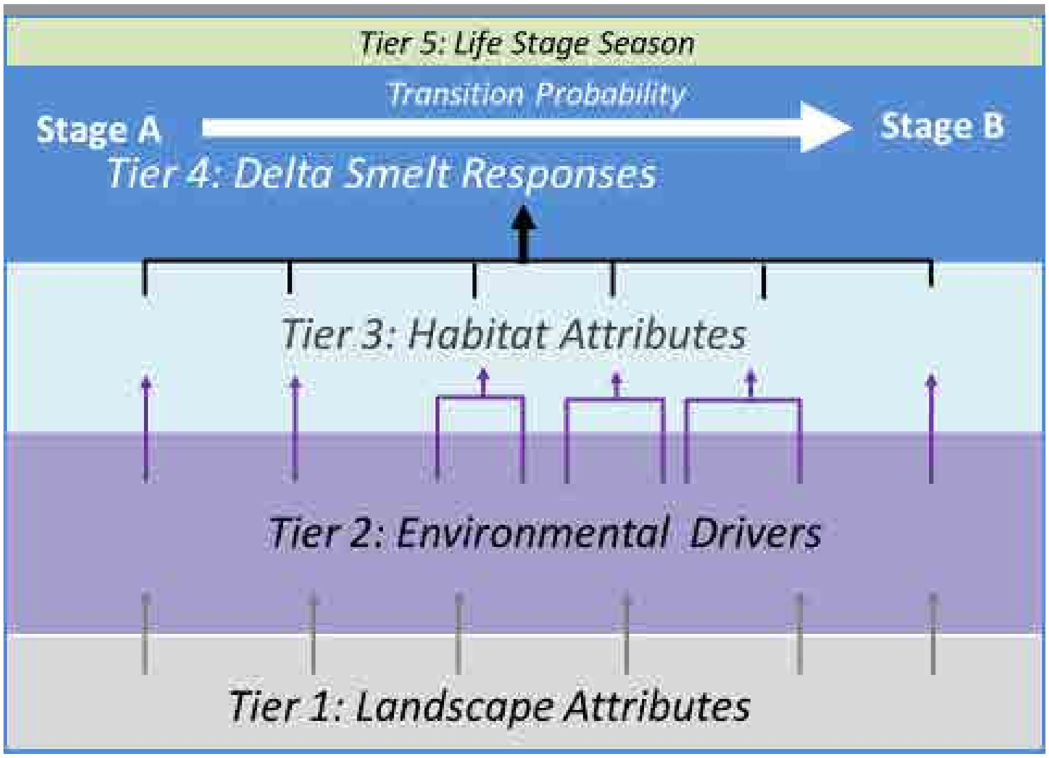
Figure 9. **Spatial and temporal scales of the component tiers in the general life cycle conceptual model framework for Delta Smelt.**



(http://www.water.ca.gov/iep/products/data.cfm). These surveys provide the long-term records and geographic coverage necessary and the data collected by these surveys are publicly available. Available data includes data on fish, invertebrates, phytoplankton, water quality variables, and flow. Use of these particular data sources does not reflect any preference for those data. Results from other ongoing research efforts were included as appropriate.

For the purposes of this report, we consider each stage, larvae through adults, of the Delta Smelt life cycle in the context of the monitoring programs that provide data on the Delta Smelt population. Delta Smelt eggs are not monitored and have in fact never been found in the wild. Monitoring surveys in the late winter and spring include the spring Kodiak trawl (SKT, Fig. 11), which samples maturing, spawning and post-spawning adults. The SKT is conducted monthly from January through May. Spring also includes the 20 mm survey (20 mm, Fig. 12), which samples larval and post-larval Delta Smelt and is conducted every two weeks from mid-March through mid-July. Summer includes the summer townet survey (TNS, Fig. 13); which samples juvenile fish and currently runs every two weeks from June through August. The Fall Midwater Trawl (FMWT, Fig. 14) survey samples subadult Delta Smelt monthly from September through mid-December. Each of these surveys samples fishes broadly within the upper SFE and generally covers the geographic habitat range used by Delta Smelt (Merz et al. 2011). Exceptions to complete coverage occur in some high outflow years when Delta Smelt can temporarily inhabit San Pablo Bay in association with decreased salinities caused by increased Delta outflows (Moyle 2002) and in other years when some adult fish move upstream of the geographic range of these surveys (probably to spawn) in the Yolo Bypass and Sacramento River (e.g., Feyrer et al. 2006, Merz et al. 2011). Also, FMWT and TNS sampling in the Cache Slough complex was instituted over several years starting in the 1990s for FMWT and 2000s for TNS. The current sampling locations have been in place since 2011. These exceptions to complete spatial coverage are believed to reflect small fractions of the population. Additional geographic coverage along

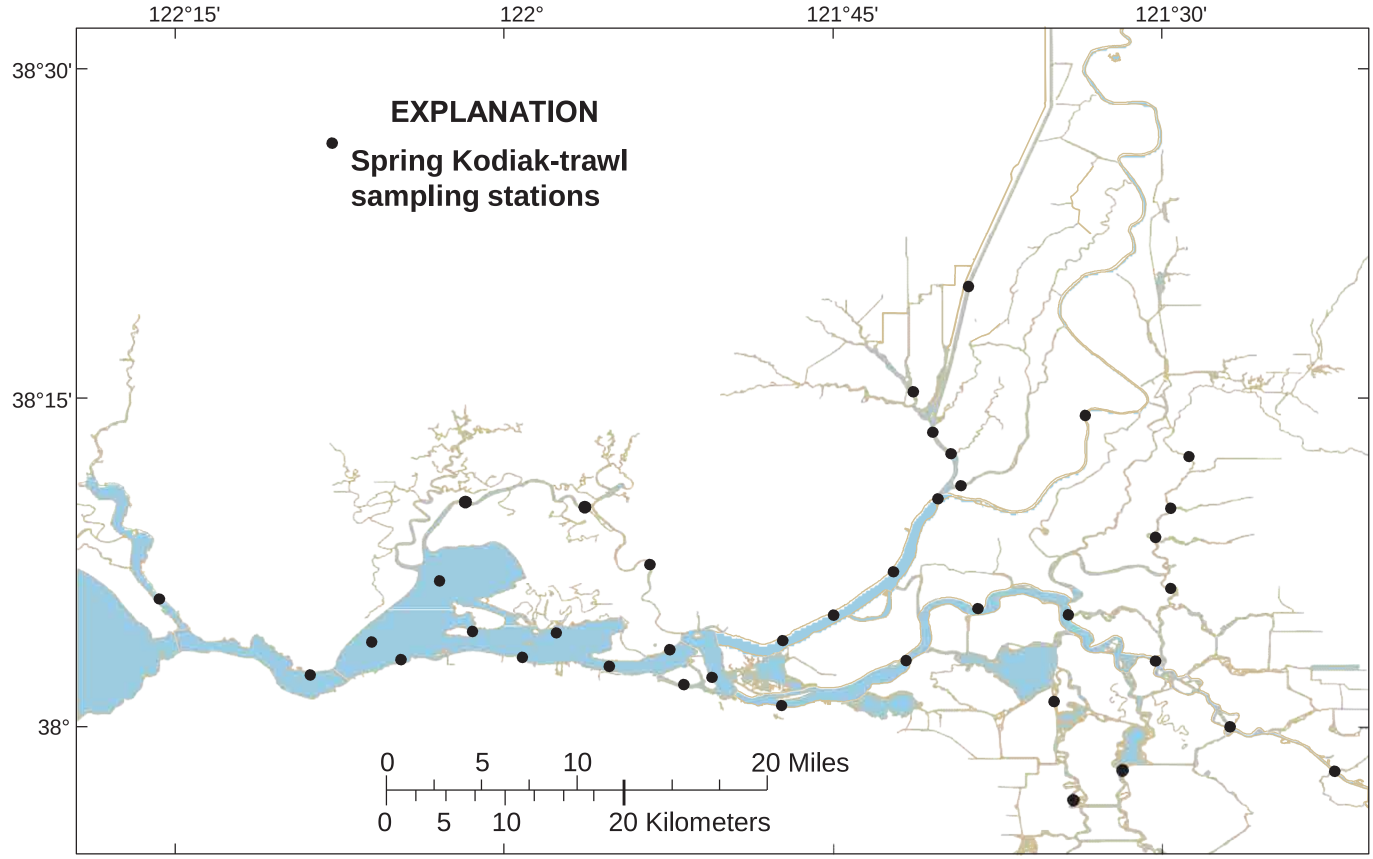
Figure 10. **Framework for the Delta Smelt life stage season conceptual models.**



or outside of the margins of the other four monitoring surveys is provided by other IEP fish monitoring surveys such as the San Francisco Bay Study, trawling and seining conducted by the Delta Juvenile Fish Monitoring Program in the Sacramento River and the north Delta, as well as the fish salvage monitoring at the fish protection facilities associated with the SWP and CVP export pumps in the south Delta. All Delta Smelt life stages (larvae-adult) are also commonly collected from nearshore habitats and in shallow open water where trawls cannot be used effectively (e.g., Aasen 1999, Nobriga et al. 2005, Brown and May 2006); however, there are no data indicating these are preferred habitats, that these fish represent different populations (see Fisch et al. 2011), or that their abundance varies differently than data from the aforementioned trawl surveys would suggest.

Annual abundance indices for Delta Smelt life stages are calculated from the catch data provided by each of the four surveys (See Appendix B for details). Together, they provide a comprehensive account of long-term changes in the relative abundance of Delta Smelt (Fig. 3). The long series of abundance index records for the summer and fall have provided the basis for many data analyses and modeling studies (e.g., Jassby et al. 1995, Kimmerer 2002a,b, Bennett 2005, Manly and Chotkowski 2006, Thomson et al. 2010, MacNally et al. 2010, Maunder and Deriso 2011, Miller et al. 2012) and for regulatory actions (USFWS 2008). They have also been used to estimate absolute population abundance (Newman 2008). The Delta Smelt and other SFE fish abundance indices are generally considered useful indicators of the status and trends of the Delta Smelt population as well as of the status of other resident fishes in the SFE in general and serve as performance metrics for the success of management actions. All monitoring surveys have strengths and weaknesses, and the long-term fish monitoring programs in the SFE are no exception (Honey et al. 2004). In the case of Delta Smelt, strengths include reasonably good coverage of the geographic extent of Delta Smelt habitat and coverage of all life stages except

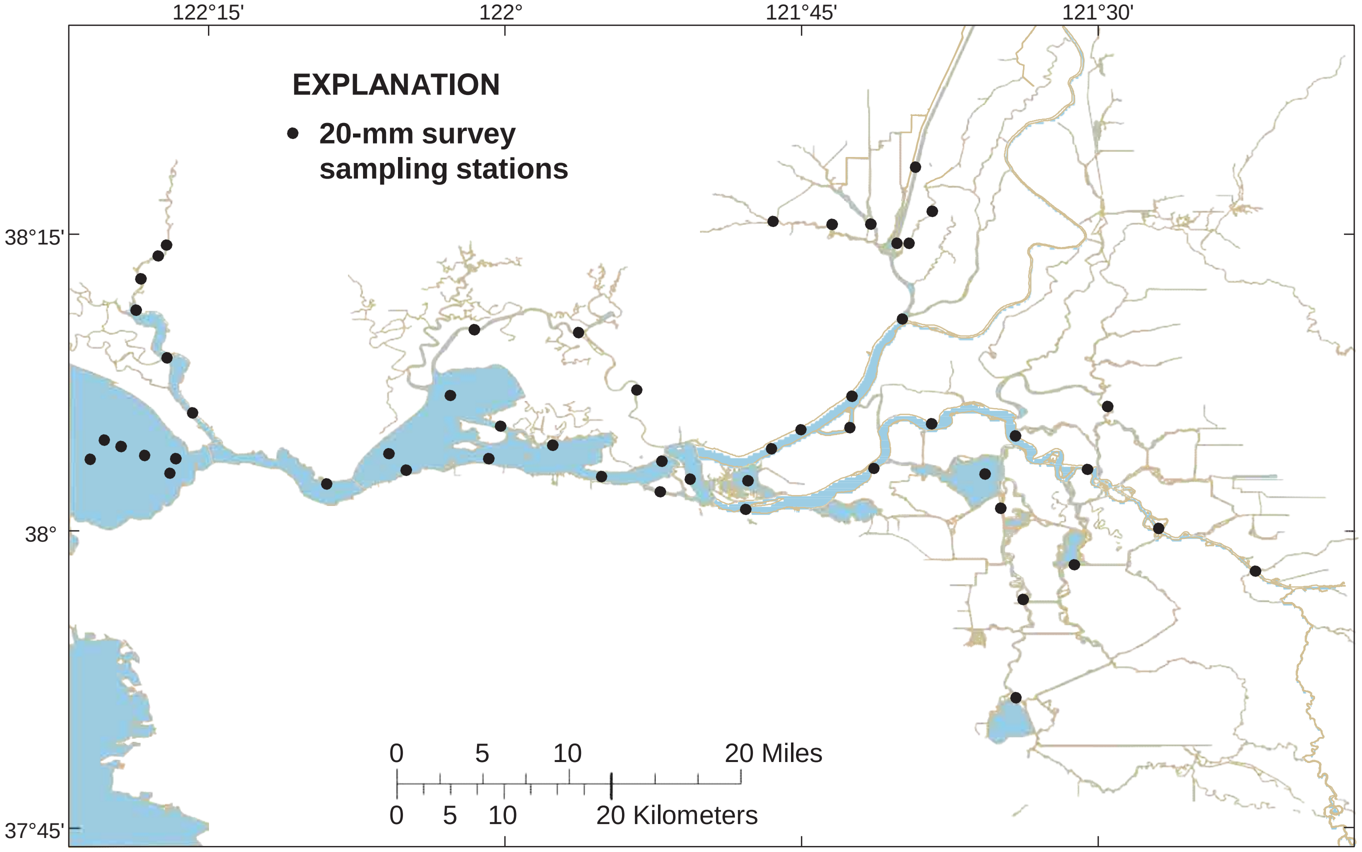
Figure 11. Map of Spring-Kodiak Trawl Survey sampling stations.



eggs (Gaines et al. 2006). They also include exceptionally long and consistent data records going back to 1959 in the case of the TNS, the oldest of the four surveys described here. There is a large amount of ancillary data (covariates), including data collected during the fish surveys, additional fish data from other monitoring surveys (Honey et al. 2004) as well as invertebrate, phytoplankton, water quality and hydrological data. Possible weaknesses include no measure of precision of abundance indices and imprecise estimates due to a high frequency of zero catches of Delta Smelt. These problems combine with survey design issues such as differences in Delta Smelt catchability with different nets and trawl regimes under changing environmental conditions, behavioral changes in distribution (Newman 2008) and the current low abundance of the species. For example, several studies have shown that Delta Smelt can exhibit lateral and vertical movements associated with tide and time of day (Bennett et al. 2002, Feyrer et al. 2013, Bennett and Burau 2014) but the overall frequency or effects of such local movements on abundance indices are unclear. Studies to further evaluate and address these issues are currently underway.

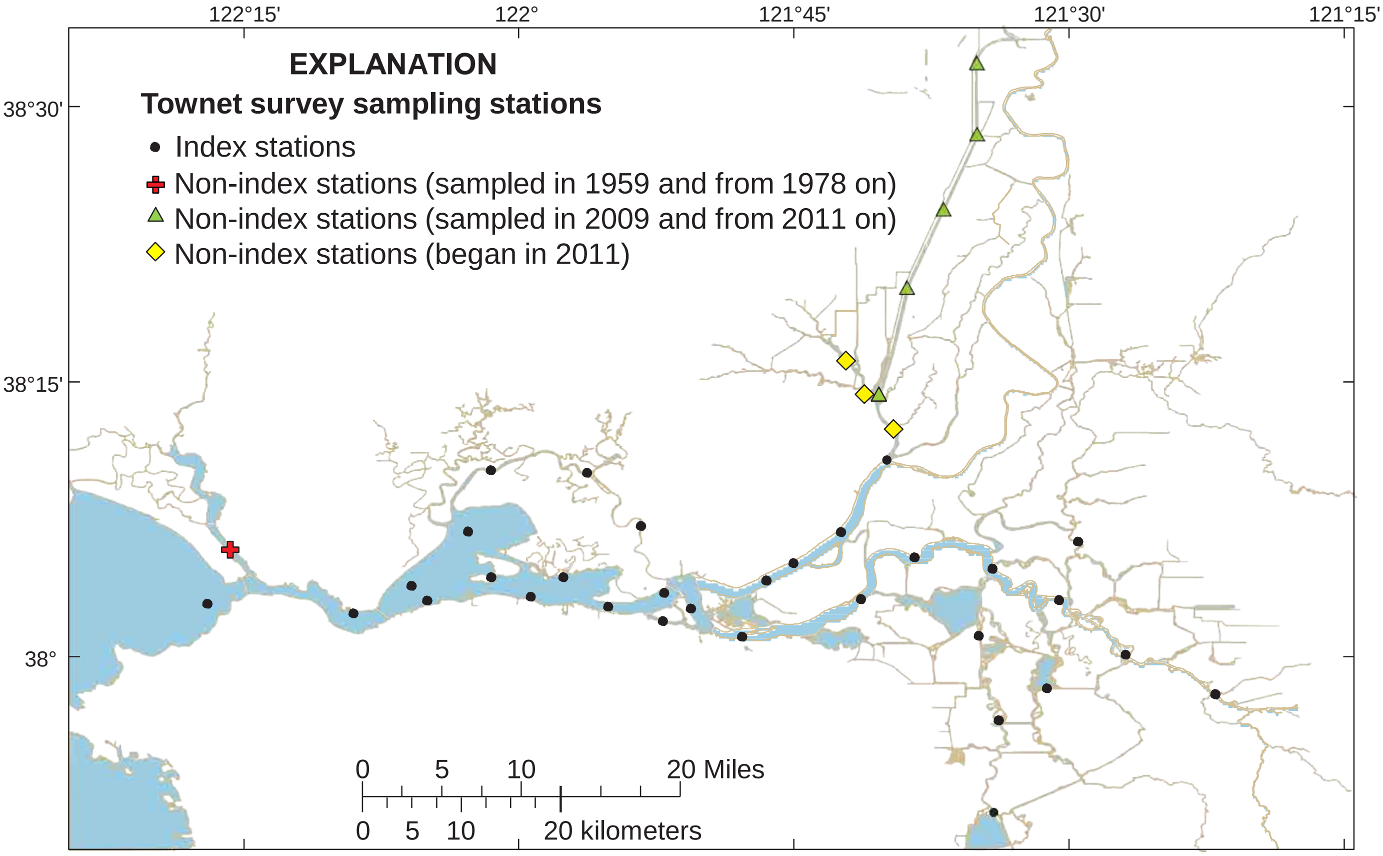
Two of the four fish monitoring surveys described here specifically target Delta Smelt; the other two do not. The SKT was designed and implemented specifically to improve detection of maturing adult Delta Smelt moving upstream in the winter and spring, particularly into the central and south Delta (Souza 2002). The 20 mm survey was designed and implemented specifically to capture late-stage larval Delta Smelt of about 20 mm in length; the SKT and 20 mm survey data help managers assess the risk of entrainment of these life stages by south Delta

Figure 12. **Map of 20 mm Survey sampling stations.**



export pumps (Dege and Brown 2004). The TNS was designed to target small juvenile Striped Bass of about 17-50 mm fork length (the distance from the snout to the indentation of the tail fin) (Stevens 1977, Turner and Chadwick 1972); however, Delta Smelt tend to be of appropriate size for capture by the TNS net during the survey period. This occurs because Delta Smelt (see below) and Striped Bass spawning overlaps in time and growth of both are linked to water temperature, such that peak larval abundance occurs in April or May in most years. The TNS traditionally started and ended based on mean length of Striped Bass; however, young Delta Smelt attain sizes vulnerable to the TNS net during the same time period Striped Bass are vulnerable (Miller 2000). The survey ends when young Striped Bass surpassed 38 mm fork length (Miller 2000). Thus, regardless of the particular number of sampling surveys in a year or the index calculation method, Delta Smelt juveniles are generally vulnerable to the TNS whenever it samples. Similarly, the FMWT survey was designed to capture young-of-the-year Striped Bass, but in the 60-140 mm fork length size range (Stevens 1977). Although the survey and gear is generally effective for small pelagic fishes, the cod-end mesh (1.3 mm stretch mesh) on the net is large enough to allow some smaller sub-adult Delta Smelt to escape during the first couple survey months (see Newman 2008 for an approach to correct this effect). Even though the gear is not completely effective at retaining all sub-adult Delta Smelt, FMWT provides a reasonable relative measure of sub-adult abundance through time (Kimmerer and Nobriga 2005), albeit with low precison at the current low catch levels and given additional variation related to changes in growth, and thus changes in retention in the net from year to year. With the aforementioned caveats, we believe these surveys provide useful and valid relative abundance measures to examine the various life stage transition

Figure 13. Map of Summer Townet Survey sampling stations.



relationships described in this report as well as in many of the previously published studies cited in this report.

In addition to the annual abundance indices for Delta Smelt provided by the monitoring surveys described above, we also present annual indices of recruitment and survival. In this report, a survival index is simply the ratio of an abundance index for a particular life stage divided by the abundance index for a preceding life stage of the same Delta Smelt cohort. A recruitment index is the ratio of an abundance index for a particular life stage divided by an abundance index for a life stage of the preceding Delta Smelt year-class. These types of indices have been used in previous analyses (e.g. Miller et al. 2012), but it is important to note that they may compound the observation errors inherent in the annual abundance indices in complicated ways. This is likely more problematic for survival and recruitment indices that use the TNS and FMWT abundance indices because these surveys were not specifically designed to target Delta Smelt. It may be less problematic for the recruitment index calculated by dividing the 20 mm abundance index for larval and post-larval Delta Smelt by the preceding SKT abundance index for adult Delta Smelt because both surveys specifically target Delta Smelt. We use this recruitment index in some additional analyses included in this report. All other survival and recruitment indices are only used as a rough approximation and illustration of differences in recruitment and survival rates among different annual cohorts and life stages; they are not used for additional analyses.

Data Analysis

As noted previously, we review long-term trends in this report using published results, but in some cases include some additional analyses of long-term monitoring data (Chapters 4 and 7). These analyses are kept deliberately simple, for example, simple graphical explorations of time series, examinations of simple statistics such as medians and arithmetic means, and investigation of univariate relationships using simple correlation and least squares regression analyses. Such analyses are readily reproducible with the publicly available data described above. The purpose of presenting the results of these new analyses is to update previously published information with the most recent data. In many cases, the data presented in this report are summarized using boxplots. The center horizontal line in each box represents the median of the data. The upper and lower ends of the box represent the upper and lower quartiles of the data. These are also known as “hinges.” The “whiskers” are the lines extending above and below the box. The whiskers show the range of values falling within 1.5 times the inter-quartile distance from the nearest hinge. Values outside this range are shown as individual symbols. Asterisks denote values within 1.5 to 3.0 times the inter-quartile distance and circles denote values greater than 3.0 times the inter-quartile distance. Other types of plots are explicitly identified in the figure caption.

Some graphs and analyses refer specifically to the POD period. Analyses suggest the POD period started as early as 2002 or as late as 2004 (Thomson et al. 2010). We somewhat arbitrarily selected 2003-present as the POD period for this report. This period is not being recommended as the baseline for management agencies to use when considering recovery of Delta Smelt. The time period simply reflects the consistently low level of Delta Smelt abundance in recent years and a useful baseline for identifying years with improved Delta Smelt abundance indices, which would indicate improved environmental conditions for Delta Smelt. Similarly, we also consider the 1982-2001 period between the two major step declines in Delta Smelt abundance identified by Thomson et al. (2010) separately in some graphs and analyses. Finally, some graphs and analyses refer to calendar years while others refer to water years. In California, a water year starts on October 1 and ends on September 30 of the next calendar year. California water year classifications are based on calculations of annual unimpaired runoff, which represents the natural water production of a river basin, unaltered by upstream diversions, storage, and export of water to or import of water from other basins.

In Chapter 7, we explore a series of hypothesized driver-outcome linkages using a comparative approach. The purpose is to demonstrate the utility of our conceptual model framework for generating hypotheses about the factors that may have contributed to the 2011 increase in Delta Smelt abundance. Specifically, we compare Delta Smelt responses to habitat conditions in four recent years with moderate to wet hydrology: the two most recent wet years (2006 and 2011) and the two drier years immediately before them (2005 and 2010). This comparative approach and data sources (described in Chapter 4) are deliberately similar to the comparative approach used in the FLaSH investigation (Brown et al. 2014). This approach allows us to place the results of the FLaSH investigation in a year-round, life cycle context and to more comprehensively evaluate factors that may have been responsible for the strong Delta Smelt abundance and survival response in 2011, including any possible relevant antecedent conditions from 2010. We attempt to draw comparisons with a similar set of data collected during 2005 and 2006. Our working assumption is that different Delta Smelt abundances in 2006 and 2011 should be attributable to differing environmental conditions, in some cases attributable to management actions, and subsequent ecological processes affecting the Delta Smelt population.

In Chapter 9 we briefly describe three examples of additional mathematical modeling approaches that can be used to further explore some of the linkages and interactions in our conceptual models and complement previously published and other ongoing mathematical modeling efforts for Delta Smelt. Importantly, results from the three modeling examples in Chapter 9 are included for illustrative purposes only; peer-reviewed publications of these analyses need to be completed before they can be used to draw firm conclusions.

Chapter 4: Environmental Drivers and Habitat Attributes

The general approach of this Chapter is to focus on how environmental drivers and interactions among them create habitat attributes of importance to Delta Smelt. Specifically, we review and synthesize existing information about drivers and habitat attributes and Delta Smelt responses to habitat attributes with a focus on new information since Baxter et al. (2010). We use the drivers and habitat attributes depicted in the basic POD conceptual model (Fig. 6) as the basis for this synthesis. We consider habitat attributes important when there are published studies suggesting ecological responses by Delta Smelt. Each section focuses on a habitat attribute that can be the outcome of one or more environmental drivers. Physical habitat attributes are presented first, followed by biological habitat attributes. The order of presentation does not imply any kind of ranking of relative importance. For simplicity, we consider all habitat attributes discussed here as equally important because, as noted in Chapter 2, habitat arises from the combination of *all* physical and biological attributes affecting a species. We fully acknowledge that as Delta Smelt research proceeds and the system continues to change, additional habitat attributes my need to be added to the conceptual model, while others may be deemphasized or even deleted.

Each section starts with the general importance of a specific habitat attribute for estuarine biota followed by a brief discussion of its linkages with environmental drivers and its dynamics in space and time. Each habitat attribute is then placed in the context of Delta Smelt biology.

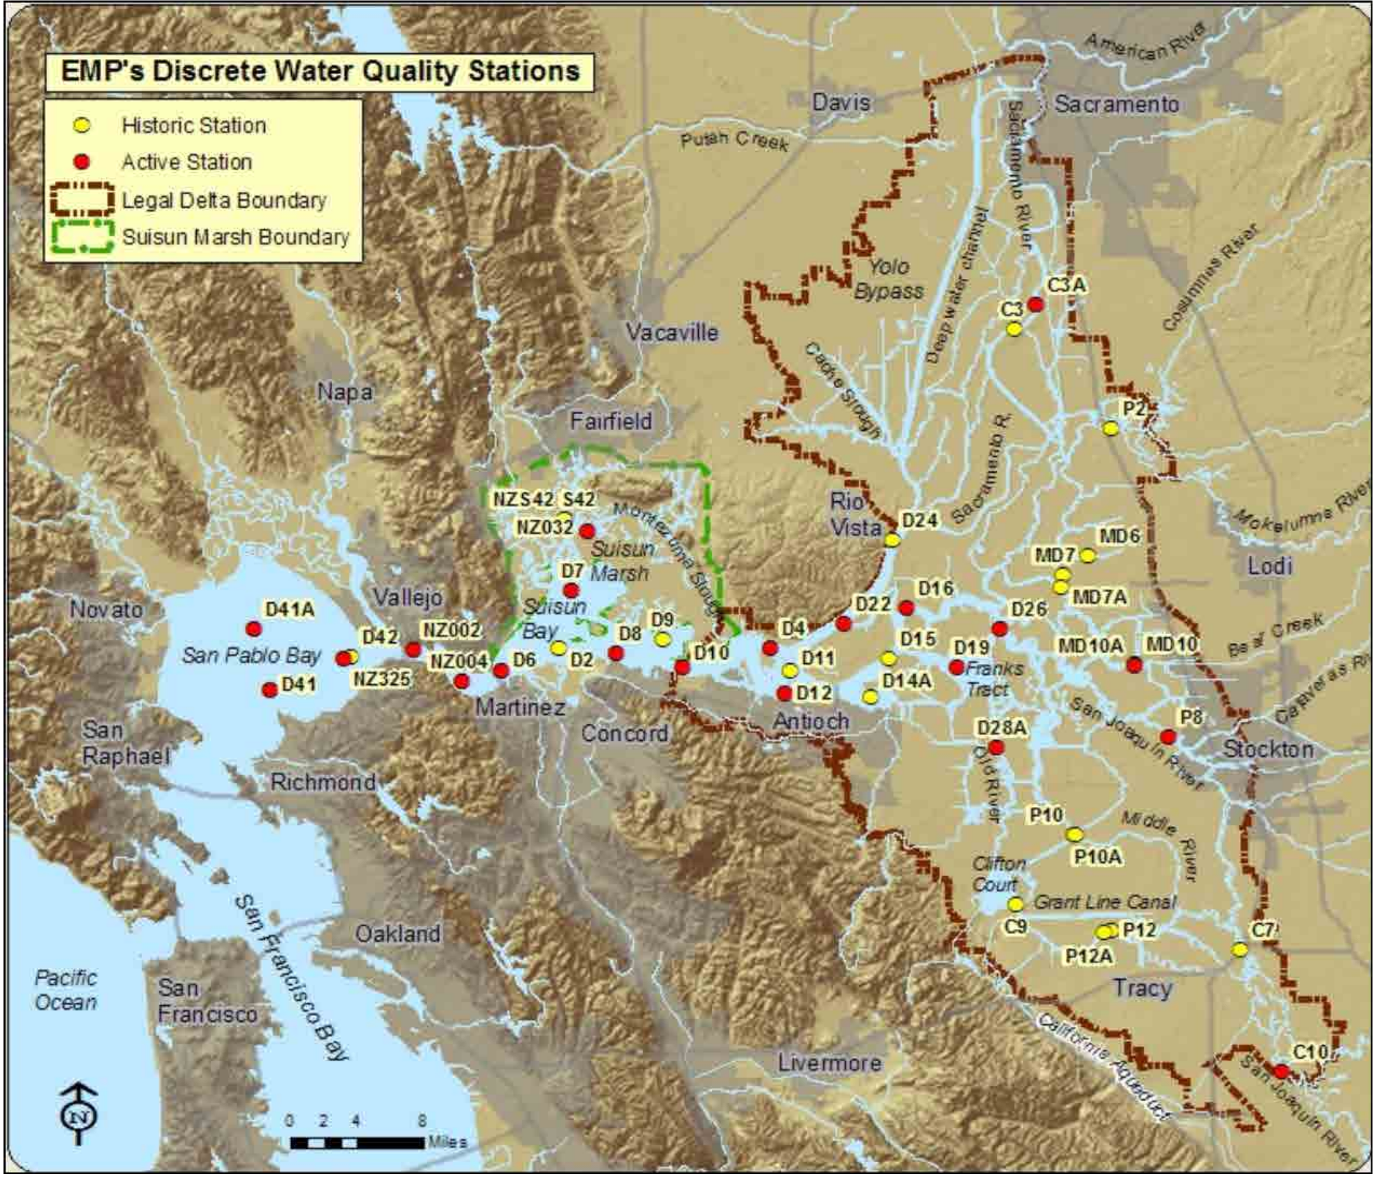
Water Temperature

Water temperature is fundamental to aquatic ecosystem health and function. It directly influences biological, physical, and chemical properties such as metabolic rates and life histories of aquatic organisms, dissolved oxygen levels, primary productivity, and cycling of nutrients and other chemicals (Vannote and Sweeney 1980, Poole and Berman 2001, Null et al. 2013). Water temperature is an important variable for ectothermic ("cold-blooded") animals, including all fishes and invertebrates in the SFE. In the most extreme case, when water temperature exceeds the thermal tolerance of an organism, it will die. Temperatures within the thermal tolerance of an organism control the rate and efficiency of many physiological processes, including activity, digestion, growth, reproductive development, and reproductive output. We return to these processes after giving an overview of water temperature variability and its drivers in the Delta.

Long term temperature records from selected sites in the SFE show substantial seasonal and daily fluctuations in water temperature (Kimmerer 2004). While daily variations are evident and likely important to organisms, seasonal variations are much greater (Wagner et al. 2011). Median water surface temperatures across all stations monitored by the IEP Environmental Monitoring Program (EMP) (Fig. 15) from 1975-2012 range from 9 °C in January (minimum: 6 °C) to 22 °C in July (maximum: 28 °C). There are also clear regional variations in water temperature (Fig. 16). In July and August, the hottest summer months, water temperatures are usually highest at monitoring stations in the south Delta (average 23-26 °C, maximum 28 °C), lower at stations in the northern and western Delta (average 21-23 °C, maximum 25 °C) and lowest at stations in Suisun and San Pablo Bays (average 19-21 °C, maximum 24 °C). In January, the coldest winter month, average water temperatures are uniformly below 10 °C in the entire Delta, but above 10 °C in San Pablo Bay.

There is currently little evidence for increasing water temperatures in the Delta, although with climate change such increases are expected over the course of the century (Cloern et al. 2011, Wagner et al. 2011, Brown et al. 2013). In Spring (March-June) water temperature at IEP EMP water quality monitoring stations in the Delta increased during 1996–2005 by about 0.2 °C per year, but a similar trend was not apparent for the longer-term data record from 1975-2005 or for stations in Suisun Bay (Jassby 2008). These findings are similar to the results of Nobriga et al. (2008) who found no long-term (1970-2004) trends in temperature data collected during summer fish monitoring surveys in the Delta. Nobriga et al. (2008) also noted that the long-term (1970-2004) mean July water temperature at TNS fish monitoring stations in the southern region of the Delta is 24 °C, with current mid-summer temperatures often exceeding 25 °C. This agrees with average monthly EMP data from 1975-2012 which shows July and August water temperatures at

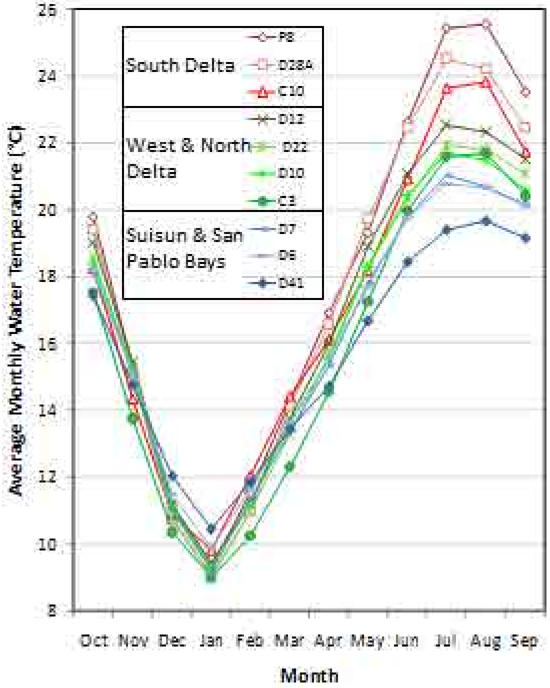
Figure 15. Map of active and historic IEP Environmental Monitoring Program (EMP) sampling stations.



a monitoring station located in Old River (station D28A) and in the San Joaquin River near the Port of Stockton (station P8) of more than 24 °C and 25 °C, respectively (Fig. 16).

In tidal systems, water temperature at a particular location is determined by the interaction between atmospheric forcing (e.g., air temperature and wind), tidal dispersion and riverine flows across the estuarine landscape (Monismith et al. 2009). In particular, estuarine water temperature is driven by heat exchange at the air–water interface and mediated by tidal and riverine flow dynamics and estuarine geomorphology (Enright et al. 2013). Wagner et al. (2011) found that regional weather patterns including air temperature and insolation (sunlight), are the primary drivers of water temperature variations in the SFE. Water flow and interaction with the stationary topography of the system also affects water temperature in the SFE, especially over shorter time scales and at smaller spatial scales. For example, Enright et al. (2013) showed that interaction

Figure 16. **Average monthly water temperature for stations monitored by the Environmental Monitoring Program from 1975-2012.**



of tides with tidal marsh topography can have a mediating effect on water temperature in tidal sloughs and on thermal variability at smaller spatial scales. Wagner et al. (2011) showed that high winter and spring flows can temporarily lower water temperatures. Greenberg et al. (2012) found that the present riparian vegetation on Delta levees lowers insolation by about 9% compared to a hypothetical situation without vegetation and suggested that riparian vegetation thus contributes to locally cooler water temperatures. This suggests that at least to some degree, water temperature can be managed locally and for short periods. Over larger scales, however, these types of locally mediated effects are overwhelmed by the effects of air temperature and insolation.

Air temperature and insolation in the SFE are correlated with each other (Wagner 2012) and vary strongly with proximity to the Pacific Ocean because of the contrasting climate regimes prevailing in inland central California and the central California coast. While inland central California has a large annual air temperature range with hot, dry, sunny summers and cool, wet, and often foggy winters, the central California coast has a smaller annual air temperature range with cooler and often foggy summers and milder winters (Conomos et al. 1985). The SFE has a transitional climate with greater spatial and temporal variability in air temperature than either the coastal or the inland regions (Whipple et al. 2012). This is due to the interplay of the dynamic air masses from these regions across the stationary estuarine topography. In the summer, this interplay often results in strong afternoon winds from the ocean locally known as the “Delta breeze.” These onshore winds usually advance into the western and central Delta and, depending on the depth of the marine layer, often also into its marginal areas. In the Delta, these southwest to northeast winds can persist throughout the night and into the next morning and produce a marked decline in daily temperature. In the morning, this low is often followed by rapid warming once the winds subside and the high temperature inland air masses return to dominance (National Weather Service 2003). In the winter, ocean winds are weak and, during calm periods, cold air flows from the mountains into the estuary. This results in the formation of dense, overnight, near-surface fog locally known as “tule fog.” These calm and foggy periods are interrupted by winter storms. Many of these storms arrive from the south and southeast as “atmospheric rivers” that can often produce gale force winds and heavy rains lasting several days (Conomos et al. 1985, Dettinger and Ingram 2013).

The large variability in air temperature in the Delta is reflected by the larger annual variability in water temperature measured from 1998-2002 at continuous monitoring stations in the interior Delta compared to stations further upstream or downstream (Wagner et al. 2011). This high variability is also apparent in monthly water temperature data collected by the IEP Environmental

Monitoring Program since 1975 (Fig. 11). From 1975 to 2012, annual fluctuations in average monthly water temperature were greatest at stations in the south Delta (14-16 °C), smaller at stations in the northern and western Delta (12-13 °C), and lowest at stations in Suisun and San Pablo Bays (9-12 °C). Jassby (2008) reported that maximum daily air temperature could explain almost half the variability in maximum daily water temperature at the continuous monitoring station at Antioch during the summer months. The relationship between air and water temperature was also strong in all other months except January.

Wagner et al. (2011) and Wagner (2012) developed simple regression models for predicting water temperature at fixed temperature monitoring stations in the SFE using only air temperature and insolation on the day of interest and the water temperature from the previous day. Water temperature from the previous day accounts for both previous air temperature and the sources of water to the site, including advective flow from rivers or dispersive flow from more downstream reaches of the SFE. Each model had a different set of coefficients because of the differing influences of incoming river water or tidal exchange with San Francisco Bay. For stations with greater than 1 year of calibration data, model R^2 for daily average temperature exceeded 0.93, indicating that water temperature was highly predictable within the limits of the calibration data sets. High winter and spring flows were responsible for the largest divergences of the model outputs from measured temperatures.

The simple statistical models for water temperature developed by Wagner et al. (2011) and Wagner (2012) should be used with caution because they only predict temperature at the site of the recording instrument and do not explicitly account for mechanistic heat exchange. The analyses therefore do not incorporate the possible effect of site-specific features such as shading by riparian vegetation (Greenberg et al. 2012). Similarly, there are lateral and vertical variations in temperature on daily time scales (Wagner 2012) that could be important to organisms. For example, such variation might include substantial heterogeneity and formation of thermal refugia, which may be important to Delta Smelt.

In contrast to statistical modeling, which produces site-specific results, water temperature across regions is commonly modeled with computation-intensive deterministic simulation models. Such models use energy budgets to predict water temperature. Simple stochastic models are also possible. Like most statistical models, these stochastic models generally rely on the relationship between air and water temperature (Caissie 2006, Null et al. 2013). We are not aware that these types of models have been developed for the San Francisco Estuary.

Upper temperature limits for juvenile Delta Smelt survival are based on laboratory studies and corroborated by field data. Interpretation of the laboratory results is somewhat complicated as temperature tolerances can be affected by various factors including acclimation temperature, salinity, turbidity, and feeding status. Based on the critical thermal maximum, CT_{max}, juvenile Delta Smelt acclimated to 17 °C could not tolerate temperatures higher than 25.4 °C (Swanson et al. 2000). However, for juvenile Delta Smelt acclimated to 11.9, 15.7 and 19.7 °C, consistently higher CT_{max} were estimated (27.1, 28.2 and 28.9 °C, respectively; Komoroske et al. 2014), which corresponded closely to the maximum water temperatures recorded in the TNS and FMWT surveys. Swanson et al. (2000) used wild-caught fish, while Komoroske et al. (2014) used hatchery-reared fish, which may have contributed to the differences in results. Based on the TNS (Nobriga et al. 2008) and the 20 mm Survey (Sommer and Mejia 2013), most juvenile Delta Smelt were predicted to occur in field samples when water temperature was below 25 °C. In a multivariate autoregressive modeling analysis with 16 independent variables, MacNally et al. (2010) found that high summer (June – September) water temperature had a negative effect on Delta Smelt subadult abundance in the fall. Water temperature was also one of several factors affecting Delta Smelt life stage dynamics in the state-space model of Maunder and Deriso (2011) and in an individual-based Delta Smelt life-cycle model (Rose et al. 2013a,b).

In addition to lethal effects, water temperature also has direct effects on the bioenergetics (interaction of metabolism and prey density) of Delta Smelt (Bennett et al. 2008) and it may affect their tolerance to other habitat attributes, such as toxicity (Brooks et al. 2012) and predation risk. Responses of different life stages of Delta Smelt to various temperature, salinity, and turbidity conditions are currently being further assessed as part of a larger UC Davis laboratory study about the “fundamental niche” of Delta Smelt (Komoroske et al. 2014, R. Connon et al., U.C. Davis, unpublished data).

The topic of bioenergetics is an important consideration in much of the remainder of this report, so we address it in more detail here. In general, the total metabolic rate of a fish will increase with temperature to an optimum temperature at which, given unlimited food, there is the maximum ability to grow and develop reproductive products (eggs or sperm) in addition to maintaining the basal metabolic rate required for survival, which also increases with temperature (Houde 1989, Hartman and Brandt 1995). As temperature increases beyond the optimum, metabolic rate continues to increase but physiological processes become less and less efficient and more energy is required just to meet the basal metabolic rate of the organism. Eventually, the metabolic rate begins to decline as temperatures approach the physiological limits of the organism and the basal metabolic rate can no longer be maintained.

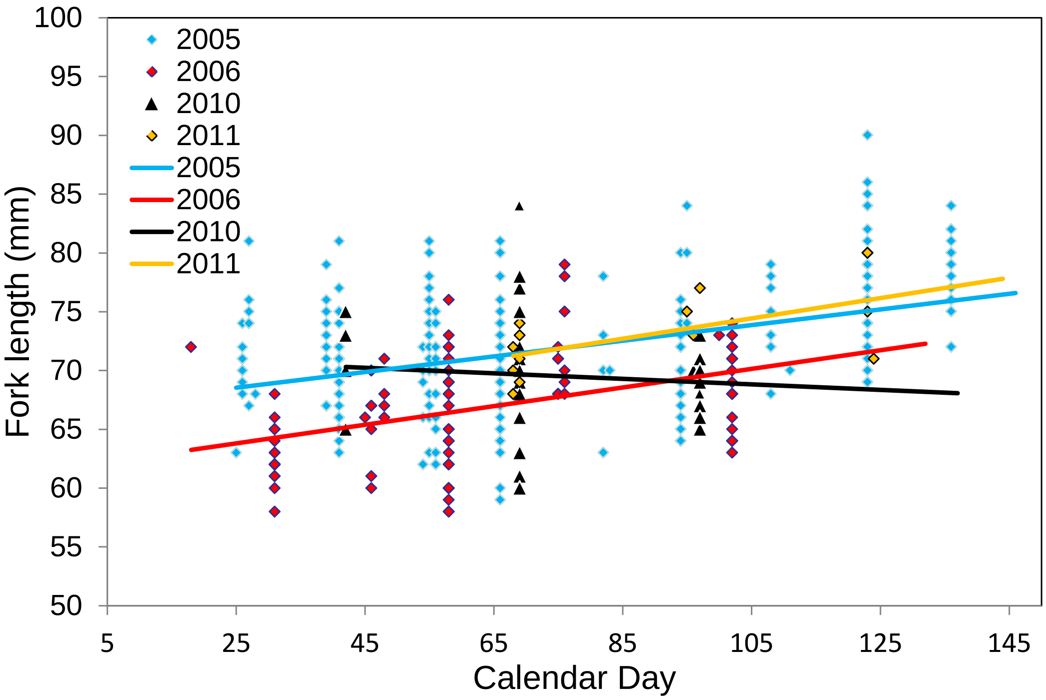
At temperatures beyond the optimum, the ability to grow and mature becomes increasingly impaired. Long-term exposure to such stressful temperatures can eventually be lethal. In addition, resistance to disease and contaminants can also be affected (Brooks et al. 2012). The responses to contaminants can vary depending on the type of contaminant. For example, low temperatures can decrease the toxicity of organophosphate insecticides, but increase the toxicity of pyrethroid and organochlorine insecticides (Harwood et al. 2009), a characteristic that has been used in toxicity identification and evaluation (Weston and Lydy 2010). The previous discussion assumes unlimited food, which is unlikely to be the case for Delta Smelt or any organism in nature. Even at the optimum temperature, growth and reproductive development will depend on the quantity and quality (energy and nutrient content) of the food consumed. If the fish is unable to ingest enough food to meet its nutrient and energetic requirements, including the energy expended to capture and digest prey, it will starve, after first depleting any available energy stores (fat or muscle). Given an array of food items, fish will generally choose larger prey items. This is because the energy required to detect, chase, and capture multiple smaller prey that are equivalent in nutritional value to a single large prey item will, in many cases, exceed the energy required to capture the single prey item. Note that these same ideas apply to predatory fish that might consume Delta Smelt.

Water temperature is also thought to affect the number of eggs produced by female Delta Smelt. Egg production (i.e., fecundity) of the population is influenced not only by individual female size and number (Bennett 2005, DFW unpublished), but also by the duration of a temperature “spawning window” (Bennett 2005, Mac Nally et al. 2010), variously defined as: 15-20 °C by Bennett (2005); 7-15 °C by Wang (1986); and 12-15 °C by Baskerville-Bridges et al. (2004b). Bennett (2005) further stated that during cool springs this spawning window persists longer, allowing more cohorts to recruit. Given a sufficiently long spawning window, individual females may also repeat-spawn during the spawning season. This has been documented in culture (see Bennett 2005; J. Lindberg, U.C. Davis, personal communication 2013) and appears to occur in the wild as well (L. Damon, CDFW, written communication 2012). Lindberg (U.C. Davis, personal communication 2013) observed that most females in culture spawned twice, some spawned three times and a very small number spawned four times. Each spawning was separated by a 4-5 week refractory period during February through June when water temperatures remained within the spawning window. Though laboratory conditions may not necessarily be representative of conditions in the wild, ripe females ready to release their second complete batch of eggs and developing a third batch have been detected in the wild during March and April (i.e., mid-season) suggesting that three spawns are possible (L. Damon, CDFW, written communication 2012). Thus, a longer spawning window would allow more females to repeat spawn adding both additional cohorts hatching under different conditions, and multiplying the fecundity of each repeat spawner (i.e., increasing the total fecundity of the individual), and thus, the total fecundity of the population. Moreover, in culture, individual females continued to grow through the spawning season and become more fecund with each batch of eggs (J. Lindberg, U.C. Davis, personal communication 2013). In the wild, the size of mature females generally increases month to month through the spawning season (Fig. 17), suggesting a potential increase in fecundity with each batch, but this has yet to be confirmed for wild fish. However, in culture, fish hatched later in the spawning season (mid-May to mid-June) grew up to be smaller-sized adults that started spawning later and had progeny with lower survival than the progeny of fish hatched earlier in the season (Lindberg et al. 2013). These observations are consistent with the reproductive patterns suggested for the wild Delta Smelt population (Bennett 2011). Overall, the effect of a prolonged spawning season on Delta Smelt population size and dynamics would seem to be positive; however, there is some uncertainty.

In the culture experiments reported by Bennett (2005), temperature strongly influenced hatching success of eggs. Specifically, Bennett (2005) reported that optimal hatching success and larval survival were estimated to occur at 15–17 °C based on studies conducted at 10, 15, and 20 °C. The data indicated that as incubation and early rearing temperatures increased, size at hatching and size at first feeding linearly decreased, possibly because basal metabolism of the developing embryo used more energy leaving less for growth. Fish that hatch relatively late in the season may experience high temperatures at a small size, which may reduce larval survival by several possible mechanisms. First, small size would limit the size of food items that the larvae could ingest because of smaller mouth size (see Nobriga 2002). Temperature may also affect food type and availability as discussed below. Second, small larvae are likely vulnerable to a larger range of predators for a longer period compared to larger larvae (e.g., “stage duration hypothesis;” Anderson 1988). Third, these fish could be potentially more vulnerable to transport toward the CVP and SWP export facilities, when Old and Middle River (OMR) flow restrictions are lifted. Restrictions are lifted when the 3-day mean water temperatures in Clifton Court Forebay (CCF) reach 25 °C or by the end of June.

As explained above, higher water temperatures increase energetic requirements and thus the food requirements of fish. To meet the increased need for food, it is possible that Delta Smelt spend more time foraging during the day. Since greater foraging time during the day increases visibility to predators, and those predators would also increase their foraging rates at higher temperatures, the encounter rate of predator and prey would likely increase at higher water temperatures. The net effect could be an increase in Delta Smelt predation risk (e.g., Walters and Juanes 1993). High temperatures can also decrease antipredator behavior, as described for Sacramento River Chinook Salmon (*Oncorhynchus tshawytscha*) (Marine and Cech 2004). In other words, the fish may make a behavioral choice to feed, grow, and become less vulnerable to predators as rapidly as possible, even though the short-term predation risk might increase. Water temperatures in the upper SFE are usually highest from June to September and decline rapidly between October and December

Figure 17. Individual female fork lengths by calendar day for mature female Delta Smelt collected in the Spring Kodiak Trawl Survey, January through May, 2005, 2006, 2010 and 2011. These data include both monthly distribution survey fish and directed survey fish. The directed survey (which targeted smelt spawning areas) was discontinued after January 2010.



(Fig. 16). The reported optimal culture temperatures for Delta Smelt larvae and late-larvae are 16.4 ± 0.25 °C (Komoroske et al 2014). Moreover, the chronic lethal thermal maximum for Delta Smelt varies by life stage (Komoroske et al. 2014). Juvenile and subadult Delta Smelt are observed in the field most commonly at temperature near or below 20 °C (Bennett et al. 2008, Nobriga et al. 2008), a temperature which is often exceeded beginning in May or June and continuing through September and more rarely in October (see Chapter 7). Thus, we suggest that the same tradeoffs between feeding and predation risk may persist through the warmer months and into early fall, but become less likely as the season progresses into late fall and winter. Note, however, that predation risk is also influenced by a complex suite of other factors such as turbidity, life stage, and proximity to predator habitat, so the level of risk to Delta Smelt can’t be determined.

Another possible indirect effect of higher water temperatures is that they may promote harmful agal blooms (HAB) (Lehman et al. 2005), which may degrade Delta Smelt habitat quality in the summer and early fall (Baxter et al. 2010). In the Delta, Lehman et al. (2013) found that blooms of the harmful cyanobacteria (blue-green algae) *Microcystis aeruginosa* required a water temperature of at least 19 °C for initiation. Other drivers of HABs and the possible effects of HABs are discussed more fully in a separate section of this Chapter. The combination of large seasonal and regional water temperature variability in the SFE and substantial direct and indirect effects of water temperature for all life stages of Delta Smelt means that this variable should be considered one of the most important habitat attributes for Delta Smelt. Differences in water temperature between regions or time periods may have important effects on the Delta Smelt population (Rose et al. 2013b).

Salinity and the Size and Location of the Low Salinity Zone

A dynamic salinity gradient from fresh water to salt water is one of the most characteristic features of an estuary (Kimmerer 2004). It originates from the mixing of fresh inland water with salty ocean water through tidal dispersion and gravitational circulation (Monismith et al. 2002). Many estuarine-dependent organisms occur in distinct salinity ranges (e.g., Kimmerer 2002a) and the extent and location of water with suitable salinities is thus an important habitat attribute for estuarine organisms. Over the time period of available monitoring data, there is no clear long-term trend in salinity levels and distributions in the estuary. Significant increases and decreases linked to changing flow patterns have been detected for various stations and months (e.g., Jassby et al. 1995, Enright and Culberson 2009, Shellenbarger and Schoellhamer 2011, Cloern and Jassby 2012).

The brackish (oligohaline) "low salinity zone" (LSZ) is an important region for retention of organisms and particles and for nutrient cycling. In the SFE, the LSZ provides important habitat for numerous organisms including Delta Smelt (Turner and Chadwick 1972, Kimmerer 2004, Bennett 2005). In this report we define the LSZ as salinity 1-6; however, other salinity ranges have been used by others, such 0.5-6 (Kimmerer et al. 2013) or 0.5-5 (Jassby 2008).

In the SFE, the position of the LSZ is commonly expressed in terms of X2, which is the distance from the Golden Gate in km along the axis of the estuary to the salinity 2 isohaline measured near the bottom of the water column (Jassby et al. 1995). X2 represents the approximate center of the LSZ (Kimmerer et al. 2013).

X2 is an index of the physical response of the estuary to freshwater outflow from the Delta; it decreases with increasing outflow because increasing freshwater outflow prevents seawater from moving landward. The X2 index was developed two decades ago as an easily-measured, policy-relevant "habitat indicator." Its ecological significance for multiple species and processes was established through statistical analyses of biological responses to seasonally or annually averaged X2 values (Jassby et al. 1995) and has since been reaffirmed in additional studies (e.g., Kimmerer et al. 2002a,b, 2009, 2013, Thomson et al. 2010, Mac Nally et al. 2010). There is, however, still much uncertainty regarding the causal mechanisms for the observed biological responses of biota to X2. As with all statistically derived functional relationships, biological responses to X2 do not necessarily reflect direct causal relationships and it is generally recognized that some of the causal mechanisms may not be directly linked to the size and location of the LSZ.

Most of the scientific and management attention has focused on the LSZ and X2 from late winter to early summer (hereafter "spring X2") depending on the species of interest, but in recent years the LSZ and X2 during the fall months ("fall X2") has also received considerable scientific and policy attention. Annual abundance indices of several estuarine fish and invertebrate species have a negative relationship with spring X2, meaning that abundance indices increase when X2 and the LSZ are more westward and Delta outflow is higher in the late winter and spring months (Jassby et al. 1995, Kimmerer 2002a, Kimmerer et al. 2009). Delta Smelt summer abundance indices have a significant relationship with prior fall X2 and fall abundance (USFWS 2008, Mount et al.

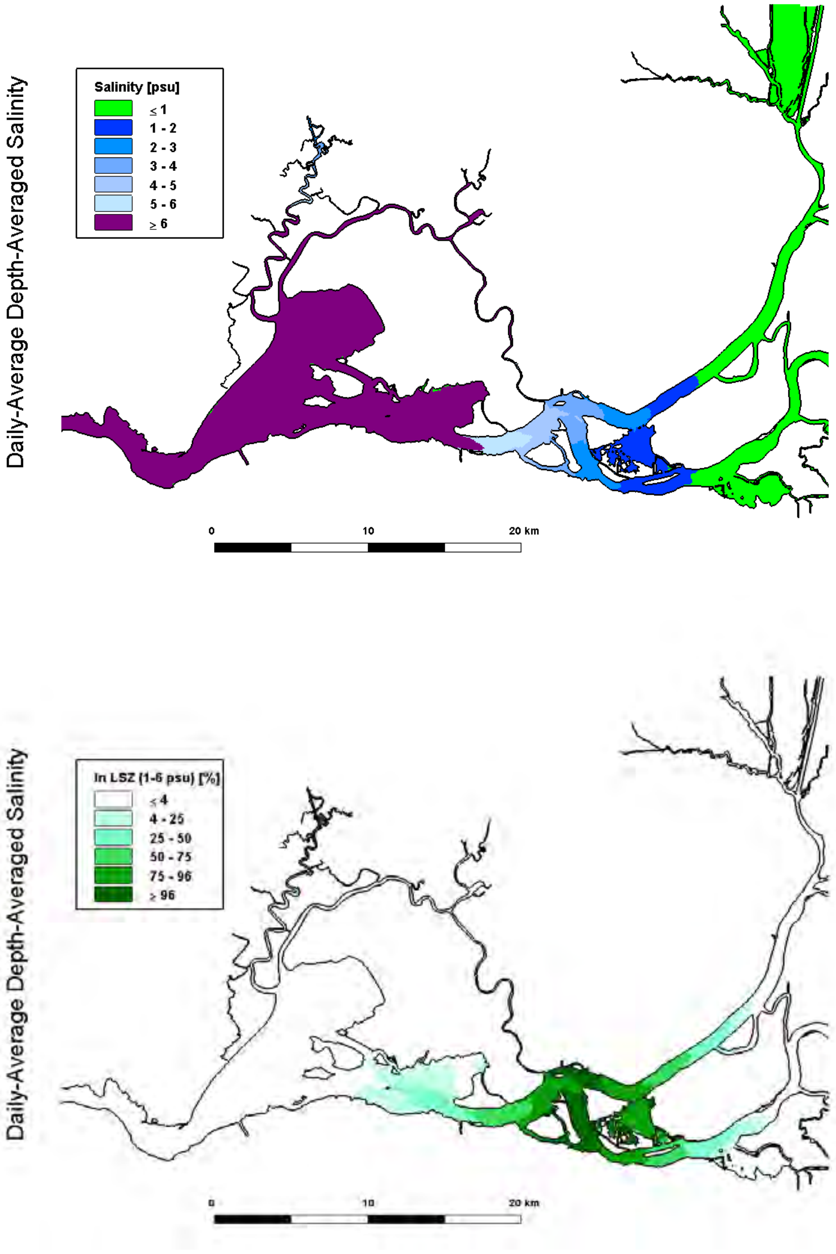
2013). Changes in spring and fall X2 have also been linked to long-term fish declines in the SFE (Thomson et al. 2010, Mac Nally et al. 2010).

The size and location of the LSZ are considered key factors determining the quanity and quality of low salinity rearing habitat available to Delta Smelt and other estuarine species. LSZ size and location are determined by the interaction of dynamic tidal and river flows with the stationary topography of the region (Reclamation 2011, 2012, Kimmerer et al. 2013). In a recent study, Kimmerer et al. (2013) used the three-dimensional hydrodynamic “UnTRIM” model which has an unstructured grid (Casulli and Zanolli 2002, 2005) to produce detailed maps of the distribution of salinity in the SFE under different outflow conditions. These maps (figure 2 in Kimmerer et al. 2013 and Fig. 18 and 19 in this report) show that under low outflow conditions typical of summer and fall months (outflow = 140 $m^3 s^{-1}$, X2 = 85 km), the LSZ is in the western Delta confluence region, including the Sacramento and San Joaquin Rivers upstream of Chipps Island (Fig. 18), while under high outflow conditions typical of wet winter months (outflow = 1,440 $m^3 s^{-1}$, X2 = 51 km), the LSZ is much further west in San Pablo Bay. At intermediate outflows (intermediate X2 = 74 km).), it is located east of Carquinez Strait and covers Suisun Bay and parts of Suisun Marsh (Fig. 19).

Kimmerer et al. (2013) also examined the relationships between X2 and the area, average depth, and volume of the LSZ. They found that these relationships were bimodal, with the largest volumes and areas and shallowest depths at X2 values below 50 km when the LSZ is located in the large San Pablo Bay, and secondary peaks at X2 values between 60 and 75 km when the LSZ overlays the smaller Suisun Bay (Fig. 20). Area and volume were smallest and depth greatest when the LSZ was constricted in Carquinez Strait (X2~50-60 km) and in the confluence region of the Sacramento and San Joaquin Rivers (X2~80-85 km).

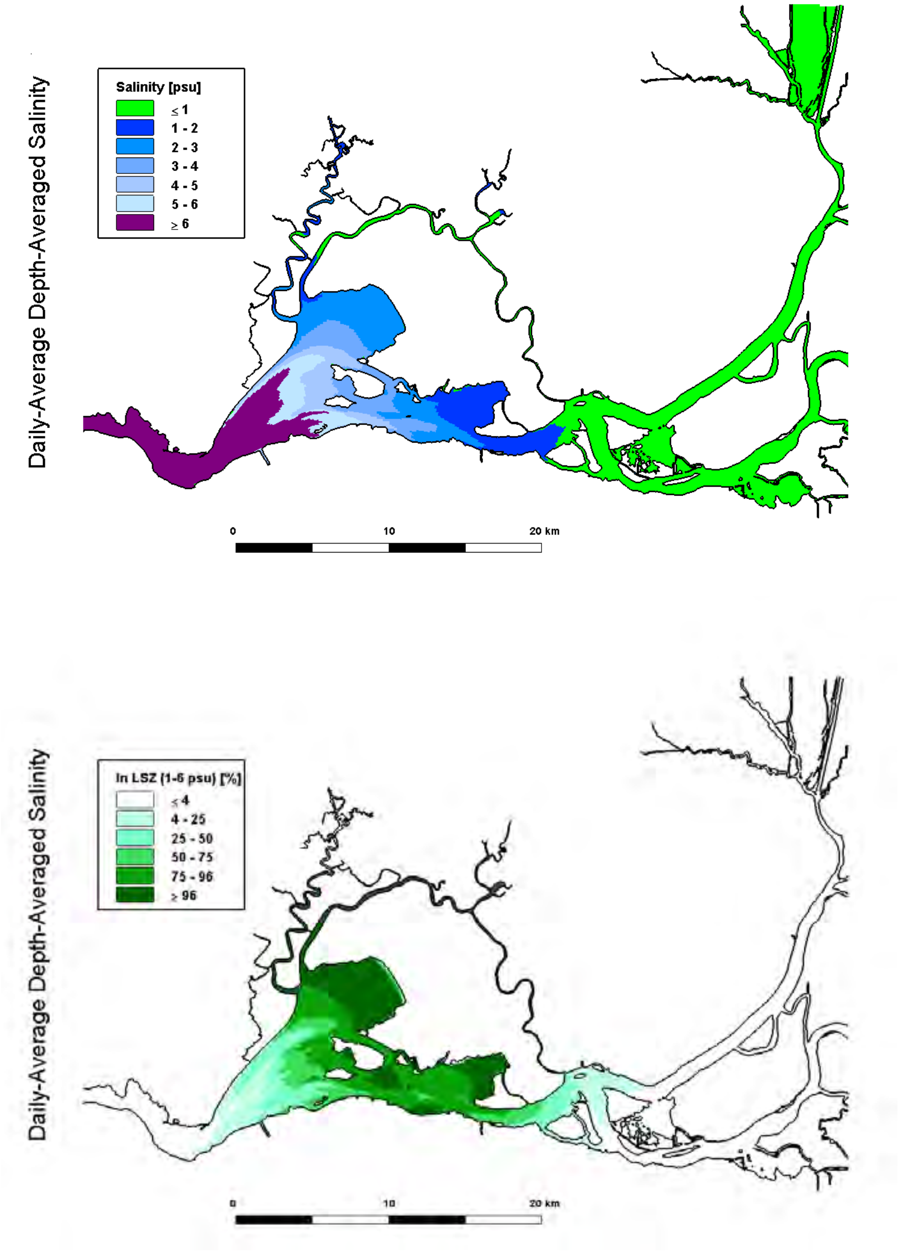
Paleosalinity investigations going back several thousand years indicate that the Delta has historically been largely fresh, while the Suisun region has alternated between brackish (oligohaline) and fresh (Ingram and Malamud-Roam 2013, Drexler et al. 2014). The LSZ and X2 likely moved according to predictable annual and interannual rhythms. Interannually, X2 was most variable in the higher-flow winter and spring months and least variable in the low-flow fall months. Seasonally X2 moved from the west in winter and spring to the east in summer and fall. CDWR (CDWR 2007) computes monthly “unimpaired” outflows which remove the effects of dam operations and water diversions. Annual X2 dynamics based on these unimpaired flows may give a sense of these historical fluctuations (Fig. 21). It is important to note, however, that unimpaired flows are not the same as historical “natural” flows because they do not take into account upstream water losses (e.g., consumption and evaporation) or physical water body alterations such as channelization, groundwater depletion, draining of wetlands, and disconnection of floodplains. The historical wetlands, floodplains, and groundwater basins would have naturally retained and released water (Whipple et al. 2012) and likely affected flows and the LSZ in different ways than today’s man-made reservoirs. Work is currently underway at UC Davis, the San Francisco Estuary Institute, and elsewhere to explore these issues, but results have not yet been published (W. Fleenor, U.C. Davis, personal communication). At this time, considerable uncertainty remains regarding the natural ranges in the timing and volume of the historical seasonal and interannual freshwater flows and how they caused the LSZ to spread out and contract across the estuary’s historical landscape. There is, however, little doubt that interannual variations in precipitation and hence river flows caused a high degree of interannual variability in the size and location of the low-salinity zone (Dettinger 2011).

Figure 18. Salinity distribution at low outflow. The upper panel shows the area of the low-salinity zone (4,262 hectares) at X2 = 85 km, when positioned mostly between Antioch and Pittsburg. Connections to Suisun Bay and Suisun Marsh are minimal. The lower panel shows the percentage of day that the low-salinity zone occupies different areas.



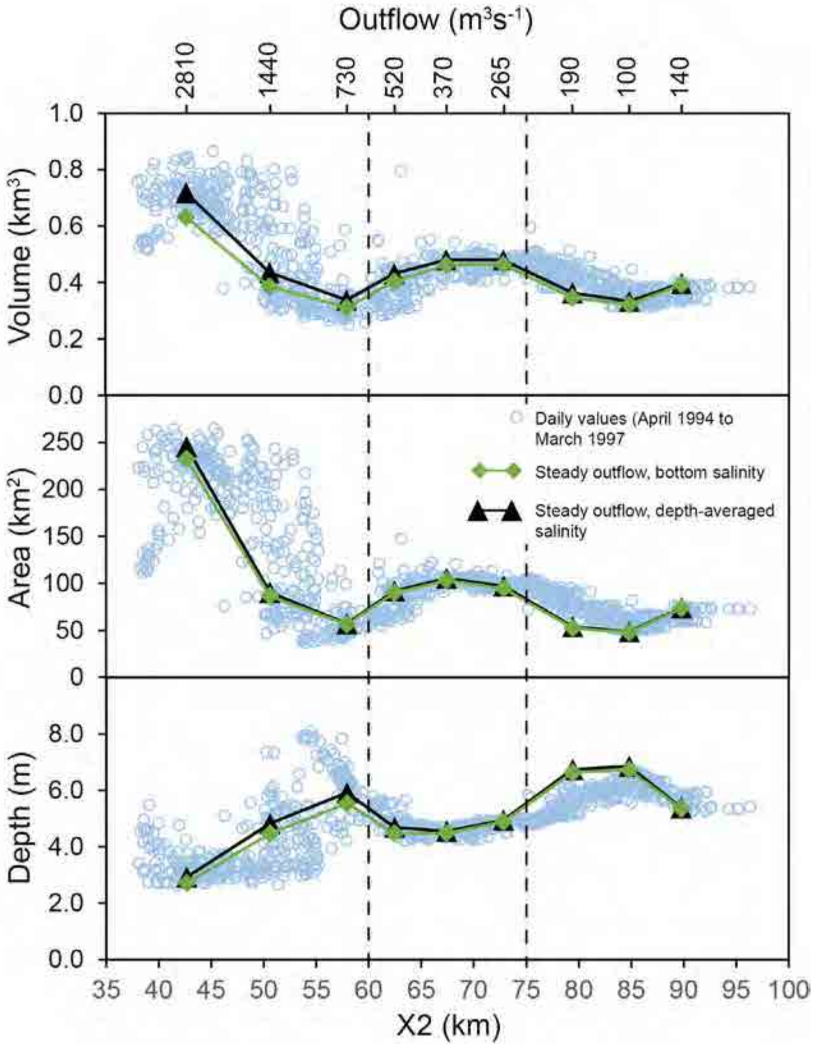
There is also no doubt that human water use and landscape alterations have changed flows into and out of the Delta and, consequently, salinity dynamics in the SFE, though changing precipitation patterns also play a role (Enright and Culberson 2009). Before the construction of today's major reservoirs, upstream water diversions coupled with the isolation of floodplains and wetlands, which had naturally stored runoff, from river channels by levees exacerbated salinity intrusions into the Delta in dry years. This was especially evident during the severe drought from

Figure 19. **Salinity distribution at intermediate outflow. The upper panel shows the area of the low-salinity zone (9,140 hectares) at X2 = 74 km (at Chipps Island). The lower panel shows the percentage of day that the low-salinity zone occupies different areas.**



1929 to 1934 when salinities of 2 were observed at Paintersville Bridge which is located on the Sacramento River at a distance of about 136 km from the Golden Gate (Mathew 1931). Operation of the large CVP and SWP reservoirs that were constructed after this drought has prevented such severe salinity intrusions since then and X2 has remained west of Rio Vista located on the Sacramento River 100 km upstream of the Golden Gate. Beginning with the salinity requirements in SWRCB water right decision D-1275 of 1967, salinity and the position of the LSZ have also

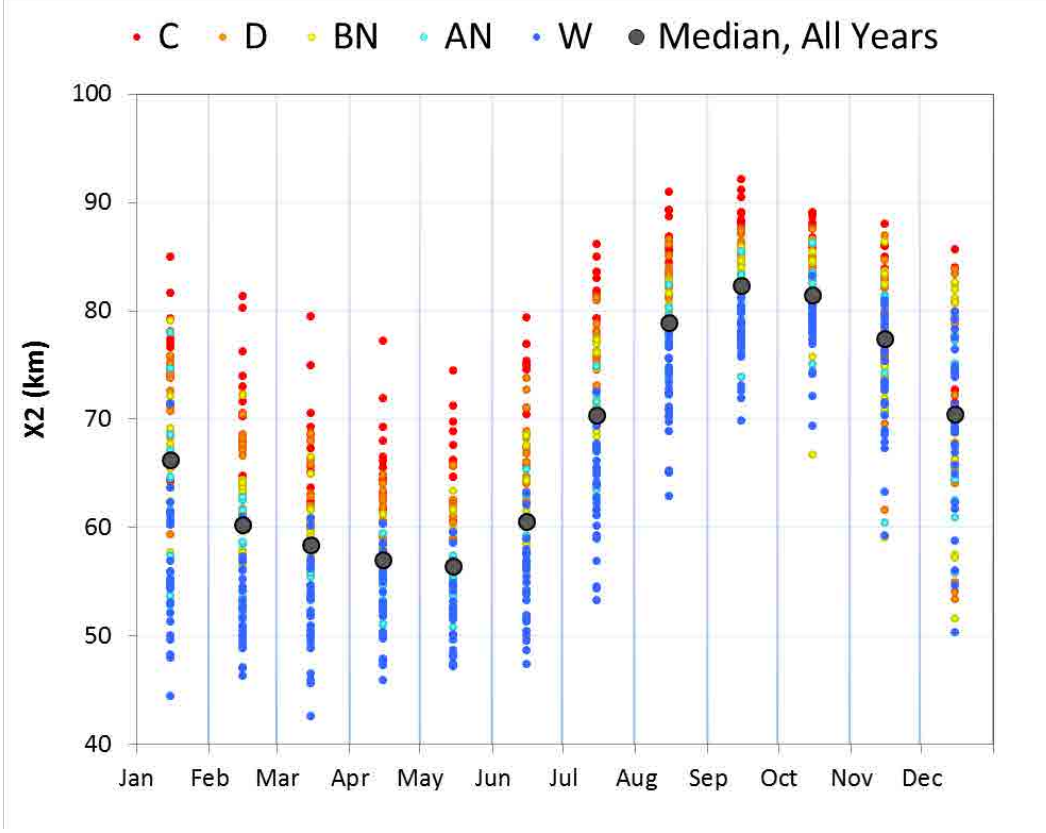
Figure 20. Modeled volume, area, and depth of the low salinity zone (salinity 0.5 to 6 at various values of X2 for 9 steady state values of outlow using bottom salinity (green diamonds) and depth-averaged salinity (black diamonds and for daily values based on variable values from April 1994 through March 1997 (blue circles) (modified from Kimmerer et al. 2013). The top axis gives the Delta outflow corresponding to the 9 steady state scenarios.



been increasingly regulated to protect "beneficial uses," including habitat and fish protections (see Chapter 1).

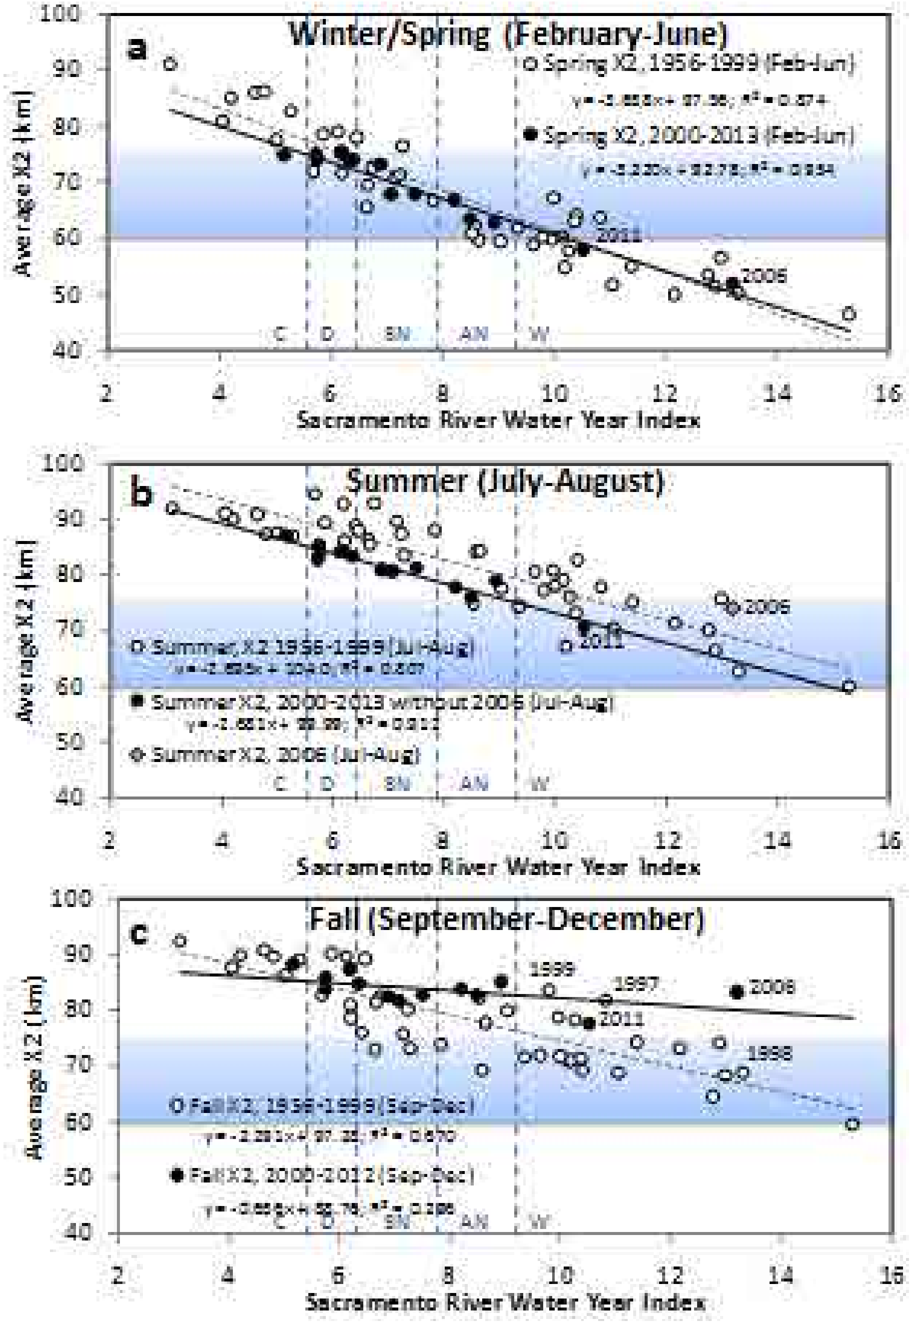
CVP and SWP water exports from the Delta began in the early 1950s with the completion of the CVP C.W. Bill Jones Pumping Plant (formerly known as the Tracy Pumping Plant) in 1951 and then increased with the completion of SWP's Harvey O. Banks Pumping Plant in 1968. Long-term variability in the trend of Delta outflow has been reduced seasonally for the period 1921-2006, in part due to water project operations (Enright and Culberson 2009), but also due to overriding climate changes. Analyzing data from 1956–2010, Cloern and Jassby (2012) found significant increases in water exports from the Delta in all months of the year except May, but in the first half of the year, these increases in exports did not significantly affect Delta outflow. We

Figure 21. **Plot of monthly X2 (km) values calculated from mean monthly unimpaired Delta outflows from 1921-2003. X2 values are categorized by water year type for the Sacramento Valley. Also shown are the median X2 values from 1921-2003 across all water year types (grey circles) C, red dots: critically dry; D, orange dots: dry; BN, yellow dots: below normal; AN, light blue dots: above normal; W, dark blue dots: wet. Water year type data from http://cdec.water.ca.gov/cgi-progs/iodir/WSIHIST. Unimpaired flow data from DWR 2007 (available at http://www.waterboards.ca.gov/waterrights/water_issues/programs/bay_delta/bay_delta_plan/water_quality_control_planning/docs/sjrf_spprtinfo/dwr_2007a.pdf). X2 equation from Jassby et al. 2005.**



show this by plotting the relationship between the Sacramento River Water Year Index, a measure of runoff, and average spring X2 (February-June) for two periods before (1956 to 1999) and after (2000-2013) the current flow and salinity requirements in SWRCB water right decision D-1641 became mandatory. The relationship appeared to remain essentially unchanged when the two time periods were compared (Fig. 22a). Cloern and Jassby (2012) further found that inflow to the Delta significantly increased in July and August, but these increases in inflow did not translate into significant increases in Delta outflow due to concurrent increases in exports during these months. Nevertheless, plots of recent data show that July and August outflows increased and the relationship between the Sacramento River Water Year Index and summer-time X2 (July-August) shifted downward in the years since the SWRCB water right decision 1641 went into effect in 2000 relative to previous years (Fig. 22b). The wet year 2006 did not fit this pattern because it had high summer X2 in spite of a high water year index. This means that with the exception of 2006, the LSZ has generally been located somewhat more westward in July and August since 2000 than from 1956 to 1999 under similar runoff conditions.

Figure 22. Plots of monthly X2 as a function of the Sacramento River Water Year Index (a measure of runoff) for the years 1956 to 1999 and 2000 to 2013 for: a, winter/spring; b, summer; and c, fall. The regression equation for each set of points is also shown. The index is calculated as: 0.4 * Current April to July Runoff Forecast (in millions of acre feet, maf) + 0.3 * Current October to March Runoff in (maf) + 0.3 * Previous Water Year's Index (if the Previous Water Year's Index exceeds 10.0, then 10.0 is used) (see http://cdec.water.ca.gov/cgi-progs/iodir/WSIHIST for futher detail).



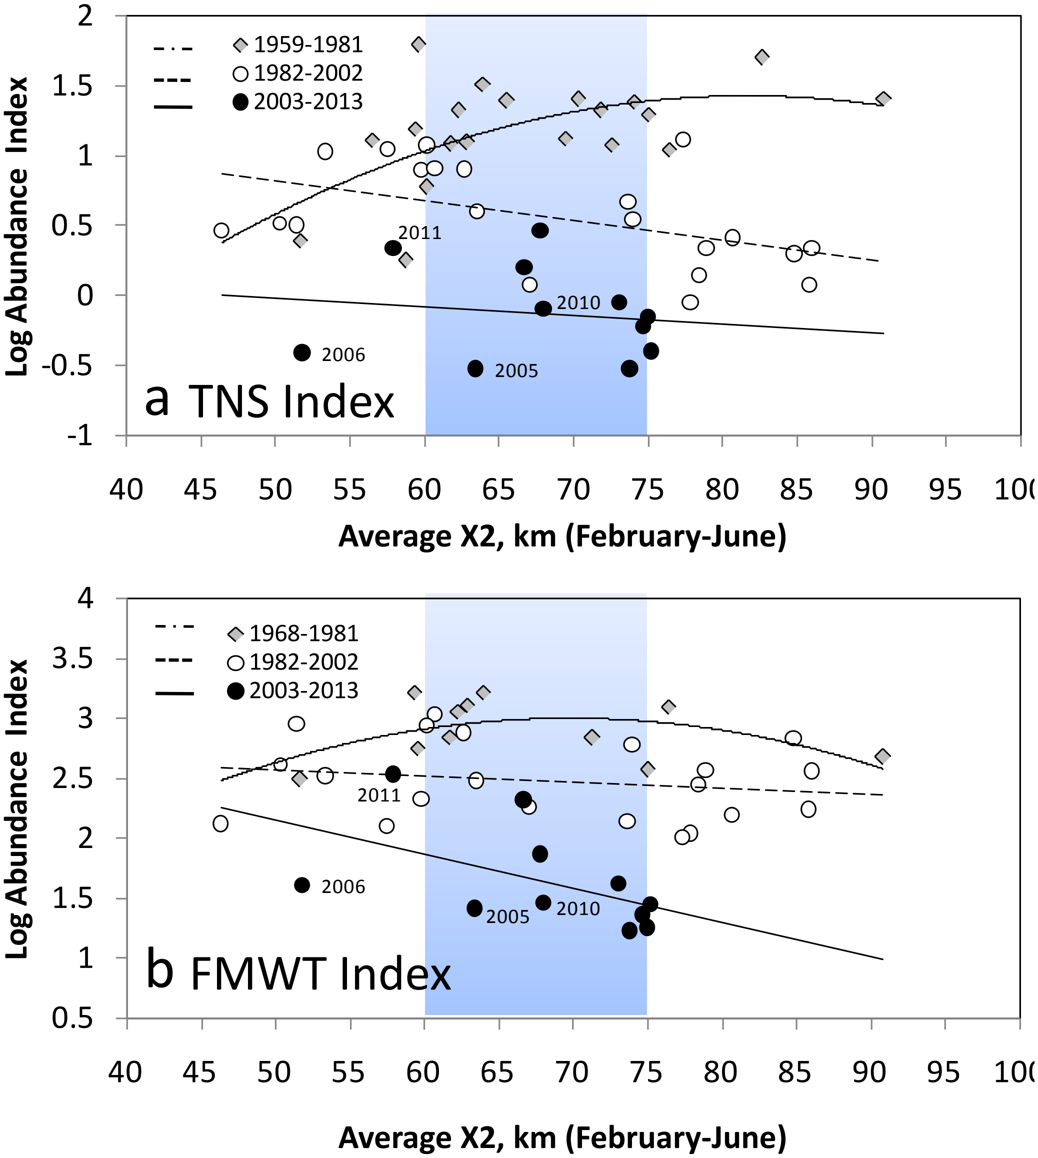
Cloern and Jassby (2012) also showed that significantly increasing exports combined with declining inflows led to significant declines in Delta outflow in each month from September to December. In plots of recent data, this led to a shallower slope of the relationship between the Sacramento River Water Year Index and fall X2 (September-December) and a more eastward LSZ location in the fall months of wetter years (below normal, above normal, and wet water year types) during 2000-2012 compared to 1956-1999, with the exception of two wet years at the end of the time series, 1997 and 1999, which fall on the 2000-2012 line (Fig. 16c, see also Feyrer et al. 2007, 2010). The areas with light blue shading in the three plots shown in Figure 16 show the range of X2 that places the LSZ over Suisun Bay and are associated with a high LSZ volume, area, and shallow LSZ depths (Kimmerer et al. 2013, Fig. 14). Fall X2 commonly fell into this range from 1956-1999 (in 18 of 44 years; Fig. 22c), but never after 2000. In 2011, the most recent wet year, fall X2 was lower than in the preceding wet years of 2006, 1997, and 1999, but still elevated relative to the majority of previous wet years. Overall, the changes in flows in the summer and fall months described by Cloern and Jassby (2012) have resulted in more muted seasonal and interannual variations in X2 and in the size and location of the LSZ in more recent years and possibly also relative to historical variability (Fig. 21).

Delta Smelt are found in the estuary at salinities up to 18 (Bennett 2005), but are most common in the in the LSZ (< 6) (Moyle et al. 1992, Sommer and Mejia 2013, Kimmerer et al. 2013). Sommer et al. (2011a) described Delta Smelt as a “diadromous species that is a seasonal reproductive migrant.” In the winter, adult Delta Smelt move upstream into fresh water for spawning. In the spring and summer, young Delta Smelt are transported or swim downstream into the LSZ (Dege and Brown 2004). Delta Smelt usually rear in low salinity habitat in the summer (Nobriga et al. 2008) and fall (Feyrer et al. 2007), although some Delta Smelt remain year-round in fresh water (Sommer et al. 2011a, Merz et al. 2011, Sommer and Mejia 2013).

The recruitment success of Longfin Smelt and age-0 Striped Bass increases linearly with more westward positions of the LSZ during spring (Jassby et al. 1995, Kimmerer 2002a). In contrast, the relationships of annual Delta Smelt indices with spring X2 are more complex because they have not been consistent over the period of record (Fig. 23). Jassby et al. (1995) found that from 1968-1991, the highest fall abundance indices for Delta Smelt coincided with intermediate values of average April-July X2 when the LSZ was positioned in Suisun Bay. Low fall abundances were, however, also observed at these intermediate X2 values. The analyses by Jassby et al. (1995) were later updated and augmented with an analysis of the relationship between Delta Smelt summer abundance and spring X2 (Kimmerer 2002a, Kimmerer et al. 2009).

We updated the analyses by Jassby et al. (1995) with more recent data and data from additional monitoring surveys to examine the hypothesis that during periods of relatively stable abundance (i.e. without step changes, Thomson et al. 2010), the abundance of different Delta Smelt life stages is related to spring outflow and the position of the LSZ as expressed by spring X2. To obtain spring X2, we first calculated mean monthly X2 values calculated from daily X2 values. We then averaged the mean monthly X2 values for February to June. This is different from the April-July period used by Jassby et al. (1995) for their Delta Smelt analyses, but similar to the spring X2 averaging period used by Kimmerer (2002a). Note that different averaging methods for calculating seasonal X2 values account for the small quantitative differences between results presented here and those of previously published analyses that used the same data, but this does not affect the overall patterns. We partitioned the data into the periods before, between, and after the 1981 and 2002 step declines in Delta Smelt abundance identified by Thomson et al. (2010). The 1981-1982 partition, but not the 2002-2003 partition, has been previously applied by Kimmerer (2002a) and Kimmerer et al. (2009).

Figure 23. Plots of the log transformed a) Delta Smelt Summer Townet Survey abundance index and b) Delta Smelt Fall Midwater Trawl Survey abundance index, in relation to monthly averaged daily X2 position from February to June. Lines are either simple linear least squares regression (lines) or quadratic regression (curves).



Kimmerer (2002a) and Kimmerer et al. (2009) found that the relationship between spring X2 and Delta Smelt juvenile abundance indices was positive before the step decline in Delta Smelt abundance that started in 1981 (Thomson et al. 2010), suggesting that historically, Delta Smelt population recruitment may have benefitted from lower outflows and a more upstream LSZ in the late winter and spring. In our analysis, we found that the relationship was perhaps more unimodal than linear (Table 1, Fig. 23a) because a model that included a quadratic spring X2 term explained more of the variation in the data than a linear model that did not, although the statistical significance of the linear model was slightly higher than that of the quadratic model because of the loss of a degree of freedom due to the additional quadratic term included in the quadratic model. Similar to Kimmerer (2002a) and Kimmerer et al. (2009), we found that in the period after the 1981 step change and also in the period after the 2002 step change, the relationship of log-transformed summer abundance with spring X2 shifted downward and became more clearly negative than unimodal (Fig. 23a). The relationship remained statistically significant at the $P < 0.05$ level in the period after the 1981 step decline, but is no longer statistically significant after 2001. Similarly, the relationship is also not significant across the entire 52-year time series (Table 1).

Kimmerer et al. (2009) found a non-significant and essentially flat relationship between spring X2 and the entire log-transformed sub-adult abundance time series for Delta Smelt; this remains the case when data from the five most recent years is included in the analysis (Table 1). Similar to Jassby et al. (1995), we found a weakly unimodal relationship between spring X2 and log-transformed Delta Smelt subadult abundance indices before the first step change, but this relationship was not statistically significant at the $P < 0.05$ level (Table 1, Fig. 23b). Similar to juvenile abundance, the relationship of log-transformed subadult abundance with spring X2 shifted downward in the periods after each of the two step changes and became more negative than unimodal (Fig. 23b), but again these relationships were not statistically significant at the $P < 0.05$ level (Table 1).

Taken together, these findings are generally consistent with previous conclusions that moderate hydrological conditions in the late winter and spring and a large LSZ located in the Suisun region can be beneficial to Delta Smelt population abundance (Jassby et al. 1995). Historically, this may have been the case for several life stages. At present, however, juvenile and subadult Delta Smelt seem to barely respond to spring X2. As Jassby et al. (1995) point out, this does not mean that there is no longer an effect of spring X2 on juveniles and subadults; the spring X2 effect may just be masked or weakened by changes in other habitat attributes. The relationships between these life stages and spring X2 clearly underwent downward shifts after each step decline. These persistent downward shifts indicate that occasional years with beneficial spring X2 conditions continue to have a positive effect on Delta Smelt, but they are by themselves not enough to overcome the depressed abundance levels and recover the population.

The downward shifts and changes in shape of the spring X2-Delta Smelt abundance index relationships (Fig. 23) also illustrate the difficulties of determining and understanding functional responses of biota to dynamic physical habitat attributes in changing ecosystems; the species of interest, other habitat attributes, and their interactions may all change as much or more than the habitat attribute under consideration. Further, these changes may not always be gradual, but can take the form of sudden step changes that may be associated with system-wide regime shifts (Davis et al. 2010, Baxter et al. 2010, Cloern and Jassby 2012). Moreover, prior conditions and prior abundance may also influence outcomes. In Chapter 9 of this report we give a relatively simple example of additional multivariate analyses aimed at exploring the effects of hydrology and prior abundance on the abundance and recruitment of Delta Smelt larvae. More sophisticated multivariate life cycle modeling that greatly exceeds the scope of this report is needed to account for these simultaneous changes and interactive effects on all life stages.

Changes in the size, location, and dynamics of the LSZ likely also interact in complex ways with other changes, such as changes in sediment and nutrient loadings and resulting turbidity and nutrient dynamics and their effects on Delta Smelt and the food web. For example, LSZ position affects recruitment of the invasive clam *Potamocorbula amurensis,* which may in turn affect phytoplankton and zooplankton biomass, size, and production (Thompson 2005, Winder and Jassby 2011), and has likely affected fish-X2 relationships (Kimmerer et al. 2002a).

Table 1. Summary of relationships between log-transformed annual abundance indices for four Delta Smelt life stages (response variable) and spring X2 (February-June, see text): Survey: see description of monitoring surveys in Chapter 3; Regression: least squares linear or quadratic regression: n, number of observations (years); P, statistical significance level for the model; R^2, coefficient of determination; adjusted R^2, R^2 adjusted for the number of predictor terms in the regression model. Bold font indicates statistically significant relationships.

Ongoing studies coordinated by the IEP as part of the POD and FLaSH studies focus on the processes that link physics, chemistry, and biology in the LSZ and its habitat value for Delta Smelt and other native and non-native species. Similar to Monismith et al. (2002), preliminary results indicate that the strength of physical mixing (lateral dispersion) in the LSZ changes with the volume of freshwater outflow, underscoring the importance of variable hydrodynamics on not just the location of the LSZ, but how ecological services (nutrient mixing, organism dispersal) are influenced by variable estuarine outflow (Monismith, U.C. Berkeley, personal communication).

Turbidity

In this report, turbidity is considered an environmental driver that interacts with other environmental drivers, resulting in habitat attributes that directly affect Delta Smelt responses, rather than a stand-alone habitat attribute. Clearly, studies have shown that distribution of Delta Smelt is correlated with turbidity (e.g., Feyrer et al. 2007, Nobriga et al. 2008, Grimaldo et al. 2009, Sommer and Mejia 2013). In the conceptual model we chose to incorporate turbidity as a modifier of several important linkages between environmental drivers and habitat attributes that are important to Delta Smelt, primarily food visibility for small larvae and predation risk for all life stages. If we had incorporated turbidity as a habitat attribute and, for example, predation risk was discussed separately from turbidity, there would have been a great deal of overlapping text between the two sections because turbidity interacts with the presence of predators to determine predation risk. Our approach is not ideal but should reduce redundant text and contribute to clarity of presentation. Nonetheless, we recognize that turbidity by itself could reasonably be considered as a habitat attribute. For example, it is possible that Delta Smelt experience stress in low turbidity habitat, which would in turn affect survival (likely through predation) but also in other direct ways such as lower growth and reduced egg production. However, we do not have evidence at this point to support that hypothesis.

In addition to salinity gradients, estuaries often have turbidity gradients. Turbidity is an optical property of water, which is the loss of transparency due to scattering of light by suspended particles. Typically, the upper reaches of estuaries have areas with high levels of suspended particles known as “estuarine turbidity maxima.” In many estuaries, these areas are located in or near the low salinity zone and are associated with higher numbers and enhanced growth for larvae of some species (Sirois and Dodson 2000a, b, Shoji et al. 2005). In the SFE, turbidity is largely determined by the amount of suspended inorganic sediment in the water (Cloern 1987, Ganju et al. 2007, Schoellhamer et al. 2012), although organic components can also play a role (USGS 2008). Sediment particles are constantly deposited, eroded, and resuspended, and are transported into, within, and out of the estuary. The amount of sediment that is suspended in the water column depends on the available hydrodynamic energy, which determines transport capacity, and on the supply of erodible sediment in the estuary and suspended sediments from the watershed.

In the upper SFE there are two main physical processes controlling turbidity. Suspended sediment is transported from the tributary watersheds into the system during high flows associated with winter and spring storm runoff (Schoellhamer et al. 2012). The first large storm of the rainy season often carries the highest concentrations of suspended sediment. Some portion of the transported sediment moves through the system to San Pablo and San Francisco Bay and the remainder is stored within the system as bottom sediment. During the remainder of the year, turbidity is primarily caused by interactions of this stored sediment with other environmental drivers (Schoellhamer et al. 2012). Water moving with the tides can resuspend fine sediments because of turbulence resulting from interactions between the bottom and water moving at high tidal velocities. At a larger scale, irregularities in the bottom topography may define geographic regions of greater turbulence and greater turbidity. In the upper estuary, such regions occur at a large bathymetric sill between Carquinez Strait and Suisun Bay and at another location within Suisun Bay (Schoellhamer 2001). Sediments may also be resuspended by turbulence related to wind waves. This process is mainly limited to areas with fine sediments on relatively shallow shoals where wind wave turbulence reaches the bottom. This process is most important in the shallows of Suisun, Grizzly, and Honker Bays and Liberty Island (Ruhl and Schoellhamer 2004, Warner et al. 2004, Morgan-King and Schoellhamer 2013). Thus, turbidity at any particular location is the result of several environmental drivers, including hydrology (transport from the watershed) and weather (wind and precipitation) interacting with the physical configuration of the upper SFE. Further, annual variation in these factors may have important effects. For example, during a drought there is little transport of suspended sediment and the same wind patterns during the summer may result in less turbidity than would occur after a wet year because less sediment was stored as benthic sediment during the winter. There is also evidence of longer term changes in turbidity (Schoellhamer et al. 2011, Hestir et al. 2013), along with regional differences.

In addition to the inorganic component of turbidity, organic matter (e.g., phytoplankton) also contributes to both suspended solids and the sediment load on the bed that is re-suspended with wind and wave action (McGann et al. 2013). In the SFE, phytoplankton concentration varies spatially, seasonally, and on an inter-annual scale (Cloern et al. 1985, Jassby 2008, Cloern and Jassby 2012), and is controlled by multiple factors, including benthic grazing, climate, river inflows (Jassby et al. 2002), and nutrient dynamics (Glibert et al. 2011, Parker et al. 2012, Dugdale et al. 2013), which in turn are likely to affect the organic component of turbidity. Phytoplankton dynamics are discussed in detail in the 'Food and Feeding' section (below), but it is important to note here that plankton concentration comprises part of the SFE turbidity and is significant as it relates to productivity at higher trophic levels.

Among the geographic regions of the upper SFE, the Suisun region is one of the most turbid, when the system is not being influenced by storm flows. This results from strong turbulent hydrodynamics in the Suisun region caused by strongly interacting tidal and riverine flows, bathymetric complexity, and high wind speeds, which create waves that resuspend erodible benthic sediment in the large and open shallow bays of the Suisun region. The North Delta, especially the large open expanse of Liberty Island (flooded since 1998) and the adjacent Cache Slough region are also relatively turbid. Recent evidence suggests that Liberty Island acts as a sediment sink in the winter and a sediment source for the surrounding Cache Slough complex in the summer (Morgan-King and Schoellhamer 2013).

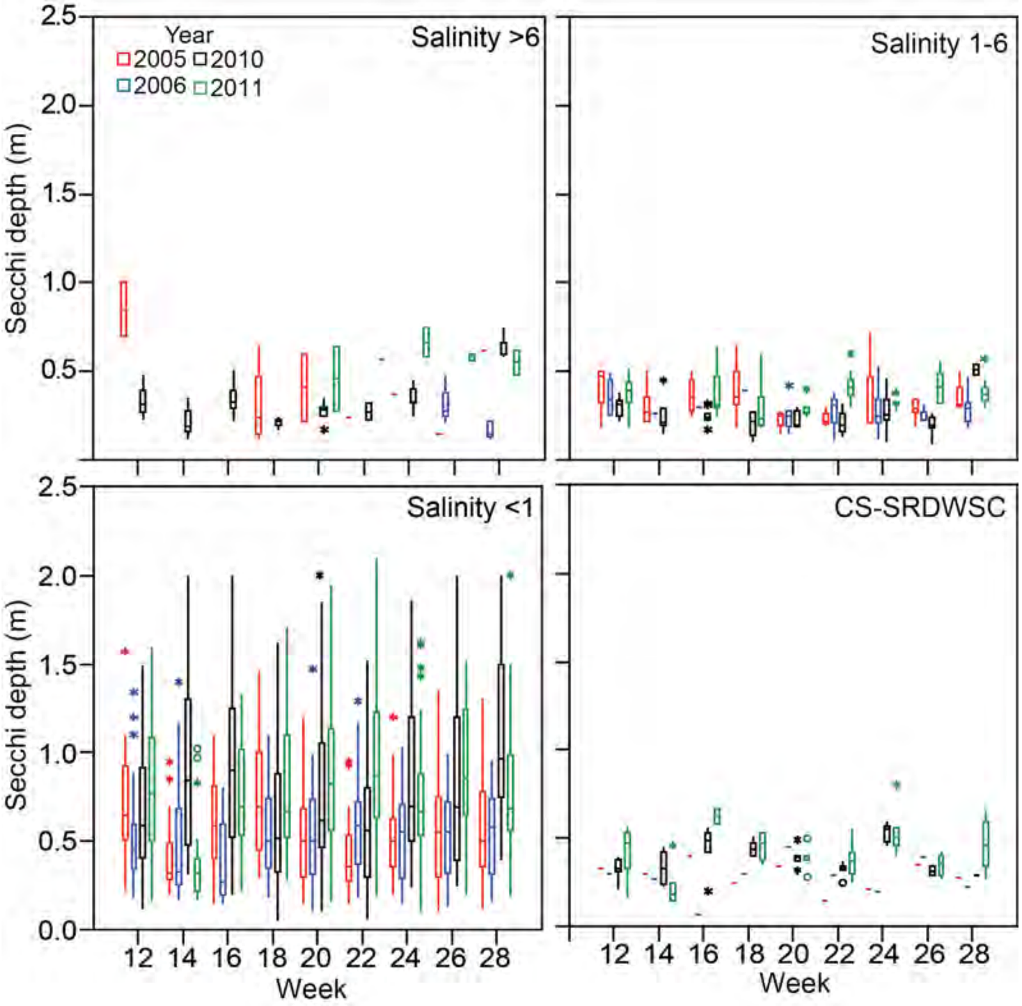
Turbidity is usually lower in the channels of the confluence of the Sacramento and San Joaquin Rivers compared to the Suisun region and North Delta region. Turbidity dynamics in the deep channels of the river confluence are driven more by riverine and tidal processes while high wind and associated sediment resuspension has little if any effect (Ruhl and Schoellhamer 2004). Turbidity is generally lowest in the south Delta (Nobriga et al. 2008). This may in part be due to sediment trapping by large, dense beds of *Egeria densa*, an invasive species of submerged aquatic vegetation (Hestir 2010). In winter/spring during the comparison years the highest Secchi disc depths (lowest turbidity) were found in the freshwater regions of the estuary (< 1 salinity), except for the Cache Slough region in the north Delta which was as turbid as the saltier regions of the estuary (Fig. 24).

There is strong evidence for an initial increase followed by a more recent long-term decline in sediment transport into the upper estuary, likely due to anthropogenic activities during the last century and a half (Schoellhamer et al. 2013, Wright and Schoellhamer 2004). Schoellhamer et al. (2013) presented a conceptual model of the effects of human activities on the sediment supplies in the SFE with four successive regimes:

1. The natural state.
2. Increasing sediment supplies due to mining, deforestation, agricultural expansion, etc.
3. Decreasing sediment supply due to sediment flushing during high flow events and sediment trapping behind dams and dikes.
4. A new altered state of low sediment supplies. The pulse of increased sediment inputs during and after the California gold rush and the more recent decline in these inputs is apparent in isotopic data from sediment cores taken in the estuary (Drexler et al. 2014).

The recent declines in sediment supplies have led to a long-term increase in water clarity in the upper Estuary (Jassby et al. 2002, Feyrer et al. 2007, Jassby 2008). Jassby et al. (2002) documented a 50% decrease in total suspended-solids concentration (TSS, a laboratory measurement of total suspended solids), approximated by suspended sediment concentration

Figure 24. **Secchi depth data collected during the 20 mm Survey. Surveys are conducted biweekly March-July. See Chapter 3: Data Analyses for explanation of boxplots.**



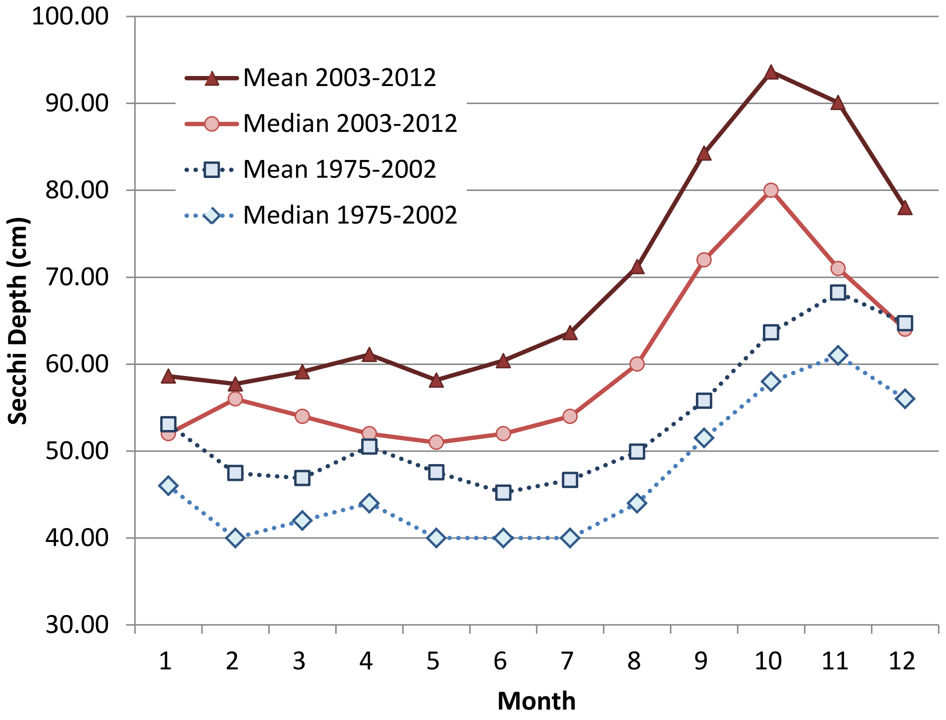
(SSC, an optical measurement done in the field for these data) in the Delta from 1975-1995. Jassby (2008) found that the downward trend continued in the decade after 1995, although at a slower pace than over the entire 1975-2005. From 1975-2005, there were significant declines in SSC of up to 6% per year at 8 of 10 Delta stations (Jassby 2008). Jassby et al. (2005) showed that TSS concentrations in the north Delta dropped sharply toward the end of the 1982–1983 El Niño-Southern Oscillation (ENSO) event, which was associated with extremely high outflows, and did not recover afterward. This step decrease after 1983 has been corroborated by further trend analyses of TSS (Hestir 2013). Following the El Niño event of 1997–1998, there was a 36% step decrease in SSC in San Francisco Bay as the threshold from transport to supply regulation was crossed as an anthropogenic erodible sediment pool was depleted (Schoellhamer 2011). Sediment trapping by dense beds of *Egeria densa* may be further reducing available sediment in the Delta (Hestir 2010). While other anthropogenic factors may have also contributed to long-term changes in turbidity (e.g., export operations; Arthur et al. 1996), quantitative analyses of the effects of these factors have not been conducted.

Before the step decline in SSC and the onset of the pelagic organism decline in the late 1990s and early 2000s (i.e. the "pre-POD" period), water transparency (roughly the opposite of turbidity) measured with a Secchi disc at all IEP EMP stations was usually highest in November and lowest in June (Fig. 25). From 2003-2012 (i.e. the "POD" period), average water transparency was not only higher (by an average of 16 cm Secchi depth) than in the previous period, but the annual dynamics also shifted forward by a month, to greatest transparency (i.e. lowest turbidity) in October and lowest transparency in May. The greatest differences in average water transparency between the pre-POD and POD periods occurred in September and October (28 and 30 cm difference between monthly averages, respectively) and the smallest differences in January-May (10 cm). While the EMP has collected turbidity data (nephelometric turbidity (NTU) measurements) since 1975, long-term fish monitoring surveys have traditionally collected Secchi disc data and only in recent years have incorporated turbidity. Therefore, Secchi disc data are presented in the majority of this report when relating Delta Smelt abundance to water clarity conditions.

Multiple field and modeling studies have established the association between elevated turbidity and the occurrence and abundance of Delta Smelt. The abundance of larval/postlarval Delta Smelt larvae was well explained by salinity and Secchi depth, a proxy for turbidity (Kimmerer et al. 2009). Sommer and Mejia (2013) and Nobriga et al. (2008) found that late-larval and juvenile Delta Smelt are strongly associated with turbid water, a pattern that continues through fall (Feyrer et al. 2007). Long term declines in turbidity may also be a key reason that juvenile Delta Smelt now rarely occur in the south Delta during summer (Nobriga et al. 2008). Thomson et al. (2010) found that turbidity (water clarity) was the only significant predictor variable that was shared by three of the four POD species; all other significant predictor variables were unique to each species. Grimaldo et al. (2009) found that the occurrence of adult Delta Smelt at the fish salvage facilities was linked, in part, with high turbidity associated with winter "first flush" events. Turbidity may also serve as a behavioral cue for small-scale (lateral and vertical movements in the water column) and larger-scale (migratory) Delta Smelt movements (Bennett and Burau 2014).

Delta Smelt are visual feeders, and feed primarily between dawn and dusk (Hobbs et al. 2006, Slater and Baxter 2014). As for all visual feeders, visual range and prey density determine feeding success of Delta Smelt. Visual range depends on size, contrast and mobility of the prey, retinal sensitivity and eye size of the visual feeder, and on the optical habitat attributes such as light scattering, absorption, and intensity (Aksnes and Giske 1993). Optical habitat attributes are affected by turbidity from suspended organic particles, such as algae and detritus, and inorganic particles, such as sand and silt. Somewhat counterintuitively, some level of turbidity appears important to the feeding success of larval Delta Smelt. Baskerville-Bridges et al. (2004a) conducted laboratory experiments in which alga densities (0, 0.5 x 10^6 cell/mL, and 2 x 10^6 cell/mL or 1, 3, and 11 NTU) and light levels (range tested: 0.01 µmoles/s x m^2, 0.3 µmoles/s x m^2, 1.9 µmoles/s x m^2) were manipulated and first-feeding success of larval Delta Smelt was quantified. They found that maximum feeding response occurred at the highest alga concentrations and light levels tested. In a subsequent experiment, when algae were removed entirely, the feeding response was very low. The addition of algae or some other form of suspended particle is standard practice for successfully rearing Delta Smelt larvae in culture facilities (Mager et al. 2004, Baskerville-Bridges et al. 2005, Werner et al. 2010b, Lindberg et al. 2013). Presumably the suspended particles provide a background of stationary particles that helps the larvae detect moving prey. Sufficient turbidity also appears to be important to reduce overall environmental stress and increase survival of larval Delta Smelt (Lindberg et al. 2013). Thus, it seems likely that turbidity is important to the feeding success and survival of larval Delta

Figure 25. Average and median Secchi depth in cm from monthly sampling at IEP Environmental Monitoring Program stations. Data are shown for the time period up to the pelagic organism decline (1975-2002) and after the decline (2003-2012).



Smelt in the wild. Recent research on juvenile Delta Smelt, however, suggests that influence of turbidity on feeding success may vary across life stages and field conditions. Hasenbein et al. (2013) exposed juveniles to varying turbidities (5-250 NTU) and observed a negative relationship between turbidity and feeding rates, with a marked decline in feeding at 250 NTU. However, feeding rates were highest at 12 NTU and stable in the 12-120 NTU turbidity range, which is likely within the range experienced by juvenile Delta Smelt in typical summer conditions in the Delta. Turbidity values of 250 NTU are generally not observed during the summer; therefore, the typical summer turbidity range in the Delta likely does not limit juvenile feeding success.

In addition to its effects on feeding, turbidity may also reduce predation risk. Based on the general recognition that fish assemblages are often partitioned between turbid-water and clear-water assemblages (Rodríguez and Lewis 1997, Whitfield 1999, Quist et al. 2004), and that turbidity can influence the predation rate on turbid-adapted fishes (Rodríguez and Lewis 1997, Gregory and Levings 1998, Quist et al. 2004), it has generally been assumed that juvenile and adult Delta Smelt are closely associated with turbidity in order to minimize their risk of predation in their generally open-water habitat. There may also be complex interactions between feeding and predation risk that are mediated by turbidity. Recent laboratory work has shown that in light (as opposed to dark) conditions, the vertical distribution of larval Delta Smelt shifts upward in the water column when turbidity is increased from clear (< 2 NTU) to 24 NTU (L. Sullivan, San Francisco State University, unpublished data), suggesting that larval Delta Smelt may use turbidity to safely forage in surface waters that may be more food-rich. Interestingly, when a predator cue (water, after containing juvenile Striped Bass for 1 hr) is added to clear water, the distribution of larval Delta Smelt becomes bimodal, with increased densities near the surface and closer to the bottom (L. Sullivan, San Francisco State University, unpublished data). Thus, while laboratory studies have demonstrated that larvae have improved feeding success at higher (but not too high, see above) turbidities, in natural settings, turbidity and predation risk may interact (e.g., Miner and Stein 1996) to affect Delta Smelt habitat choice and feeding success.

Turbidity may also be a migration cue for Delta Smelt. A recent field study investigated behavioral responses of Delta Smelt to winter "first flush" events in the Sacramento and San Joaquin Rivers near their confluence (W. Bennett, U.C. Davis, unpublished data). A first flush is defined as an increase in flow and turbidity associated with the onset of winter rain. This study found lateral turbidity gradients that changed with the tides and before and after first flush events and coincided with lateral Delta Smelt movements toward the channel during flood tides and toward the shoreline during ebb tides. The researchers concluded that this behavior likely facilitates maintaining channel position or moving upriver and cross-channel gradients in water turbidity may act as a behavioral cue. Feyrer et al. (2013) also found small-scale lateral and vertical gradients in turbidity in the lower Sacramento River just prior to a winter-time first flush event. In their study, turbidity and salinity were highest in the lower half of the water column and during flood tides and lowest during ebb tides in the center of the channel in the upper half of the water column. This coincided with observations of Delta Smelt which were more frequently caught throughout the water column during flood tides than during ebb tides when they were observed only in the lower half of the water column and sides of the channel. Feyrer et al. (2013) concluded that Delta Smelt may actively move in the water column by keying in on turbidity and salinity gradients or because of the physics underlying them.

Entrainment and Transport

The egg, larval, and juvenile stages of estuarine fishes and invertebrates along with small and weakly swimming adult stages are subject to involuntary transport (advection) by riverine and tidal flows. Entrainment is a specific case of involuntary transport. It refers to situations when altered flows misdirect and transport fish and other organisms in directions in which they would not normally travel or where they will encounter unfavorable conditions and increased risk of mortality. In this report, we use the term entraiment to specifically refer to the incidental removal of fishes and other organisms in water diverted from the estuary, primarily by CVP and SWP export pumping (Arthur et al. 1996, Grimaldo et al. 2009, Castillo et al. 2012).

Ultimately, watershed hydrology determines how much water can flow into and through the Delta; however, water flows into, within, and out of the Delta are manipulated in many ways. Water is: routed through and around artificial channels, gates, and barriers; stored in and released from reservoirs; discharged from agricultural and urban drains; and diverted with large and small pumps. Perhaps the greatest flow alterations in the Delta have taken place in Old and Middle Rivers (collectively referred to as "OMR") in the central Delta (Fig. 2). Historically, these river channels were part of the tidal distributary channel network of the San Joaquin River (Whipple et al. 2012). Today, they are a central component of the CVP and SWP water conveyance system through the Delta. Water from the Sacramento River in the north now flows through the northern Delta (down Georgiana Slough, through Three-Mile Slough and around Sherman Island) and eastern Delta (via the artificial "Delta cross-channel" and down the forks of the Mokelumne River) to OMR in the central Delta, then to the SWP and CVP. The SWP and CVP pumps are capable of pumping water at rates sufficient to cause the loss of ebb tide flows and to cause negative net flows (the advective component of flow after removal of the diffusive tidal flow component) through OMR toward the pumps (see Grimaldo et al. 2009), thus greatly altering regional hydrodynamics and water quality (Monsen et al. 2007). Under these conditions, fish and other aquatic species in the Delta may be transported toward the pumps (Arthur et al 1996, Brown et al. 1996, Moyle et al. 2010), may swim toward the pumps if they are behaviorally inclined to follow net flow (Grimaldo et al. 2009), or may move toward the pumps if they are employing tidal surfing behavior (Sommer et al. 2011).

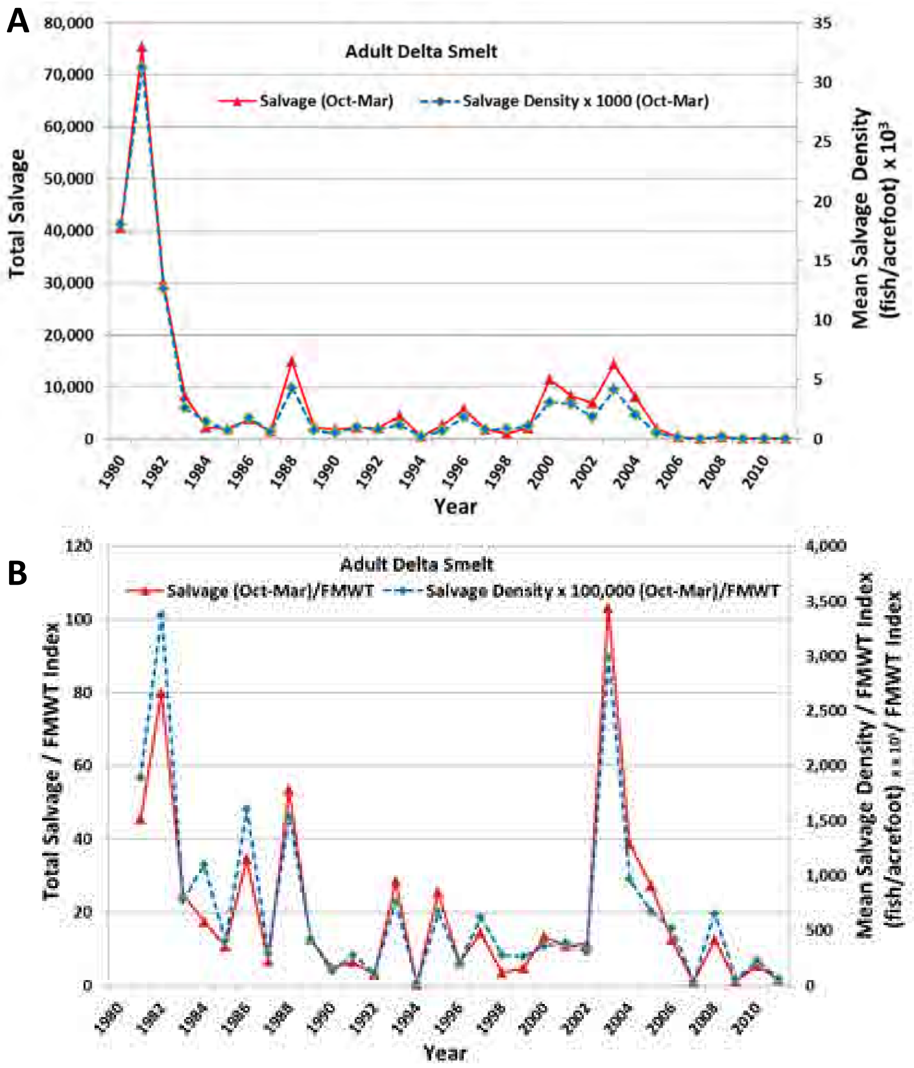
The SWP and CVP have large fish salvage facilities intended to reduce fish loss from the system due to entrainment - the State Skinner Fish Protective Facility (SFPF) and the federal Tracy Fish Collection Facility (TFCF). The SFPF and TFCF are located at the intakes to the State and federal export pumps on Old River in the southwestern Delta (Fig. 2). Both facilities have fish directing louvers and collecting screens that are used to capture and collect fish before they reach the pumps. The "salvaged" fish are then trucked to and released back into the western Delta. A variable fraction of these fish survive the capture, handling, trucking and release process (Miranda et al. 2010a,b, Aasen 2013, Afentoulis et al. 2013, Morinaka 2013a). The number of salvaged fish is monitored and reported as an index of SWP and CVP salvage and entrainment losses (Morinaka 2013b, more information and data available at http://www.dfg.ca.gov/delta/apps/salvage/Default.aspx). The SWP differs from the CVP in having a regulating reservoir, Clifton Court Forebay that temporarily stores water from Old River to improve operations of the SWP pumps. A change in the location of SWP water diversion from Italian Slough to Old River through CCF in 1969 may have led to a substantial increase in pre-screen losses at the SWP (Heubach ca. 1973, Kano 1990).

Fish have been salvaged since 1958 at the TFCF and since 1968 at SFPF, and the quality of the historical salvage data has improved over time. Delta Smelt salvage data is available since May 1979 for both the TFCF and SFPF (ftp://ftp.delta.dfg.ca.gov/salvage/). Juveniles less than 30 mm fork length are less efficiently captured in the salvage facilities (Kimmerer 2008, Morinaka 2013a) and Delta Smelt larvae less than 20 mm fork length have not been reported in the salvage data, although entrainment losses of Delta Smelt larvae have been calculated to be substantial under some circumstances (Kimmerer 2008). Development of a quantitative monitoring methodology for entrained Delta Smelt larvae at the CVP and SWP was recognized as necessary to refine triggers for protective actions (USFWS 2008). The current methodology for monitoring larval Delta Smelt at the TFCF and SFPF has provided presence-absence data since 2008 (Morinaka 2013b). Improved methods for sampling fish larvae have been reported at the TFCF (Reyes et al. 2012).

Despite these caveats salvage of Delta Smelt has been used as a rough index of entrainment losses. Delta Smelt salvage data since 1993 is considered more reliable than salvage data from earlier years. The difference in reliability is due to a change in count frequency from twice a day (0100 and 1300) from July 1978 to July 1992 to every two hours thereafter and an increased focus on proper identification of Delta Smelt following its State and federal listings as threatened (Morinaka 2013b).

Similar to the TNS and FMWT results for Delta Smelt, Delta Smelt salvage has declined dramatically since the beginning of this time series (Fig. 26). This is similar to trends for Chinook Salmon and Striped Bass salvage (not shown), but opposite to trends for Largemouth Bass and Bluegill (*Lepomis macrochirus*) salvage (Fig. 27), two species that may be benefiting from conditions resulting from an apparent ecological regime shift (Baxter et al. 2010). The ratio of Delta Smelt salvage divided by the previous year's FMWT index has been used as a simple indicator of relative interannual entrainment losses. For adult (December-March) salvage, this ratio has been variable over time, but particularly high in the first three years of this time series (1980-1982, with 1982 being a wet year) and again during the beginning of a series of drought years in 1989 and in the fairly dry "POD" years 2003-2005 (Fig. 26). Current management

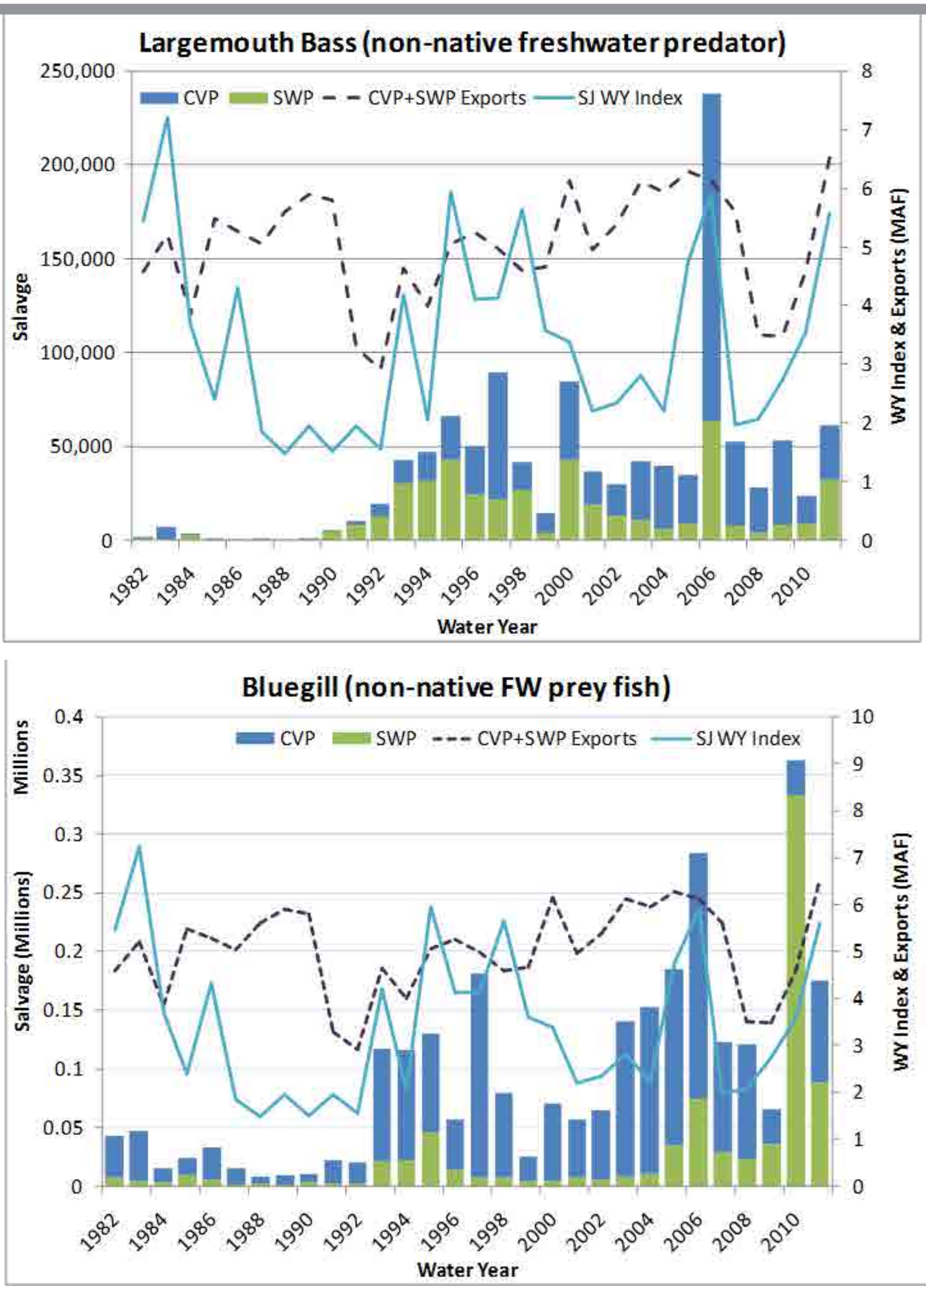
Figure 26. **A: Total reported October-March salvage for adult Delta Smelt and the corresponding mean salvage density based on the total monthly salvage and water volume exported by CVP and SWP. B: Both salvage and salvage density standardized by the Fall Midwater Trawl (FMWT) index for the previous year.**



provisions to protect Delta Smelt (USFWS 2008) are aimed at keeping this ratio at no more than the average during the period of 2006-2008.

Delta Smelt were salvaged nearly year-round in the beginning of this time series. Delta Smelt salvage since 2005 has occurred mostly from January through June, with substantial decline of May-June juvenile salvage since the mid 2000s (Fig. 28) and virtual disappearance of older juveniles from July-August salvage since the year 2000 (Fig. 29) and subadults since the early 1990s (Fig. 30). These patterns coincide with the near disappearance of Delta Smelt from the central and southern Delta in the summer (Nobriga et al 2008) and in the south Delta in the fall (Feyrer et al. 2007). Historically, adult and larval-juvenile (> 20 mm FL) Delta Smelt salvaged were not separately recorded and reported, but based on length measurements of a subset of salvaged fish, adults were predominantly salvaged between December and March or April

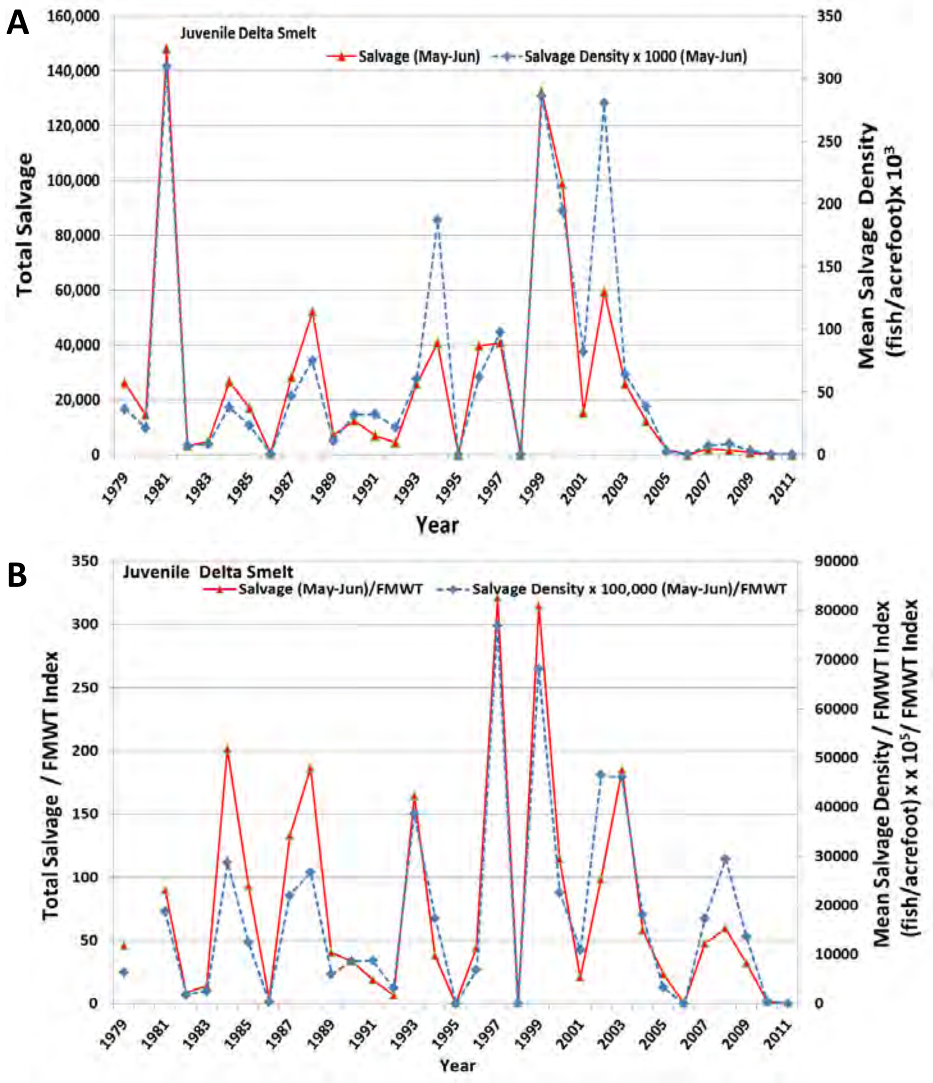
Figure 27. Annual time series of Largemouth Bass (top graph) and Bluegill (bottom graph) salvage at the CVP (blue bars) and SWP (green bars) fish protection facilities. Also shown are the annual San Joaquin Valley Water Year Index (SJWY Index) (blue line) and the combined annual (water year) SWP and CVP water export volume (purple line; MAF, million acre feet).



and most Delta Smelt larvae and juveniles were historically salvaged from April through July (Kimmerer 2008, Grimaldo et al. 2009).

Salvage data are routinely used to track and manage incidental take at the SWP and CVP and have been used to explore factors affecting entrainment and to estimate the effects of the SWP and CVP on Delta fishes. For example, Grimaldo et al. (2009) found that OMR flows and

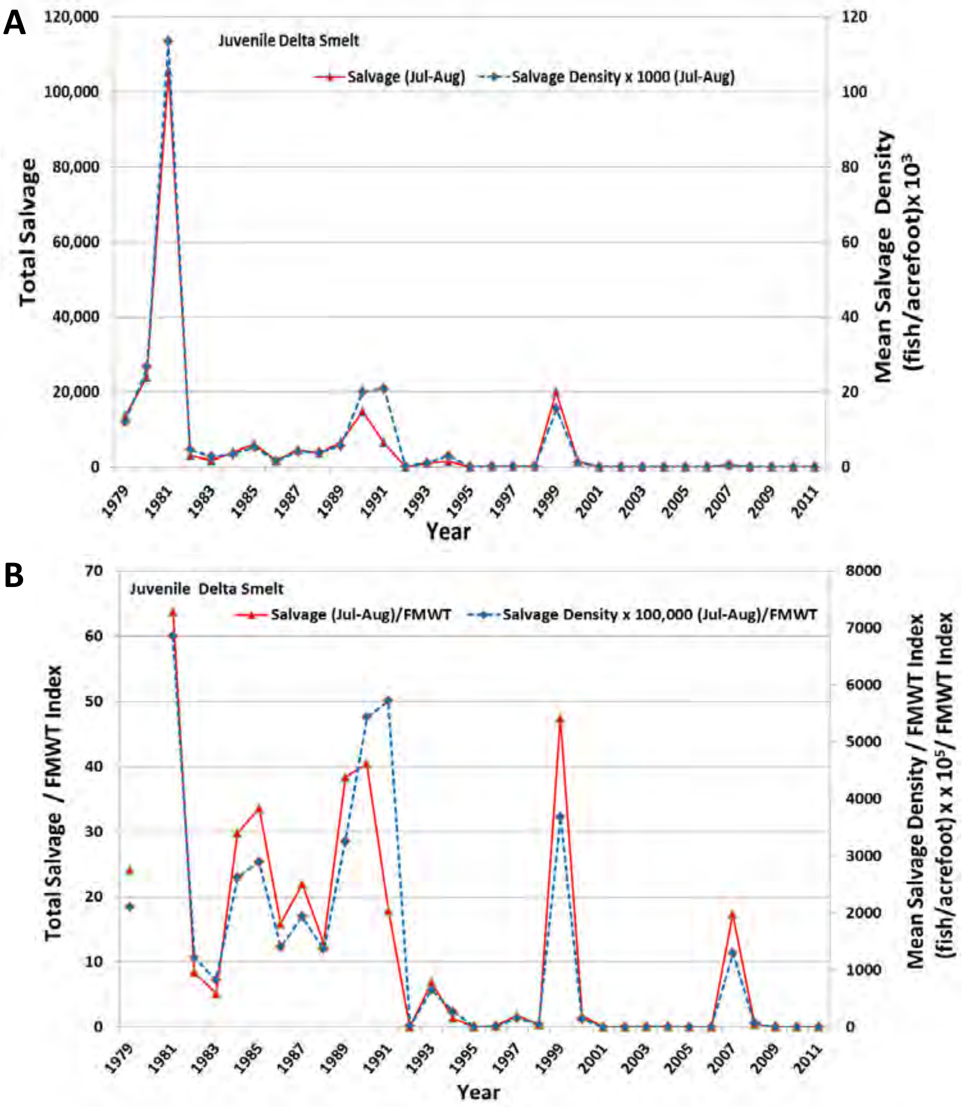
Figure 28. A: Total reported May-June salvage for juvenile Delta Smelt and the corresponding mean salvage density based on the total monthly salvage and water volume exported by CVP and SWP. B: Both salvage and salvage density standardized by the Fall Midwater Trawl (FMWT) index for the previous year.



turbidity account for much of the intra-annual variability in the salvage for juvenile and adult Delta Smelt.

It is important to remember, however, that salvage is only a very rough indicator of Delta Smelt entrainment. Based on mark-recapture experiments using cultured Delta Smelt, salvage was a very small fraction of total entrainment losses because of major pre-screen losses and low fish facility efficiency (Castillo et al. 2012). Experimental studies with cultured Chinook Salmon, Steelhead (*Oncorhynchus mykiss*), and Striped Bass have consistently shown that a large fraction (63% to 100%) of the entrained fish are not salvaged due to pre-screen losses and capture inefficiencies at the SWP fish facility (Brown et al. 1996, Gingras 1997, Clark et al. 2009). In addition, a mark–recapture test using field collected juvenile Chinook Salmon in CCF resulted in only 0.32% of the fish being salvaged (see Castillo et al. 2012). Pre-screen losses are generally

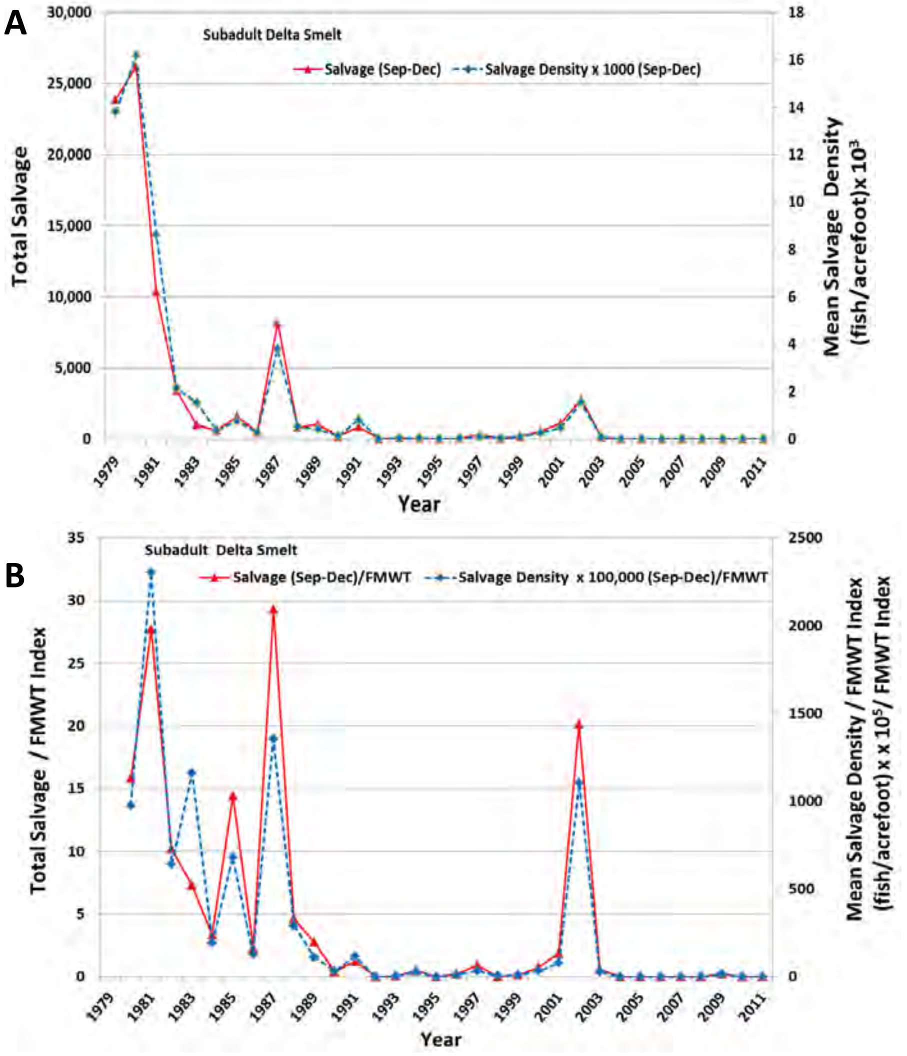
Figure 29. A: Total reported July-August salvage for juvenile Delta Smelt and the corresponding mean salvage density based on the total monthly salvage and water volume exported by CVP and SWP. B: Both salvage and salvage density standardized by the Fall Midwater Trawl (FMWT) index for the previous year.



attributed to increased predation and other unfavorable habitat conditions near the SWP and CVP pumps (e.g. Kano 1990, Brown et al. 1996, Gringas and McGee 1997, Clark et al. 2009, Castillo et al. 2012). For juvenile and adult Delta Smelt, Castillo et al. (2012) found that 94.3% to 100% of marked fish groups released into the SWP CCF were never salvaged and that salvage of marked fish decreased as the distance from the release site to SFPF increased and as residence time in CCF increased.

Large pre-screen losses of Delta Smelt in CCF are likely due to increased predation, especially when Delta Smelt spend a relatively long time in the reservoir in the presence of predators. MacWilliams and Gross (2013) used a particle tracking model to estimate residence time of passive particles, which can be considered surrogates for weakly swimming Delta Smelt. In 21-

Figure 30. **A: Total reported July-August salvage for sub-adult Delta Smelt and the corresponding mean salvage density based on the total monthly salvage and water volume exported by CVP and SWP. B: Both salvage and salvage density standardized by the Fall Midwater Trawl (FMWT) index for the same year.**



day simulations with the three-dimensional (3D) hydrodynamic model UnTRIM, MacWilliams and Gross (2013) found that the time particles spend in CCF varies greatly with wind and SWP operating conditions. They estimated transit times for passive particles (e.g., larval Delta Smelt) from the radial gates to the SFPF of 4.3 days under moderate export conditions (average daily SWP export rate of 2,351 cfs) and 9.1 days under low export conditions (689 cfs). The CVP does not have a regulating reservoir in the Delta and CVP pre-screen losses in the river channels leading to the TFCF are likely different from SWP pre-screen losses, but there are no studies quantifying these differences.

In general, Delta Smelt salvage increases with increasing net OMR flow reversal (i.e., more negative net OMR flows) and when turbidity exceeds 10-12 NTU (USFWS 2008, Grimaldo et al. 2009). Based on field and salvage data, Kimmerer (2008) calculated that from near 0% to 25% of larval-juvenile and 0% to 50 % of the adult Delta Smelt population can be entrained at the CVP and SWP annually, in years with periods of high exports. Although methods to calculate proportional loss estimates have since been debated (Kimmerer 2011, Miller 2011), a number of modeling efforts suggest that entrainment losses can adversely affect the Delta Smelt population (Kimmerer 2011, Maunder and Deriso 2011, Rose et al. 2013a, b).

High winter entrainment of Delta Smelt has been suspected as a contributing cause of both the early 1980s (Moyle et al. 1992) and the POD-era declines of Delta Smelt (Baxter et al. 2010). In addition to entraining Delta Smelt, water exports may likely also have indirect effects on Delta Smelt by contributing to adverse alterations of their habitat, for example, by changing Delta outflow and the size and location of the LSZ (see above) or by entraining food organisms (Jassby et al. 2002). The magnitude of these indirect effects of water exports on the Delta Smelt population has, however, not yet been quantified.

Delta Smelt are most vulnerable to entrainment when, as adults, they move from brackish water into fresh water, or as larvae, when they move from freshwater in the southern and central Delta into the brackish water of Suisun Bay. While some Delta Smelt live year-round in fresh water far from the CVP and SWP, most rear in the low-salinity regions of the estuary, also at a relatively safe distance from the SWP and CVP pumps. The timing, direction and geographic extent of the spawning movements of adult Delta Smelt affect their entrainment risk (Sweetnam 1999, Sommer et al. 2011a). Unlike the years prior to the 1990s, when high salvage of adult and juvenile Delta Smelt occurred at high, intermediate or low export levels, the risk of entrainment for fish that move into the central and south Delta is currently highest when net Delta outflow is at intermediate levels (~20,000 to 75,000 cfs) and OMR flow is more negative than -5000 cfs (USFWS 2008). In contrast, when adult Delta Smelt move upstream to the Sacramento River and into the Cache Slough region or do not move upstream at all, entrainment risk is appreciably lower. As explained later in this report, adult Delta Smelt may not move very far upstream during extreme wet years because the region of low salinity habitat becomes fresh and suitable for spawning (e.g., Suisun Bay or Napa River).

Transport mechanisms are most relevant to larval fishes, which have comparatively little ability to swim or otherwise affect their location. Dispersal from hatching areas to favorable nursery areas with sufficient food and low predation is generally considered one of the most important factors affecting the mortality of fish larvae (Hjort 1914, Hunter 1980, Anderson 1988, Leggett and Deblois 1994). Larvae of various smelt species exhibit diverse behaviors to reach and maintain favorable position within estuaries (Laprise and Dodson 1989, Bennett et al. 2002). Such nursery areas provide increased feeding success, growth rates and survival (Laprise and Dodson 1989, Sirois and Dodson 2000a, b, Peterson 2003, Hobbs et al. 2006). Until recently it was thought that larval Delta Smelt were transported from upstream hatching areas to downstream rearing areas, particularly the shallow productive waters of Suisun Bay (Moyle et al. 1992). Spring distributions of post-larval and small juvenile Delta Smelt support this view (Dege and Brown 2004). The distributions of these life stages were centered upstream of X2, but approached X2 as fish aged. These distributions could be displaced, and shifted up or down estuary with outflow and the shifting position of X2 (Dege and Brown 2004). More recent evidence suggests, however, that the timing and extent of downstream movement by young Delta Smelt is more variable than previously thought and that some may remain in upstream areas throughout the year (Sommer et al. 2011a, Contreras et al. 2011, Merz et al. 2011, Sommer and Mejia 2013).

Adult spawning site selection affects the potential importance of transport and entrainment to larvae. The risk of larval entrainment appears to increase with proximity to the south Delta export pumps (Kimmerer and Nobriga 2008). Larvae hatching in the San Joaquin River channel from

Big Break upstream to the city of Stockton and tidal channels south of these locations, can be affected by several interacting processes. Flows from the San Joaquin, Calaveras, Mokelumne and Cosumnes rivers act to cause net downstream flow, whereas export levels at the south Delta pumps act to reverse net flows in the lower San Joaquin River. High export rates can create negative flows past Jersey Point on the lower San Joaquin River ("Qwest," see Dayflow documentation: http://www.water.ca.gov/dayflow/output/Output.cfm) and negative OMR flows (Fig. 31). Since the onset of the POD in 2002, positive average monthly OMR flows have only occurred in 9 months (6%) during the wettest years and average monthly Qwest flows were negative in just under half (49%) of all months (Fig. 31). Tidal conditions can also act in favor of downstream transport or entrainment depending upon whether the Delta is filling or draining in response to the fortnightly spring-neap cycle (Arthur et al. 1996). The combination of high export and low inflow can create very asymmetrical tides in OMR that covary with net negative flow resulting in stronger floods compared to ebbs, which may also contribute to fish entrainment.

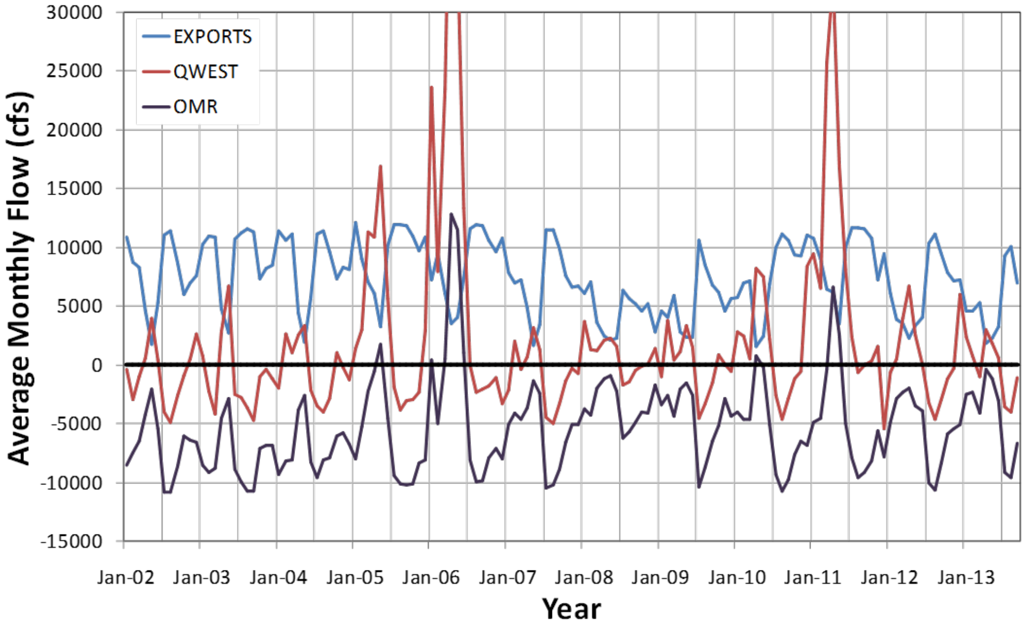
Predation Risk

Small planktivorous fishes, including osmerids, serve as prey for larger fishes, birds and mammals. As prey, they have the critically important trophic function of transferring energy to higher trophic levels. Consequently, they are often subjected to intense predation pressure (Gleason and Bengsten 1996, Jung and Houde 2004, Hallfredsson and Pedersen 2009). Prey fish populations compensate for high mortality through high reproductive rates, including strategies such as repeat spawning by individuals and rapid maturation (Winemiller and Rose 1992, Rose et al. 2001). Predation can be a dominant source of mortality for fish larvae, along with starvation and dispersion to inhospitable habitats (Hjort 1914, Hunter 1980, Anderson 1988, Leggett and Deblois 1994).

Since predation is a natural part of functional aquatic ecosystems, predators are likely not responsible for long-term declines in populations of prey fishes, such as Delta Smelt, without some additional sources of stress that disrupt the predator-prey relationship (Nobriga et al. 2013). Predation may become an issue when established predator-prey relationships are disrupted by habitat change or species invasions (Kitchell et al. 1994). As described in Chapter 1, the SFE has been extensively modified (Nichols et al. 1986, Cohen and Carlton 1998, Whipple et al. 2012, Cloern and Jassby 2012) so disrupted relationships between predators and prey are certainly plausible. For example, prey may be more susceptible to predation if they are weakened by disease, contaminants, poor water quality, or starvation. Similarly, the creation of more "ambush habitat" (e.g. structures, weed beds), declines in turbidity levels, or the introduction of a novel piscivore also may dramatically shift the existing predator-prey relationships (Ferrari et al. 2014). All of these changes have in fact taken place in the estuary, especially in the central and south Delta (Feyrer and Healey 2003, Nobriga et al. 2005, Brown and Michniuk 2007).

Virtually all fishes of appropriate size will feed on fish larvae when available and predation is theoretically maximal when larvae lengths are 10% of the length of the predator (Paradis et al. 1996). Presently, Mississippi Silverside (*Menidia audens*) is thought to be the most substantial predator of Delta Smelt larvae (Bennett and Moyle 1996, Bennett 2005, Baerwald et al. 2012). Juvenile and adult Delta Smelt have also been reported from the stomach contents of Striped Bass (Stevens 1963, Stevens 1966, Thomas 1967), White Catfish (*Ictalurus catus*) and Black Crappie (*Pomoxis nigromaculatus*) (Turner 1966a,b). Stevens (1963) reported "freshwater smelt" to be a very common component of Striped Bass stomach contents (nearly 100% frequency of occurrence in fifteen stomachs with food) on the Sacramento River near Paintersville Bridge

Figure 31. **Flows in cubic feet per second for Qwest (positive values are seaward), Old and Middle River (OMR) (positive values are seaward), and total exports for years since the beginning of the pelagic organism decline (POD). Maximum monthly average Qwest values in 2006 and 2011 omitted to improve graph display, values are 50,086 cfs in April 2006, 35,477 in May 2006, and 32,884 cfs in April 2011 (Qwest and Export data are from 2013 Dayflow, OMR data are from USGS).**



during March-April 1963. During 1963-1964, Stevens (1966) also evaluated seasonal variation in the diets of juvenile Striped Bass throughout the Delta; only age 2 and age 3 Striped Bass contained more than trace amounts of Delta Smelt. The highest reported predation on Delta Smelt was 8% of the age 2 Striped Bass diet by volume during the summer. Thomas (1967) reported on spatial variation in Striped Bass diet composition based on collections throughout the SFE and the Sacramento River above tidal influence. The field collections occurred from 1957-1961; data were collected on age 1 and older Striped Bass but data were only summarized as all ages combined. Delta Smelt accounted for 8% of the spring diet composition and about 16% of the summer diet composition in the Delta.

Several authors tested hypotheses about inverse correlations between estimates of adult and juvenile Striped Bass abundance and indices of Delta Smelt relative abundance or survival (Mac Nally et al. 2010, Thomson et al. 2010, Maunder and Deriso 2011, Miller et al. 2012, Nobriga et al. 2013). None of these statistical analyses has found evidence for the expected inverse correlation. Modeling studies indicate that Striped Bass predation rates on prey are affected by temperature and predator abundance (mostly the latter; Loboschefsky et al. 2012). However, the links between prey abundance and predator abundance vary from strong to non-existent, depending on the strength of their interaction in the food web (Essington and Hansson 2004). It is not currently known if changes in juvenile Striped Bass abundance correspond with changes in population-level or per capita Striped Bass predation rate on Delta Smelt (Nobriga et al. 2013).

Recent modeling efforts show that Delta Smelt declines are negatively associated with metrics assumed to reflect the abundance of predators in the estuary (Maunder and Deriso 2011, Miller et al. 2012). These metrics are composites of the relative abundance of Mississippi Silverside, Largemouth Bass and other centrarchids; species that are potential predators of concern because of their increasing abundance (Fig. 27; Bennett and Moyle 1996, Brown and Michniuk 2007, Thomson et al. 2010), and because of inverse correlations between Largemouth Bass abundance and Delta Smelt abundance (Nobriga and Feyrer 2007, Thomson et al. 2010, Maunder and Deriso 2011). These correlations could represent predation on Delta Smelt by Largemouth Bass, or alternatively, the very different responses of the two species to changing habitat within the Delta (Moyle and Bennett 2008). Current data suggest that Largemouth Bass populations have expanded as the SAV *Egeria densa* has expanded and have come to dominate parts of the Delta (Brown and Michniuk 2007). *E. densa* and Largemouth Bass are particularly prevalent in the central and southern Delta (Brown and Michniuk 2007) and Largemouth Bass may contribute to the pre-screen losses of Delta Smelt entrained into the SWP and CVP export pumps (see above). Largemouth Bass will readily eat Delta Smelt when the opportunity exists (Ferrari et al. 2014). However, there is little evidence that Largemouth Bass are major consumers of Delta Smelt due to low spatial co-occurrence (Nobriga et al. 2005, Baxter et al. 2010; L. Conrad, California Department of Water Resources, unpublished data). Thus, the inverse correlations between these species may not be mechanistic. Rather, they may reflect adaptation to, and selection for, different environmental conditions.

As noted above, predation on fish larvae can also be an important source of mortality. Juvenile and small adult fishes of many species will consume fish larvae when they are available. Major predators of the eggs and larvae of nearshore coastal and pelagic estuarine forage fishes can include invertebrates (DeBlois and Leggett 1993) and numerous small fishes not typically thought of as “piscivorous” (Johnson and Dropkin 1992), including adults of their own species (Takasuka et al. 2003). Bennett and Moyle (1996) and Bennett (2005) noted this and specifically identified Mississippi Silversides (hereafter, Silversides) as potential predators on Delta Smelt larvae. These authors also documented increases in the Silverside population from the mid-1970s through 2002. Consumption of Delta Smelt larvae by Silversides in the Delta was recently verified using DNA techniques (Baerwald et al. 2012). Larval predation is discussed in more detail in the next Chapter.

Contaminants

Fish are particularly sensitive to alterations in the chemical composition of the natural aquatic environment, as these changes can have significant impacts on their behavioral and physiological systems (Radhaiah et al. 1987). Chemical alterations can be the result of natural processes, for example the changes in local water quality associated with tidal water movements or natural biogeochemical processes, or they can be caused by pollution from watershed- or land-based sources of nutrients, such as nitrogen compounds, and contaminants, such as pesticides, metals, and contaminants of emerging concerns (CECs). The movement of contaminants through aquatic ecosystems is complex and dynamic, and many contaminants are difficult to detect and expensive to monitor (Scholz et al. 2012).

Portions of the SFE are listed as “impaired” on California’s 303(d) list of Impaired Water Bodies due to metals, pesticides, legacy pollutants, and nutrients that exceed established water quality objectives (SWRCB 2010). In particular, the entire SFE has been listed as impaired due to pollution with metals, such as mercury and selenium, and pesticides such as chlorpyrifos, DDT (Dichlorodiphenyltrichloroethane), and diazinon. The entire Delta, but not the bays of the SFE, is also listed for observed toxicity to aquatic organisms. In addition, the Stockton Ship Channel in the southeastern Delta is listed for enrichment with nutrients, organic compounds, and low dissolved oxygen levels; Old River in the south-central Delta is listed for elevated salinity (electrical conductivity; EC) and total dissolved solids (TDS). Delta Smelt are likely exposed to a variety of these contaminants throughout their life cycle; however, the frequency and magnitude of the effects of contaminants on Delta Smelt health and reproduction are not very well understood in the SFE (Johnson et al. 2010, Brooks et al. 2012). The following sections describe the potential effects of key contaminants on Delta Smelt.

Pesticides

Pesticides produce many physiological and biochemical changes in freshwater organisms through their influence on the activities of several enzymes (Khan and Law 2005). Specifically, pesticides can have an adverse effect on hormones or other chemical messengers important to the health of an individual. Previous work has shown that chronic exposure to low levels of pesticides may even have a more adverse effect on fish than a single acute exposure to high levels. Chronic exposures were associated with changes in behavior and physiology that could influence survival and reproduction of wild fish (Ewing 1999). Biochemical and physiological stresses induced by exposure to pesticides can result in metabolic disturbances, retardation of growth, as well as reduction in longevity and fecundity (Murty 1986).

Pesticides are among the key contaminants believed to have contributed to the Delta Smelt decline (Johnson et al. 2010, Brooks et al. 2012, NRC 2012). Because pesticide concentrations in surface water are typically highest during the winter and spring, pesticides are most likely to affect the adult and larval life stages; however, effects may occur during any life stage as pesticides are seasonally and geographically widespread (Kuivila and Hladik 2008). Kuivila and Moon (2004) found that peak densities of larval and juvenile Delta Smelt sometimes coincided in time and space with elevated concentrations of dissolved pesticides in the spring. These periods of co-occurrence lasted for up to 2–3 weeks. While concentrations of individual pesticides were lower than would be expected to cause acute mortality, little is known of the sublethal effects of pesticides on Delta Smelt. Although little evidence exists for acute effects of pesticides on fish or invertebrates, several studies have documented sublethal effects on fish health (Werner et al. 2008, Werner et al. 2010a, Werner et al. 2010b).

Herbicides and fungicides were among the most commonly detected classes of pesticides observed in water and sediment in the Delta and are also found in fish tissue (Orlando et al. 2013, Smalling et al. 2013). Herbicides are known to affect primary producers, while insecticides can affect invertebrate prey species (e.g., Brander et al. 2009, Weston et al. 2012), which could lead to contaminant-mediated food limitation for Delta Smelt. Fungicides have been found to cause endocrine disruption in fish, including reduced fecundity (Ankley et al. 2005). Recent work has shown that the insecticide esfenvalerate affects swimming behavior of exposed larval Delta Smelt (Connon et al. 2009). It was also found to alter the expression of genes involved in neuromuscular activity and immune response, detoxification, and growth and development (Connon et al. 2009). Additionally, insecticides are known to affect predator-prey relationships for fish, as well as lead to endocrine disruptions (Scholz et al. 2000, Junges et al. 2010, Relyea and Edwards 2010, Riar et al 2013, Forsgren et al. 2013). Contamination of aquatic systems by pyrethroid insecticides was recently found to lead to genetic point mutations in the nontarget, aquatic amphipod *Hyalella azteca*, resulting in differences in pyrethroid sensitivity. Wild populations of *H. azteca* collected from areas with high sediment concentrations of pyrethroids exhibited remarkable resistance to pyrethroids compared to laboratory cultures and the observed resistance was highly coupled to the presence of a genetic mutation. The LC50s (concentration that is lethal to 50% of the exposed population) of previously-exposed wild populations were up to two orders of magnitude greater than LC50s of laboratory cultures. Moreover, the presence of a genetic mutation was detected in 100% of *H. azteca* that survived exposure to high pyrethroid concentrations. The development of such resistance can result in costs to genetic and biological diversity, including reduced fitness, and may lead to impacts to the food web (Weston et al. 2013). The presence of such resistance and genetic mutations in Delta Smelt as a result of pyrethroids or other pesticide exposure has not been investigated

It is also important to note that environmental factors such as temperature and salinity affect pesticide toxicity in fish (Coats et al. 1989, Lavado et al. 2009). For that reason, seasonal variation in environmental factors may result in greater risk to certain life stages. The results above are for dissolved pesticides; pesticides may also be bound to sediments, representing another possible mechanism of exposure. Pesticides, such as pyrethroids and organochlorines, that strongly bind to sediment may be particularly important to the adult and larval life stage of Delta Smelt as these life stages occur during the winter and spring, when rain events (including the “first flush”) transport sediment and associated contaminants into the Delta; however, as the mechanisms that influence the desorption rates of pesticides are complex (e.g., temperature, contact time, pesticide) (e.g., Xu et al. 2008, Cornelissen et al. 1998), exposure rates for Delta Smelt lifestages are likely multifaceted and difficult to predict.

Ammonia and Ammonium

Agricultural operations, wastewater treatment plant effluent, and other sources contribute to the accumulation of nutrients in the Delta. Nutrients, such as ammonium (a cation) and ammonia (its toxic, unionized form) are of particular concern in the Delta, as they can have significant negative effects on Delta Smelt and their habitat. Ammonium is increasingly converted into ammonia as pH rises. Delta Smelt spawning and larval nursery areas in the northern Delta are at particular risk to exposure to ammonia/um, mainly due to discharge by the Sacramento Regional Wastewater Treatment Plant (SRWTP) into the lower Sacramento River (Connon et al. 2011a). However, effects of nutrients such as ammonia/um are likely at all Delta Smelt life stages, as nutrients are discharged throughout the Delta year-round.

Recent work demonstrated that Delta Smelt exposed to ammonia exhibited membrane destabilization, which may lead to increased membrane permeability as well as increased susceptibility to synergistic effects of multi-contaminant exposures (Connon et al. 2011a, Hasenbein et al. 2013b); however, the concentrations of ammonia used in these studies were higher than the concentrations typically experienced by Delta Smelt in the wild. In other fish species, sublethal concentrations of ammonia/um have also led to histological effects such as gill lamellae fusions and deformities (Benli et al. 2008). Other work has also shown that neurological and muscular impacts of ammonia/um resulted in slowed escape response and subsequent mortality (McKenzie et al. 2008).

Metals and Other Elements of Concern

Historic mining sites, industrial and domestic wastewater discharges, and agricultural runoff are largely responsible for the presence of metals and other elements of concern in the Delta. Metals of particular importance in the Delta include copper and mercury; selenium is a trace element of concern. Delta Smelt exposed to copper exhibited reduced swimming velocities and suffered digestive and neurological effects (Connon et al. 2011b). Other sublethal effects on fish caused by exposure to these elements include reduced fertility and growth, impaired neurological and endocrine functions, and skeletal deformities that affect swimming performance (Boening 2000, Chapman et al. 2010). These elements are often associated with sediment and may be particularly important to the adult and larval life stages, since sediment is transported with significant rain events, including the "first flush."

Contaminants of Emerging Concern

Contaminants of emerging concern (CECs) such as pharmaceuticals, hormones, personal care products, and industrial chemicals are of increasing concern because they are widespread in the aquatic environment, biologically active, and are relatively unregulated (Kolpin et al. 2002, Pal et al. 2010). The California State Water Resources Control Board is currently investigating CECs in the Delta (http://www.sccwrp.org/ResearchAreas/Contaminants/ContaminantsOfEmergingConcern/ EcosystemsAdvisoryPanel.aspx). CECs originate from many sources including industrial and domestic wastewater. They are responsible for a myriad of sublethal effects in fish including endocrine disruption, changes in gene transcription and protein expression, and morphological and behavioral changes (Brander 2013). Though the effects of CECs have been well studied in other fish species, the extent to which they influence Delta Smelt remains unclear.

Polycyclic Aromatic Hydrocarbons (PAHs) and Polychlorinated Biphenyls (PCBs)

The PAHs and PCBs found in the Delta are largely from urban and industrial sources. PAHs are formed during the incomplete burning of coal, oil, gas, garbage, and other organic substances. PCBs are synthetic organic chemicals that were used in many industrial and commercial applications. PCBs were banned in 1979, but continue to persist in the environment. PAHs and PCBs bind strongly to sediment and therefore are likely to be associated with the "first flush" and may be particularly important to the adult and larval life stages of Delta Smelt. Almost all sediments sampled in the Delta in 2006 contained PAHs (mean concentration of 0.3 parts per million in Suisun Bay) and PCBs (mean concentration of 0.8 parts per million in Suisun Bay) (SFEI 2007). Studies have found PAHs and PCBs in surface water, with concentrations in excess of established water quality objectives (Thomson et al. 2000, Oros et al. 2006). Both PCBs and PAHs can cause endocrine disruption in fish (Brar et al. 2010, Nicolas, 1999); however, specific impacts on Delta Smelt have not been documented.

Contaminant Mixtures

While the individual effects of the aforementioned contaminants can be severe, recent work has demonstrated that the interaction of the contaminants within mixtures can have both synergistic and antagonistic effects, exacerbating potential impacts on fish physiology (e.g., Jordan et al. 2012). There is increasing evidence that compounds in mixtures show adverse effects at concentrations at which no effects were observed for single toxicants (e.g., Baas et al. 2009, Silva et al. 2002, Walter et al. 2002). For example, recent work on Mississippi Silversides has demonstrated that contaminant mixtures resulted in endocrine disruptions such as varied expression of mRNA levels for estrogen-responsive genes, reduced mean gonadal somatic indices (GSI), testicular necrosis, and biased sex ratios (Brander et al. 2013). Studies have also shown that mixtures can affect predator-prey interactions (Relyea and Edwards 2010) and cause liver abnormalities (Sacramento Splittail, *Pogonichthys macrolepidotus*; Greenfield et al. 2008). Other work on Striped Bass has demonstrated that contaminant mixtures can be maternally-transferred to fish eggs, resulting in larvae with impaired growth and abnormal brain and liver development (Ostrach et al. 2008).

Due to the unpredictability of their effects on organisms, the synergistic effects of contaminant mixtures have received a great deal of attention both within pharmacology and environmental sciences (Arnold et al. 1996, Ashby et al. 1997, Berenbaum 1989, Greco et al. 1995, Liang and Lichtenstein 1974). Currently, one of the greatest challenges in chemical mixture research is how to deal with the infinite number of combinations of chemicals and other stressors, as well as their interactive effects, on organisms (Baas et al. 2010). Additional challenges also exist trying to relate lab-based findings to wild populations for studies examining the effects of individual contaminants and contaminant mixtures on organisms using exposure concentrations that are environmentally representative. Therefore, while the potential for exposure to contaminant mixtures in all Delta Smelt life stages is highly probable, any specific effects of such interactions on Delta Smelt remain unknown.

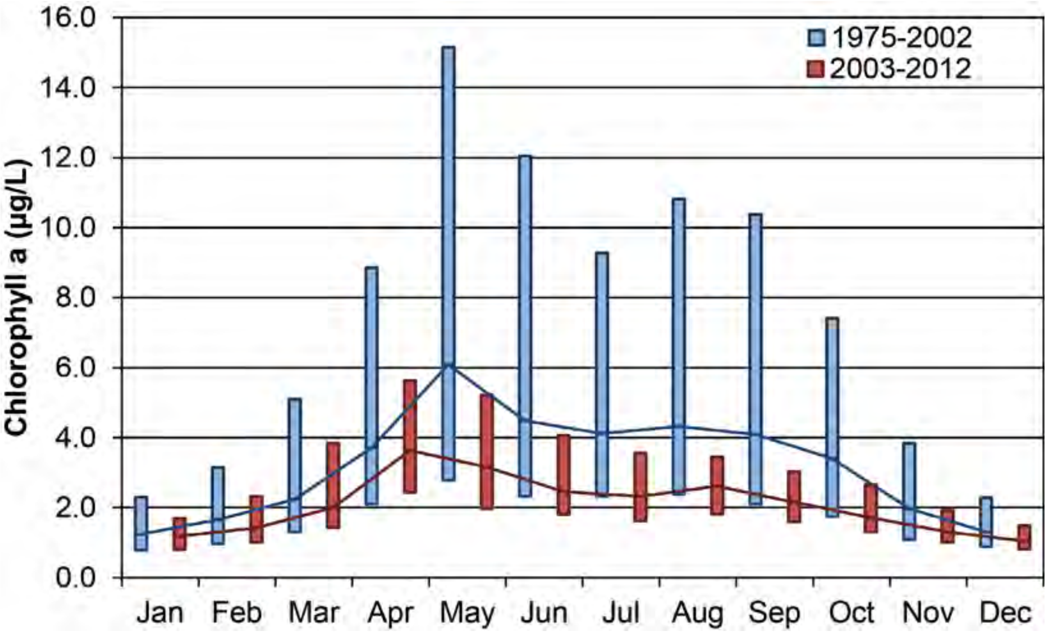
Food and Feeding

The presence of food is, obviously, a critical habitat attribute for any organism; however, the factors determining the quantity and quality of available food can be quite complex. In this section, we begin with a brief review of information about trophic processes in the upper SFE. We then discuss the available data on prey consumed by Delta Smelt. Finally, we provide a review of information on factors possibly affecting abundance and quality of food organisms.

Estuaries are commonly characterized as highly productive nursery areas for a suite of organisms. Productivity of estuarine ecosystems is often fueled by detritus-based food webs. In the SFE, much of the community metabolism in pelagic waters does result from microbial consumption of organic detritus. However, evidence suggests that metazoan production in pelagic waters is primarily driven by phytoplankton production (Sobczak et al. 2002, 2005, Mueller-Solger et al. 2002, 2006, Kimmerer et al. 2005). Protists (flagellates and ciliates) consume both microbial and phytoplankton prey (Murrell and Hollibaugh 1998, York et al. 2010) and are an additional important food source for many copepod species in the estuary (Rollwagen-Bollens and Penry 2003, Bouley and Kimmerer 2006, Gifford et al. 2007, McManus et al. 2008). However, the conversion of dissolved and particulate organic matter to microbial biomass and then to zooplankton is a relatively slow and inefficient process. Shifts in phytoplankton and microbial food resources for zooplankton might favor different zooplankton species. Moreover, phytoplankton production and biomass in the SFE is low compared to many other estuaries (e.g., Jassby et al. 2002, Kimmerer et al. 2005, Wilkerson et al. 2006, Cloern and Jassby 2012). The recognition that phytoplankton production might impose limits on pelagic fishes, such as Delta Smelt, through food availability has led to intense interest in factors affecting phytoplankton production and species composition and in management actions aimed at enhancing high-quality phytoplankton production. In addition, there is a major need to understand other trophic pathways given the observation that larger Delta Smelt periodically can take advantage of epibenthic prey (see below).

Phytoplankton biomass (measured as chlorophyll-*a*) has been routinely monitored in the estuary since the 1970s. The 1975-2012 median chlorophyll-*a* concentration across all IEP EMP stations is 2.8 µg/L (n = 13482, interquartile range (IQR) = 5 µg/L). Seasonally, the highest chlorophyll-*a* concentrations tend to be observed in May and June and the lowest concentrations in December and January (Fig. 32). Regionally, monitoring stations in the South Delta/San Joaquin River usually have the highest chlorophyll-*a* concentrations. There has been a well-documented long-term decline in phytoplankton biomass (chlorophyll-*a*) and primary productivity (estimated from measurements of chlorophyll-*a* and of water column light utilization efficiency) to very low levels in the Suisun Bay region and the lower Delta (Jassby et al. 2002). Jassby et al. (2002) detected a 47% decline in June–November chlorophyll-*a* and a 36% decline in June–November primary production between the periods 1975–1985 and 1986–1995. Jassby (2008) updated the phytoplankton analysis to include the more recent data (1996–2005) from the Delta and Suisun Bay. Jassby (2008) confirmed a long-term decline in chlorophyll-*a* from 1975 to 2005 but also found that March–September chlorophyll-*a* had an increasing trend in the Delta from 1996 to 2005. Suisun Bay did not exhibit any trend during 1996–2005. A similar pattern was noted for primary production in the Delta. These chlorophyll-*a* patterns continued to hold through 2008 according to a more recent study by Winder and Jassby (2011). In the most recent decade (2003-2012), the median chlorophyll-*a* concentration across all IEP EMP stations was 2 ug/L (n = 2620, IQR = 2 ug/L), compared to the 1975-2002 median chlorophyll-*a* concentration of 3 ug/L (n = 10862, IQR = 6 ug/L) (Fig. 32). Most of the decrease was due to declines during May-October and especially the near-elimination of the formerly common “spring bloom” of phytoplankton in May (Fig. 32). In summary, phytoplankton biomass and production in the Delta and Suisun Bay seem to have reached a low point by the end of the 1987–1994 drought. While they recovered somewhat in the Delta, chlorophyll-*a* stayed consistently low in Suisun Bay through the POD years.

Figure 32. **Interquartile ranges (boxes) and medians (lines) for chlorophyll-*a* measured monthly at all IEP EMP stations from 1975-2002 (blue) and 2003-2012 (red). Data from http://www.water.ca.gov/bdma/.**



A major reason for the long-term phytoplankton reduction in the upper SFE after 1985 is benthic grazing by the invasive overbite clam (*Potamocorbula amurensis* also known as *Corbula amurensis*) (Alpine and Cloern 1992), which became abundant by the late 1980s (Kimmerer 2002). The overbite clam was first reported from San Francisco Estuary in 1986 and it was well established by 1987 (Carlton et al. 1990). Prior to the overbite clam invasion, the invasive Asiatic freshwater clam (*Corbicula fluminea*) (introduced in the 1940s) colonized Suisun Bay during high flow periods and the estuarine clam *Mya arenaria* (also known as *Macoma balthica*, an earlier introduction) colonized Suisun Bay during prolonged (> 14 month) low flow periods (Nichols et al. 1990). Thus, there were periods of relatively low clam grazing rates while one species was dying back and the other was colonizing, resulting in neither reaching high abundances. The *P. amurensis* invasion changed this formerly dynamic clam assemblage because *P. amurensis*, which is tolerant of a wide range of salinity, can maintain large, permanent populations in the brackish water regions of the estuary. *P. amurensis* biomass and grazing usually increase from spring to fall which contributes to the reduction in phytoplankton biomass from May to October relative to historical levels. In addition, the grazing influence of *P. amurensis* extends into the freshwater Delta beyond the clam's typical brackish salinity range, presumably due to tidal dispersion of phytoplankton-depleted water between regions of brackish water and fresh water (Kimmerer and Orsi 1996, Jassby et al. 2002).

Phytoplankton production in the SFE has been considered primarily light-limited because nutrient concentrations commonly exceed concentrations limiting primary production. According to some recent work, shifts in nutrient concentrations and ratios may, however, also contribute to the phytoplankton reduction and changes in algal species composition in the SFE. Nutrients may also play a larger role in regulating phytoplankton dynamics in the estuary as the estuary clears and light availability increases (see turbidity section above).

While phosphorus (total phosphorous and soluble reactive phosphorous) concentrations declined in the Delta and Suisun Bay region over the last few decades, nitrogen (total nitrogen and ammonium) concentrations increased. These changes have been attributed to the operation of the Sacramento Regional Wastewater Treatment Plant (SRWTP), a large secondary treatment facility that was completed in 1984 (VanNieuwenhuyse 2007, Jassby 2008). As stated previously, ammonia has two forms, un-ionized ammonia (NH_3) which is toxic to aquatic organisms and the ammonium ion (NH_4+) which is considerably less toxic to animals and an important nutrient for plants and algae (Thurston et al. 1981). Ammonia exists in equilibrium between the two forms dependent primarily on the pH of the water, but also temperature, with increases in pH and temperature favoring the un-ionized form (Thurston et al. 1981). Dugdale et al. (2007) and Wilkerson et al. (2006) found that high ammonium concentrations prevented the formation of diatom blooms but stimulated flagellate blooms in the lower estuary. They propose that this occurs because diatoms preferentially utilize ammonium in their physiological processes even though it is used less efficiently and at high concentrations ammonium can prevent uptake of nitrate (Dugdale et al. 2007). Thus, diatom populations must consume available ammonium before nitrate, which supports higher growth rates, can be utilized or concentrations of ammonium need to be diluted. A recent independent review panel (Reed et al. 2014) found that there is good evidence for preferential uptake of ammonium and sequential uptake of first ammonium and then nitrate, but that a large amount of uncertainty remains regarding the growth rates on ammonium relative to nitrate and the role of ammonium in suppressing spring blooms.

Glibert (2012) analyzed long-term data (from 1975 or 1979 to 2006 depending on the variable considered) from the Delta and Suisun Bay and related changing forms and ratios of nutrients, particularly changes in ammonium, to declines in diatoms and increases in flagellates and cyanobacteria. Similar shifts in species composition were noted by Brown (2009), with loss of diatom species, such as *Thalassiosira sp*., an important food for calanoid copepods, including *Eurytemora affinis* and *Sinocalanus doerri* (Orsi 1995). More recently, Parker et al. (2012) found that the region where blooms are suppressed extends upstream into the Sacramento River to the SRWTP, the source of the majority of the ammonium in the river (Jassby 2008). Parker et al. (2012) found that at high ambient ammonium concentrations, river phytoplankton cannot efficiently take up any form of nitrogen including ammonium, leading to often extremely low biomass in the river. A study using multiple stable isotope tracers (Lehman et al. 2014) found that the cyanobacteria *M. aeruginosa* utilized ammonium, not nitrate, as the primary source of nitrogen in the central and western Delta. In 2009, the ammonia concentration in effluent from SRWTP was reduced by approximately 10%, due to changes in operation (K. Ohlinger, Sacramento Regional County Sanitation District, personal communication). In spring 2010 unusually strong spring diatom blooms were observed in Suisun Bay that co-occurred with low ammonia concentrations (Dugdale et al. 2013).

Jassby (2008) suggested the following comprehensive explanation for his observations. Phytoplankton production in the lower Delta is associated with flow and residence time; however, other factors introduce a substantial degree of interannual variability. Benthic grazing by *C. fluminea* is likely a major factor as grazing can exceed rates of primary production (Lucas et al. 2002, Lopez et al. 2006) and are abundant year round at some locations in the Delta (Fuller 2012). Current data are inadequate to estimate the overall magnitude of the grazing effect of *C. fluminea*. In Suisun Bay, benthic grazing by *P. amurensis* is a controlling factor that keeps phytoplankton at low levels. Thus, metazoan populations in Suisun Bay are dependent on importation of phytoplankton production from the upstream portions of the Delta. Upstream Delta phytoplankton can be lost via exports and within-Delta depletion; Cloern and Jassby (2012) reported phytoplankton losses equivalent to 30% of the primary production in the Delta. Ammonium concentrations and water clarity have increased; however, these two factors should have opposing effects on phytoplankton production. These factors likely also contribute to variability in the interannual pattern but the relative importance of each is unknown. The interactions among primary production, grazing, and transport time can be complex (Lucas et al. 2002, 2009a,b, Lucas and Thompson 2012).

The changes in phytoplankton production and invasion and establishment of the overbite clam *P. amurensis* were also accompanied by a series of major changes in consumers (Winder and Jassby 2011). Many of these changes likely negatively influenced pelagic fish production, including Delta Smelt. The quantity of food available to Delta Smelt is a function of several factors, including but not limited to seasonal trends in prey abundance and prey species specific salinity tolerances, which influence distribution (Kimmerer and Orsi 1996, Hennessy and Enderlein 2013). Seasonal peaks in abundance vary among calanoid copepods consumed as prey by Delta Smelt, *E. affinis* in April-May (Fig. 33), *P. forbesi* in July (Fig. 34), and *A. sinensis* in Sep-Oct (Fig. 35). Upstream, the calanoid copepod *S. doerrii* is most abundant May-June (Fig. 36). The seasonal trend in cladocerans (Fig. 37) and mysid (Fig. 38) prey are similar, being most abundant in summer.

From March through June, larval Delta Smelt rely heavily on first juvenile, then adult stages of the calanoid copepods *Eurytemora affinis* and *Pseudodiaptomus forbesi*, as well as cladocerans (Nobriga 2002, Hobbs et al. 2006, Slater and Baxter 2014), and *Sinocalanus doerrii* (Fig. 39). Nobriga (2002) found that Delta Smelt larvae expressed positive selection for *E. affinis* and *P. forbesi*, consuming these prey species in greater proportion than available in the environment. Such selection was not noted for other zooplankton prey. Regional differences in food use occur,

with *E. affinis* and *P. forbesi* being major prey items downstream in the LSZ with a transition to *S. doerrii* and cyclopoid copepods as major prey items upstream into the Cache Slough-Sacramento River Deepwater Ship Channel (CS-SRDWSC) (Fig. 39).

Juvenile Delta Smelt (June-September) rely extensively on calanoid copepods such as *E. affinis* and *P. forbesi*, especially in freshwater (salinity < 1) and CS-SRDWSC but there is great variability among regions (figs. 40-43). Larger fish are also able to take advantage of mysids,

cladocerans, and amphipods (Moyle et al. 1992, Lott 1998, Feyrer et al. 2003, Steven Slater, California Department of Fish and Wildlife, unpublished data) (Figs. 34-37). The presence of several epibenthic species in diets therefore indicates that food sources for this species are not confined to pelagic pathways. Such food sources may be especially important in regions of the estuary where there is extensive shoal habitat such as Liberty Island (Steven Slater, California Department of Fish and Wildlife, unpublished data).

Subadult Delta Smelt (September through December) prey items are very similar to those of juvenile Delta Smelt but with increased variability in diet composition (Moyle et al. 1992, Lott 1998, Steven Slater, California Department of Fish and Wildlife, unpublished data) (Figs. 40-43) coinciding with the seasonal decline in pelagic zooplankton, such as *P. forbesi* (Fig. 34) and mysids (Fig. 38). Food habits of adult Delta Smelt during the winter and spring (January-May) have been less well documented (Moyle et al. 1992). In 2012, diet of adults in the LSZ and

< 1 ppt were found to include cyclopoid copepods, other than *Limnoithona* spp., with a mix of larger prey types, amphipods, cladocerans, cumaceans, and larval fish and in CS-SRDWSC the calanoid copepod *S. doerrii* continued to be a large portion of the diet (Steven Slater, California Department of Fish and Wildlife, unpublished data) (Fig. 44). Larval fish found in stomachs of Delta Smelt in the higher salinity areas were primarily Pacific Herring (*Clupea pallasii*), with

some Longfin Smelt, and Prickly Sculpin (*Cottus asper*) in the Sacramento River and CS-SRDWSC region; no Delta Smelt larvae were found in the stomachs of adults (Steven Slater, California Department of Fish and Wildlife, unpublished data).

The large proportion of benthic amphipods, cumaceans, and some cladocerans (*Camptocercus* spp.) in the diet is a notable change from Delta Smelt diet in the 1970s. Delta Smelt diets historically did include amphipods, notably *Corophium* spp. (Moyle et al. 1992), yet it was a small fraction of a mostly pelagic based diet. The considerable use of benthic invertebrates for food in recent years is believed to be in large part due to food limitation associated with the long-term decline and changes in composition of the pelagic food web (Slater and Baxter 2014). The quality of benthic invertebrates as food is not currently understood, but amphipods are lower in energy (calories per gram) than copepods (Cummins and Wuychek 1971, Davis 1993) and mysids (Davis 1993).

As noted previously, the changes in phytoplankton production and phytoplankton species abundances observed and the invasion of *P. amurensis* may have had important consequences for consumer species preyed upon by Delta Smelt. For example, there has been a decrease in mean zooplankton size (Winder and Jassby 2011) and a long-term decline in calanoid copepods, including a major step-decline in the abundance of the copepod *E. affinis*. These changes are possibly due to predation by the overbite clam (Kimmerer et al. 1994) or indirect effects of clam grazing on copepod food supply. Predation by *P. amurensis* may also have been important for other zooplankton species (Kimmerer 2008). Northern Anchovy *Engraulis mordax* abandoned the low salinity zone coincident with the *P. amurensis* invasion, presumably because the clam reduced planktonic food abundance to the point that occupation of the low-salinity waters was no longer energetically efficient for this marine fish (Kimmerer 2006). Similarly, Longfin Smelt *Spirinchus thaleichthys* shifted its distribution toward higher salinity in the early 1990s, also presumably because of reduced pelagic food in the upper estuary (Fish et al. 2009). There was also a decline in mysid shrimp (Winder and Jassby 2011), including a major step-decline in 1987–1988, likely due to competition with the overbite clam for phytoplankton (Orsi and Mecum 1996). Mysid shrimp had been an extremely important food item for larger fishes like Longfin Smelt and juvenile Striped Bass (Orsi and Mecum 1996), and may be consumed by larger Delta Smelt (Moyle et al. 1992). The decline in mysids was associated with substantial changes in the diet composition of these and other fishes, including Delta Smelt (Feyrer et al. 2003, Bryant and Arnold 2007). The population responses of Longfin Smelt and juvenile Striped Bass to winter–spring outflows changed after the *P. amurensis* invasion. Longfin Smelt relative abundance was lower per unit outflow after the overbite clam became established (Kimmerer 2002b). Age-0 Striped Bass relative abundance stopped responding to outflow altogether (Sommer et al. 2007). One hypothesis to explain these changes in fish population dynamics is that lower prey abundance reduced the system carrying capacity (Kimmerer et al. 2000, Sommer et al. 2007).

In addition to a long-term decline in calanoid copepods and mysids in the upper Estuary, there have been numerous copepod species introductions (Winder and Jassby 2011). *P. forbesi*, a calanoid copepod that was first observed in the estuary in the late 1980s, has replaced *E. affinis* as the most common Delta Smelt prey during the summer. It may have a competitive advantage over *E. affinis* due to its more selective feeding ability. Selective feeding may allow *P. forbesi* to utilize the remaining high-quality algae in the system while avoiding increasingly more prevalent low-quality and potentially toxic food items such as *M. aeruginosa* (Mueller-Solger et al. 2006, Ger et al. 2010a). After an initial rapid increase in abundance, *P. forbesi* declined somewhat in abundance from the early 1990s in the Suisun Bay and Suisun Marsh regions but maintained its abundance, with some variability, in the central and southern Delta (Winder and Jassby 2011).

Although substantial uncertainties about mechanisms remain, the decline of *P. forbesi* in the Suisun region may be related to increasing recruitment failure and mortality in this region due to competition and predation by *P. amurensis*, contaminant exposures, and entrainment of source populations in the Delta (Mueller-Solger et al. 2006, Winder and Jassby 2011, Durand 2010).

The abundance of a more recent invader, the cyclopoid copepod *Limnoithona tetraspina*, significantly increased in the Suisun Bay region beginning in the mid-1990s. It is now the most abundant copepod species in the Suisun Bay and confluence region of the estuary (Bouley and Kimmerer 2006, Winder and Jassby 2011). Gould and Kimmerer (2010) found that it grows slowly and has low fecundity. Based on these findings they concluded that the population success of *L. tetraspina* must be due to low mortality and that this small copepod may be able to avoid visual predation to which larger copepods are more susceptible. It has been hypothesized that *L. tetraspina* is an inferior food for pelagic fishes including Delta Smelt because of its small size, generally sedentary behavior, and ability to detect and avoid predators (Bouley and Kimmerer 2006, Gould and Kimmerer 2010). Nevertheless, this copepod has been found in the guts of Delta Smelt when *Limnoithona* spp. occurrs at extremely high densities relative to other zooplankton (Slater and Baxter 2014). Recent experimental studies addressing this issue suggest that larval Delta Smelt will consume and grow on *L. tetraspina*, but growth is slower than with *P. forbesi* (Kimmerer et al. 2011). It remains unclear if consuming this small prey is energetically beneficial for Delta Smelt at all sizes or if there is a breakpoint above which larger Delta Smelt receive little benefit from such prey. *Acartiella sinensis*, a calanoid copepod species that invaded at the same time as *L. tetraspina*, also reached considerable densities in Suisun Bay and the western Delta over the last decade (Hennessy 2010), although its suitability as food for pelagic fish species remains unclear.

Preliminary information from studies on pelagic fish growth, condition, and histology provide additional evidence for food limitation in pelagic fishes in the estuary (IEP 2005). In 1999 and 2004, Delta Smelt growth was low from the Sacramento-San Joaquin confluence through Suisun Bay relative to other parts of the system. Delta Smelt collected in 2005 from the Sacramento-San Joaquin confluence and Suisun Bay also had high incidence of liver glycogen depletion, a possible indicator of food limitation (Bennett et al. 2008). As previously noted, warm water temperatures during the summer period may have exacerbated lack of food by raising the metabolic rate of Delta Smelt. Based on data for histopathology, date of birth from otoliths, and growth rates from otoliths of Delta Smelt in 2005, Bennett et al. (2008) proposed a novel strategy for Delta Smelt survival in 2005. Natural selection appeared to favor individuals with a specific set of characters, including relatively slow larval development, but faster than average juvenile growth in July. Water temperatures in July typically include the annual maximum (Fig. 16). The salinity field can also change rapidly as freshwater flow out of the Delta changes. Many of these fish surviving into the pre-adult stage had also hatched earlier in the spawning season (i.e., before May).

For many fishes, success at first feeding is believed to be critical to larval survival and a major cause of year-class variability (e.g., “critical period hypothesis,” Hjort 1914, Leggett and DeBlois 1994). In Rainbow Smelt *Osmerus mordax* a related smelt species, calculated larva mortality rates were related to feeding conditions at first feeding that varied on a predictable cycle of 15 days associated with tide and photoperiod (Sirois and Dodson 2000b). In feeding experiments, copepod evasion behavior affected capture by larval Striped Bass, and *E. affinis* was among the more easily captured species (Meng and Orsi 1991). There has been a long-term decline in calanoid copepods in the upper estuary, particularly in the Suisun Region (Winder and Jassby 2011), potentially reducing feeding success, growth and thereby survival. Currently, *E. affinis* abundance peaks in spring (Hennessy 2010, 2011) coincident with hatching of Delta Smelt. *E. affinis* abundance has been negatively related to X2 since the overbite clam invasion (Kimmerer 2002b). When X2 is "high" outflow is low and *E. affinis* densities are low. These lines of evidence suggest that the first feeding conditions may improve in springs with higher outflow.

Changes in the quality and quantity of available prey may have contributed to the observed reduction in the mean size of Delta Smelt in fall since the early 1990s (Sweetnam 1999, Bennett 2005); however, mean size subsequently increased. The importance of food resources as a driver is supported by Kimmerer (2008), who showed that Delta Smelt survival from summer to fall is correlated with biomass of copepods in the low salinity zone, the central 50% of the summer Delta Smelt distribution. Other variations of this correlation were shown by Maunder and Deriso (2011) and Miller et al. (2012). Miller et al. (2012) have tested for an explicit influence of prey density during the fall. Miller et al. (2012) found a stronger correlation between Delta Smelt abundance during the fall and prey density during the fall than for prey density during the summer.

Harmful algal blooms

Periodic blooms of the toxic blue-green alga *Microcystis aeruginosa* during late summer, most commonly August and September are an emerging concern for Delta Smelt (Lehman et al. 2005, Lehman et al. 2013). Although this harmful algal bloom (HAB) typically occurs in the San Joaquin River away from the core summer distribution of Delta Smelt, some overlap is apparent during blooms and as cells and toxins are dispersed downstream after blooms (Baxter et al. 2010). Density rankings of *Microcystis* at TNS stations were highest in the south Delta, east Delta and lower San Joaquin River regions; yet *Microcystis* distribution may be expanding north over time (Morris 2013). Moreover, studies by Lehman et al. (2010) suggest that Delta Smelt likely are exposed to microcystins, which may degrade their habitat and perhaps affect the distribution of Delta Smelt (Baxter et al. 2010). For example, these HABs are known to be toxic to another native fish of the region, Sacramento Splittail (Acuña et al. 2012a) and the alien Threadfin Shad (Acuña et al. 2012b). Histopathology evidence from Lehman et al. (2010) suggested the health of two common fish in the estuary, Striped Bass, and Mississippi Silversides, was worse at locations where microcystin concentrations were elevated.

Indirect effects are also likely as *Microcystis* blooms are toxic to copepods that serve as the primary food resources of Delta Smelt (Ger et al. 2009, 2010a,b). Ger et al. (2009) determined toxicity of one form of microcystin (LR) to two species of calanoid copepods, *E. affinis* and *P. forbesi*, which are important as food to Delta Smelt. They found that, although the copepods tested were relatively sensitive to microcystin-LR compared to other types of zooplankton, ambient concentrations in the Delta were unlikely to be acutely toxic. However, chronic effects were not determined and Lehman et al. (2010) found that *Microcystis* may indeed contribute to changes in phytoplankton, zooplankton and fish populations in the Delta.

Factors that are thought to cause more intensive *Microcystis* blooms include warmer temperatures, lower flows, high nitrogen levels, and relatively clear water (Lehman et al. 2005, Baxter et al. 2010, Lehman et al. 2013, Morris 2013). These conditions occur during dry years in the SFE. Both *Microcystis* abundance and microcystin concentrations have been greater in recent years with dry year conditions (Lehman et al. 2013). These factors can also interact. For example, low flows can provide less dilution of ammonium from wastewater treatment plants (Jassby and Van Nieuwenhuyse 2005, Dugdale et al. 2012, Dugdale et al. 2013) and *Microcystis* can readily utilize ammonium as a primary nitrogen source during blooms (Lehman et al. 2013). The intensity and duration of *Microcystis* blooms are expected to increase over the long-term, along with any negative impact on aquatic organisms, due to increased frequency of drought conditions associated with climate change (Lehman et al. 2013).

Chapter 5: Updated Conceptual Models for Delta Smelt

In this Chapter we transfer the information on drivers and Delta Smelt responses reviewed and presented in Chapter 4 into the conceptual model framework established in Chapter 3. The Delta Smelt general life cycle conceptual model recognizes the pervasive, year-round importance of the tier 1 landscape attributes and the seasonal importance of the various tier 2 environmental drivers and tier 3 habitat attributes to the tier 4 life stage transitions of Delta Smelt in the four tier 5 “transition seasons” (Fig. 45). Some habitat attributes – food, toxicity, and predation – affect life stage transitions in all seasons, while other habitat attributes – temperature, entrainment and transport, size and location of the low salinity zone, and harmful algal blooms – affect some life stage transition more than others. Clearly, adequate food must be available at all life stages for Delta Smelt to survive. Toxicity is included during all seasons because we know that contaminants of various types are present throughout the year; however, little is known about the direct or indirect effects of contaminants at ambient concentrations on individual Delta Smelt or the population as a whole. Predation is included in all seasons because we recognize that predation is likely the ultimate cause of mortality for most individual fish; however, responses of Delta Smelt to other habitat attributes and environmental drivers such as food availability and turbidity can modify predation risk.

The mechanistic linkages between landscape attributes, environmental drivers, habitat attributes and Delta Smelt responses in the four life stage seasons are depicted as one-way arrows in four new “life stage transition” conceptual models (Figs. 46-49). As mentioned in Chapter 3, the life stage transition conceptual models are nested components of the general life cycle conceptual model (Fig. 8). Each life stage transition conceptual model (Figs. 46-49) includes the habitat attributes hypothesized to affect the transition of Delta Smelt from one life-stage to the next. Hypotheses selected for detailed consideration in Chapter 7 are indicated by “H” in the diagrams. The models also show the landscape attributes and environmental drivers. While the models include many linkages among individual landscape attributes, environmental drivers, and habitat attributes, they do not include linkages between individual habitat attributes and the specific biological processes (growth, survival, reproduction) underlying the life stage transitions. The primary reason for this simplification is that the available data are generally inadequate to fully describe and differentiate among specific functional relationships and mathematical modeling that could help estimate them is beyond the scope of this report. Instead, the combined effects of all habitat attributes on the life stage transition probability are depicted by one upward arrow in each life stage transition conceptual model. This does not imply, however, that all habitat attributes have an equal role in determining life stage transition probability and population success or that the role of each habitat attribute remains constant from year to year.

In the remainder of this Chapter we briefly describe the linkages and associated hypotheses depicted in each of the life stage transition conceptual model diagrams (figs. 46-49). These

Figure 45. **Delta Smelt general life cycle conceptual model.**

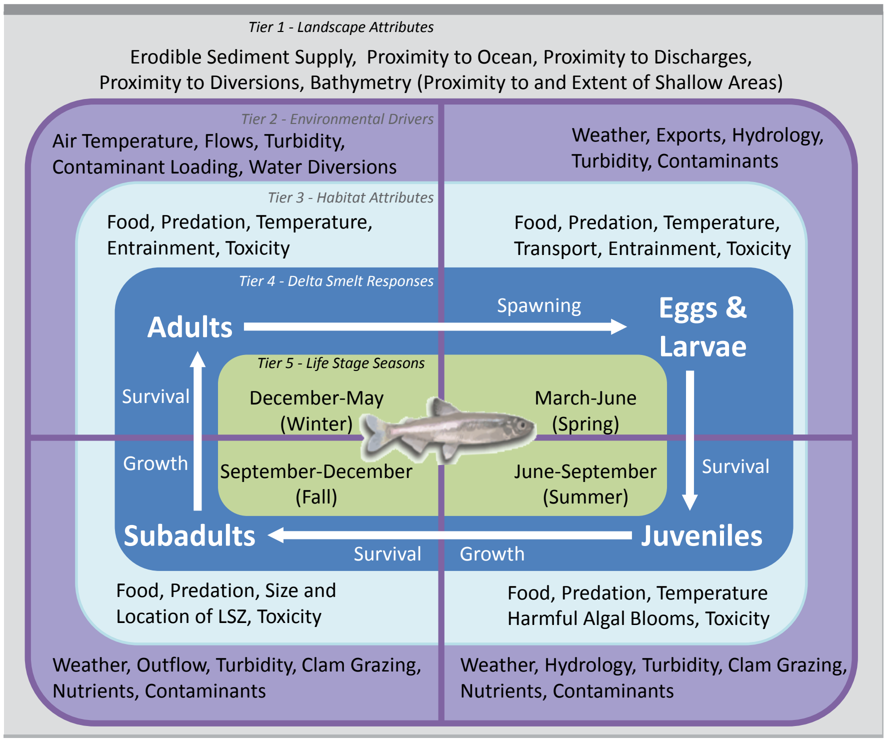

Figure 46. **Conceptual model of drivers affecting the transition from Delta Smelt adults to larvae. Hypotheses addressed in Chapter 7 are indicated by the "H-number" combinations.**

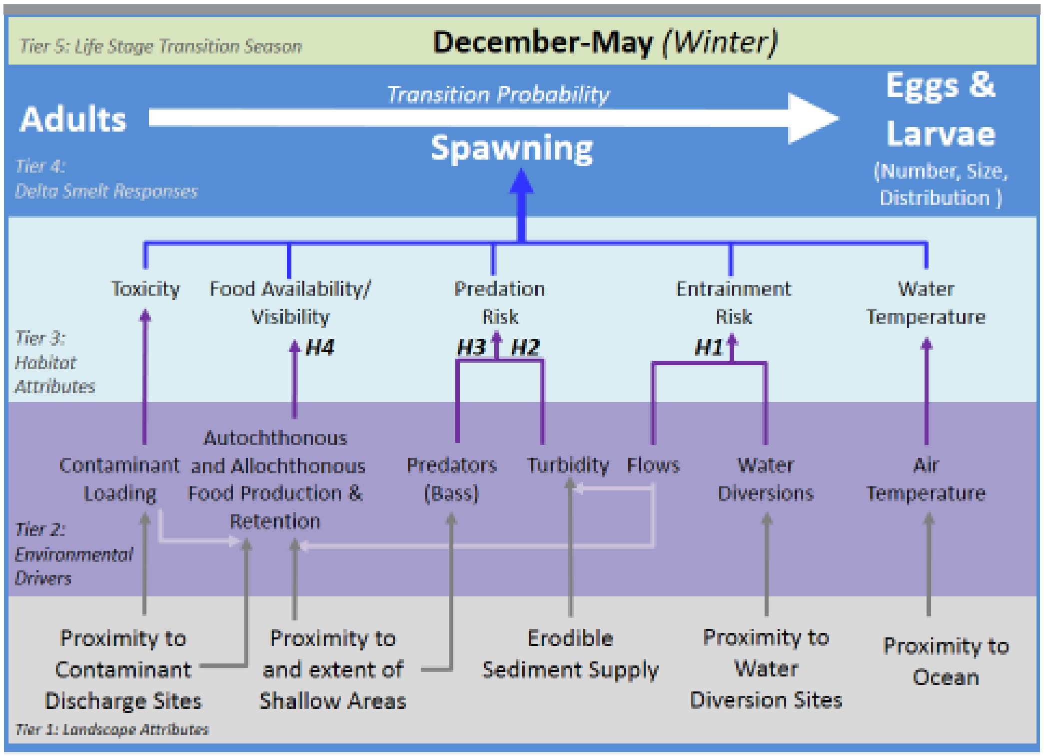

Figure 47. Conceptual model of drivers affecting the transition from Delta Smelt larvae to juveniles. Hypotheses addressed in Chapter 7 are indicated by the “H-number” combinations.

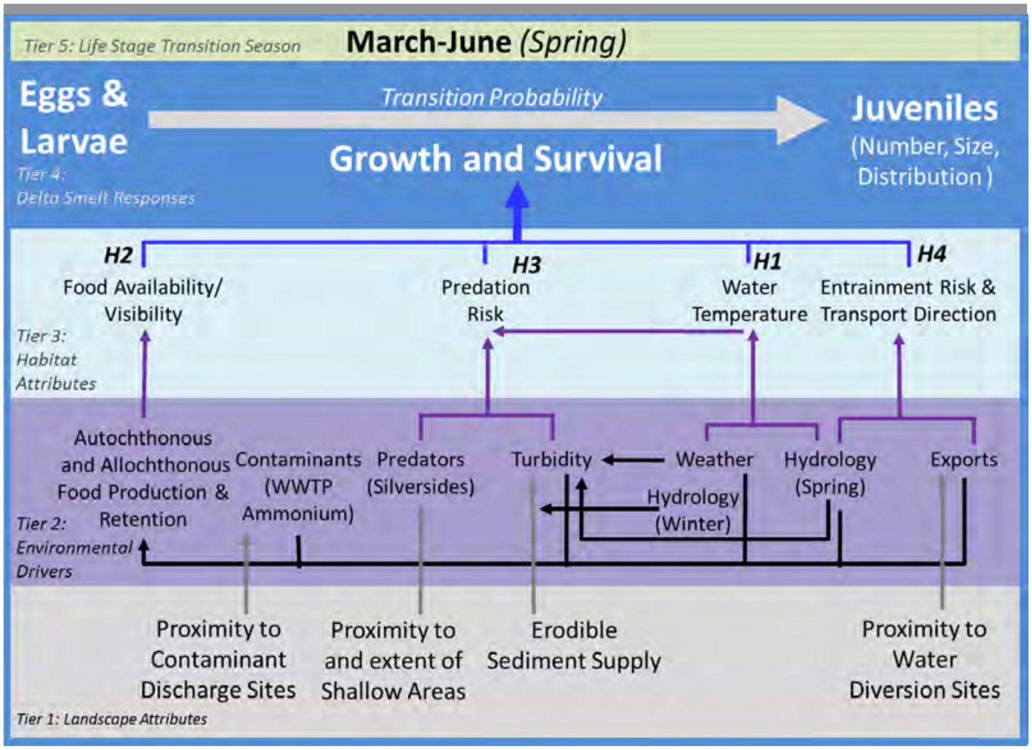

Figure 48. Conceptual model of drivers affecting the transition from Delta Smelt juveniles to subadults. Hypotheses addressed in Chapter 7 are indicated by the “H-number” combinations.

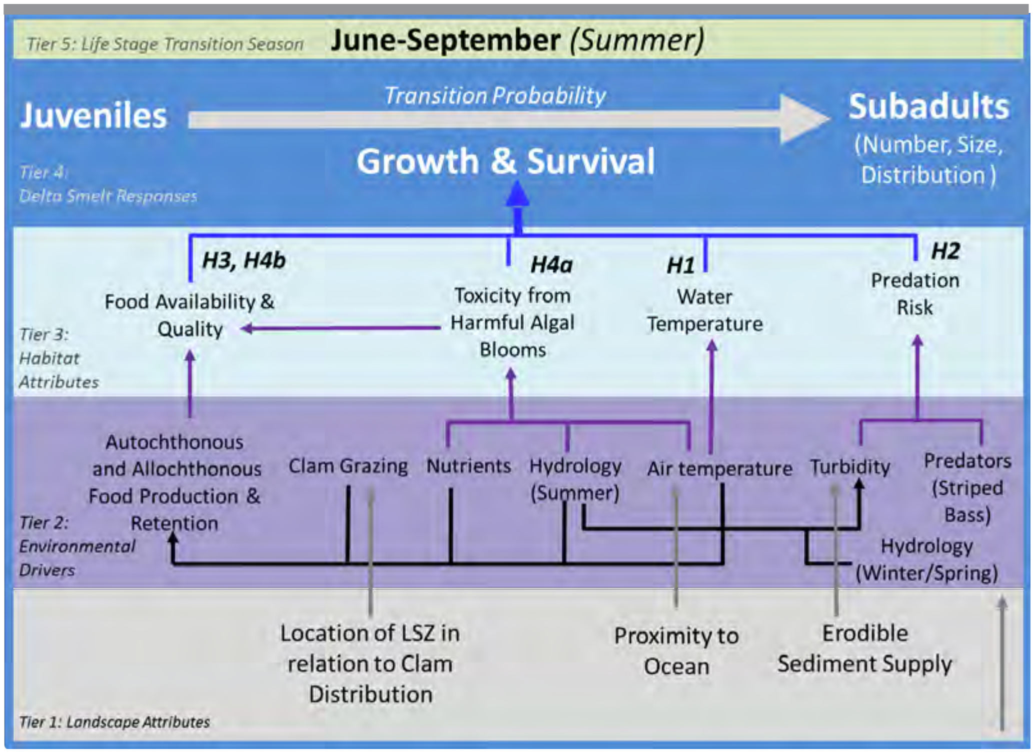

Figure 49. **Conceptual model of drivers affecting the transition from Delta Smelt subadults to adults. Hypotheses addressed in Chapter 7 are indicated by the "H-number" combinations.**

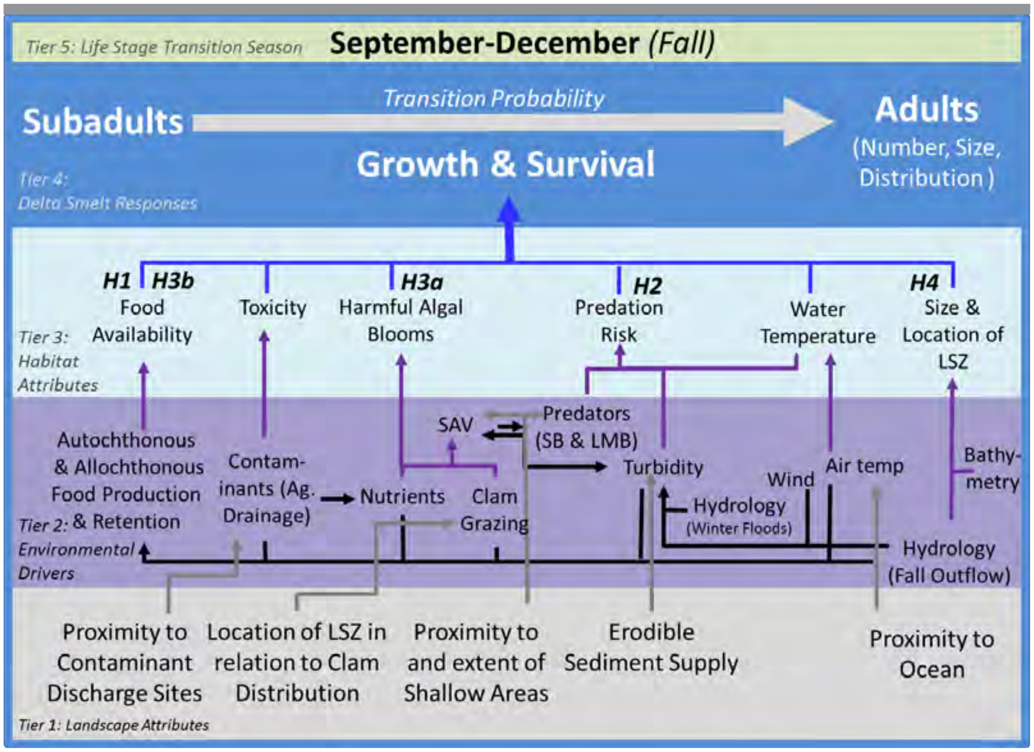


hypotheses are stated and addressed in more detail in Chapter 7. All hypotheses focus on the life stage that is transitioning to (i.e. occurs prior to) the next life stage, for example, adults but not eggs and larvae, larvae and post-larvae but not juveniles, and so on. That said, it is important to remember that all life stages overlap and all transitions except for the transitions from adults to eggs and from eggs to freshly hatched larvae are gradual, not abrupt, and delineations of life stages are somewhat arbitrary (see Chapter 3).

The life stage conceptual model for the transition of adult Delta Smelt to eggs and larvae (Fig. 46) includes 5 habitat attributes. Because of the lack of information about specific contaminant effects on Delta Smelt noted above, there are no specific hypotheses regarding the effects of contaminants and possible direct or indirect toxicity on Delta Smelt, but based on the information discussed in Chapter 4, the model does recognize that effects on Delta Smelt or its food supply may be occurring. Food availability and visibility are hypothesized to be important with respect to providing nutrition that allows Delta Smelt to grow into healthy, large adults that can produce a large numbers of high quality eggs as well as multiple clutches of eggs over the spawning season. The availability of food is considered dependent on both food production and the availability of such food to the fish. There are two hypotheses related to predation risk. The first is that turbidity, created by the interaction of high winter and spring flows with the erodible sediment supply in the watershed and within the Delta, influences the vulnerability of Delta Smelt to predators that co-occur with them. The second is that Delta Smelt behaviors that bring Delta Smelt close to channel edges may increase their vulnerability to Largemouth Bass, which generally occupy nearshore and vegetated habitats such as SAV beds. Entrainment risk in this life stage transition conceptual model is focused on adults. Entrainment of adults would reduce the reproductive potential of the population. Entrainment risk depends on the distribution of the adult Delta Smelt in relation to water diversions, and the magnitudes of water diversions and flows. Delta water temperature determines the beginning and duration of the spawning season (hereafter “spawning window”).

The life stage conceptual model for the transition of Delta Smelt eggs and larvae to juveniles includes 4 habitat attributes (Fig. 47). Food production and availability is important for the survival of larvae to juveniles. Food quantity is dependent on multiple interacting factors. Turbidity is important for early feeding by delta smelt larvae. Predation risk focuses on predation of Mississippi Silversides on Delta Smelt larvae because of recent evidence that such predation occurs. Predation risk is hypothesized to depend on co-occurrence of the two species, with Mississippi Silverside generally being associated with shallower waters, turbidity, which decreases the effectiveness of predators, and water temperature, which affects energy requirements of predators (hunger level). In addition to its effect on predator bioenergetics, water temperature is hypothesized to affect the length of the spawning season (spawning window). If food availability is sufficient, then a longer spawning window may allow the adult population to produce multiple clutches of eggs, resulting in more young. This hypothesis could arguably be included in the previous life stage transition conceptual model, but considering it here allows for consideration of predation on larvae in the context of the time period over which larvae are being produced. Larvae are also at risk of entrainment or transport to unfavorable areas. The magnitude of this risk is hypothesized to depend on an interaction of spring hydrology and water exports. As indicated by numerous arrows, winter and spring hydrology affect Delta Smelt spawning and larval rearing habitat in many ways. We thus also include a more general hypothesis about the hydrological effects on Delta Smelt larval abundance and recruitment.

The life stage conceptual model for the transition of Delta Smelt juveniles to subadults includes 4 habitat attributes (Fig. 48). In addition, there is a stand-alone hypothesis dealing with population dynamics. Juvenile growth and survival is hypothesized to depend on availability and quantity of food. Food production during this summer period is hypothesized to involve complex interactions of clam grazing, nutrients, hydrology and harmful algal blooms. The probability of observing a harmful algal bloom is hypothesized to be a function of the same factors but with temperature playing an important role. Harmful algal blooms may also affect Delta Smelt directly through production of toxic microcystins. Summer water temperatures are hypothesized to have a very direct effect on juvenile Delta Smelt with water temperatures hypothesized to reach stressful levels, affecting their bioenergetics and the area of suitable habitat. The transition probability hypothesis is that at the currently small population sizes, survival from juvenile to subadult is density independent, meaning independent of the number of individuals present (see Chapter 6 for details).

The life stage conceptual model for the transition of Delta Smelt subadults to adults includes 6 habitat attributes (Fig. 49). As for the previous conceptual model, there is a stand-alone hypothesis dealing with population dynamics. As in the previous conceptual model, growth and survival are hypothesized to depend on food availability and food production and availability depends on interactions of a variety of landscape attributes and environmental drivers. Toxicity is recognized as potentially important but no specific hypotheses have been tested. Harmful algal blooms may still be present with hypothesized direct effects on Delta Smelt subadults and indirect effects on their food. Predation risk on subadult Delta Smelt is hypothesized to depend on co-occurrence of Delta Smelt with the two most likely predators, Largemouth Bass and Striped Bass. Largemouth Bass occurrence is linked with that of SAV and the vulnerability of prey to both predators is affected by turbidity and bioenergetics. Water temperature is mainly hypothesized to have an effect through bioenergetics because water temperature becomes less stressful than in the summer. In this conceptual model the size and location of the LSZ is considered both a landscape attribute and a habitat attribute. In the earlier conceptual models, the LSZ was mainly viewed as a landscape attribute that interacted with other landscape attributes and environmental drivers to create habitat attributes. In this conceptual model the size and position of the LSZ is hypothesized to have certain characteristics that directly determine habitat quantity and quality for Delta Smelt. The transition probability hypothesis is that at the currently small population sizes, survival from subadult to adult is density independent, meaning independent of the number of individuals present (see Chapter 6 for details).

Chapter 6: Delta Smelt Population Biology

This Chapter consists of two main parts. In the first part, we introduce general concepts in population biology that are utilized in the following sections of this Chapter and to generally describe Delta Smelt population dynamics. Explaining these concepts and population trends now is intended to reduce repetitive text in the remaining sections and to reduce possible confusion for readers unfamiliar with the concepts. The concepts are discussed specifically in the context of Delta Smelt.

In the second part of this Chapter, we review information about the life history and population trends of each Delta Smelt life stage represented in our conceptual models, starting with adults. While we describe trends over the entire available time series for each life stage, we pay particular attention to differences in Delta Smelt abundance and life stage transitions between the two most recent wet years, 2006 and 2011. Our working assumption is that these differences should be attributable to differing habitat conditions and, in some cases, management actions. Differences in habitat conditions between these two years will be further explored in Chapter 7.

Population Biology

Recruitment is the addition of new individuals to a population through reproduction or immigration. In fisheries science, the term recruitment was first used by Ricker (1954) to describe the addition of fish of a new generation to a fish population, in other words, the number of young surviving to a particular age or life stage. We use the term recruitment to refer to production of larvae, juveniles, subadults, or adults by adults of the previous generation. Relationships between numbers of spawning fish or other measures of potential spawning stock (e.g., numbers of subadult or mature prespawning fish) and the numbers of fish of a given age or life stage in the subsequent generation are known as stock-recruitment relationships.

Stock-recruitment relationships have been described for many species and are a central part of the management of commercially and recreationally fished species (Myers et al. 1995, Touzeau and Gouze 1998). Different forms of stock-recruitment relationships are possible, including density-independent, density-dependent, and density-vague types. The density-independent type occurs when the current size of the population has little or no effect on the number of recruits (except possibly when stock size is extremely low). This type of population growth is rare in fish populations and occurs when environmental factors largely determine the survival and number of recruits (e.g., the Longfin Smelt outflow abundance relationship; see Myers 1998). Density dependence occurs when the current population size affects survival and abundance of recruits and thus population growth. In such populations, within the lower range of stock size, the number of recruits is strongly and positively related to stock size. At some point as stock size increases, competition for food (or some other limiting factor) between the adult population and recruits affects survival and abundance of recruits; cannibalism is another means by which recruitment can be affected by stock size. Thus, the growth and survival of the recruit population strongly depends on the density of the stock population. In reality it's difficult to determine which type of response is occurring (e.g., Myers and Barrowman 1996). Moreover, a predominantly annual fish, such as Delta Smelt, is predicted to conform poorly to models that assume density-dependent recruitment (Winemiller 2005), which appears to be the case (e.g., Rose et al. 2013).

The idea of density dependence is related to the idea of carrying capacity. The carrying capacity of an ecosystem is the number of individuals of all species that can be supported by the available resources. In reality it can be very difficult to apply this idea to a single species in an ecosystem because of the complex relationships among species and the seasonal, annual, and other changes in resource availability. The density vague type of population growth refers to situations where there is not a statistically demonstrable stock-recruitment relationship observable in available data.

In density-dependent stock-recruitment relationships, the factors causing the density dependence can operate at various points in the life cycle of the new generation. For some species, the concept of density dependence is separated into two concepts. In this formulation, density-dependent stock recruitment is limited to the direct effects of the adult stock on recruitment of the next generation, as described above. For example, if a large spawning stock has a limited spawning area, as in the case of salmonids, then successive waves of female spawners are known to re-excavate previous nests while building their own, substantially increasing mortality of the eggs. Density dependence could also occur at the larval or juvenile stage if adults are predatory and feed on young, or if adults are in direct competition for food or space with young. The second concept of density-dependent survival is often inextricably linked to density-dependent stock-recruit relationships because the mechanisms causing declines in recruits at high stock levels are unknown. In density-dependent survival, the abundance of young affects their own survival.

In the case of Delta Smelt, density dependent survival could occur if many of the larvae starved because of insufficient food supplies due to competition with other Delta Smelt larvae, or other species. Because many Delta Smelt die after their first spawning, density-dependent survival is certainly the dominant mechanism for the species and for the remainder of this report the direct effects of adults on survival of eggs and larvae are assumed to be minimal. If resources were sufficient for larvae and juvenile fish to survive in large numbers, the surviving subadults might overwhelm food sources (i.e., surpass carrying capacity), resulting in low survival and poor reproductive output. Thus, it is important to understand species ecology and survival between life stages to understand how density dependence is affecting a population. This is particularly important for fishes in estuaries where environmental factors can create large variation in habitat size and food web productivity from season to season and year to year, thus affecting carrying capacity and the potential for density-dependent survival.

Density-independence is more straightforward. In this case, the population is controlled by factors unrelated to the density of the population. For example, high water temperatures will affect individual fish, whether the population is large or small. In reality, populations can be affected by both density-dependent and density-independent factors at different times. This interaction is the basis for the idea of compensatory density dependence. In this formulation, a population is governed by density independent factors when population size is small. As the population increases and approaches the carrying capacity, density-dependent factors become important and the population growth rate declines. Fluctuations in carrying capacity, as noted above, are an added complication. Again, it is essential to understand the ecology of the species and survival between life stages to understand the relative importance of density dependent and density independent factors.

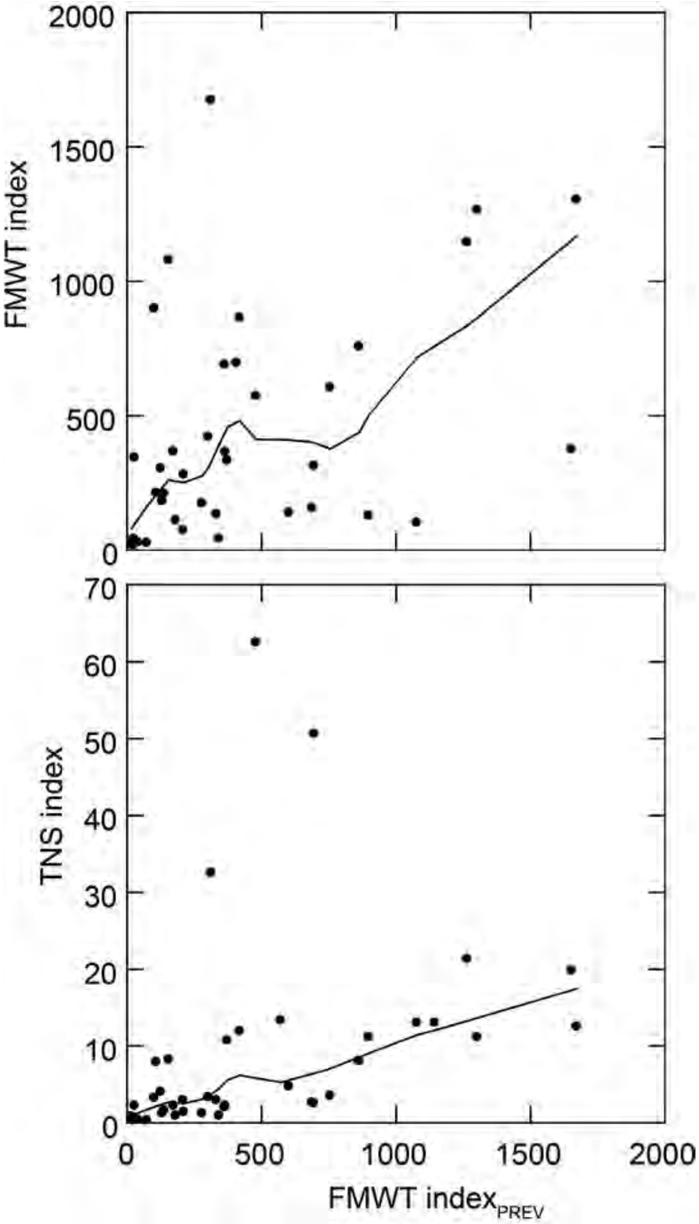
Unfortunately, Delta Smelt were never of sufficient interest as a commercial or recreational species to warrant development of stock-recruitment models until they were listed. Data now used to develop stock-recruitment models for Delta Smelt started becoming available after the initiation of fisheries studies and monitoring surveys in the late 1950s (TNS initiated 1959; FMWT initiated 1967) in association with the planning and operation of the CVP and SWP. These IEP fish monitoring surveys were designed to produce relative abundance indices or catch-per-unit-effort (CPUE, e.g., number per trawl) that could be used to monitor trends in abundance over time. More recently, annual abundance indices based on these surveys have also been incorporated into stock-recruit relationships (e.g., Moyle et al. 1992, Sweetnam and Stevens 1993, Miller 2000, Bennett 2005, Maunder and Deriso 2011). Neither of these early IEP fish monitoring surveys (TNS, FMWT) were specifically designed to monitor Delta Smelt, but instead targeted primarily the commercially and recreationally more important Striped Bass. As researchers began using TNS and FMWT indices for Delta Smelt analyses, they began investigating how the indices performed and means to improve them (see Wadsworth and Sommer 1996, Miller 2000, Newman 2008). This work is ongoing and also includes similar investigations for the newer SKT (initiated in 2002) and 20 mm survey (initiated in 1995) monitoring surveys.

The two stock-recruitment relations based on the longest data records include the relationsip of the FMWT abundance index with the FMWT adundance index in the previous year and the relationship of the TNS abundance index with the FMWT adundance index in the previous year (Fig. 50). Because of the large changes that have occurred in the Delta ecosystem, including the invasion by *P. amurensis* and the POD, these plots can be difficult to interpret because carrying capacity is assumed to have changed (Bennett 2005, Kimmerer et al. 2000, Sommer et al. 2007). It does appear that there is much more variability associated with the FMWT relationship compared to the TNS relationship. This might indicate variable survival between the juvenile and subadult life stage.

In any form of a stock-recruitment model, there is a point at which low adult stock will result in low juvenile abundance and subsequent low recruitment to future adult stocks. This can occur even under favorable environmental conditions while the stock “rebuilds” itself. From a stock-recruitment perspective, the recent low abundance of Delta Smelt is of particular concern. Since about 2002, the current population is smaller than at any time previously in the record, with the exception of the 2011 year class. This strong year class suggests that Delta Smelt have yet to reach low levels where the stock will need years to rebuild, at least to pre-POD levels (Fig. 3).

In addition to their use in exploring stock-recruitment relationships, ratios of annual Delta Smelt abundance indices can also be used to obtain rough estimates of relative annual recruitment and survival rates (figs. 51 and 52). As for the stock-recruitment relationships these recruitment and survival indices should be interpreted with caution given the large changes that have taken place in the Delta and the absence of estimates of variability for the indices. The main utility of these

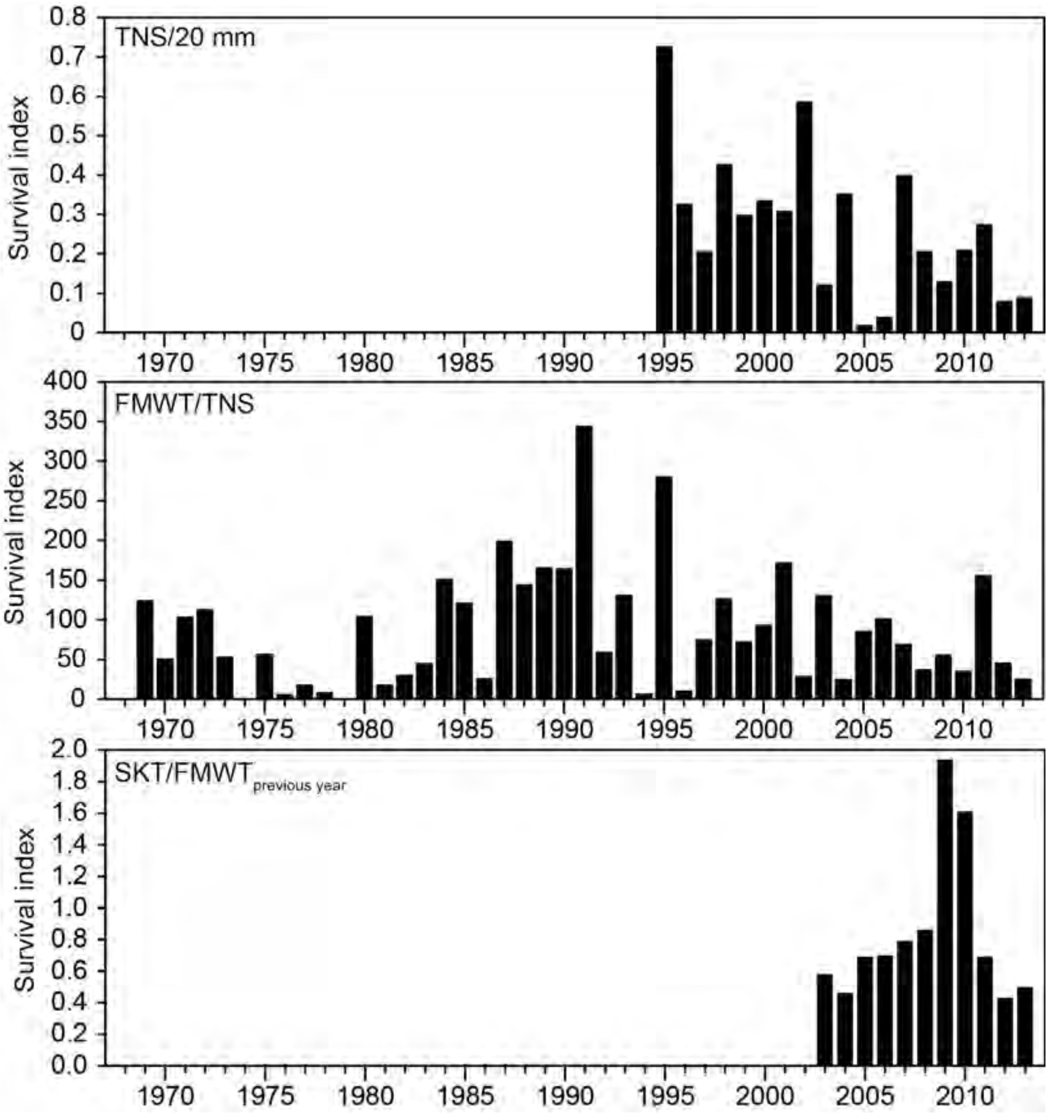
Figure 50. Scatterplots and LOWESS splines depicting the relationship of the Fall Midwater Trawl index of Delta Smelt relative abundance (FMWT) (1968-2012) and Summer Townet Survey (TNS) (1969-2012) with the FMWT in the previous year.



indices is identifying years with relatively high or low survival for a specific life stage transition or life stage transitions with differences in annual variability.

Here, we use the ratios of abundance indices for different life stages of the same generation as indices of survival (survival indices, Fig. 51) and the ratios of current to preceding year abundance indices as indices of recruitment (recruitment indices, Fig. 52). For the density-independent case, recruitment rate is independent of the size of the adult population. The number

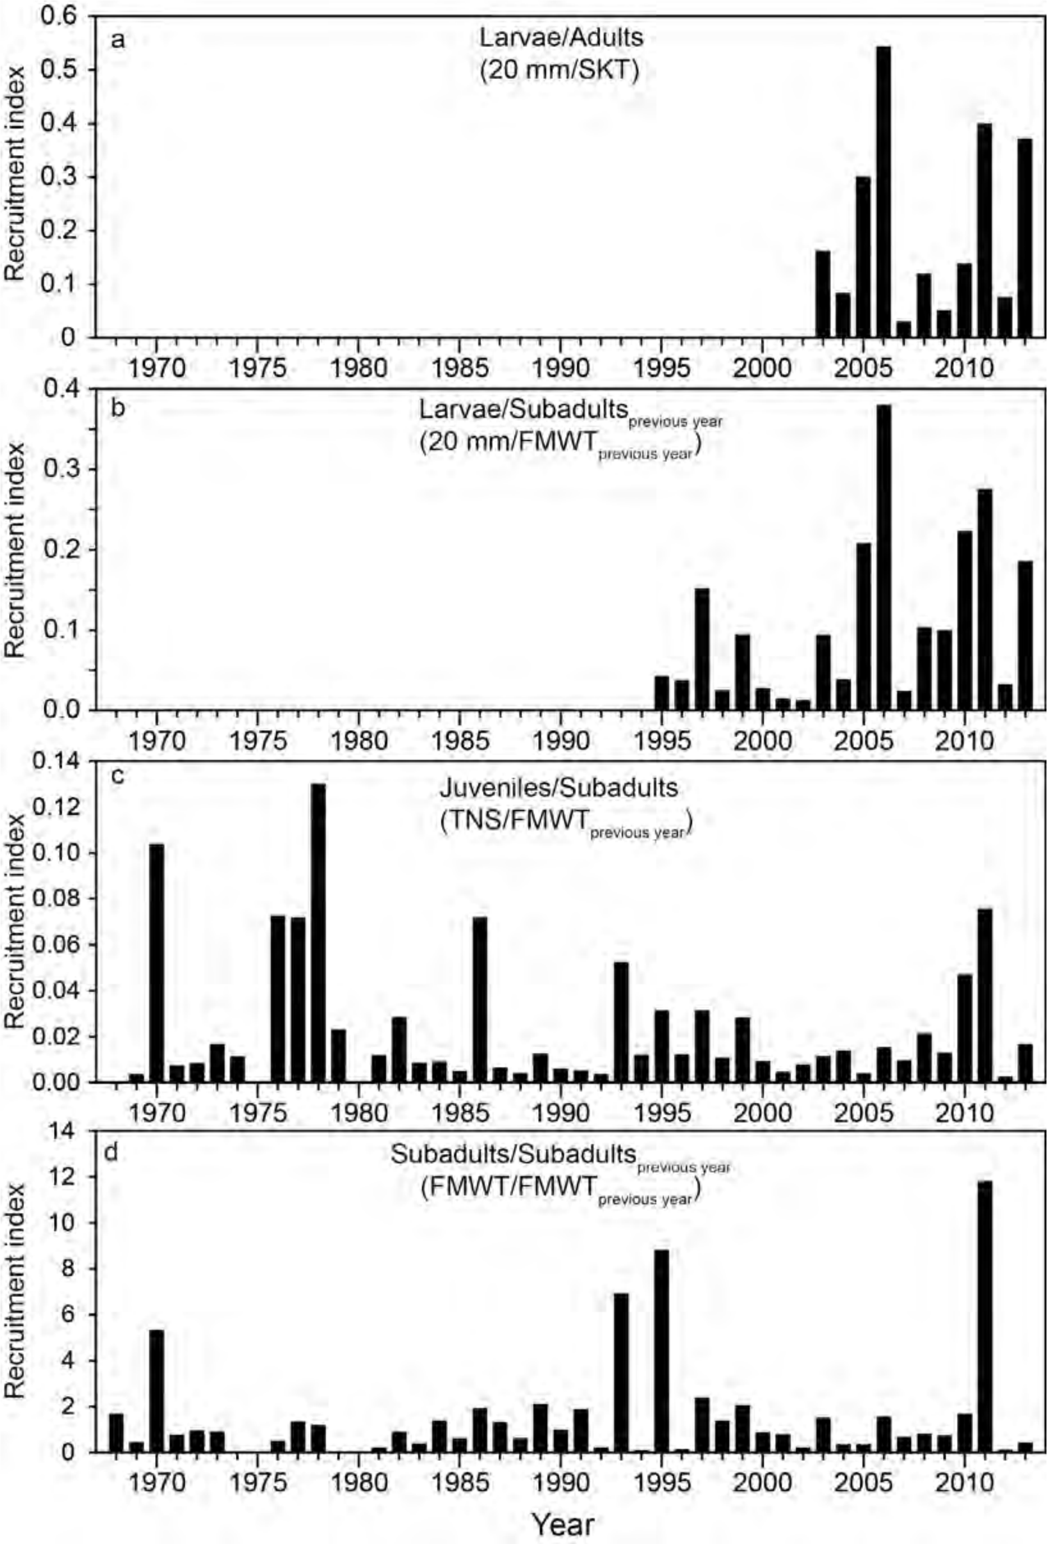
Figure 51. Stage to stage survival indices based on data from Summer Townet Survey (TNS), Fall Midwater Trawl (FMWT), and Spring Kodiak Trawl (SKT).



of recruits produced is the product of recruitment rate and the size of the adult population. For this report, we assume that the estimates have sufficiently low and comparable uncertainty to provide worthwhile interpretations, as long as caution is exercised. It is also important to remember that abundance, survival, and recruitment index values are only meaningful in a relative, not in an absolute sense.

The annual stage to stage survival indices from larvae to juveniles, subadults, and adults are shown in Figure 51. The relative recruitment rates from adults and subadults in one year to larvae, juveniles, and subadults the next year are shown in Figure 52. We recognize that a life cycle model with environmental covariates is needed to fully assess the combined effects of stock-recruitment and stage-to-stage survival indices on Delta Smelt population dynamics. Nevertheless, examination of the recruitment and survival index data sets reveal several interesting patterns for the POD period (2003-2013).

Figure 52. Delta Smelt recruitment indices based on the annual adult, larval, juvenile, and subadult abundance indices provided by the Spring Kodiak Trawl (SKT, adults), 20 mm Survey (20 mm, larvae), Summer Townet Survey (TNS. juveniles), and Fall Midwater Trawl (FMWT, subadults).



First, interannual variability in these stock and survival indices declines from larval recruitment (coefficient of variation (CV): 92%), to subsequent larvae to juvenile survival (CV: 67%), juvenile to subadult survival (CV: 43%), to subadult to adult survival (CV: 38%). This result is consistent with expected highly dynamic patterns of recruitment and survival for an annual opportunistic species such as Delta Smelt. The pattern of reduced variability in survival for larger fish suggests that older fish may no longer be vulnerable to some forms of mortality affecting earlier life stages either because a factor is no longer important when larger fish are present (e.g., effect of summer high water temperatures on juveniles) or that larger fish escape some forms of mortality (e.g., larger fish are no longer eaten by the large variety of predators able to consume larvae).

Second, the patterns of adult and larval abundance (Fig. 3) and adult to larvae recruitment (Fig. 52a) suggest: (1) even a small adult Delta Smelt stock can produce a large number of larvae under the right habitat conditions; but (2) larval recruitment is not a good predictor of juvenile survival and subsequent adult stock size. In other words, good larval recruitment sets the stage for population recovery, but good survival through subsequent life stage transitions is needed to realize its potential.

Third, there are clear contrasts in Delta Smelt responses between the two wet years 2006 and 2011 (the years of particular interest in this report) (Figs. 51 and 52). Since the initiation of the SKT survey for adult Delta Smelt in 2002 (indices calculated beginning in 2003), the recruitment of larvae from adults was greatest in the two wet years 2006 and 2011 (Fig. 52a) compared to the other, drier years in the time series, but in 2006 very strong adult to larvae recruitment was followed by very poor larvae to juvenile survival in the summer (Fig. 51a) and only average survival in the fall (Fig. 51b) and winter (Fig. 51c). This led to low abundance of the subsequent life stages of the 2006 cohort. Survival from larvae to juveniles and subadults was much better in 2011 and, along with good recruitment, led to the highest juvenile and adult abundance indices since the onset of the POD (Fig. 3). In other words, good recruitment set the stage for population recovery in both recent wet years, but a substantial abundance increase was realized only in 2011. Unfortunately the 2011 abundance increase was short-lived; it was immediately followed by poor recruitment and survival in 2012 and abundance indices for the 2012 and 2013 cohorts were once again at the low levels typical for the POD period (Fig. 3). Several consecutive years of good recruitment and survival are likely needed for a more sustained increase of the Delta Smelt population abundance to pre-POD abundance levels. Population declines such as the decline experienced by Delta Smelt do not only reduce the number of individuals, but can also reduce the genetic diversity present in the population. While the 2011-2012 data suggest that recovery of Delta Smelt abundance can still be fairly rapid via high larval recruitment followed by good survival (Figs. 51 and 52) recovery of genetic diversity is a much slower process which is an important conservation concern (Fisch et al. 2011).

Small Delta Smelt population size affects the effective population size (*Ne*), a measure of the genetic properties of a population and the abundance at which significant genetic diversity is lost due to inbreeding (Falconer and Mackay 1996, Schwartz et al. 2007, Antao et al. 2010). In many species *Ne* may be orders of magnitude smaller than the census population size (*N*) and low *Ne*/*N* ratios indicate the population may be in danger of losing genetic variability, potentially resulting in reduced adaptability, population persistence, and productivity (Hauser et al. 2002). For Delta Smelt, Fisch et al. (2011) detected a genetic bottleneck in each of four sampling years (2003, 2005, 2007 and 2009) and observed a significant decline in effective population size between sampling years 2003 and 2007 (Fisch et at. 2011). The genetic signal of the decline in *Ne* is corroborated by the observed abundance index declines and support the hypothesis that decreases in *Ne* and allelic richness have likely occurred over the last few decades (Fisch et al. 2011). Genetic changes within the Delta Smelt population deserve continued evaluation with respect to changes in population size.

In addition, Delta Smelt recruitment and the fecundity of adult Delta Smelt likely vary substantially from year to year (Rose et al. 2013b). Delta Smelt fecundity is a function of female size (Bennett 2005, Lindberg et al. 2013). The mean size of adult Delta Smelt declined in the early 1990s (Sweetnam 1999), possibly due to changes in the food web (see Chapter 4), but substantially recovered in the late 2000s. Another possible reason is that in some recent years, there may have been selection for smaller, late-spawned larvae as a result of export pumping schedules (Bennnett 2011). For example, Bennett (2011) proposed that high export pumping in late winter may have resulted in high entrainment mortality of offspring from larger, fitter, early spawning females, which produced larger, fitter offspring (Bennett 2011). Further, Bennett et al. (2008) and Bennett (2011) posited that curtailment of export pumping in mid-April related to the Vernalis Adaptive Management Program (VAMP), allowed for greater survival of later-spawned, smaller larvae. The major concern is that these smaller later-spawned larvae have less opportunity to grow to large adult size, especially when food is scarce. If correct, the combined effects of export pumping and food supply on Delta Smelt growth and size could have a nonlinear impact on overall fecundity and population success. This is corroborated by the results from individual-based modeling which showed that growth in fall-winter and the subsequent number of eggs produced per adult were the most important factor determining the success of the next generation (Rose et al. 2013b). Moreover, repeated losses of early-spawned larvae could potentially have a negative effect on expression of this important phenotype and result in eventual loss of genetic variability in the population, and contribute to the genetic bottlenecks reported by Fisch et al. (2011).

Given the unprecedented low abundance of Delta Smelt since 2002 (Fig. 3, summer and fall), serious consideration should be given to evaluation of Allee effects. Allee effects occur when reproductive output per fish declines at low population levels (Berec et al. 2006). In other words, below a certain threshold the individuals in a population can no longer reproduce rapidly enough to replace themselves and the population, exhibiting inverse density dependence, spirals to extinction. For Delta Smelt, possible mechanisms for Allee effects include processes directly related to reproduction and genetic fitness such as difficulty finding mates, genetic drift, and inbreeding (Gascoigne et al. 2009), although none of these effects have been documented yet in Delta Smelt (Fisch et al. 2011). Other mechanisms related to survival such as increased vulnerability to predation (Gascoigne and Lipcius 2004) are also possible. While theoretical work suggests that Allee effects might be common in nature, empirical evidence for Allee effects in natural populations of fishes remains relatively sparse (Myers et al. 1995, Liermann and Hillborn 1997), possibly because they are often masked by measurement errors (Gregory et al. 2010). Recent meta-analytical work by Keith and Hutchings (2012) suggests that Allee effects in marine fish species might be more common than previously thought. But even in the absence of "true" Allee mechanisms, small population size (Hutchings 2013) can produce an emergent Allee effect and prevent recovery of collapsed fish populations even when threats are reduced (Kuparinen et al. 2012). This may be one of the reasons why recovery of many collapsed fish populations remains slow despite large reductions in fishing (Pauly et al. 1998, Hutchings et al. 2010). This finding challenges the traditional fisheries management view that depleted populations will grow and recover rapidly when fishing pressure is relaxed (Hilborn and Walters 1992). In addition, the interactive effects of multiple Allee effects may have important implications for species conservation, but have not yet been well explored in ecology (Berec et al. 2006).

Compensatory density dependence predicts that a fish's population growth or survival rates can increase when abundance is low and decrease if abundance increases beyond a carrying capacity (Rose et al. 2001). If compensatory density dependence occurred in 2011, Delta Smelt survival would be expected to increase as long as the carrying capacity of the environment was not exceeded. Therefore, the sudden increase in subadult abundance in 2011 is consistent with the higher survival predicted by compensatory density dependence at low population abundance coupled with widespread availability of good habitat conditions throughout the year. Among the remaining comparison years, both 2005 and 2006 show evidence of compensatory recruitment to larvae (Fig. 52a). Adult abundance was moderately high in 2005, but low in 2006 and 2010 (Fig. 3). As predicted by compensatory density dependence processes, the recruitment index to larvae was higher in 2006 than in 2005. However, low adult abundance in 2010 did not give way to a similarly high recruitment index (Fig. 52a). In addition, the relatively high recruitment index in 2006 did not result in a higher larval abundance index compared to 2005 (Fig. 3). These inconsistences, combined with a small number of comparison years, prevent any firm conclusion regarding compensatory recruitment or survival.

Similarly, if compensatory density-dependent survival was important we might expect larva to juvenile survival to be lower when larva production per adult was higher assuming similar adult populations. This was not the case for 2006, 2010, and 2011, which had relatively similar values for the SKT abundance index (figs. 3). In 2006, larval survival was low with high larval production per adult, and 2010 and 2011 had very similar larval survivals with similar adult abundances. Finally, in 2011, the highest population of juveniles led to the highest population of subadults and adults (2012 SKT), which argues against compensatory density-dependent survival. These comparisons argue against strict compensatory density dependence operating within the POD years. It seems more likely that population dynamics are driven by density independent relationships with factors such as summer water temperatures and resource availability (fluctuations in carrying capacity); however, the evidence is not conclusive. In particular, we do not understand how carrying capacity fluctuates over seasons and years or how other factors, such as predation, affect carrying capacity (Walters and Juanes 1993; Walters and Korman 1999).

Adults

Life History

The Delta Smelt is generally considered a diadromous seasonal reproductive migrant, and in the winter, many adult Delta Smelt move upstream into fresh water for spawning (Moyle et al. 1992, Bennett 2005, Sommer et al. 2011). These movements may be a specific change in behavior in response to one or more environmental cues, for example, to the rapid and often dramatic environmental changes during winter first flush periods (Sommer et al. 2011, Bennett and Burau 2014). Focused, fixed-station sampling in the winters of 2009-10 and 2010-11 revealed higher catch of Delta Smelt at higher turbidity levels, as well as an asymmetry in probability of catch with respect to tidal phase; catch was highest in the channels during flood tide, but highest near the shoreline during ebb tides (Bennett and Burau 2014). This change in horizontal channel position with respect to tidal direction has recently been confirmed by a second study in the fall of 2012 that used the "SmeltCam," an underwater video camera attached to the cod-end of the FMWT net to detect Delta Smelt (Feyrer et al. 2013). This study demonstrated that during flood tides, Delta Smelt were relatively abundant throughout the water column, but less abundant during ebb tides, and found only in the lower portion of the water column and closer to shorelines. This asymmetry in catch supports the idea of a “tidal surfing” behavior during migration that may minimize energetic costs of upstream movement and allow Delta Smelt to follow favorable conditions with respect to turbidity and salinity (Feyrer et al. 2013). Variations of this behavior would allow fish to maintain position in the channel (stay on the edge during flood or ebb tide) or move downstream (move into the channel on ebb tide).

It is also possible that Delta Smelt movements do not represent a change in behavior; rather, fish are simply expanding their foraging or refuge distribution to habitat upstream when it becomes turbid or otherwise more suitable during and after the first flush period (Murphy and Hamilton 2013). The specific mechanism for the seasonal change in distribution, however, may be more a matter of terminology than of ecological relevance for a fish with as small a home range as Delta Smelt. Here, we acknowledge the existence of both possibilities, but will use the term “spawning migration” to simply refer to a directed movement upstream or downstream occurring prior to and during the spawning season. Using this definition, this seasonal change counts as a migration since it represents a relatively predictable and substantial change in distribution that has adaptive value including potential spawning, foraging and refuge functions (Lucas and Bara 2001).

The Delta Smelt spawning migration from their low-salinity rearing habitat into freshwater usually occurs between late December and late February, typically during first flush periods when inflow and turbidity increase on the Sacramento and San Joaquin Rivers (Grimaldo et al. 2009, Sommer et al. 2011a). Increased catches of Delta Smelt in the Delta Juvenile Fish Monitoring Program’s Chipps Island Trawl Survey and at the south Delta salvage facilities are unimodal in most years and occur within a couple of weeks of first flush events, suggesting that adult Delta Smelt are responding to environmental changes and migrating rapidly upstream once the first flush occurs (Grimaldo et al. 2009, Sommer et al. 2011a). However, spawning migrations are not always upstream. During occasional periods of very high river flows that spread freshwater habitat throughout much of the estuary, some Delta Smelt “migrate downstream” from rearing habitats in Suisun Bay and the Delta to freshwater spawning habitats as far west as the Napa River (Hobbs et al. 2007). Also under high flow conditions, it is possible that some Delta Smelt may not migrate in any direction; if their brackish-water rearing habitat becomes fresh, they can presumably spawn in suitable areas nearby. In addition, there is a small subset of the population that appears to remain in the Cache Slough complex year around; these fish presumably stay in the region for spawning (Sommer et al. 2011).

Osmerids generally spawn in shallow waters (Moulton 1974, Murawski et al. 1980, Hirose and Kawaguchi 1998, Martin and Swiderski 2001, Bennett 2005). It is believed that Delta Smelt spawn over sandy substrates in shallow areas based on the observation that first hatch larvae are collected in high concentrations in areas near expansive sandy shoals (Bennett 2005, L. Grimaldo, U.S. Bureau of Reclamation, unpublished data); confirmation of this hypothesis has not been verified through egg collections or observations of spawning adults, except in mesocosm studies (J. Lindberg, U.C. Davis, unpublished data). Pilot studies to identify egg deposition areas have been conducted by the IEP but these efforts were unsuccessful; it is unknown whether it was due to the method used, locations selected, or because of the low probability of detecting eggs from a relatively rare species.

The Delta Smelt is an opportunistic strategist (Nobriga et al. 2005). Opportunistic strategists are characterized by their short life spans, but high intrinsic rates of population increase driven by rapid maturation and repeat spawns over a protracted spawning season (Winemiller and Rose 1992). The importance of per capita fecundity to the success of the Delta Smelt population was recently highlighted in an individual-based modeling study (Rose et al. 2013a,b). In culture, Delta Smelt can spawn up to four times per year depending on water temperature (J. Lindberg, U.C. Davis, unpublished data). Recent evidence indicates that Delta Smelt can spawn multiple times in the wild if water temperatures stay cool in the later winter and early spring (Wang 2007, L. Damon, CDFW, written comm. 2013). The ability of Delta Smelt to spawn multiple times in the wild could substantially increase per capita fecundity over previous estimates for individuals of a specific size. It could also be a contributing factor to the large interannual variability in adult to larvae recruitment (Fig. 52a).

Population Trends

Adult Delta Smelt are monitored by the Spring Kodiak Trawl (SKT) survey which was initiated by CDFW (then CDFG) in 2002 and runs from January to May each year (Honey et al 2004). An indexing method was recently developed by CDFW for the SKT survey, allowing for year to year comparisons as well as comparisons with the abundance indices for other life stages (Fig. 3). The SKT index time series used in this report comprises 11 annual indices, from 2003 to 2013; no index is available for 2002. Each index represents the abundance of adult fish hatched in the previous calendar year that survive to spawn at the beginning of the next calendar year. The highest SKT index on record occurred in 2012 (147), as a result of the high 2011 abundance of younger fish, and the lowest in 2006 (18). Of the four comparison years, 2005 had the highest SKT index (51), followed by 2010 (27) and 2011 (20) and then 2006 (18). While the SKT index was thus lower in the two wet years than in the two drier years, the SKT index increased substantially in each of the years following the two wet years; however it increased only 2-fold from 2006 to 2007 while it increased 7-fold from 2011 to 2012 (Fig. 3). It is also possible that the SKT is less effective during very high flow events. Delta outflow at times exceeded 200,000 cfs in winter 2011 and 300,000 cfs in winter 2006. These high flow events might have contributed to the low SKT indices in these two wet years, if Delta Smelt remained near shore to avoid displacement or moved into San Pablo Bay with the LSZ. In both cases they would be outside of SKT sampling range. Further evaluations are needed, however, to investigate and quantify this hypothesized effect.

The annual adult Delta Smelt abundance indices track the annual abundance indices of sub-adults calculated from the previous years' FMWT survey closely (Fig. 53; see also Kimmerer 2008). The relationship is particularly strong at higher fall abundance indices (FMWT index > 50), with more variability at lower abundance indices. Before the POD decline in 2002, all Delta Smelt FMWT indices were greater than 50 (Fig. 3). Thus, the FMWT might provide a useful surrogate for estimating long-term abundance trends in the adult Delta Smelt population prior to the initiation of the SKT survey in 2002, but great caution is warranted with the approach because this hindcasting would rest on only four data points with high leverage (2003-2005, 2012) and assume stable subadult to adult survival relationships and habitat conditions, neither of which is likely true. Moreover, the Kodiak trawl more efficiently captures Delta Smelt than the FMWT net. The SKT survey was set up to target Delta Smelt, while the FMWT survey was designed to monitor young Striped Bass, which tend to be larger than Delta Smelt during fall; however, there is no reason to expect the difference in capture efficiency to affect the relationship, unless such differences were a function of population size (i.e., efficiency was different above and below FMWT = 50). The utility of the FMWT as a descriptor of long-term adult population trends in the absence of long-term data from the SKT will benefit from ongoing IEP efforts to quantitatively estimate the efficiency of the FMWT and to compare efficiencies of different trawling gear and protocols. While survival from subadults in the fall (FMWT) to adults in the winter and spring (SKT) (Fig. 53) has been more stable than adult to larvae recruitment and survival between other life stages (Figs. 51 and 52), it nevertheless shows some variability, especially when abundance is low. These data suggest that at least in the POD decade, adult numbers appear largely driven by juvenile abundance and the influence of changes in winter-time habitat attributes is less important and relatively stable from year to year.

The number of adult spawners affects population dynamics through production of eggs. Potential reproductive output is proportional to the number of adult female spawners, the clutch size for females of a specific size, and the number of egg clutches produced by each female. Although egg production in the wild has not yet been documented, we can evaluate the relationship of the SKT adult population index to the 20 mm Survey abundance index (Fig. 54). This relationship does not appear to be strong during the POD period (linear regression, $P > 0.05$). This suggests that egg production or subsequent hatching of eggs and survival of larvae and thus overall recruitment of larvae from the previous generation's adults is affected by other factors than adult population size. Hypotheses about the effects of habitat attributes in our conceptual model on adult growth and fecundity and recruitment of young are explored in Chapter 7.

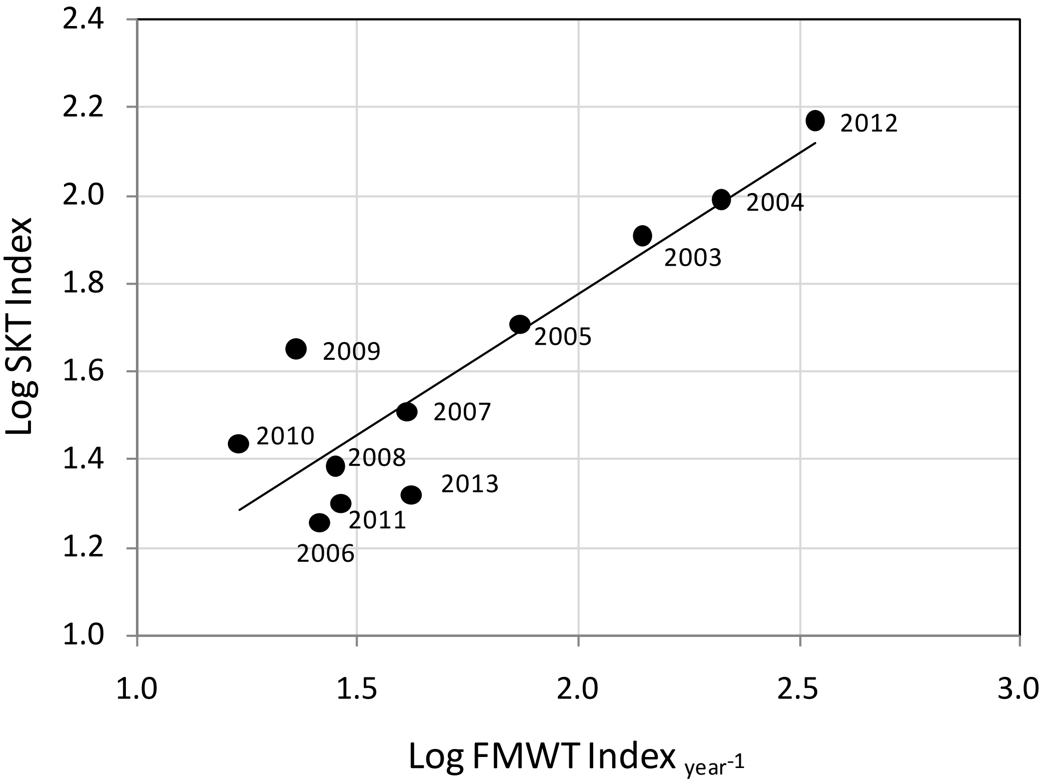
Clutch sizes of fish collected in the SKT were not measured, but annual fork lengths of Delta Smelt collected in the SKT did not vary greatly (Fig. 55). It does not appear that clutch size should have varied much in the POD years, including the four comparison years 2005-6 and 2010-11, with 2003 as the exception where the median length was greater than 70 mm standard length (Fig. 55). For Delta Smelt, which are now considered seasonal indeterminant spawners (i.e., they spawn multiple times), total reproductive output of an individual female should vary with: 1) size at the onset of the spawning window because batch fecundity is a function of size (Bennett 2005, CDFW unpublished data), 2) length of the spawning window, which is the number of days with suitable water temperatures for spawning (see larvae section below) and determines the number of batches possible; and 3) growth during the spawning window, which can potentially improve batch fecundity over time (see larval section below). Obviously, reproductive output will be higher in years when adult females are larger, abundances are higher, and the spawning window is prolonged such that multiple clutches are produced. Note that maximum reproductive output of the adult population at the beginning of spawning is not often realized due to mortality arising from density-dependent (e.g., food limitation or predation) or density-independent (e.g., entrainment, contaminants) mechanisms. According to Bennett (2011), larvae from bigger, early-spawning females may be disproportionally lost to CVP and SWP entrainment. In this report, we consider years when there are bigger females and/or a higher spawning stock size to be better in terms of reproductive potential than years when adult female size and spawning stock are smaller.

Larvae

Life History

Adult Delta Smelt, through their selection of spawning sites and spawn timing, largely determine the early rearing habitat and environmental conditions encountered by larvae. Given the Delta Smelt's annual life cycle, small size at maturity, relatively low fecundity, and small egg size compared to other fishes, life history theory suggests that parental care, here limited to selection of spawning sites and spawn timing, should be an important factor in reproductive success (Winemiller and Rose 1992). Since eggs have not been detected routinely in the wild, spawning and early rearing habitat locations are inferred from collection of ripe adults and early stage

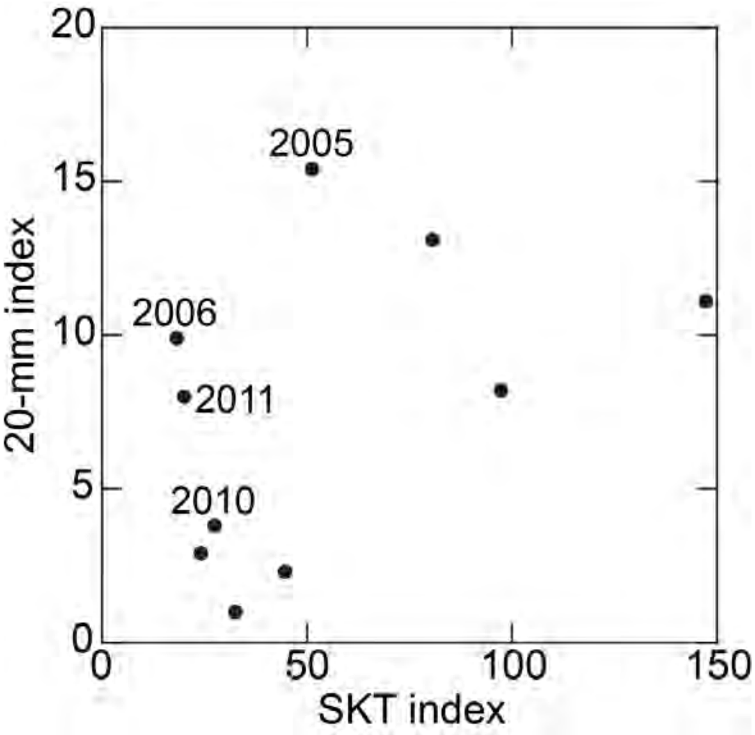
Figure 53. Relationship of annual indices of Delta Smelt abundance from the Spring Kodiak Trawl (SKT) and Fall Widwater Trawl (FMWT) from the previous year. Year labels correspond to the year of the SKT. The linear regression with all index values log-transformed to address non-normal distributions in the raw data is: Log SKT Index = 0.4997 + 0.6381(Log FMWT Index Year^{-1}), n = 11, p < 0.001, R^2 = 0.79.



larvae, which occur from the Delta margins through eastern Suisun Bay (see: http://www.dfg.ca.gov/delta/projects.asp?ProjectID=SKT; Wang 1986, 1991, 2007). In culture, Delta Smelt begin spawning as water temperatures increase to 10-12 °C, at which time individual females accompanied by several males select appropriate water velocities and release gametes close to the substrate from dusk to dawn (Baskerville-Bridges et al. 2004b). In lab experiments, females deposited significantly more eggs on sand and gravel substrates as compared to other substrates offered for egg deposition (J. Lindberg, U.C. Davis, unpublished data). Based on periodicity in egg deposition in culture, Bennett (2005) proposed that spawning likely coincides with peak tidal currents (i.e., spring tides), which would result in hatching near neap tides. Such a strategy would limit the initial tidal dispersal of larvae.

In culture, larvae hatch after an 11-13 day incubation period at 14.8-16.0 °C and begin a short period of buoyancy (or positive phototaxis; Baskerville-Bridges et al. 2004b) prior to slowly settling to the bottom (Mager et al. 2004). After this buoyant period, Mager et al. (2004) found that larvae were demersal unless actively swimming to feed, which occurred only during daylight hours. Exogenous feeding begins at 5-6 days post-hatch as the last of the yolk sac is absorbed; the lipid globule is absorbed at 10 days (Mager et al. 2004) providing some nutritional reserve if feeding conditions are poor. Larvae probably remain somewhat bottom oriented until swim

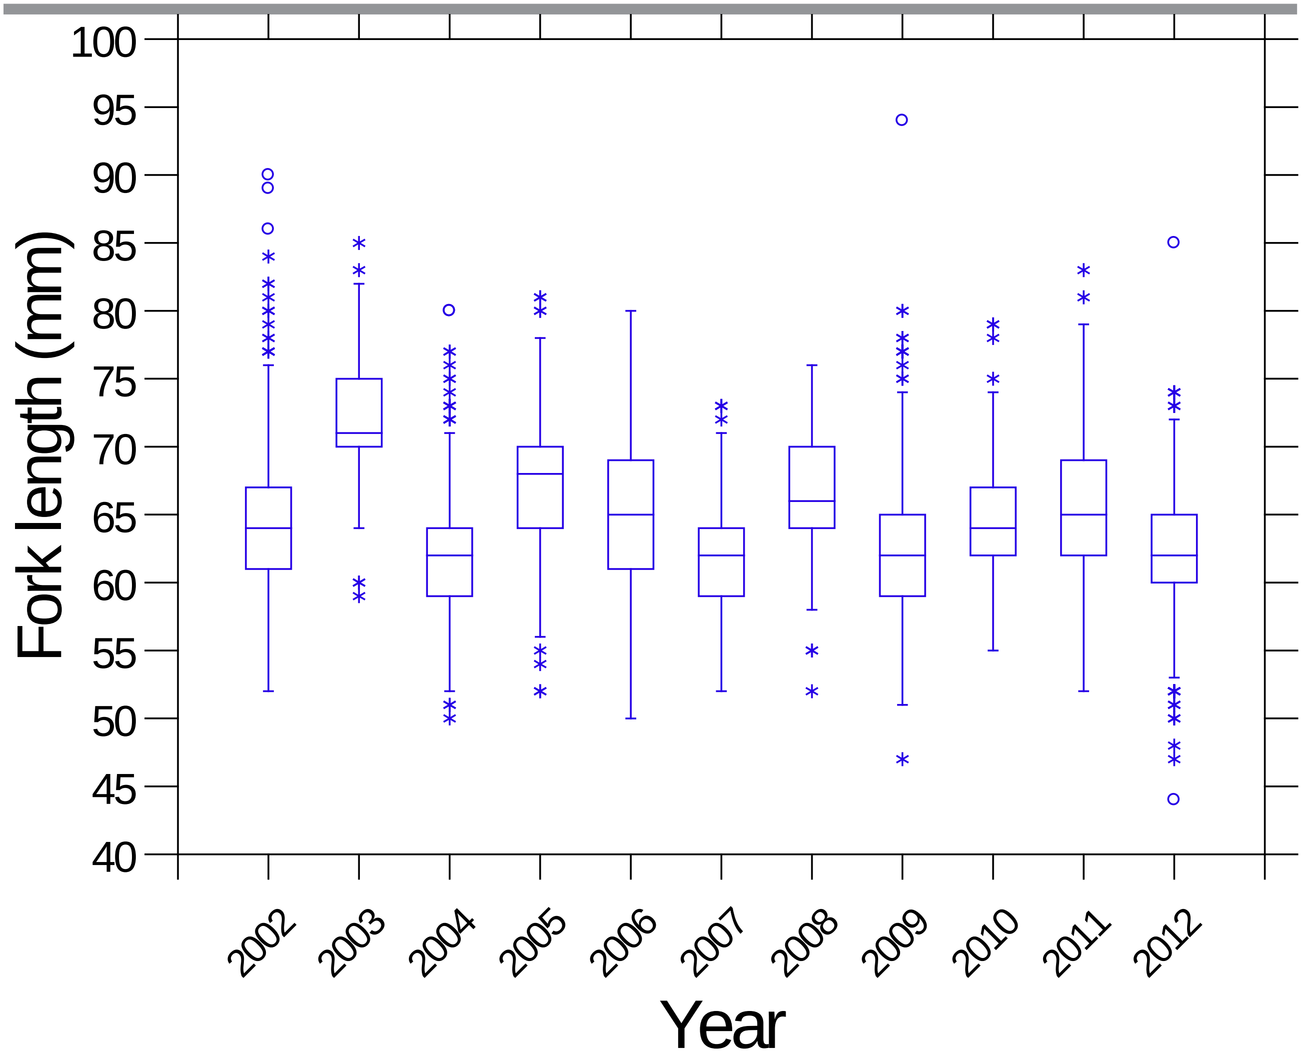
Figure 54. **Plot of the Spring Kodiak Trawl (SKT) adult abundance index against the 20 mm Survey larval abundance index 2003-2012. The comparison years of 2005, 2006, 2010, and 2011 are labeled.**



bladder and fin development are complete at about 65 days of age and about 20 mm TL (Mager et al. 2004, Baskerville-Bridges et al. 2004b), at which time they can fully control their buoyancy and efficiently use tidal and river currents to migrate. The center of distribution for Delta Smelt larvae and young juveniles is generally downstream of the spawning habitat, but upstream of and varying in association with X2 during spring (Dege and Brown 2004).

Early larval stages of Delta Smelt (4-15 mm) tended to be poorly collected by gear previously used in historical SFE egg and larval surveys (Striped Bass Egg and Larva Survey; sled-mounted 500 micron mesh net with 0.38 m^2 mouth area), but with growth and development greater proportions of the population become vulnerable. This observation led to a sampling gear change in the mid-1990s from the historical egg and larval gear to new gear targeting more vulnerable post-larvae and early juvenile Delta Smelt (i.e., 20 mm Survey). The improved catch and distribution information resulting from this change has since proven valuable to the management of Delta Smelt, and the 20 mm Survey results are now considered essential information (USFWS 2008). In the mid-2000s, an abundance index was developed from 20 mm data (Gleason and Adib-Samii 2007) that has since been used to index abundance trends of larvae in spring (e.g., Hieb et al. 2005, Contreras et al. 2011). We use 20 mm Survey abundance indices as one Delta Smelt end-point to evaluate the support for our hypotheses concerning the environmental drivers and habitat attributes responsible for abundance and survival of larvae.

Figure 55. **Median fork length (mm) of Delta Smelt collected in January and February by the Spring Kodiak Trawl by year, 2002-2012. See Chapter 3: Data Analyses for explanation of boxplots.**



Population Trends

The highest larval abundance indices on record occurred in the late 1990s, shortly after the initiation of the 20 mm survey in 1995. The lowest larval abundances were observed in 2007-2010 (Fig. 3). In 2011, larval abundance improved substantially from the recent minimum in 2007, and achieved levels comparable to those earlier in the 2000s (Fig. 3). Although 2011 larval abundance compared favorably to that of 2010, it remained below levels of 2005 and 2006. Thus, the modest larva abundance in 2011 did not appear sufficient to explain the high FMWT index observed in 2011 (Fig. 3). As explained above, larval abundance does not track the abundance of the parent generation very well (Fig. 54). In contrast, subsequent life stages of the same cohort track larval abundance and abundance relationships of larvae (log 20 mm index) with juveniles (log TNS index) and subadults (log FMWT index) in the same year are statistically significant (Fig. 56). However, the linear regression based on the FMWT explains less variance than the linear regression based on the TNS suggesting more variability in the abundance of the older life stages. This suggests that factors affecting juvenile mortality rates also play an important role in eventual recruitment.

Juveniles

Life History

During summer, juvenile Delta Smelt primarily rear in the west Delta, Suisun Bay, and Cache Slough complex (Moyle 2002, Bennett 2005, Merz et al. 2011, Sommer and Mejia 2013). As in late spring and fall, the center of distribution of the fish occurs in the low salinity zone, with the exception of the Cache Slough complex. The degree to which the fish use particular geographic areas depends on salinity, temperature, and turbidity (Nobriga et al. 2008); other factors that may affect their summer distribution include *Microcystis* distribution, and possibly prey density, bathymetric features, or other water quality constituents. As noted previously, Delta Smelt used to be common in the central and south Delta during the summer months, but this is no longer the case (Nobriga et al. 2008).

Population Trends

Relative abundance of juvenile Delta Smelt is presently indexed by the Summer Townet Survey (TNS). The survey was not designed specifically to measure Delta Smelt abundance and catches are low (Honey et al. 2004). Nonetheless, patterns in the annual abundance index provide a useful basic measure of population trends.

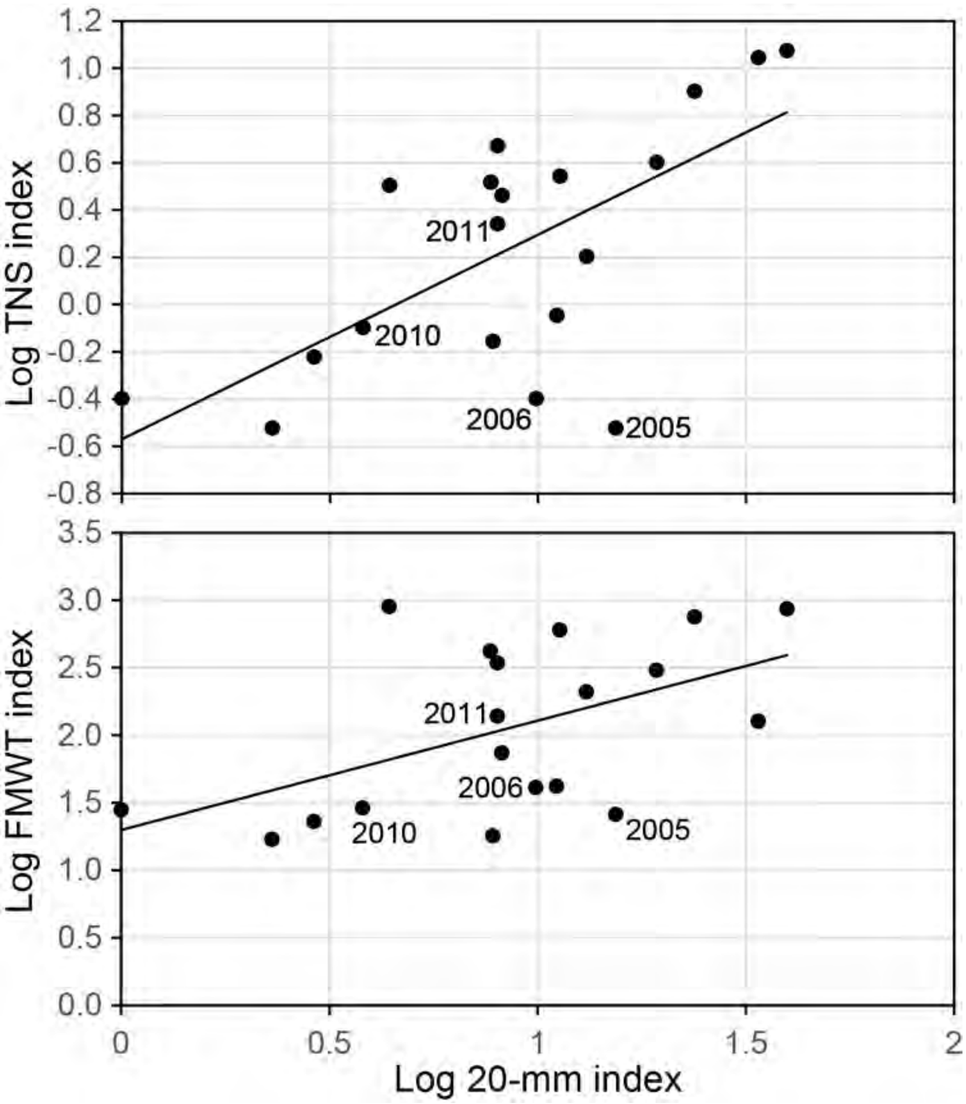
The TNS index rebounded substantially in 2011, but declined to a value consistent with low recent year indices in 2012 (Fig. 3). This pattern of persistently low abundance is consistent with the POD, which began over a decade ago (Sommer et al. 2007, Thomson et al. 2010). During the last decade, TNS abundance indices were especially low from 2005-2009 (Fig. 3). The onset of the 2005-2009 period of low juvenile abundance was characterized by extremely low larvae to juvenile survival in 2005 and 2006 (Fig. 51). Larval survival to juveniles recovered somewhat in the following years, but TNS indices stayed low (Fig. 3). Historically (e.g., early 1970s), high levels of Delta Smelt abundance during summer apparently allowed density dependent effects to occur between summer and fall in some years; this conclusion was still supported after the species declined in the early 1980s, but the apparent carrying capacity was lower (Bennett 2005). The available trawl data suggest that this trend of declining carrying capacity has continued as suggested by the very low Fall Midwater Trawl indices produced by a range of juvenile TNS abundance levels, during the POD years (Fig. 57).

Subadults

Life History

During fall, subadult Delta Smelt primarily rear in the western Delta, Suisun Bay, and Cache Slough complex (Moyle 2002, Bennett 2005, Sommer and Mejia 2013). The center of distribution is in the low-salinity zone (Sommer et al. 2011), with the exception of the Cache Slough complex. The degree to which the fish use particular geographic areas depends on salinity and turbidity (Feyrer et al. 2007). Other factors that may affect their distribution during the fall include *Microcystis* distribution and water temperature in the early fall (September-October), and possibly prey density.

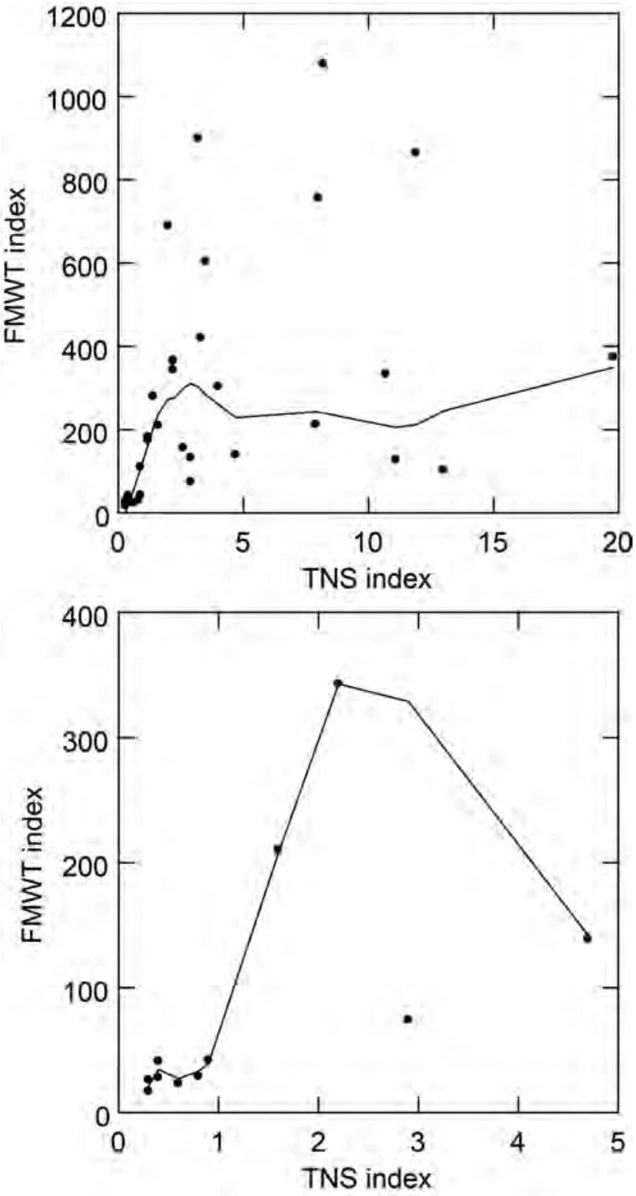
Figure 56. **Relationship of annual index of Delta Smelt abundance from the 20 mm survey (20 mm) with the annual indices from the summer townet survey (TNS) and fall midwater trawl survey (FMWT). Year labels correspond to the comparison years of interest. The linear regressions with all index values log-transformed to address non-normal distributions in the raw data are: Log 20 mm index = 0.57 + 0.87(Log TNS index), n = 19, $p < 0.05$, $R^2 = 0.44$ and Log 20 mm index = 1.30 + 0.81(Log FMWT index), n = 19, $p < 0.05$, $R^2 = 0.27$.**



Population Trends

Population trends for subadult Delta Smelt are presently indexed by the FMWT. Like the TNS, the FMWT was not designed specifically to measure Delta Smelt relative abundance and catches are low (Honey et al. 2004, Newman 2008). The data are nonetheless a useful basic measure of population trends, except perhaps at very low abundance (i.e., FMWT index values less than about 50; Fig. 53). However, the general agreement between the FMWT and subsequent Spring Kodiak Trawl (SKT) sampling (Fig. 53), suggests that FMWT results are a reasonable indicator

Figure 57. Plots of fall midwater trawl (FMWT) abundance index as a function of summer townet survey (TNS) abundance index for 1982-2013 and 2003-2013. Note the very different scales for both axes. Lines are LOWESS smooths.



of general trends in abundance of adult Delta Smelt.

The FMWT index rebounded substantially in 2011, but declined to a value consistent with low recent-year indices in 2012 (Fig. 3). During the last decade, FMWT indices were especially low from 2005-2010 (Fig. 3). After the rebound in 2011, the index went back to a lower level similar to the 2005-2010 period. Since 2003, the juvenile to subadult survival index was lowest in 2004. During the four comparison years, the juvenile to subadult survival index was lowest in 2010, but relatively high in the other three years and highest in 2011 (Fig. 51).

Historically, high levels of Delta Smelt abundance during summer apparently resulted in density-dependent mortality between summer and fall in some years (Bennett 2005). This conclusion was still supported after the species declined in the early 1980s, but the apparent carrying capacity, meaning the magnitude of the FMWT index relative to the TNS index, was lower (Fig. 57). The available FMWT data suggest that these trends of density-dependent mortality during the summer-fall and declining carrying capacity have continued (Fig. 57). The close correlation of the FMWT and SKT (Fig. 53) indicates that the factors likely affecting survival of Delta Smelt to the adult spawning population operate earlier in the life cycle (i.e., between the egg and subadult life stages). Additional mortality certainly occurs between the FMWT and SKT but the lack of variability around the regression line suggests there is not a lot of variability in the rate of that mortality. Thus, the relative annual spawning stock appears to be largely determined by fall of the birth year.

Chapter 7: Using the Conceptual Model–Why did Delta Smelt abundance increase in 2011?

In this Chapter, we further explore Delta Smelt responses and habitat attributes as depicted in the driver and life stage transition conceptual model diagrams presented in Chapter 5. The purpose is to demonstrate the utility of our conceptual model framework for generating hypotheses about the factors that may have contributed to the 2011 increase in Delta Smelt abundance. For each life stage transition, we explore a series of hypothesized linkages among ecosystem drivers, habitat attributes, and Delta Smelt responses. We evaluate these hypotheses by comparing habitat conditions and Delta Smelt responses in the wet year 2011 to those in the prior wet year 2006 and in the drier years 2005 and 2010.

In this Chapter we briefly describe the comparative approach and the hydrological conditions during the four years that are the focus of our comparisons. We then state and explore each hypothesis for the adult, larval, juvenile, and subadult life stages of Delta Smelt using data sources described in Chapter 3. Key points from these evaluations, as well as previous report Chapters, along with benefits and limitations of the comparative approach are summarized and discussed in Chapter 8. In several cases, we lacked suitable data or other necessary information to evaluate our hypotheses; these data and information gaps are described in Chapter 9. Chapter 9 also includes a brief review of some of the more complex mathematical analyses used in recent peer-reviewed publications, such approaches currently being used by others, and three examples of additional mathematical modeling approaches that can be used to further explore some of the linkages and interactions in our conceptual model and complement previously published and other ongoing mathematical modeling efforts for Delta Smelt.

Comparative Approach

The comparative approach used for evaluating the hypotheses stated in this Chapter is similar to the approach taken in the FLaSH investigation (Brown et al. 2014, see also http://deltacouncil.ca.gov/science-program/fall-low-salinity-habitat-flash-studies-and-adaptive-management-plan-review-0). This allowed us to place the results of the FLaSH investigation in a year-round, life cycle context as recommended by the FLaSH Panel (FLaSH Panel 2012). Specifically, we compared data from the two most recent wet years, 2006 and 2011, and the two years that immediately preceded them, 2005 and 2010. To conduct our comparisons, we determined how Delta Smelt responses or habitat attributes would be expected to respond in the different years and then compared the expected response to the observed response. If the expected and observed responses were similar, the hypothesis was considered to be supported.

Moderate to wet hydrological conditions tend to benefit many estuarine organisms, including Delta Smelt (Sommer et al. 2007). But low recruitment or low survival at any point in the predominantly annual Delta Smelt life cycle can lead to low abundance even in a wet year. Identifying the reason(s) for low abundance in a wet year may give important insights into key habitat attributes and environmental drivers that could be managed in a way that would improve the likelihood of abundance increases in all wet years.

The two wettest years after the onset of the POD were 2006 and 2011 (Fig. 58). Delta Smelt abundance increased substantially in 2011, but not in 2006 (Fig. 3). The failure of the Delta Smelt population to increase in the wet year 2006 and the increase of Delta Smelt in the wet year 2011 provides an opportunity to compare and contrast habitat attributes in these two years and possibly identify new options for management actions. As stated in Chapter 3, our working assumption is that different Delta Smelt abundances in 2006 and 2011 should be attributable to differing environmental conditions, in some cases attributable to management actions, and subsequent ecological processes influencing the Delta Smelt population.

Preceding habitat conditions may have important implications for the response of a population to the environmental conditions present during a wet year; therefore, we also consider data from 2005 and 2010. Further, we also consider adult and larval abundance in 2012 following the wet year of 2011. We did not include any years predating the POD period in this analysis. This was done to prevent the possibly more subtle, but management-relevant, environmental changes occurring during the POD period from being overwhelmed by effects of the strong POD step changes in the early 2000s as well as similarly strong changes that occurred before the POD (e.g., after the invasion of the clam *Potamocorbula amurensis*).

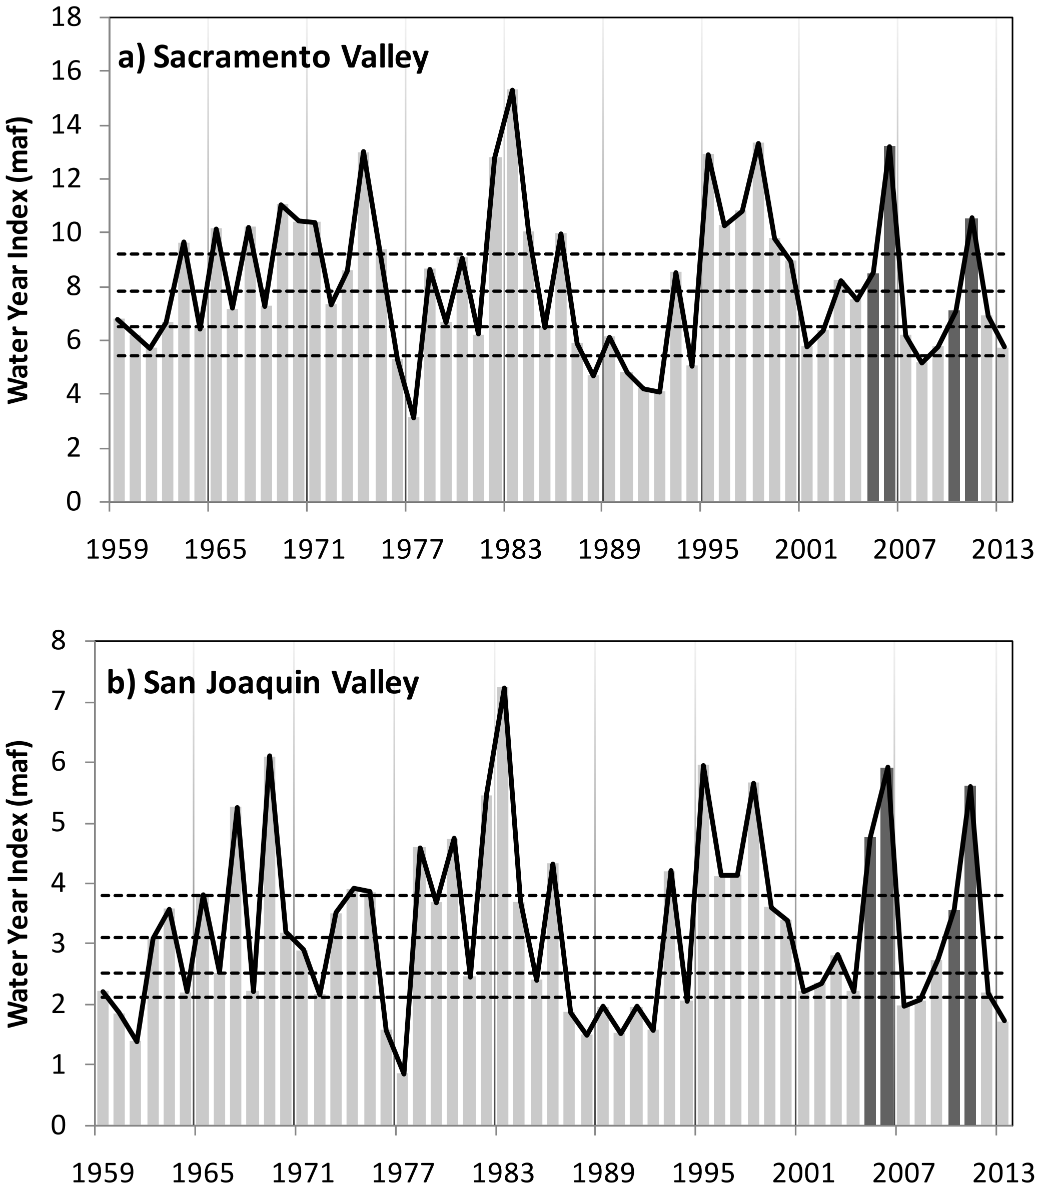
For the purpose of this report, we call 2005, 2006, 2010, and 2011 our "study years." We use "year" rather loosely because the Delta Smelt life cycle does not follow the calendar year. As already explained, life stages can overlap and can be observed during different months in different years. Mature adults of a cohort produced in one year are generally not observed until the following year. Similarly, the life cycle does not strictly follow the water year type. We do our best to explain these mismatches when they occur and keep the presentation focused on the life cycle and the conceptual models.

Note that we do not examine the complex interactions that may occur when more than one hypothesis is true (or false), nor do we rule out that a hypothesis may be true in some years and false in others. Therefore, it is important to recognize that data contrary to a hypothesis may indicate that the habitat attribute was not controlling in the selected years, or that complex interactions among multiple habitat attributes (and corresponding hypotheses) contributed to the observed effects. Addressing such complexities is more appropriate for quantitative models as discussed in Chapter 9.

Hydrological Conditions

According to annual water year indices and classifications for overall hydrological conditions in the Sacramento and San Joaquin Valleys that provide the freshwater inflow into the Delta, 2005, 2006 and 2011 were the wettest years of the POD period (Fig. 58, see also http://cdec.water.ca.gov/cgi-progs/iodir/WSIHIST). In the San Joaquin Valley, 2010 was the fourth wettest year of this period. In the Sacramento Valley, 2003 and 2004 were wetter than 2010. Specifically, water year 2010 was classified as "below normal" in the Sacramento Valley and "above normal" in the San Joaquin Valley and 2011 was classified as wet in both areas, according to the water year index classifications. Water year 2005 was classified as "above normal" in the Sacramento Valley and "wet" in the San Joaquin Valley and 2006 was classified as wet in both areas. (Fig. 58). Water year 2012 was classified as "below normal" in the Sacramento Valley and "dry" in the San Joaquin Valley.

Figure 58. Annual water year indices for the a) Sacramento and b) San Joaquin Valleys since the initiation of the Summer Townet Survey in 1959. Horizontal dashed lines: threshold levels for water year type classifications as wet (W), above normal (AN), below normal (BN), dry (D) and critically dry (C). Darker grey bars indicate the four study years (2005, 2006, 2010, 2011) examined in Chapter 7 of this report. (Data are from http://cdec.water.ca.gov/cgi-progs/iodir/WSIHIST).



The overall wet hydrological conditions in the Sacramento and San Joaquin Valleys in 2005-6 and 2010-11 resulted in relatively prolonged periods of high Delta inflow and outflow and low X2 values in the winter and spring months of the four study years (Fig. 59). In the first half of the year, 2006 had the highest outflow and lowest X2 values followed by 2011, 2005, and 2010. In the second half of 2011, outflow was higher and X2 values were lower than in the second half of 2006 and of all other years during the POD period. In spite of having the lowest spring X2, 2006 had the highest fall X2 (September to October) of all study years, followed by 2005, 2010, and 2011 (Fig. 60).

The overall high flows during these four years allowed for periods of very high fresh water exports from the Delta (Fig. 59). This led to record high volumes of fresh water exported in water year 2011 (6.7 maf) and in water year 2005 (6.5 maf) and a somewhat lower export volume in water year 2006 (6.3 maf). The total water export volume was substantially lower in water year 2010 (4.8 maf) because 2010 immediately followed a three-year drought and the below normal hydrological conditions in the Sacramento Valley (Fig. 58) were not sufficient to rapidly replenish reservoirs and allow for greater exports.

Hypotheses

Individual hypotheses are indicated in the life stage transition conceptual model diagrams next to the arrows depicting each hypothesized linkage or outcome (figs. 46-49). While all linkages are considered important, we only developed hypotheses for selected linkages. We developed hypotheses for linkages with sufficient data for quantitative assessments and where there is disagreement or uncertainty regarding the outcome resulting from a driver. We also developed hypotheses for linkages considered important but where we found critical information was missing; thus, highlighting topics where new work is needed. For each of these hypotheses, we then considered the available data to examine whether the Delta Smelt response expected under the hypothesis was consistent with the observed trends in habitat attributes or population dynamics. While we would have liked to test hypotheses about the linkages between habitat attributes and the specific life stage transition processes shown in the life stage transition conceptual model diagrams, the available data often only allowed us to test “lower tier” hypotheses about the linkages between ecosystem drivers and habitat attributes.

Note that we have not examined the complex interactions that may have occurred when more than one hypothesis was true (or false), nor have we ruled out that a hypothesis may be true in some years and false in others. Therefore, it is important to recognize that data contrary to a hypothesis may indicate that the habitat attribute was not controlling in the selected years, or that complex interactions among multiple habitat attributes (and corresponding hypotheses) contributed to the observed effects. Addressing such complexities is likely more appropriate for quantitative models as discussed in Chapter 9. Our overall objective in this Chapter is to provide a demonstration of how the conceptual model can be used to generate and test hypotheses and highlight data gaps while addressing a specific topic of management interest—the increased Delta Smelt abundance index in 2011.

Adult Hypotheses

Hypothesis 1: Hydrology and water exports interact to **influence entrainment risk for adult Delta Smelt.**

As discussed earlier, we do not currently have a reliable measure of actual entrainment of fishes by the SWP and CVP export pumps. We also do not have actual population abundance estimates for Delta Smelt. As discussed by Kimmerer (2008, 2011) and Miller (2011), it is thus difficult to estimate proportional population losses due to entrainment. We consider the published

Figure 59. Net daily flows in cubic feet per second for a) Delta inflow from all tributaries, b) Delta outflow into Suisun Bay, and d) total freshwater exports from the Delta. Also shown are daily values for c) X2 (see Chapter 4 for explanation). Flow data are from Dayflow (http://www.water.ca.gov/dayflow/). X2 values are calculated from daily Delta outflow with the equation in Jassby et al. (1995.)

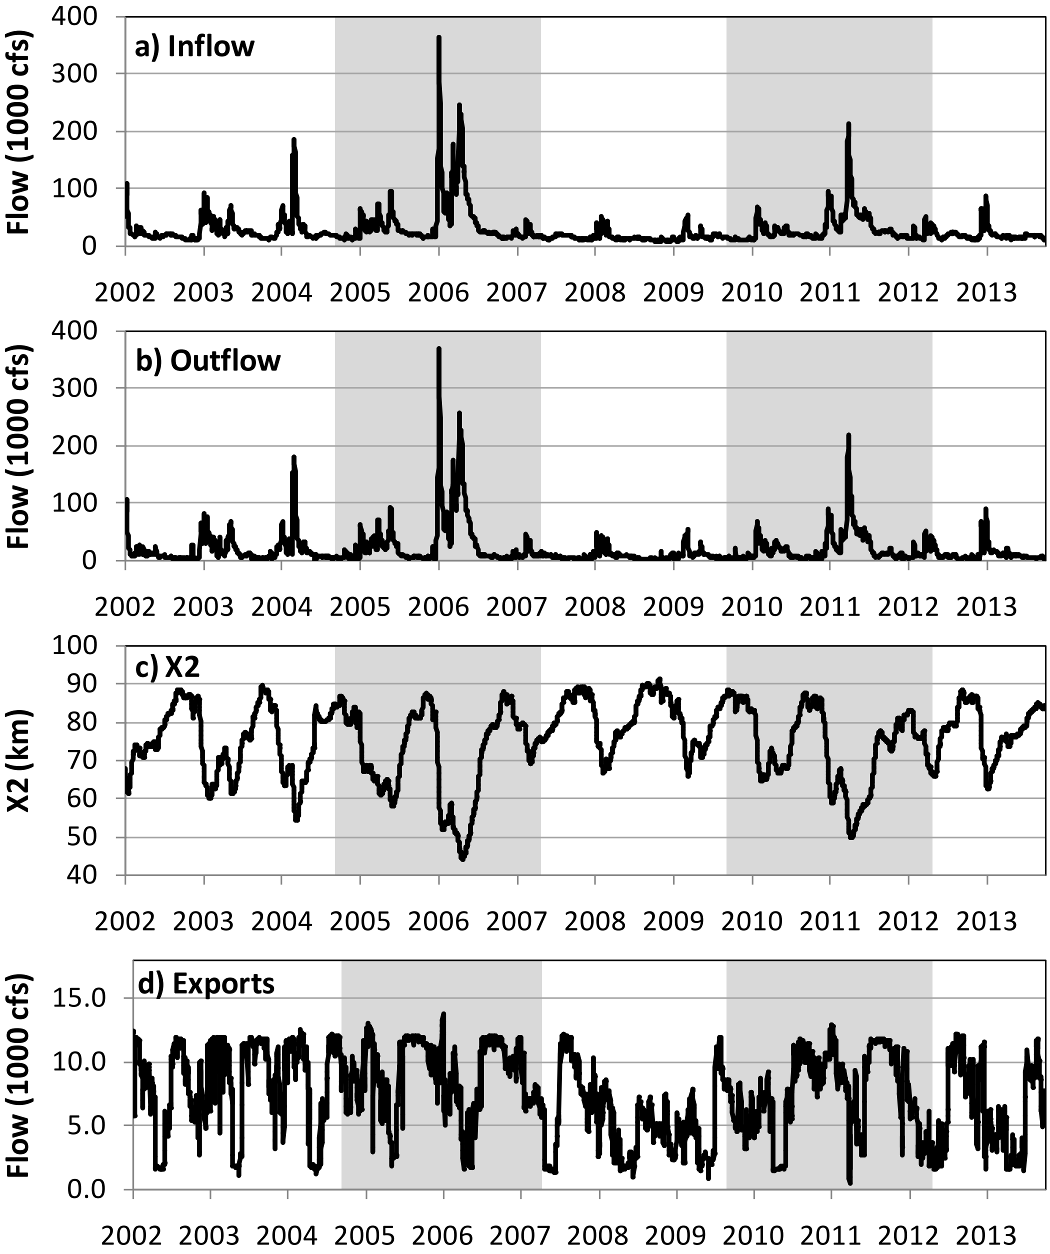


Figure 60. **Daily X2 values in January to December for each of the four study years. Seasonal X2 averages are indicated by horizontal lines for spring X2 (February to June), summer X2 (July and August), and fall X2 (September to December). See Fig. 15 for seasonal X2 in other years.**

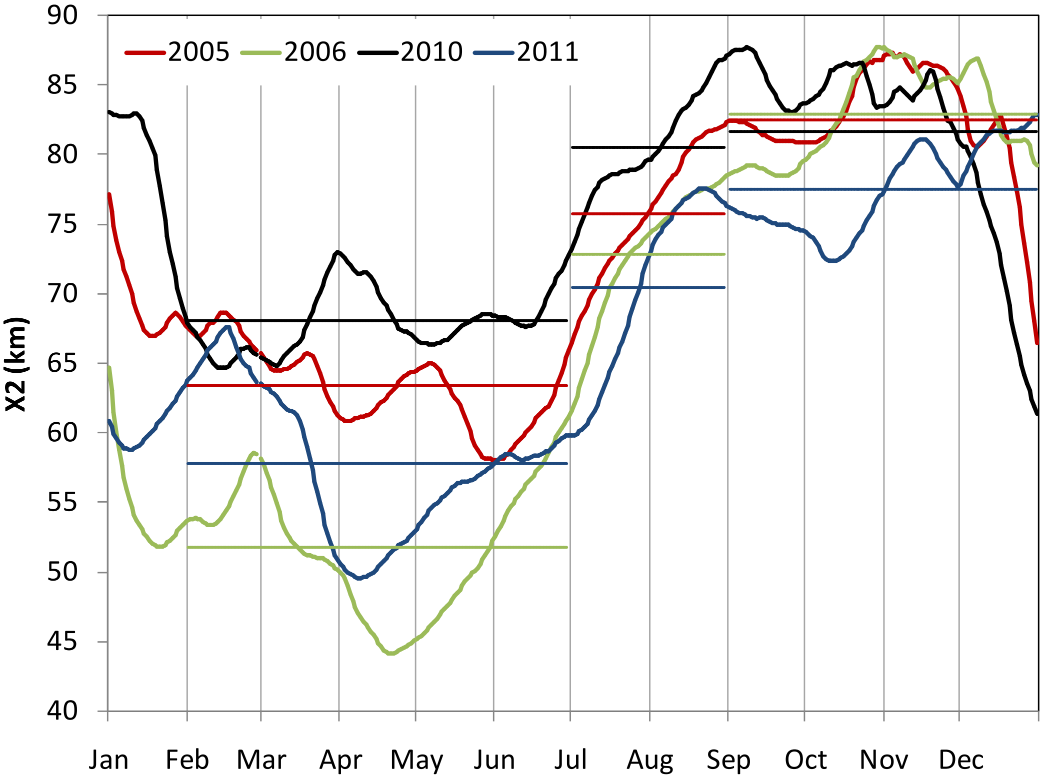

proportional loss estimates for adult Delta Smelt entrainment losses for the two years for which they are available (2005 and 2006; Kimmerer 2008). However, we otherwise restrict our analysis – and this hypothesis – to an assessment of entrainment risk based on salvage and OMR flow data. Note that high entrainment risk for an individual fish does not automatically lead to a high proportion of the population lost to entrainment mortality. For example, in wetter years when large numbers of fish are present but most of the population is distributed farther away from the pumps, a large number of fish can be entrained but only a small percentage of the entire population.

Adult (December-March) Delta Smelt salvage was highest in 2005 followed by 2006 and 2010 and lowest in 2011 (Fig. 61). In 2005, most salvage occurred in January, while in the other three years it occurred in February and March (Fig. 62). Overall, adult Delta Smelt salvage in the four comparison years was on the very low end of the historical time series starting in 1980 (Fig. 26). On the other hand, the ratio of adult salvage divided by the previous year's FMWT index was high in 2005 (6th highest on record since 1979), but much lower in 2006 and 2010, and lowest in 2011 (Fig. 26).

Low salvage levels in these years and especially in 2010 and 2011 were not particularly surprising due to the low FMWT levels of the POD years along with more active management of OMR flows for Delta Smelt and salmonid protection after 2008 in accordance with the USFWS (2008) and NMFS (2009) BioOps. For management purposes, the onset of increased adult Delta Smelt entrainment risk is inferred from distributional patterns of Delta Smelt detected by the SKT survey, Delta Smelt salvage and, more recently, consideration of Delta conditions, including turbidity patterns. Since 2009, net OMR flows during periods of increased adult Delta Smelt entrainment risk are now always less negative than they were in years prior to the BioOps. Prior to 2008, net OMR flows often reached -8,000 to -10,000 cfs (see Fig. 31, Kimmerer 2008, Grimaldo et al. 2009), when outflow was low. An exception to these strongly negative flows occurred during April-May export curtailments associated with the Vernalis Adaptive Management Program (VAMP, 2000-2012). These curtailments were especially pronounced in the first half of the VAMP period (2000-2005). During the four comparison years, winter (December-March) net OMR flows were least negative in 2006 followed by 2011 and 2010 with the most negative net OMR flows in 2005 (Fig. 63). High inflows particularly from the San Joaquin River during 2005, 2006 and 2011 moderated effects of negative OMR flows, while export pumping generally remained high. In 2010 at the end of a three-year drought, there was little water in storage to provide for Delta exports prior to the first substantial inflows in mid-January. Subsequently, export levels had to be curtailed to achieve the desired OMR flows. Average winter-time net flows past Jersey Point on the San Joaquin River were positive in all four study years and greatest in 2006 followed by 2011, 2005, and 2010 (Fig. 63).

Kimmerer (2008) used salvage, OMR flows, and fish survey data to estimate proportional population losses due to entrainment for the years 1995-2006. The years 2005 and 2006 represent some of the lower loss estimates in the years examined by Kimmerer (2008); mean population losses reached up to 22% of the adult population in some years when OMR flows were more negative than -5000 cfs (Kimmerer 2008). Even if Kimmerer's estimation method provides a potential overestimate of loss (Miller 2011), proportional losses of the adult population were less than 10% in the two years that coincide with our comparison years (2005 ≈ 3% , 2006 ≈ 9%; from Fig. 12 in Kimmerer 2008). These types of proportional loss estimates are not available for

Figure 61. **Annual adult (December-March) Delta Smelt salvage at the CVP (blue bars) and SWP (green bars) fish protection facilities for 2005-2012.**

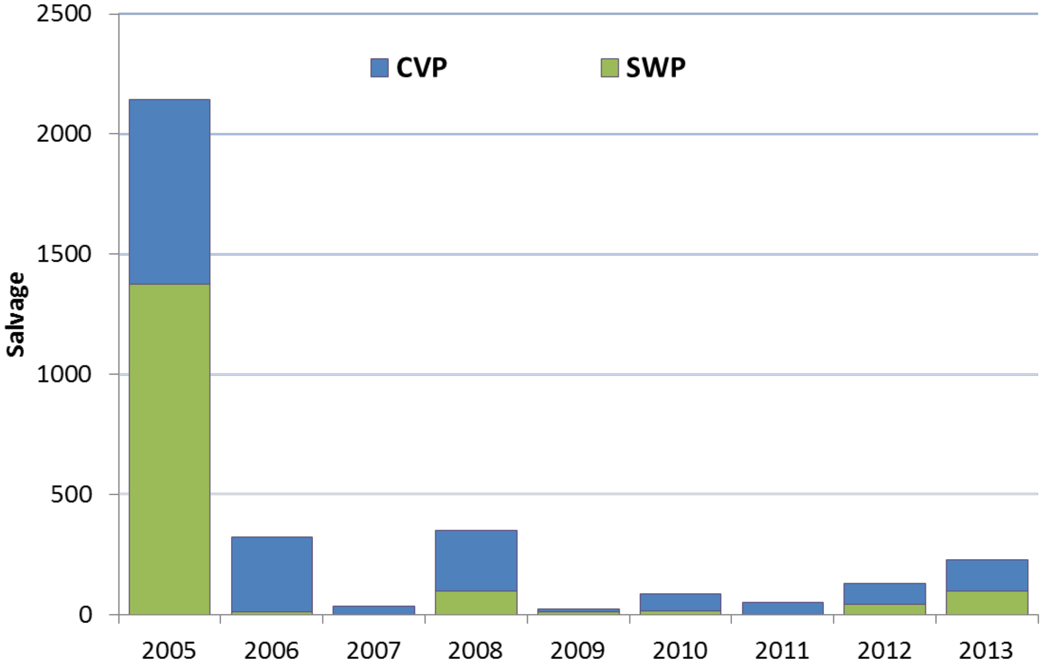

Figure 62. Annual combined adult (December-March) Delta Smelt salvage at the CVP and SWP fish protection facilities by month for 2005-2012.

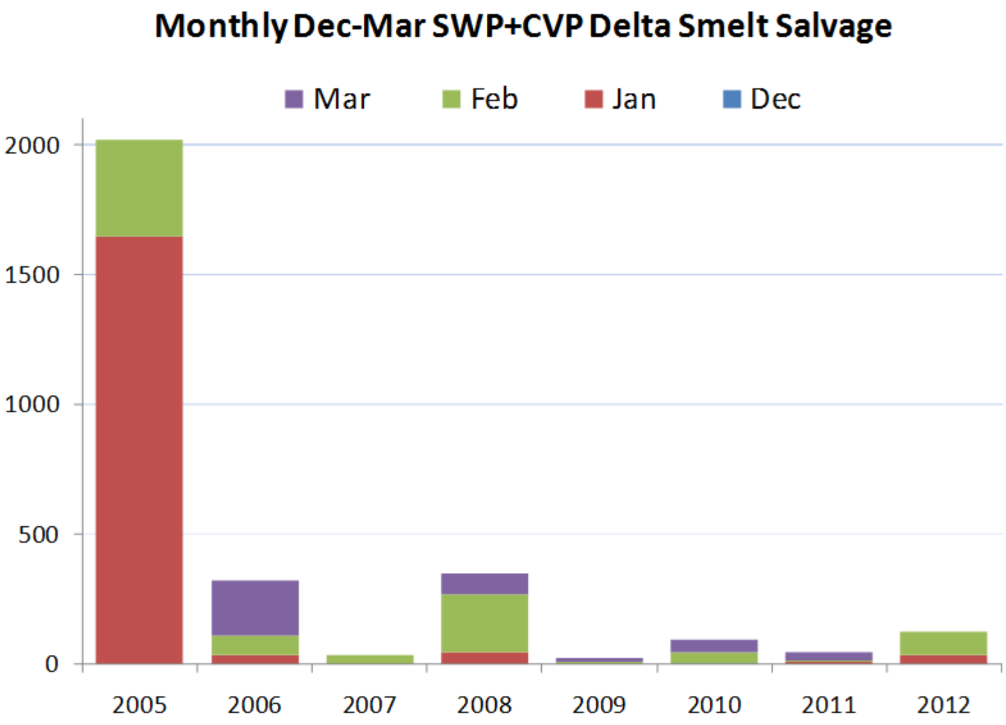


2010 and 2011, but would likely be even smaller than for 2005 due to less negative OMR flows and fish distributions away from the CVP and SWP pumps. Salvage was also lower in these two years than in 2005 and 2006.

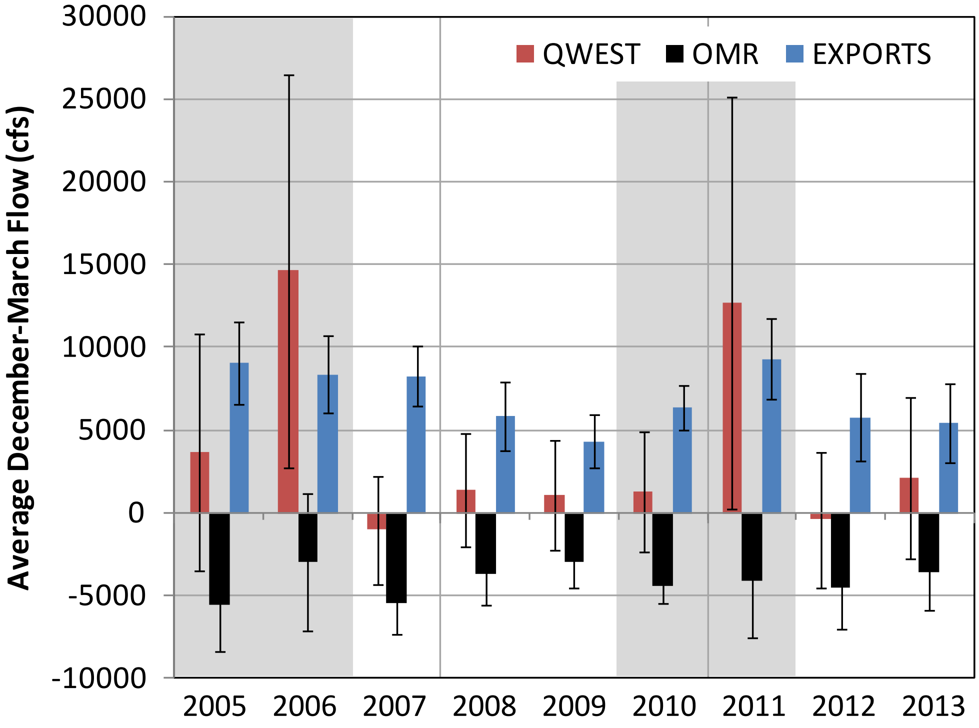
In summary, we conclude that hydrology and water exports do interact to influence entrainment risk for adult Delta Smelt and that adult Delta Smelt entrainment risk during the four comparison years was perhaps higher in 2005 than in the other years, but was low relative to historical levels in all four years.

Hypothesis 2: Hydrology interacting with turbidity affects predation risk for adult Delta Smelt.

At present, we do not have information about differences in actual predation mortality between the comparison years. As with entrainment, we thus limit this hypothesis and our analysis to to a general discussion of predation risk. Fully characterizing predation risk is exceptionally complicated, making it difficult to generate simple hypotheses that describe associated losses of all life stages of Delta Smelt. We thus limit our hypotheses about predation risk to a few factors for each life stage. For adults, we consider hydrology and turbidity as well as overlap with predators (next hypothesis).

Because Delta Smelt migrate during higher flow conditions when the water is generally turbid, it is assumed that losses to visual predators are lower or at least not substantially higher during the migration period than during other periods. First flush studies led by the USGS and UC Davis

Figure 63. **Annual average daily net flows for December through March in cubic feet per second (cfs) in Old and Middle River (OMR), past Jersey Point on the lower San Joaquin River (QWEST) and total exports in millions of acre feet (MAF), 2005-2013. Error bars are 1 standard deviation.**



suggest that Delta Smelt aggregate in the water column away from channel edges during daytime flood tides during upstream migration events (Bennett and Burau 2014), but it is not known if Striped Bass or Sacramento Pikeminnow *Ptychocheilus grandis*, the most likely predators of Delta Smelt in the water column, can detect and exploit these aggregations.

In the winters of 2005, 2006, 2010, and 2011 the highest Secchi depths (lowest turbidity) were found in the freshwater regions of the estuary (< 1 salinity), except for the Cache Slough region in the north Delta which was as turbid as the saltier regions of the estuary (Fig. 64). Winter-time Secchi depths in the freshwater region recorded during the SKT surveys (Fig. 64) were often higher (water clearer) than the average Secchi depths across all IEP EMP monitoring sites during these months since 2003 (about 60 cm) and especially when compared to pre-POD winter Secchi depths (around 50 cm on average) recorded by the EMP (Fig. 25). Winter-time Secchi depths in the other salinity regions were generally lower (water more turbid) than the EMP Secchi depth averages for the POD years and more similar to historical averages. In all four comparison years, predation risk associated with turbidity levels was thus likely not different from the historical risk in the more saline regions and the Cache Slough complex, but possibly higher in the freshwater regions, except for the Cache Slough region.

The salinity region differences were much more pronounced than the interannual differences between the four comparison years. Based on these data, it is not clear that higher flows in 2006 and 2011 contributed to higher turbidity in the winter months. The exception might be near the end of the Delta Smelt spawning season in early April when Secchi depths in the freshwater region were often substantially lower in the two wetter years 2006 and 2011 than in the two drier years 2005 and 2010 (Fig. 64). This will be discussed further in the report section about larval Delta Smelt. For adults, we conclude that interannual differences in turbidity between the wetter and drier of the four comparsion years did not likely contribute substantially to reduced predation risk and increased survival in the two wetter years.

Hypothesis 3: Predator distribution affects predation risk of adult Delta Smelt

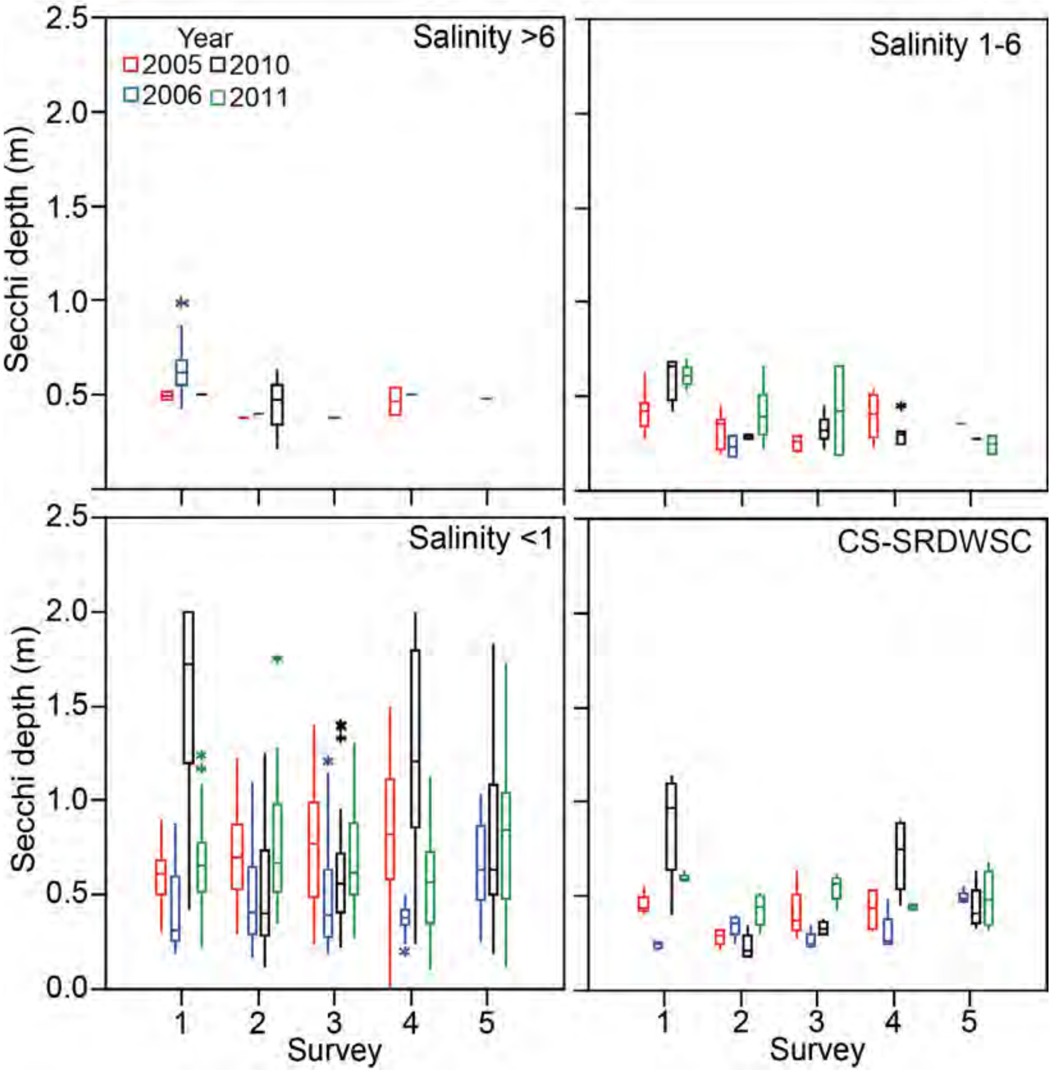
Spatial and temporal overlap with predators is a likely factor contributing to predation risk for all life stages. At present, we do not have information about how predator distribution varied between our comparison years but it is recognized that adult Delta Smelt could be vulnerable to predation if the distributions of predators and Delta Smelt populations overlapped. As already mentioned, Striped Bass and Sacramento Pikeminnow are the most likely open-water predators of adult Delta Smelt. If Delta Smelt utilize littoral habitats to a greater extent than presently assumed, then increased overlap with the distributions of Largemouth Bass and other centrarchid populations is possible. Results of field studies (Feyrer et al. 2013, Bennett and Burau 2014), described for Adult Hypothesis 2, found that adult Delta Smelt did move nearshore on a tidal basis to avoid displacement or move upstream during the “first flush.” Such movements would increase proximity to shoreline predators like Largemouth Bass, albeit during periods of increased turbidity when such visual predators would be at a disadvantage. Clearly, Hypothesis 2 and Hypothesis 3 are closely linked because predation risk is a function of predator presence and prey vulnerability. More information about predator presence is needed to evaluate this aspect of predation risk.

Hypothesis 4: Variability in prey availability during winter and spring affects growth and fecundity (eggs per clutch **and number of clutches) of female Delta Smelt.**

The hypothesis is that increased food availability leads to not only increased adult survivorship, but also growth, which in turn increases reproductive output (number of eggs per female increases with size; Bennett 2005). In addition, with cooler temperatures and lower metabolic rates, sufficient food resources during winter can contribute to energetically demanding multiple spawning events (three spawns possible in wild fish; L. Damon, CDFW, written communication 2012).

For adult females, the ability to meet the bioenergetic demands of reproductive development with sufficient food consumption may be particularly important for fish that spawn multiple times in a year. Preliminary findings from January through April 2012 indicated that adult Delta Smelt are indeed consuming large prey items, such as amphipods, mysids, and larval fish during their spawning period (Fig. 44) with feeding incidence near 98% for the period (Table 2). For this report, we cannot address whether food limitation is a relevant factor during the late winter-spring spawning period because we do not have sufficient data about adult Delta Smelt feeding, but we hypothesize that it may be a critical issue for spawners that need energy for multiple egg clutches. Evidence in support of this hypothesis comes from the modeling simulation experiment by Rose et al. (2013b) who found that food availability along with water temperature affected fall and winter growth and egg production prior to spawning and ultimately population success.

Figure 64. Secchi depth data collected during the Spring Kodiak Trawl Survey. Surveys are conducted monthly January-May. See Chapter 3: Data Analyses for explanation of boxplots.



Based on trajectories in adult fork lengths, it appears that adult growth may have been somewhat higher in 2005 and 2011 than in 2006 and 2010, although differences were not pronounced (Fig. 17) and as noted in Chapter 6, annual fork lengths of Delta Smelt collected in the SKT were similar in the four study years (Fig. 55). From these data we infer that environmental conditions were generally good, supporting both continued growth in length and maturation of eggs, except perhaps in 2010. In 2011, only 13 mature females were collected, so growth estimates are uncertain. In general, the number of mature females collected each year reflected year-class strength as measured by the SKT (Fig. 3), except in 2011 when only 13 ripe or ripening females were collected. Adults may use more energy for egg production than for continued somatic growth, but we do not have data on clutch sizes to evaluate this for the four study years.

Data on prey availability for current IEP sampling locations is also limited. Adult Delta Smelt diet is varied (Fig. 44) and includes pelagic and demersal invertebrates, as well as larval fish. Current mesozooplankton (copepod and cladoceran) and mysid sampling by the EMP

Table 2. **Percent of age-1 Delta Smelt captured during the Spring Kodiak Trawl Survey with food present in the stomach collected January through May 2012 for three salinity regions and the freshwater Cache Slough-Sacraramento River Deepwater Ship Channel (CS-SRDWSC).**

Zooplankton Study and invertebrate sampling by the EMP Benthic Monitoring Study does not sample the full geographic range occupied by adult Delta Smelt, including Cache Slough and the Sacramento River Deep Water Ship Channel. In addition, epibenthic cumaceans and amphipods consumed by Delta Smelt might not be effectively sampled with current methods (substrate grabs using a Ponar dredge), which are more suited to sampling organisms in or attached to the substrate. Amphipods found in stomachs of adult Delta Smelt collected January 2012-May 2012 (Fig. 44) were 95% *Corophium* spp., and of those, 90% were juveniles ranging 0.8 to 1.3 mm in body length. These amphipods are believed to be mostly juvenile *Americorophium spinicorne* and *A. stimpsoni*, which as adults are tube building amphipods (Hazel and Kelley 1966). Dirt, substrate debris, and tube pieces were not found in Delta Smelt stomachs with the amphipods, so it is possible these juveniles amphipods are epibenthic or pelagic prior to settling and building tubes. Size distribution of amphipods collected by the DWR EMP Benthic Monitoring Study is not currently available. The IEP Smelt Larva Survey does collect larval fish data during winter (January-March) over a wide section of the estuary, but comparisons with larval fish consumption by adult Delta Smelt are limited because this survey is still new; it was initiated in 2009.

Data were insufficient to conclusively test the hypothesis that variability in prey availability affects growth and fecundity of adult Delta Smelt. More data are needed on growth, clutch number and size, and prey availability.

Larval Hypotheses

Hypothesis 1: Delta Smelt larvae numbers are positively affected by increased duration of the temperature spawning window

To evaluate this hypothesis, we developed two water temperature measures. The first is the number of days in the temperature spawning window as indexed by mean daily water temperatures at Rio Vista between 12 and 20 °C. This temperature range was selected as representing a reasonable balance between the various temperature ranges observed in laboratory and field studies (Wang 1986, Baskerville-Bridges et al. 2004b, Bennett 2005) and reviewed in earlier sections of this report. Presumably, a longer duration spawning window would result in more repeat spawning for individual females and greater total fecundity. The second water temperature measure is the number of days in the optimal temperature for egg survival to hatch. We referred to Fig. 10a in Bennett (2005) and selected the temperature range of 12-17 °C as optimal for egg survival. As explained in previous sections, adult abundance, based on SKT sampling, peaked in 2012 as the 2011 year-class of Delta Smelt reached maturity (Fig. 3). In contrast, the spawning stock (i.e., 2011 SKT) that produced the 2011 year-class ranked second lowest to 2006 (Fig. 3, Adults). Despite this low level, the 2011 spawning stock produced the highest adult abundance observed to date in 2012. This suggests that adult stock size has not limited subsequent adult recruitment from rebounding to levels comparable to those of immediate pre-POD years (see Fig. 3, Subadult). As mentioned in Chapter 6, this suggests that even a severely depleted adult stock can still produce a substantial number of larvae and a rebound in the Delta Smelt population, albeit with potentially lower genetic variability than before (Fisch et al. 2011). It also suggests that factors acting on the survival of larval, juvenile and later stages have a substantial effect on recruitment of adults, because relatively low larval abundance in 2011, was associated with the high 2012 adult abundance (Fig. 3).

As mentioned in the adult section, mature adult female Delta Smelt appeared to grow throughout the spawning seasons of the years compared, except 2010 (Fig. 17). We used water temperatures at the Rio Vista Bridge as a surrogate for temperatures experienced by spawning Delta Smelt (Fig. 65) and calculated the duration of the spawning window and of optimal temperatures to hatch. We calculated each as the number of days between the date of first achieving the lower temperature and the date of first achieving the upper temperature. The onset of the spawning window occurred earliest in 2010, followed by 2005 and 2011 (Fig. 65; Table 3). The spawning window occurred latest in 2006 (Fig. 65; Table 3). The spawning window was broad in both 2005 and 2010 at 128-129 days, intermediate in 2011 at 113 days (20 °C not achieved until July 4, not shown), and was shortest in 2006 at 85 days (Fig. 65; Table 3). Assuming that female Delta Smelt undergo a 35-day refractory period, based on a 4-5 week refractory period (J. Lindberg, U.C. Davis, personal communication, 2013) between each spawning, even in 2006 three spawning events were possible, assuming fish were mature and ready to spawn at the initiation of the spawning window. In all other years, four spawning events were possible, so this measure does not discriminate among years well. The duration of optimal hatch temperature was also lowest in 2006, but other durations ranked differently across years than did spawning window duration (Table 3).

The data for the four study years do not provide conclusive support for the hypothesis that the duration of the spawning window or duration of optimal hatching temperature affected larval production. Relatively high larval abundance in 2005 was consistent with a long spawning window and moderate duration of optimal hatch temperatures (129 days and 68 days, respectively; not shown). However, 2006 with the shortest spawning window (85 days) and shortest optimal hatch duration among the 4 study years also had relatively good larva abundance (Fig. 3). In contrast, larval abundance was low in 2010 although the spawning window and optimal hatch duration were both relatively long. Other factors likely contributed to poor larval abundance in 2010, because ripening and ripe females were not detected after early April 2010 and female growth through the winter was poor (Fig. 17). Finally, both the spawning window and optimal hatch duration were fairly long in 2011 as compared to 2006, so slightly lower larval production in 2011 is inconsistent with these durations. This hypothesis was not supported.

Figure 65. Mean daily temperatures (°C) at Rio Vista from February 1 through June 30, 2005, 2006, 2010, 2011. The green lines enclose the spawning window, which represents temperatures at which successful spawning is expected to occur.

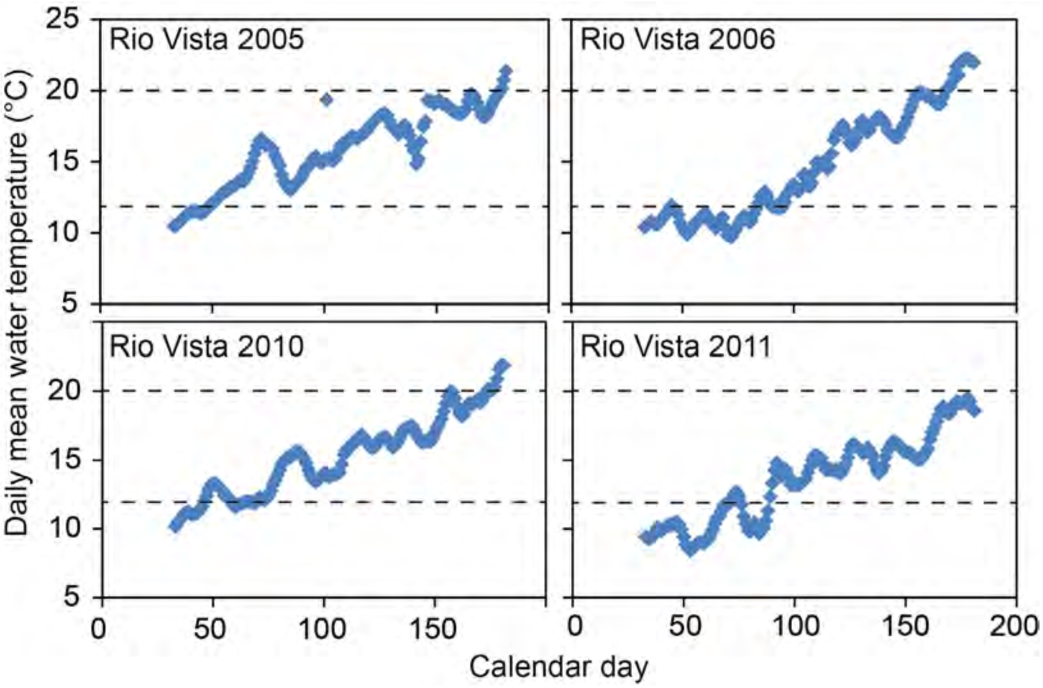

Table 3. Delta Smelt spawning window (12 to 20 °C inclusive) and optimal hatching period (12 to 17 °C inclusive) for 2005, 2006, 2010, and 2011, defined as number of days of water temperatures, based on mean daily water temperatures measured at Rio Vista. Data are calendar day when water temperature achieved 12, 17, and 20 °C and the duration (days) between those calendar days. The upper limit in 2011 was not reached until July 4, outside the spring season.

Year	Day 12 °C Achieved	Day 17 °C Achieved	Day 20 °C Surpassed	Duration 12-20	Duration 12-17	Duration 17-20
2005	50	118	179	129	68	61
2006	84	120	169	85	36	49
2010	46	136	174	128	90	38
2011	72	163	185	113	91	22

Hypothesis 2: Increased food availability results **in increased larval abundance and survival.**

This hypothesis focuses on seasonal changes in phytoplankton biomass and the zooplankton community and resulting changes in abundances of food items most often consumed by Delta Smelt larvae. Phytoplankton biomass data (chlorophyll-*a*) collected at 10 stations by the IEP

EMP show that the highest spring biomass levels were observed in May of 2010 and 2011 (Fig. 66). Median biomass levels were lower in April and May of 2005 and 2006 than in April and May of 2010 and 2011. This suggests that more food was available for zooplankton growth in the spring of 2010 and 2011 than in 2005 and 2006. In all four years, however, chlorophyll concentrations were lower than 10 ug/L at almost all stations, suggesting that zooplankton may have generally been food limited in these years (see Chapter 4). Nevertheless, greater phytoplankton biomass in late spring of 2010 and 2011 may have contributed to overall greater food availability and better survival of late larvae and early juveniles in these years.

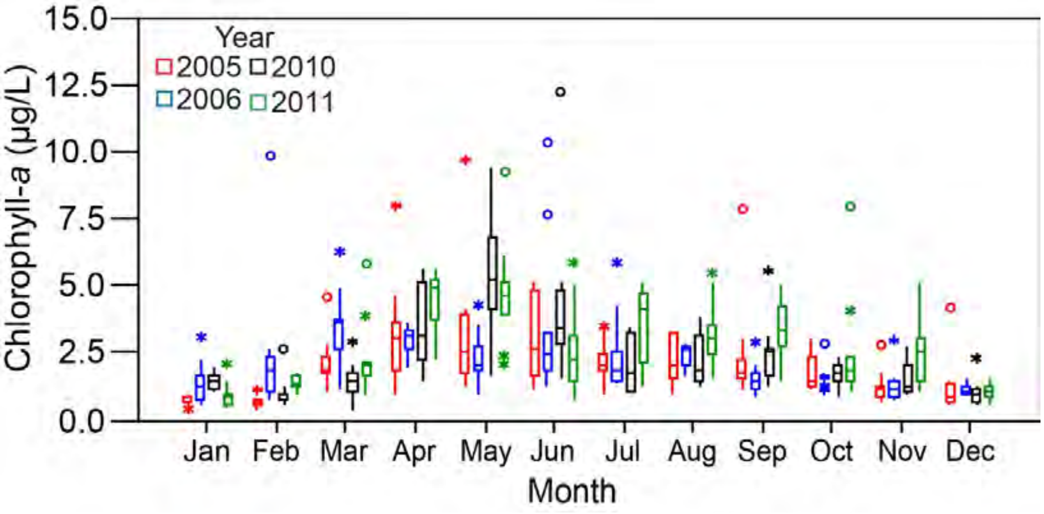
Juvenile and adult calanoid copepods, particularly *E. affinis* and *P. forbesi*, comprise most of the larval diet through June (Nobriga 2002, Slater and Baxter 2014). *E. affinis* is moderately abundant only during winter and spring and rare in summer and fall, whereas *P. forbesi* is abundant only in summer and fall (Durand 2010, Hennessy 2010, 2011, Winder and Jassby 2011). It is not clear whether the seasonal decline in abundance of *E. affinis* is related to temperature, potential competitive interactions with *P. forbesi*, differences between the species in vulnerability to consumption by *P. amurensis* (Miller and Stillman 2013), or a combination of such factors. The transition between high abundances of the two species, may create a seasonal "food gap" during late spring or early summer. This food gap has been hypothesized to be an important period for Delta Smelt larval survival (Bennett 2005, Miller et al. 2012).

To assess whether a gap in prey availability existed between periods of high abundance of *E. affinis* and *P. forbesi*, we evaluated abundance patterns in 20 mm Survey copepod data for stations with and without Delta Smelt. The food gap hypothesis was only weakly supported by the data. The density of *E. affinis* (in the presence of Delta Smelt larvae) typically reached 100 m^3 by week 16 (Figs. 67 and 68). Assuming 100 m^3 as a baseline density for *E. affinis*, this baseline was generally maintained until about week 22, when they declined at about the same time that *P. forbesi* densities increased to 100 m^3 (Figs. 67 and 68). After combining the densities of both *E. affinis* and *P. forbesi* and tracking them through time, we detected a gap in food during week 22 (late May – early June) of 2005 (Fig. 67), which is inconsistent with 2005 exhibiting the highest larva abundance among our comparison years (Fig. 3). Such density gaps were not observed in the other three comparison years (Figs. 67 and 68), which exhibited lower abundance than 2005 (Fig. 3). Survival of larvae to juveniles was very low in 2005, but was also low in 2006 (Fig. 51) with no evidence for a food gap in 2006. Survival of larvae to juveniles was relatively high in 2010 and 2011 (Fig. 51). This analysis does not support the hypothesis that differences in zooplankton availability affected larval abundance and survival in the four study years, but higher phytoplankton biomass in April and May of 2010 and 2011 could have contributed to overall greater food availability and better survival of late larvae and early juveniles in these years.

Hypothesis 3: Distributional overlap of Mississippi Silverside with Delta Smelt and high abundance of Mississippi Silverside increases predation risk/rate on larval Delta Smelt, whereas, increased turbidity, **decreases predation risk/rate on larval Delta Smelt.**

Silversides are ubiquitous within the Delta (Brown and May 2006) and have long been proposed (Bennett 1995) and more recently confirmed as a predator of Delta Smelt larvae (Baerwald et al. 2012). We do not have estimates of predation losses to Silversides during the four study years and thus focus on assessing predation risk by evaluating fish distributions, predator and prey sizes, and prey growth, which is related to temperature.

Figure 66. Trends in chlorophyll-*a* concentrations (µg/L) in samples collected by the IEP Environmental Monitoring Program during each the four study years (2005, 2006, 2010, and 2011). Sample site locations shown in figure 15. See Chapter 3: Data Analyses for explanation of boxplots.

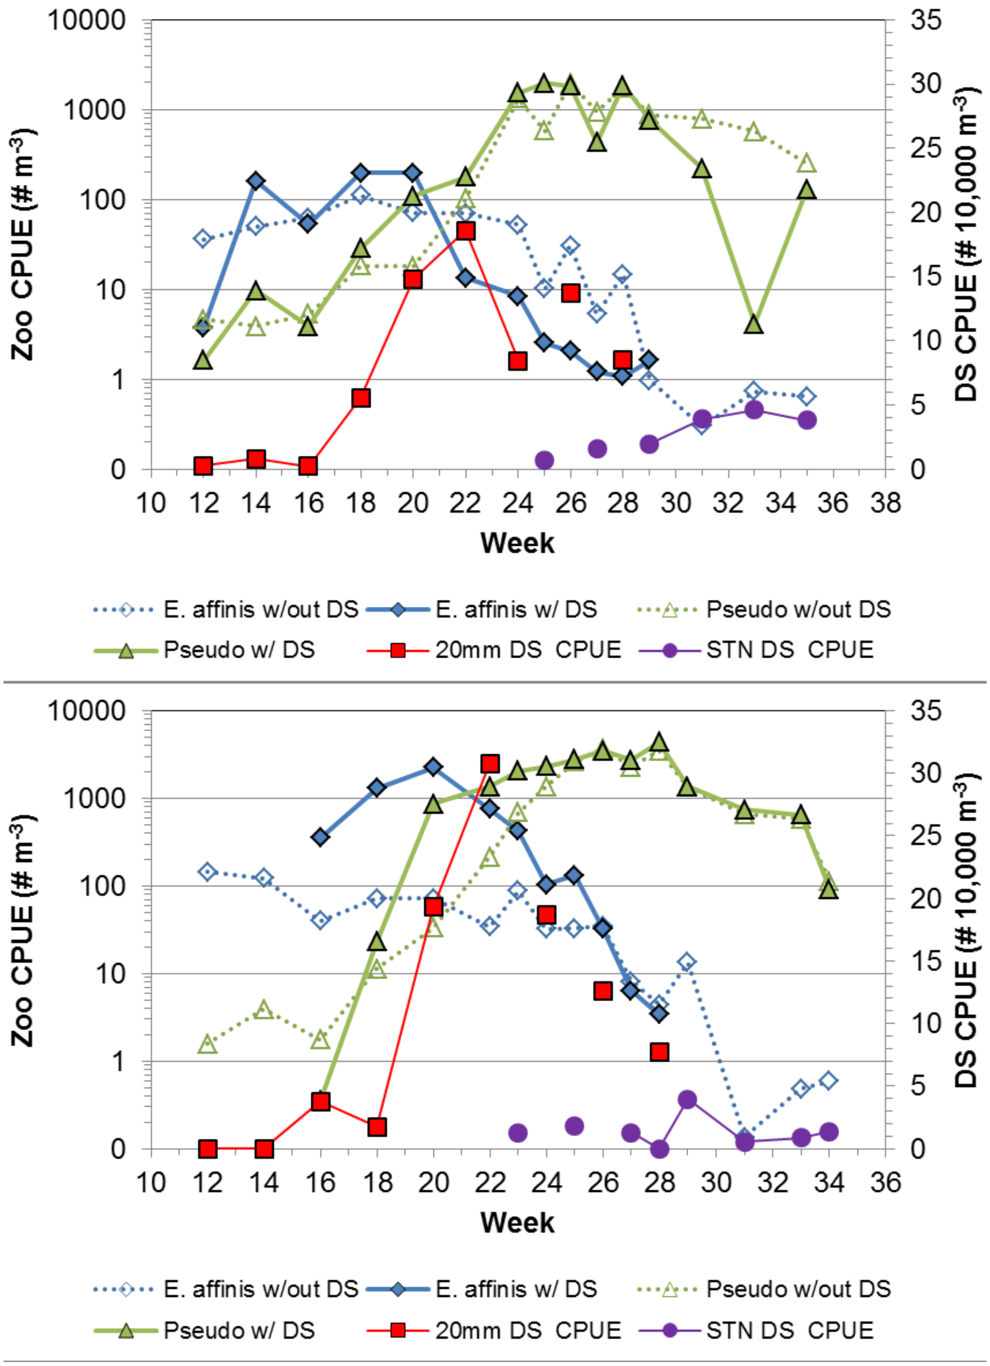


Silversides large enough to consume fish larvae are present in the Delta during spring and are likely to prey upon Delta Smelt larvae. Silverside habitat has been characterized as open water shoals and shoreline (Brown and May 2006, Grimaldo et al. 2012); however, the species also occurs in low density in deep open water primarily in summer (Grimaldo et al. 2012). Catches in the SKT confirm silverside presence in open water in spring as well, though catches tended to be low. However, SKT sampling does not occur at night when offshore Silverside densities may be higher, if foraging patterns follow those observed in Clear Lake, California (see Wurtsbaugh and Li 1985). Compared to the open embayments, SKT Silverside catches were higher in channels such as Montezuma Slough, Cache Slough, the San Joaquin River, and especially the Sacramento Deepwater Ship Channel (Table 4). This Silverside distribution matched higher March through May regional catches of Delta Smelt larvae (Table 4, see http://www.dfg.ca.gov/delta/data/20mm/CPUE_map.asp), except that larvae catches in Suisun Bay and the lower Sacramento River were occasionally high and Silversides catches were usually low. Delta Smelt larvae were found in significantly higher densities in offshore-open water habitats (Grimaldo et al. 2004), which corresponds to the habitat where Silversides consuming Delta Smelt larvae were captured (Baerwald et al. 2012). As discussed above, the relatively large-sized silversides present in the Spring Kodiak Trawl indicates some offshore movement and overlap of predator-sized foraging silversides with Delta Smelt larval habitat.

The frequency and magnitude of Silverside catches by the Spring Kodiak Trawl increased as Secchi depths approached and dropped below 50 cm (Fig. 69), suggesting that Silversides may venture offshore more frequently and in higher numbers in turbid water. This might also represent a displacement effect resulting from high flows, but high catches were most common in Montezuma Slough and the Sacramento Deepwater Ship Channel (Table 4) where displacement by flow should not have been a factor.

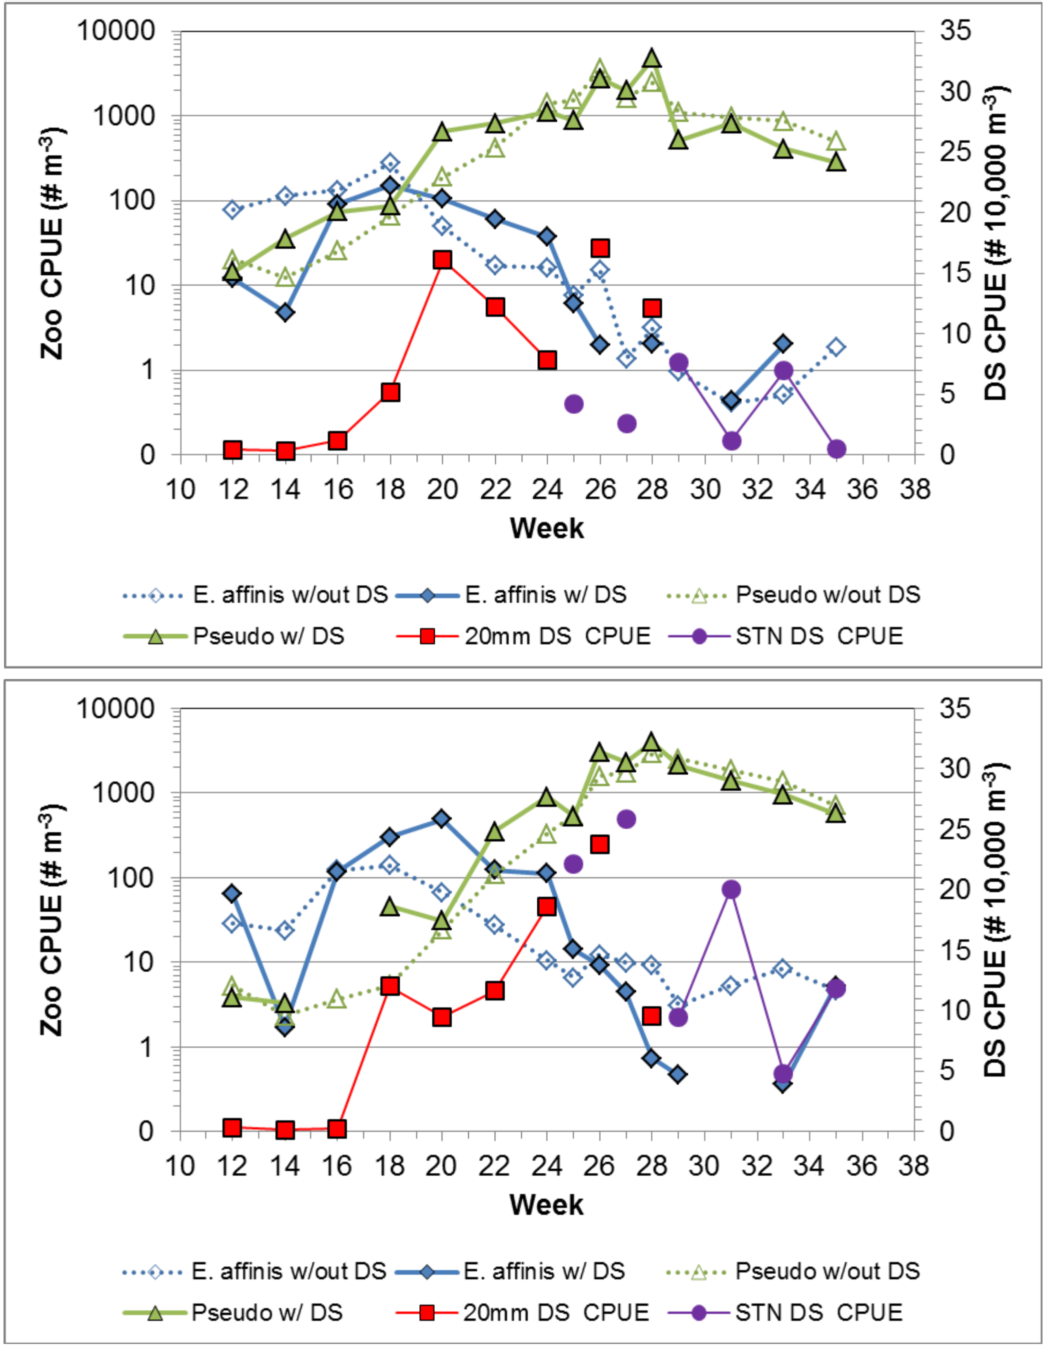
The hypothesis is somewhat supported in that: 1) Silversides are captured in Spring Kodiak Trawl in March and April (Fig. 70), when early stage Delta Smelt larvae are common; 2) Silverside

Figure 67. **Catch per unit effort (CPUE) of adult *Eurytemora affinis* and *Pseudodiaptomus forbesi* (Zoo; number individuals/m^3 sampled) and Delta Smelt (DS; number individuals/10,000 m^3 sampled) by calendar week from mesozooplankton sampling and Delta Smelt catch by the 20 mm and Summer Townet surveys, 2005 (top) and 2006 (bottom)**



catches offshore increase with increased turbidity (i.e., declining Secchi depth; Fig. 69), and 3) there is regional overlap in Cache Slough and the Sacramento Deepwater Ship Channel, and some in Montezuma Slough (cf. Table 4 and http://www.dfg.ca.gov/delta/data/20mm/CPUE_

Figure 68. Catch per unit effort (CPUE) of adult *Eurytemora affinis* and *Pseudodiaptomus forbesi* (Zoo; number individuals/m^3 sampled) and Delta Smelt (DS; number individuals/10,000 m^3 sampled) by calendar week from mesozooplankton sampling and Delta Smelt catch by the 20 mm and Summer Townet surveys, 2010 (top) and 2011 (bottom).



map.asp), known larval rearing regions. It is also possible the nighttime offshore foraging by silversides is a more common strategy (Wurtsbaugh and Li 1985), but one that goes undetected by current sampling. Silverside catch per trawl (Table 4) indicates low offshore densities and the same turbidity that facilitates offshore movement may also inhibit predation effectiveness.

Table 4. Mississippi Silverside catch by region (monthly sample number in parentheses) and year by the Spring Kodiak Trawl Survey sampling monthly March through May (months when Delta Smelt larvae are present), 2005, 2006, 2010 and 2011; distribution survey data only. Annual sampling effort summarized consisted of 3 surveys and 37 stations. Tow volume varied substantially, but averaged 6,300 m^3 per tow for the 4 years.

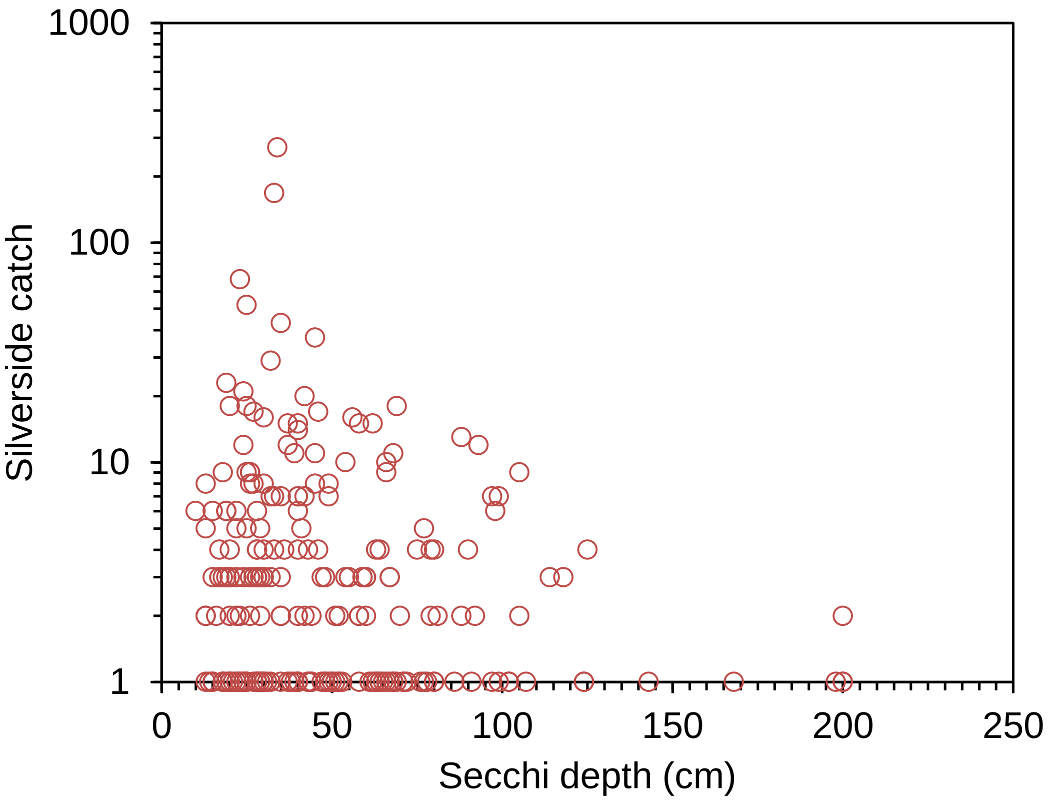
Region	2005	2006	2010	2011	Total Catch	Total Catch per Trawl
SUISUN BAY (N=10)	1	1	2	1	5	0.04
MONTEZUMA SL (N=3)	51	4	17	22	94	2.61
LOWER SACRAMENTO R (N=4)	10	1	1	3	15	0.31
CACHE SL (N=3)	9	2	4	2	17	0.47
SAC DEEPWATER SHIP CHANNEL (N=1)	14	20	45	22	101	8.42
SAN JOAQUIN R (N=8)	39	9	11	14	73	0.76
MOKLEMNE R. (N=5)	1	1	1	8	11	0.18
SOUTH DELTA (N=3)	1	0	1	1	3	0.08
ANNUAL TOTAL FOR REGIONS	126	38	82	73	319	

Overall, the conclusion regarding the effects of species distributions and abundances on predation risk is unclear. If there is an effect, it is most likely to occur in smaller channels, such as Montezuma Slough and those in the Cache Slough and the Sacramento Deepwater Ship Channel where Silversides are present in high numbers along the shoreline and larval Delta Smelt occur offshore.

Hypothesis 4: Hydrology and water exports interact with one another to influence direction of transport and risk of entrainment for larval Delta Smelt.

As for adults, we do not have proportional entrainment estimates for all four study years, so the entrainment portion of this hypothesis cannot be directly evaluated. Also, larvae (< 20 mm fork length) entrained in the State and federal water export systems are generally not quantified. To test this hypothesis we use data for the distribution and density of larvae (≥ 20 mm fork length)

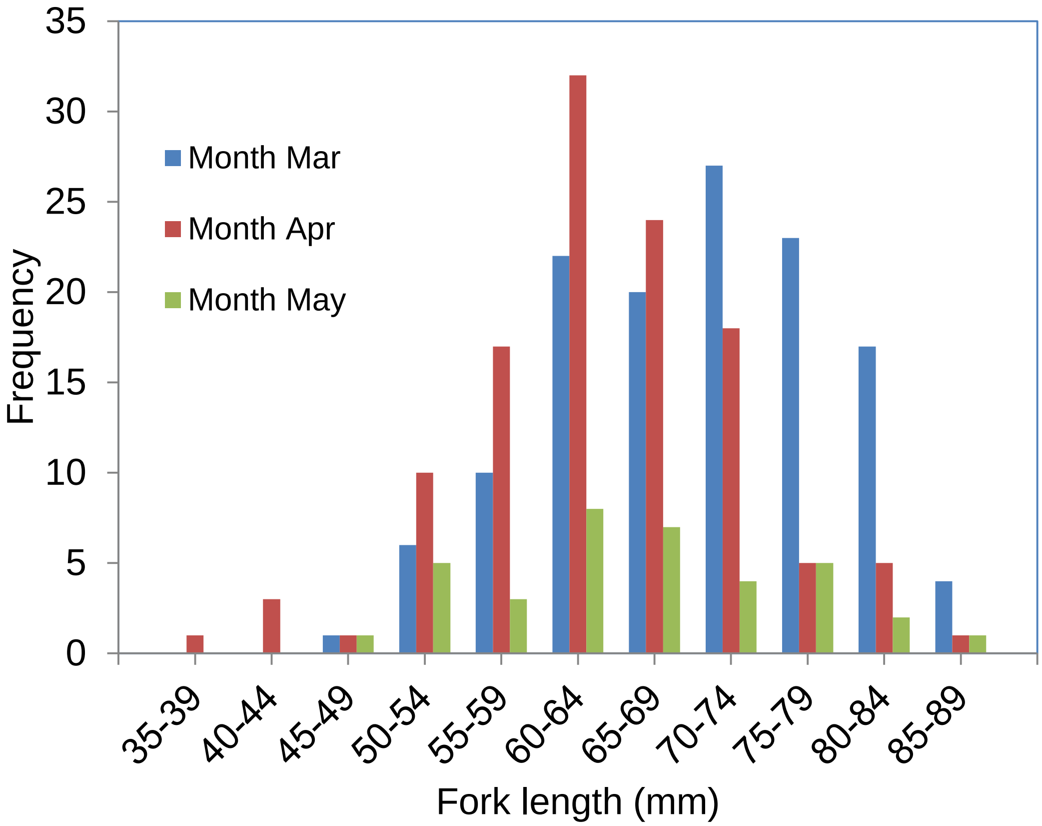
Figure 69. **Scatter plot of Mississippi Silverside catch plotted on Secchi depth (cm) at location of capture from the Spring Kodiak Trawl Survey, 2005, 2006, 2010 and 2011.**



in the central and south Delta and estimates of channel flows to infer risk of entrainment. Among the study years only 2005 larval entrainment was estimated by Kimmerer (2008), and loss to the population was relatively low. However, Delta Smelt density and distribution in the central and south Delta were greater in 2005 than in the three other study years (Table 5). This simple analysis suggests that in our 4-year comparison, entrainment risk for larval Delta Smelt may have been highest in 2005. Hardly any larval Delta Smelt were caught in this region in the two wet years, 2006 and 2011.

As for adults, we also used OMR flows (Fig. 31) to assess larval entrainment risk. Mean March through May OMR flows were positive during the two wet years 2006 and 2011 (8,221 cfs and 3,560 cfs respectively) and negative during the two dry years 2005 and 2010 (-417 cfs and -1,302 cfs, respectively). These OMR values suggest little if any risk during 2006 and 2011, and at most moderate risk in 2005 and 2010. Grimaldo et al. (2009) found that juvenile salvage was a function of abundance in the 20 mm Survey (positive) and OMR flows (negative). Looking more closely at various net daily flows from March to June of 2005, we find that OMR flows were moderately negative (i.e., toward the export pumps) only in March, and were zero to weakly positive in April and May, except for a brief period in mid-April (Fig. 31); also in 2005, Qwest was strongly positive from late March through early June, promoting downstream transport in the San Joaquin River, and exports were low from late April through late May (Fig. 31). The other dry year, 2010 exhibited a similar pattern, but lower inflows resulted in the magnitude of exports more directly influencing OMR flows (Fig. 31), and leading to moderately negative OMR flows

Figure 70. Monthly length frequency of Mississippi Silversides captured by the Spring Kodiak Trawl during distribution sampling March – May in the Sacramento River and Cache Slough sampling stations only, 2002-2012. The months and geographic range were selected to overlap with that of Delta Smelt larvae as they hatch and begin to grow.



in March and again in June, but only weakly negative flows in April and most of May coincident with positive Qwest. In the high outflow years 2006 and 2011, few larvae were detected in the central or south Delta (Table 5) and Qwest flows were strongly positive from March through at least early June, while OMR flows were near zero or weakly negative in March and positive to strongly positive by April and continuing to early June of both years (Fig. 31). Thus, for our comparison years, it appears that the available data generally support our hypothesis, but entrainment of larvae was unlikely to be an important factor during either wet year and was probably not a substantial factor in either dry year.

Table 5. Mean monthly catch of Delta Smelt per 10,000 m^3 by station for stations in the south and central Delta for the 20 mm Survey, 2005, 2006, 2010, 2011. Non-zero values are bolded.

Juvenile Hypotheses

Hypothesis 1: High water temperatures reduce juvenile Delta Smelt growth and survival through lethal and sublethal (bioenergetic stress; reduced distribution) effects.

High water temperatures have a strong effect on juvenile Delta Smelt survival (Swanson et al. 2000, Komoroske et al. 2014). In addition to the obvious potential for lethal effects, temperature can have sub-lethal effects such as reduced habitat area, higher food requirements, increased susceptibility to disease and contaminants, and increased predation. The potential for increased prey requirements and increased predation is described below for other hypotheses.

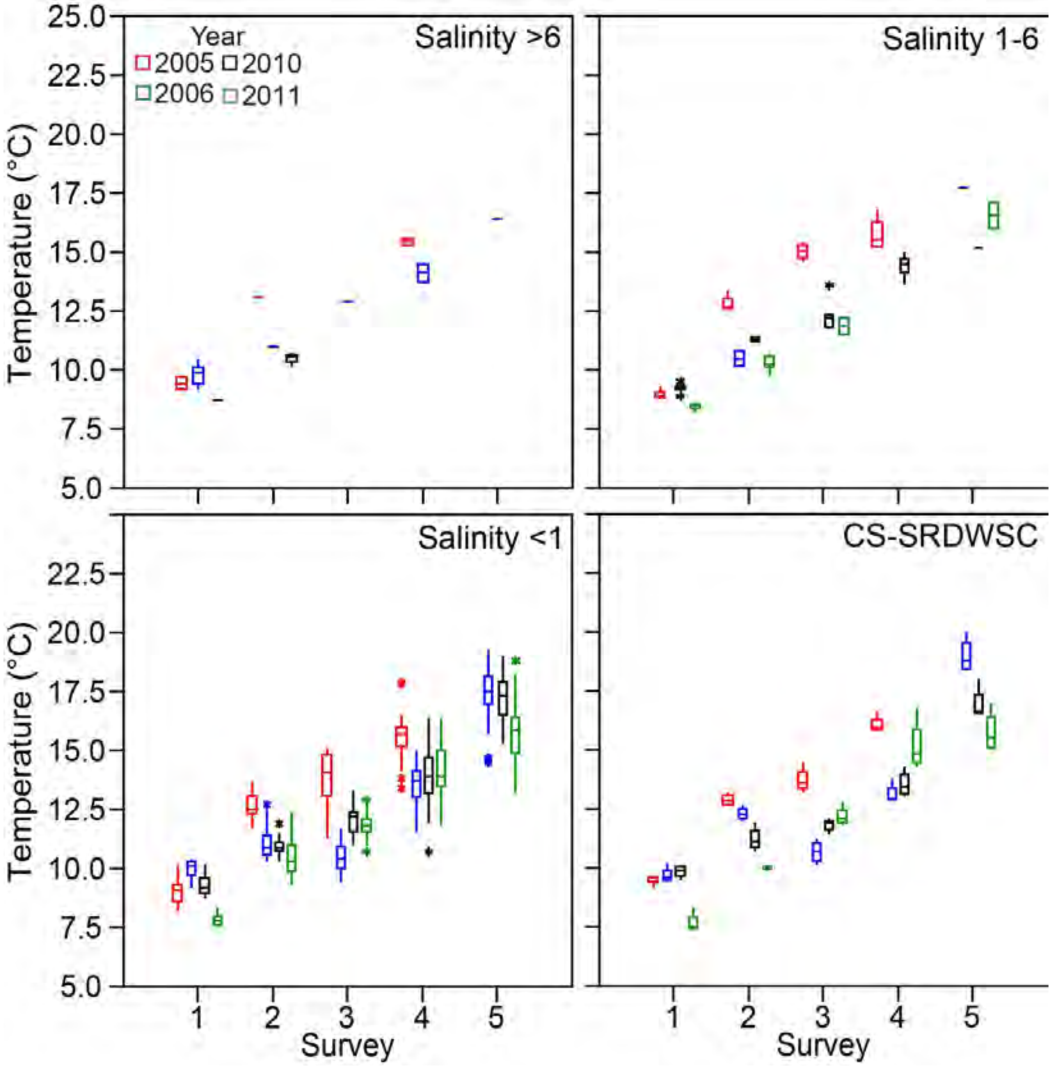
As noted in the adult section, spring water temperature was generally coolest in 2006 and 2011, but warmed up more rapidly toward the end of spring 2006 (May) than in spring 2011. Spring water temperature was overall warmest in 2005 (Fig. 71). Following the high late-spring water temperatures in 2005 and 2006, summer temperatures in 2005 and 2006 tended to be higher than in 2010 and 2011 during July and August (e.g. TNS surveys 3-5; Fig. 72). Temperatures during surveys 4 and 5 may have been particularly important as they exceeded lethal levels in freshwater at some sites, suggesting the potential for mortality. Note that this does not mean that temperatures were universally cooler in 2010 and 2011 than in 2005 and 2006; for example the region around Cache Slough had relatively high temperatures in August 2011. Larval to juvenile survival (ratio of TNS index to 20 mm index) was highest in 2011 followed by 2010, 2006, and 2005, suggesting that the cooler late spring and summer temperatures in 2011 and 2010 may have been beneficial for Delta Smelt. However, juvenile to subadult survival (ratio of FMWT index to TNS index) was highest in 2011 and lowest in 2010 (Fig. 51). While relatively high water temperature in late spring and early to mid summer of of 2005 and 2006 may thus have contributed to low survival of late-stage larvae and early juveniles, water temperature may have been less important to survival in the late summer and early fall. Overall, the results of this analysis of temperature and survival data support our hypothesis that high water temperatures reduce juvenile Delta Smelt growth and survival.

At this point, our data and analyses are inadequate to address temperature effects on juvenile Delta Smelt growth. Although there are some data for Delta Smelt growth during several of the target years, it is difficult to separate the relative effects of improved bioenergetics (see below) versus simple ontogenetic changes in fish size. Juvenile fish growth rates are typically not constant and change with size ("allometric effects;" Fuiman 1983). Specifically, daily growth rates (e.g., mm/day) are often faster for smaller fish and slower for older fish. Hence, cooler years may delay Delta Smelt transitions from faster to slower growth phases, yielding a relatively fast measured growth rate at a specific point in time (e.g., September) because at that specific time the fish are still relatively young and still on the "steepest" part of an idealized growth curve.

Hypothesis 2. Distribution and abundance of Striped Bass, temperature, and turbidity influence predation risk/rate on juvenile Delta Smelt

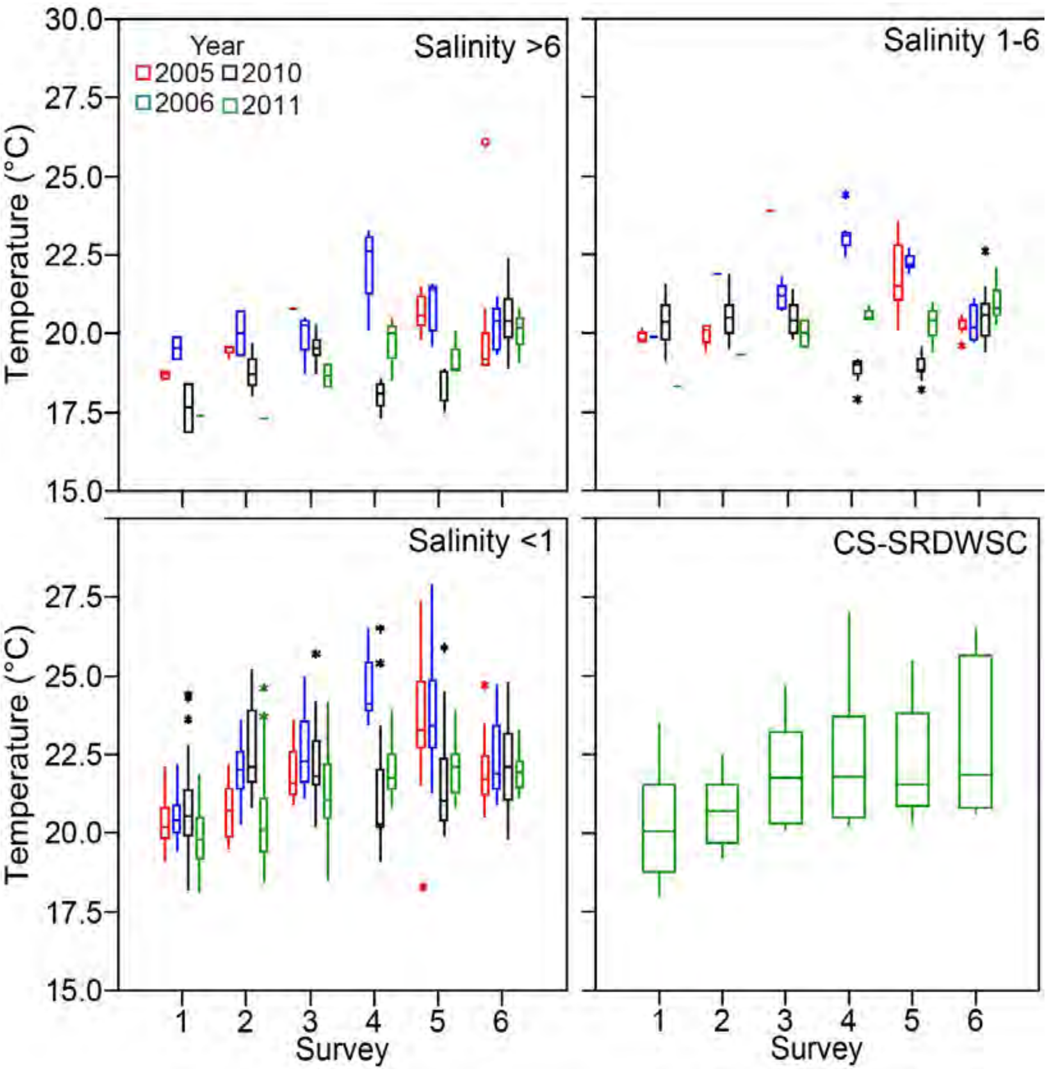
We hypothesize that subadult (age 1-3) Striped Bass are the major predator on juvenile Delta Smelt and that losses are likely affected by temperature and turbidity patterns. However, other factors likely affect predation risk (e.g., other predators such as centrarchids) and several factors

Figure 71. Water surface temperature data collected during the Spring Kodiak Trawl Survey for three salinity regions and the Cache Slough-Sacramento River Deepwater Ship Channel (CS-SRDWSC). Surveys are conducted monthly January-May. See Chapter 3: Data Analyses for explanation of boxplots.



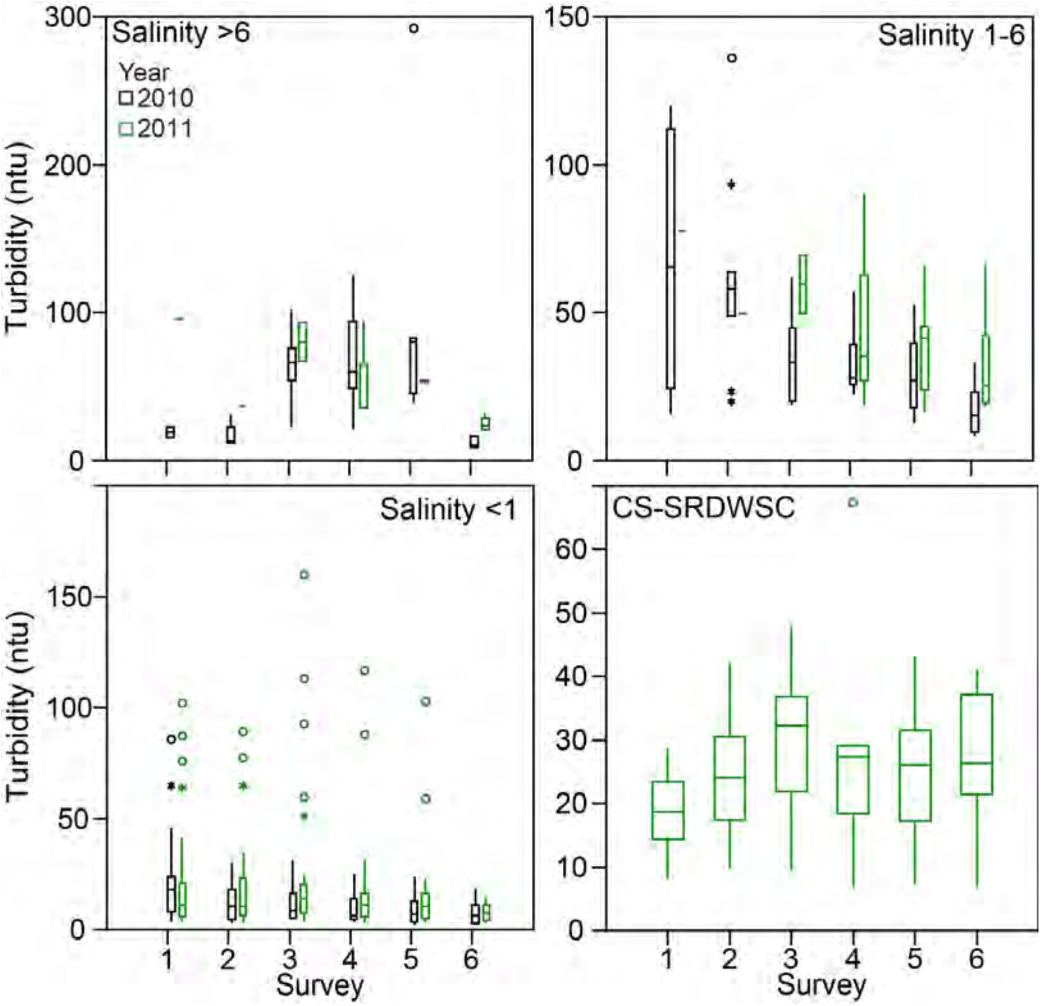
may interact. As noted above for temperature and below for food, high temperatures and low prey density likely lead to bioenergetics problems and increased foraging activity, which might reduce predator avoidance behavior (e.g., Marine and Cech 2004) in Delta Smelt. These effects may be compounded by low turbidity, which makes Delta Smelt more visible to predators in their habitat. Although higher Striped Bass abundance could theoretically result in greater consumption of prey including Delta Smelt (Loboschefsky et al. 2012), changes in habitat variables for both species such as food, temperature, and turbidity mean that predation rates on Delta Smelt periodically may be independent of predator abundance. Although there has been substantial progress in modeling (Lobschefsky et al. 2012, Nobriga et al. 2013) and genetic methods (Baerwald et al. 2012), there is not yet a standardized way to assess the effects of predation on Delta Smelt. Moreover, there are no effective surveys to assess age 1-3 Striped Bass abundance or distribution. Therefore, we are unable to directly evaluate this hypothesis. Lacking this information, we can

Figure 72. Water temperature data collected during the Summer Townet Survey for three salinity regions and the Cache Slough-Sacramento River Deepwater Ship Channel (CS-SRDWSC). Surveys are conducted biweekly June-August. See Chapter 3: Data Analyses for explanation of boxplots.



at least examine turbidity and temperature patterns for the four years. Temperature responses were described for Hypothesis 2. In general, summer 2005 and 2006 temperatures were relatively higher than 2010 and 2011 during key summer months (e.g. TNS surveys 3-5; Fig. 72). We expect that cooler temperatures in 2010 and 2011 may have contributed to reduced predation on Delta Smelt. Turbidity data are limited to 2010 and 2011 (Fig. 73). There were no consistent differences between the two years. Secchi depth data did not suggest major differences among the 4 years except at salinities > 6 when 2005-2006 had higher values in some months (Fig. 74).

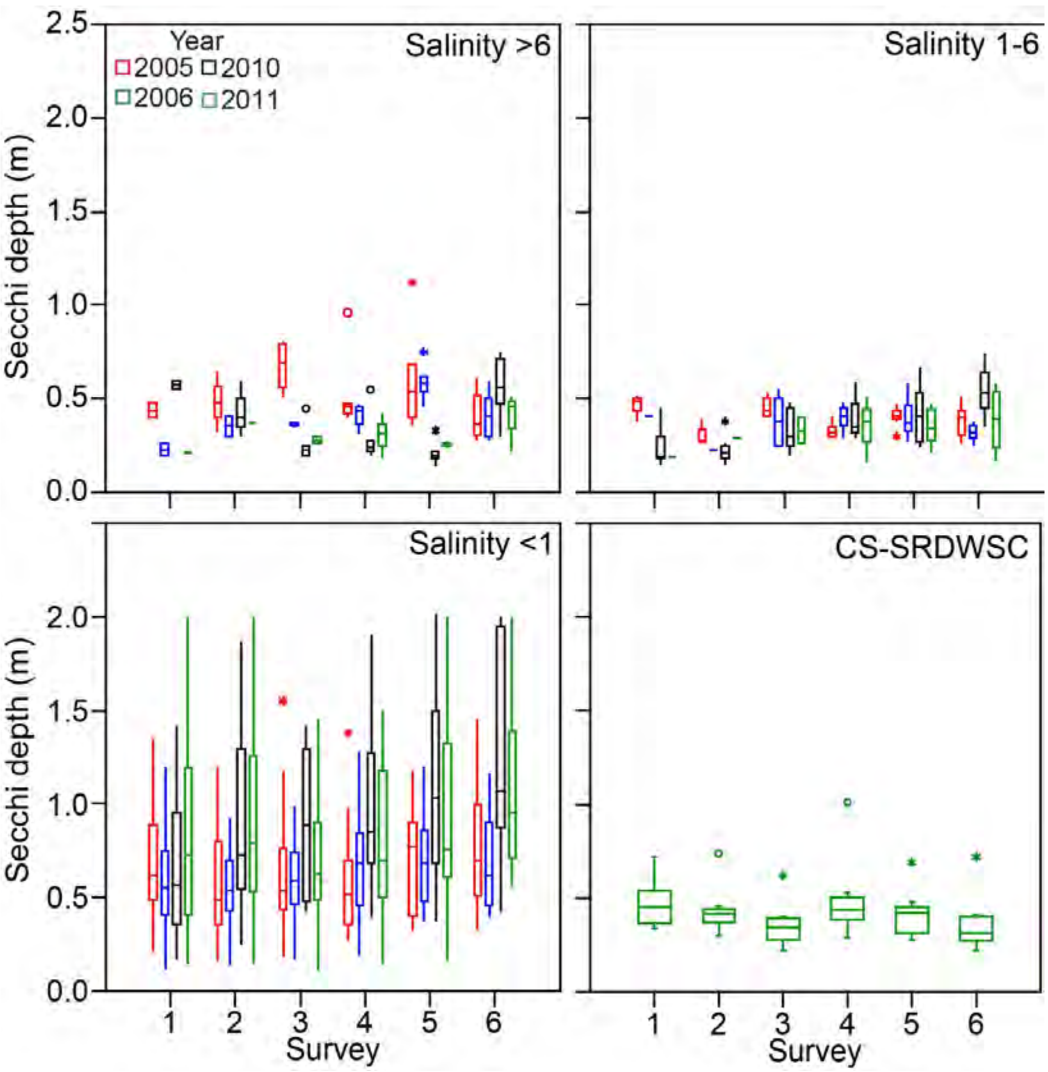
Figure 73. **Turbidity data collected during the Summer Townet Survey. Surveys are conducted biweekly June-August. Note different scales among salinity regions. See Chapter 3: Data Analyses for explanation of boxplots.**



Hypothesis 3. Juvenile Delta Smelt growth and survival is affected by food availability.

As for Hypothesis 1, we are currently unable to evaluate the growth data because water temperature affects development time, and because growth curves are complicated by allometric effects. The general conceptual model is that higher food abundance results in faster growth rates and larger, healthier fish. In addition, larger, healthier Delta Smelt are presumably less vulnerable to predators because of increased size making them difficult for smaller predators to capture and consume. In general, the median abundance of some of the key prey for juvenile Delta Smelt such as calanoid copepods is highest in summer months (Fig. 75), when juvenile Delta Smelt are present; however, the range of observed densities is broad in all months. As noted previously, Kimmerer (2008) found that Delta Smelt survival from summer to fall was positively associated with calanoid copepod biomass in the low salinity zone.

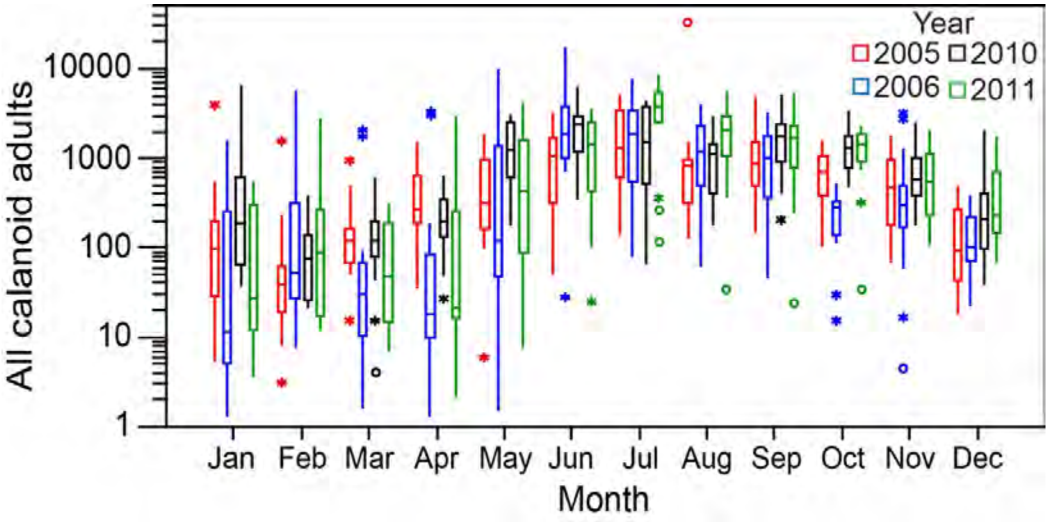
Figure 74. Secchi depth data collected during the Summer Townet Survey. Surveys are conducted biweekly June-August. See Chapter 3: Data Analyses for explanation of boxplots.



Interpretation of the field data is complicated because there are no long-term IEP EMP study stations located in some of the core habitats for Delta Smelt, for example, Cache Slough and the Sacramento River Deep Water Ship Channel. Moreover, densities of calanoid copepods vary among regions based on differing habitat (temperature and salinity) requirements of each species (Fig. 76).

Summer-time phytoplankton data (chlorophyll-*a*) suggest that the base of the food web was most enhanced in July and August 2011 and relatively depleted in 2005 (Fig. 66). There is some evidence that these changes may have affected zooplankton abundance. For example, summer densities of calanoid copepods in the LSZ and <1 ppt regions also tended to be highest in 2011 as compared to the other years (Fig. 76). This pattern generally held when individual taxa are considered including two of the most important food sources for Delta Smelt, *Eurytemora affinis* (Fig. 33) and *Pseudodiaptomus forbesi* (Fig. 34).

Figure 75. Trends in calanoid copepods (number/m^3 for all taxa combined) collected by the IEP Environmental Monitoring Program (EMP) during each the four study years (2005, 2006, 2010, and 2011).

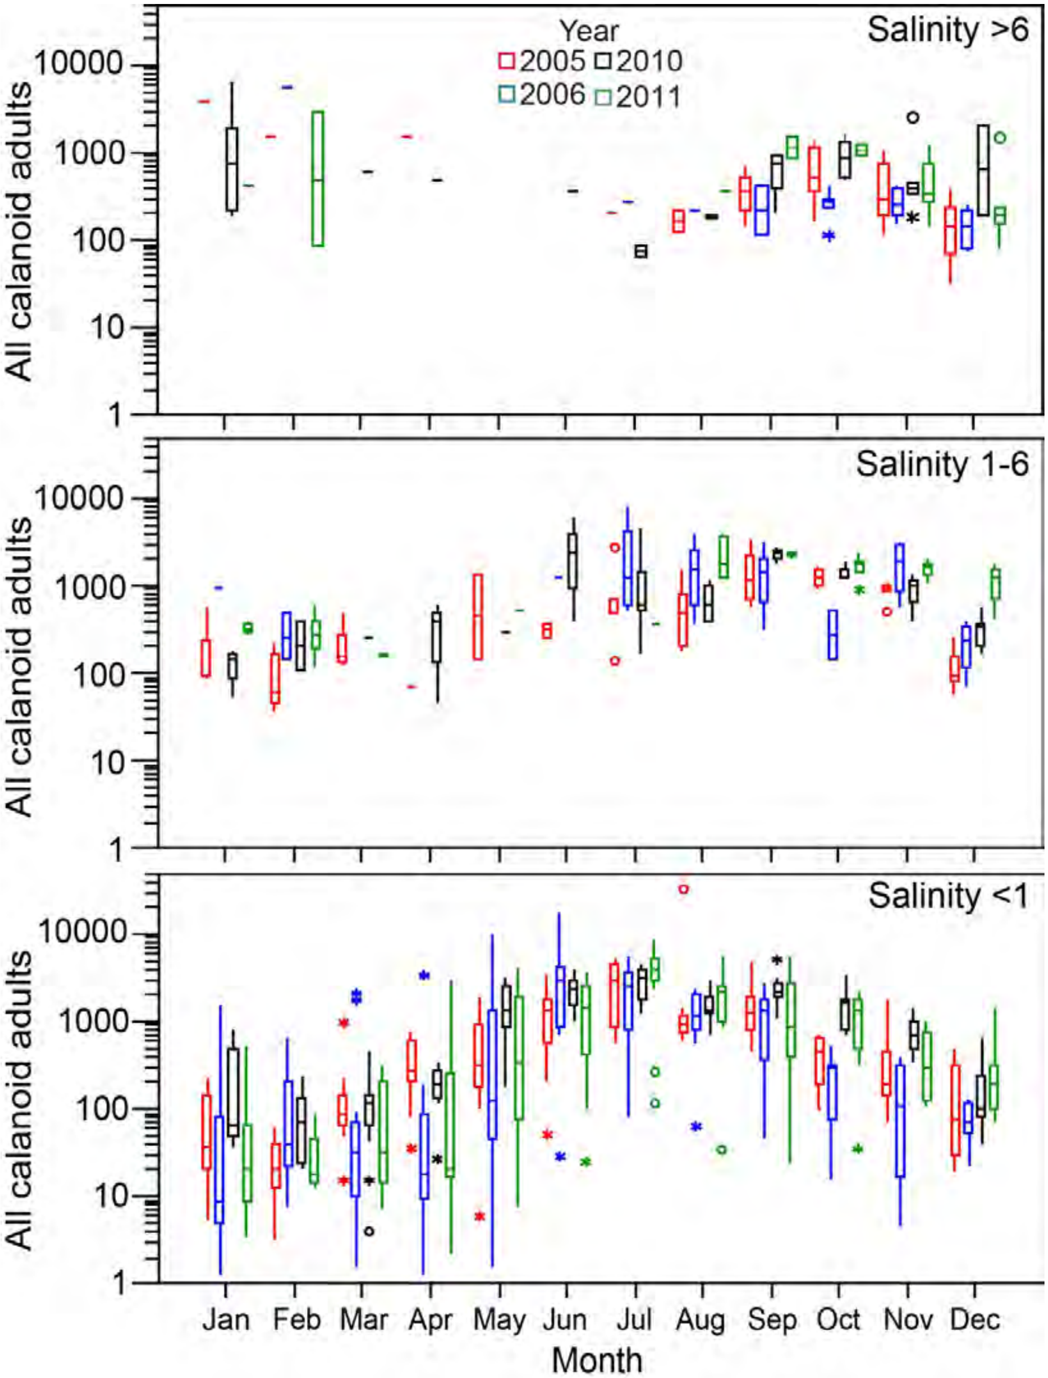


As mentioned above (Hypothesis 1), juvenile to subadult survival was highest in 2011 followed by 2006 and 2005 and lowest in 2010 (Fig. 51). If food availability was the primary habitat attribute driving juvenile survival, our expectation was that summer prey abundance would have been higher in 2011 than 2010. Figure 69 suggests that while differences were not very pronounced, prey levels were indeed somewhat higher in July and August of 2011 than 2010. Calanoid copepod levels varied across the different salinity ranges, but generally followed the same pattern (Fig. 76). In addition, calanoid copepod densities in June and August were higher in 2006 than in 2005 (Fig. 75), which may have contributed to higher juvenile to subadult survival in 2006 compared to 2005 (Fig. 51).

Fish bioenergetics are affected by both food and temperature. As mentioned above, both summer 2010 and 2011 had relatively cool temperatures as compared to 2005 and 2006, which may have affected bioenergetics. In addition, recent studies (S. Slater, CDFW, unpublished data) indicate that Delta Smelt consumption was not just limited to calanoid copepods, so our assessment does not reflect the full dietary range.

In conclusion, our analyses provide some support for the hypothesis that juvenile Delta Smelt growth and survival is affected by food availability; greater food availability may have contributed to greater juvenile survival in 2011 and 2006 compared to 2010 and 2005. However, differences in prey availability among years were not very pronounced and our analyses were limited to calanoid copepods; other species may also be important prey items for Delta Smelt.

Figure 76. Trends in calanoid copepods (number/m^3 for all types combined) collected by the IEP Environmental Monitoring Program (EMP) in three salinity ranges (> 6 ppt; 1-6 ppt; < 1 ppt) during each the four study years (2005, 2006, 2010, and 2011). See Chapter 3: Data Analyses for explanation of boxplots.



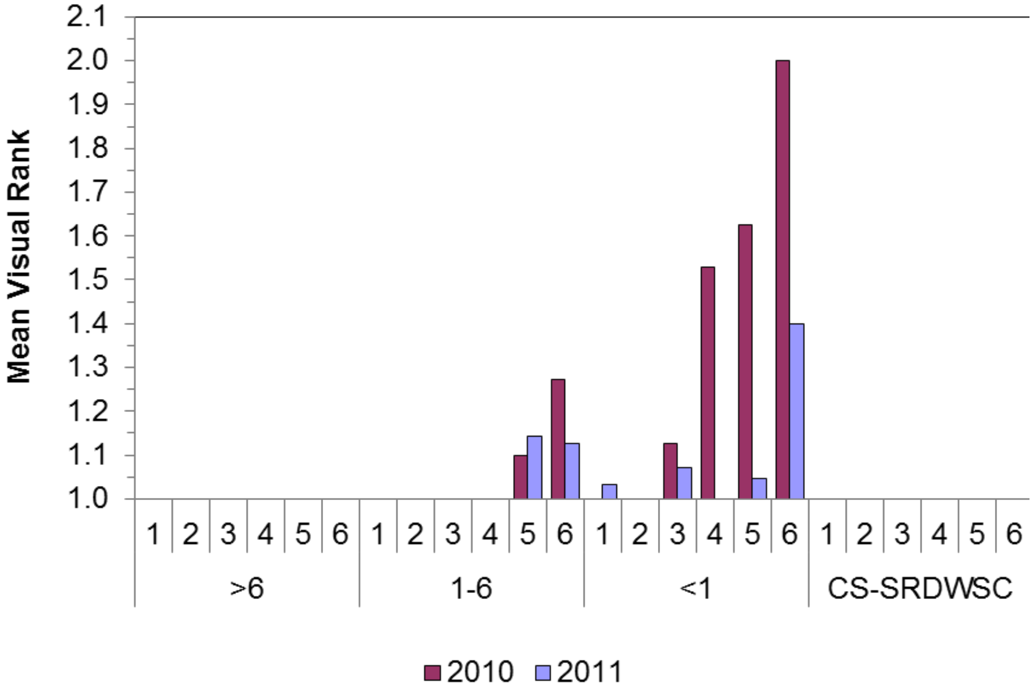
Hypothesis 4. Juvenile Delta Smelt survival and growth is reduced by harmful algal blooms (HAB) because of direct (habitat quality and toxic effects) and indirect (food quality and quantity) effects.

The appearance of late-summer HAB, especially *Microcystis*, is thought to be another component of the decline in habitat quality for Delta Smelt (Baxter et al. 2010, Lehman et al. 2010). Direct effects may include toxicity to Delta Smelt and a reduced area of suitable habitat. There also may be indirect effects on food quantity and quality, particularly with respect to their zooplankton prey (Ger et al. 2009, 2010a,b, Lehman et al. 2010).

The growth responses of Delta Smelt during the four target years are still unclear (see below), but there is evidence that Delta Smelt juvenile to subadult survival was highest in 2011 and lowest in 2010 (Fig. 51). If HABs have a negative effect on survival, we would expect that lower *Microcystis* (or other HAB) abundance would be associated with higher survival in 2011. This seems to have been the case for 2010 and 2011. Densities of *Microcystis* near the water surface were qualitatively assessed (visually ranked) at all TNS stations in these years. In agreement with our expectation, observed levels were low during the TNS in 2011 as compared to 2010 across a range of salinities (Fig. 77).

Unfortunately, we do not have data about other HAB species and more quantitative estimates, nor is similar data available for 2005 and 2006. In general, our expectation is that 2006

Figure 77. **Summer Townet Survey mean visual rank of *Microcystis* spp. (ranks 1-5 possible; 1 = absent) observed at all stations during biweekly surveys (1-6) in various salinity regions (> 6, 1-6, and < 1 ppt) and in the CS-SRDWSC during June through August 2010 and 2011. Observations were not made in Cache Slough-Sacramento River Deepwater Ship Channel (CS-SRDWSC) during 2010.**



Microcystis levels would have been relatively low as a result of higher flow levels that discourage blooms (Lehman et al. 2005). Based on the available qualitative data for 2010 and 2011, this analysis supports the hypothesis that juvenile Delta Smelt survival and growth is better when *Microcystis* does not bloom as intensely, but more data is needed to more conclusively assess this relationship.

Subadult Hypotheses

Hypothesis 1. Subadult Delta Smelt abundance, growth, and survival is affected by food availability.

Similar to juveniles, the general conceptual model is that higher food abundance results in faster growth rates and subsequently, lower predation loss and greater survival (e.g., Houde 1987, Sogard 1997, Takasuka et al. 2003); however the opposite situation in which the fastest growing fishes are most vulnerable to predators has also been observed in at least one east coast estuary (Gleason and Bengston 1996). Fall abundance of Delta Smelt was highest in 2011 followed by 2006, 2010, and 2005 (Fig. 3) while survival of subadults to adults was highest in 2010 followed by 2006 and equal in 2011 and 2005 (Fig. 45). In spite of the lower subadult survival in 2011, the relatively large number of subadults in 2011 gave rise to the highest adult abundance on record in 2012.

In general, fall calanoid copepod abundance and cladocera abundance were higher in 2011 in freshwater and the low-salinity zone compared to the other years, particularly 2005 and 2006 (Fig. 71). However, these data are highly variable, so this conclusion does not apply to each region in every month. With that caveat, the data generally support the hypothesis that food availability affects Delta Smelt abundance and survival; on average, prey density was higher for subadult Delta Smelt in 2011. This may have contributed to the high FMWT abundance index in 2011, although it did not contribute to an equally high survival to adults relative to the other three years. Nevertheless, it seems likely that the relatively good food availability in 2011 also contributed to the high number of adults in 2012. As noted above, we are currently unable to evaluate whether Delta Smelt grew faster in 2011 because water temperature affects spawning and hatch dates, which complicates the interpretation of growth rates.

Hypothesis 2. Distribution and abundance of Striped Bass, temperature, and turbidity influence predation risk/rate on subadult Delta Smelt

As already described for other life stages, predation risk is exceptionally complicated, making it difficult to generate simple hypotheses that describe associated losses of Delta Smelt. The data are not currently available to test this hypothesis (Nobriga et al. 2013). Thus, no firm conclusion can be made.

Hypothesis 3. Subadult Delta Smelt abundance, survival and growth are reduced by harmful algal blooms (HAB) because of direct (habitat quality and toxic effects) and indirect (food quality and quantity) effects.

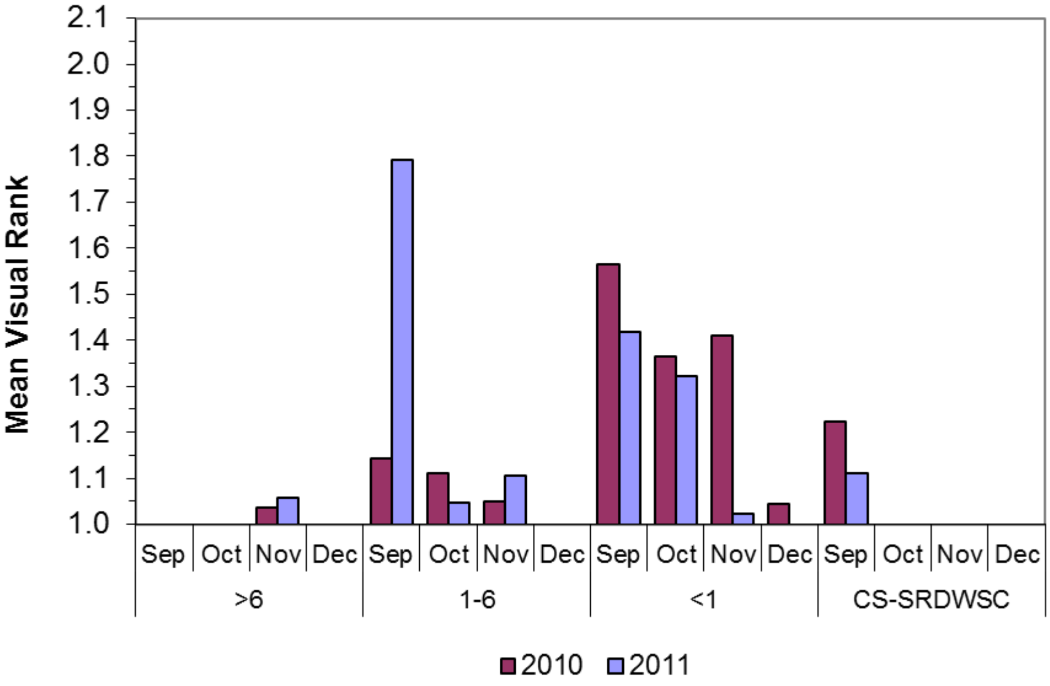
The appearance of late-summer harmful algal blooms (HAB), especially *Microcystis*, is thought to be another detriment to habitat quality for Delta Smelt (Baxter et al. 2010, Lehman et al. 2010). Direct effects may include toxicity to Delta Smelt and a reduced distribution if the fish try to limit their overlap with the bloom. There also may be indirect effects on food quantity and quality, particularly with respect to their zooplankton prey (Ger et al. 2009; 2010a,b, Lehman et al. 2010).

The growth responses of Delta Smelt during the four target years are still unclear (see above), but there is evidence that summer juvenile to subadult survival was highest in 2011, while juvenile survival to adults was highest in 2010 (Fig. 45). Our expectation is therefore that HAB were less prevalent in the summer of 2011 compared to 2010, but more prevalent in fall 2011. As already described for juveniles, the hypothesis that summer *Microcystis* bloom would be less intense in 2011 compared to 2010 was generally supported (Fig. 77). In fall, *Microcystis* levels were also overall lower in 2011 than in 2010, except in September 2011 when a high level of *Microcystis* was observed in the LSZ (Fig. 78). This may be an indication that the higher outflow in September-October 2011 displaced *Microcystis* produced in the Delta seaward into the LSZ. The comparatively high 2011 Delta Smelt FMWT index that coincided with this shift in *Microcystis* distribution is not consistent with the hypothesis; however, the occurrence of fairly high levels of *Microcystis* in the LSZ in 2011 may help explain the lower subadult to adult survival in 2011 compared to 2010. It is also important to remember that the visual survey results presented here are only qualitative and do not necessarily reflect the potential for differences in actual toxicity among years. Overall, these results are inconclusive, although they may provide limited support for the hypothesis that high *Microcystis* levels may have a negative effect on subadult to adult survival; this may help explain the lower subadult survival in 2011 compared to 2010.

Hypothesis 4. Subadult Delta Smelt abundance, survival and growth are affected by the size and position of the low salinity zone during fall.

We do not address this hypothesis in detail because it is the subject of an adaptive management experiment (FLaSH) described earlier (Reclamation 2011, 2012; see also Brown et al. 2014, http://deltacouncil.ca.gov/science-program/fall-low-salinity-habitat-flash-studies-and-adaptive-management-plan-review-0). According to the FLaSH conceptual model, conditions are supposed to be favorable for Delta Smelt when fall X2 is approximately 74 km or less, unfavorable when X2 is approximately 85 km or greater, and intermediate in between (Reclamation 2011, 2012). Surface area for the LSZ at X2s of 74 km and 85 km were predicted to be 4000 and 9000 hectares, respectively (Reclamation 2011, 2012). The data generally supported the idea that lower X2 and greater area of the LSZ would support more subadult Delta Smelt (Table 6). The greatest LSZ area and lowest X2 occurred in September and October 2011 and were associated with a high FMWT index which was followed by the highest SKT index on record, although survival from subadults to adults was actually lower in 2011 than in 2010 and 2006. There was little separation between the other years on the basis of X2, LSZ area, or FMWT index (Table 6). The position and area of the LSZ is a key factor determining the quantity and quality of low salinity rearing habitat available to Delta Smelt and other estuarine species (see Chapter 4 for more detail

Figure 78. **Fall Midwater Trawl mean visual rank of *Microcystis* spp. (ranks 1-5 possible; 1 = absent) observed at all stations during monthly surveys in various salinity regions (> 6, 1-6, and < 1 ppt) and in the CS-SRDWSC during September through December 2010 and 2011.**



and Chapter 8 for additional analysis results). In addition, the complex hydrodynamics produced during higher outflows may alter the lateral mixing environment of the Estuary (especially in shallower areas like Suisun Bay) in ways that improve the quality of Delta Smelt habitat in general (Monismith, personal communication). The limited amount of available data provides some evidence in support of this hypothesis, but additional years of data and investigations are needed.

Chapter 8: Conclusions

As with all reports focusing on conceptual models, this report is intended as a working document, not as the final word on Delta Smelt ecology, because our knowledge will continue to increase. We intend the conceptual model to be used as a framework and tool to further improve our understanding of Delta Smelt ecology and to explore and test management options for improving conditions for the Delta Smelt population. In essence, the updated conceptual model represents a synthesis of our current thinking on the factors affecting vital rates of the Delta Smelt population. We fully expect a wide range of opinion about the relevance of the conceptual models presented here and about the degree of certainty regarding many of its component dynamics and linkages. We have clearly acknowledged that we lack information on many important factors and processes that likely affect Delta Smelt, such as predation and toxicity and their functional relationships

Table 6. Mean and standard deviation (SD) for X2, surface area of low salinity zone (M. McWilliams, Delta Modeling Associates, unpublished data), and values of the Fall Midwater Trawl index (FMWT) for abundance of subadult Delta Smelt.

	X2 (km)		Surface area LSZ (hectares)		FMWT index
YEAR	MEAN	SD	MEAN	SD	
2005	83	2	4889	252	26
2006	82	3	4978	320	41
2010	85	2	4635	226	29
2011	75	1	8366	133	343

with survival and growth. The conceptual model incorporates many hypotheses that should be tested via new research, modeling, and ongoing analysis and synthesis of new and previously collected data. This is how science advances.

Conceptual models are increasingly used as tools to develop questions or hypotheses about specific mechanisms through which stressors or other environmental factors drive ecological outcomes. Conceptual models can be used as a basis for communication among managers and scientists to plan research activities and assess outcomes of management actions (Ogden et al. 2005). Because of their broad utility, conceptual models are viewed as a critical element of adaptive management programs (Thom 2000). In the SFE, conceptual models have become common and even required as the community moves toward adaptive management and collaborative science. A primary outcome of conceptual models is the identification of key areas of uncertainty due to lack of information, or areas of disagreement due to different interpretations of the available data and information. Careful examination of these areas often identifies critical data and information gaps, which if filled, would allow a more robust evaluation of the major hypotheses derived from conceptual models. In this way, conceptual models can guide the research community to the topics critical for understanding Delta Smelt biology and formulating effective management actions.

The development of our conceptual model, based on assessment of recent information, identified some key points about conceptual models that are worth highlighting, including the following:

1. Nested and linked conceptual models of increasing specificity provide a useful framework for capturing the dynamics of ecosystem drivers and habitat attributes over a large range of temporal and spatial scales and for providing a comprehensive picture about their effects.

2. Our knowledge about Delta Smelt and the SFE is constantly growing and conceptual models about them have to be regularly updated and revised to properly reflect this knowledge.

3. Construction of our conceptual model and the formulation and evaluation of hypotheses greatly benefitted from the large amount of high-quality ecological data and information available about Delta Smelt and the SFE. The most critical data about Delta Smelt dynamics came from four long-term IEP fish monitoring surveys. Other monitoring

and studies provided key data and information about habitat attributes and ecosystem drivers.

4. Our conceptual model is also useful for identifying important data and information gaps. More data and information is especially needed about predation risk and toxicity, two potentially important attributes of Delta Smelt habitat.

Conceptual models are meant to be useful tools for scientists, managers, and others. But just how useful are the new conceptual models in this report? To find out, we used them to generate and test hypotheses and highlight data gaps while addressing a specific topic of high management interest—the increased Delta Smelt abundance index in 2011.

We found that our conceptual model allowed us to formulate a variety of testable hypotheses about individual components and the linkages among them. Our hypotheses and the analyses we conducted to test them had some clear limitations (discussed below), but highlighted some key points about Delta Smelt and their habitat. In many respects, the points about Delta Smelt seem self-evident from basic biology and earlier conceptual models, but they warrant reinforcement because they are crucial to understanding Delta Smelt and to developing and assessing habitat management actions. Key points about Delta Smelt include the following:

1. Environmental conditions occurring in all four seasons contribute to year-class strength of Delta Smelt - “it takes a year to make a mature Delta Smelt.”

2. Survival and recruitment are affected by many factors that interact in complex ways and the importance of these factors and interactions varies from season to season and year to year.

3. Recovery of Delta Smelt depends on better than average larval production (recruitment) and survival in all seasons. The number of eggs and larvae sets an upper limit for the production of mature adults. Low survival between any two life stages can substantially reduce the actual production of mature adults. Success of Delta Smelt in 2011 was related to a high level of larval production (recruitment) followed by moderate to high stage-to-stage survival over the entire year. In contrast, the high level of larval production (recruitment) in 2006 was followed by very low survival from larvae to juveniles which led to low abundance of mature adults.

4. Throughout 2011, Delta Smelt may have benefitted from a combination of favorable habitat conditions: 1) adults and larvae benefitted from high winter 2010 and spring 2011 outflows which reduced entrainment risk and possibly improved other habitat conditions, prolonged cool spring water temperatures, and possibly good food availability in late spring; 2) juveniles benefitted from cool water temperatures in late spring and early summer as well as from relatively good food availability and low levels of harmful *Microcystis*; 3) subadults also benefitted from good food availability and from favorable habitat conditions in the large, westward low salinity zone.

Our hypothesis tests were carried out with the simple comparative approach used in the FLaSH investigations (Brown et al. 2014). Specifically, we compared differences in Delta Smelt responses and in individual habitat attributes during the two most recent wet years and the two years immediately preceding the two wet years. Using this approach allowed us to put the FLaSH results into a year-round context as recommended by the FLaSH Panel (FLaSH Panel 2012).

It also provided an opportunity to further assess the utility of this approach for evaluating the outcome of adaptive management actions such as the fall outflow action.

As with the FLaSH investigations (Brown et al. 2014), we restricted our analyses to simple comparisons among four recent years after the 2002 POD decline for several reasons including the following:

1. Using a comparative approach similar to that in the FLaSH investigation allowed us to place the results of the FLaSH investigation in a year-round, life cycle context as recommended by the FLaSH Panel (FLaSH Panel 2012).
2. This report is intended for a broad audience. Simple comparisons are easily replicated and understood by all.
3. More pertinent data is available for recent years than for earlier years. For example, adult Delta Smelt monitoring began in 2002 with abundance index values available starting in 2003.
4. The POD regime shift (Baxter et al. 2010) changed ecological relationships and the strong pre-POD signals would have likely overwhelmed more subtle, yet meaningful, signals in the period after the POD. For example, it appears that high larval recruitment may now be positively associated with wet hydrology, but that this may not have been the case before the onset of the POD.
5. Clear differences in habitat conditions among years might point to new or refined management strategies aimed at improving specific habitat conditions.
6. More complex modeling approaches take much more time and effort than was available to produce this report. A complex life cycle modeling effort is currently underway (see Chapter 9).

As noted above, our analytical approach yielded some interesting results, but it also raised more questions than it could answer. In many cases this was due to critical data and information gaps; these will be described in more detail in Chapter 9. It also illustrates, however, several limitations of our simple comparative approach as well as difficulties associated with posing and testing hypotheses about ecological phenomena in general. Examples of specific limitations and difficulties include the following:

1. Our hypotheses focused on individual habitat attributes and were tested with a series of separate univariate analyses even though we know that Delta Smelt are affected by multiple interacting habitat atributes. We did not conduct multivariate tests or examine the complex interactions that may have occurred when more than one hypothesis was true (or false), nor did we consider or rule out that a hypothesis may be true in some years and false in others.
2. Our simple comparisons of differences in individual habitat attributes among different years cannot conclusively establish whether these differences are indeed mechanistically linked to the observed differences in Delta Smelt dynamics. In addition, an absence of observed differences does not prove that there is really no effect because actual effects can be masked or counteracted by interactions with other causal factors that differ among years. For example predation in the South Delta may mask actual entrainment

effects and toxicity of anthropogenic contaminants may counteract the effects of abundant food in some years, but not in others.

3. Results contrary to our observations may simply indicate different outcomes in other years or that complex interactions among multiple habitat attributes (and corresponding hypotheses) contributed to the observed effects.
4. We restricted our analyses to observational data collected in a small number of moderately and very wet years during the POD period; including data from additional, more historical, and drier years may have provided more conclusive results.
5. Data available for our analyses were not necessarily collected to test hypotheses similar to the ones in this report; targeted data collections are needed in addition to routine status and trends monitoring.

Many of these difficulties and limitations were expected because hypothesis testing in an ecological context is nearly always problematic. For example, Quinn and Dunham (1983) warned that attempts to follow a strictly hypothetico-deductive scheme (Popper 1959, Platt 1964) to draw “strong inference” from a series of univariate tests aiming to falsify hypotheses about the ecological effects of individual causal factors often lead to inconclusive or even erroneous results. One reason for this is that by design, they generally do not consider non-additive interactions among causal factors. While we did not necessarily set out to strictly follow such a scheme, we nevertheless treated habitat attributes as largely independent from each other and formulated a series of distinct hypotheses about their univariate effects on Delta Smelt. But habitat attributes are not necessarily additive and habitat is indeed more than the “sum of its parts.” A more inductive, multivariate modeling approach with hypotheses about interactive effects and evaluations of the relative contributions of multiple interacting habitat attributes to these effects would have likely been more appropriate, but would have required analyses beyond the scope of this report.

We give some examples of multivariate approaches in Chapter 9, but note that even with the most sophisticated modeling techniques, ecological responses to management manipulations and other changes of the SFE have been notoriously difficult to assess and interpret. Reasons for this persistent difficulty include limited opportunities for experimental control, multiple interacting causal factors, multiple ecological response pathways, and changing environmental conditions due to species invasions, species declines, and the many physical and chemical changes and management manipulations described in this report. In other words, the signal to noise ratio of management actions to environmental variation tends to be low in the SFE because of its size and complexity. The fact that Delta Smelt is now a rare species adds another considerable difficulty. Together, these difficulties are part of the reason why adaptive management actions such as those described in the ongoing Fall Outflow Adaptive Management Plan (Reclamation 2011, 2012) and the now concluded Vernalis Adaptive Management Plan (VAMP, San Joaquin River Group Authority 2013) are planned for a minimum of 10 years, allowing accumulation of data, development of appropriate interpretation of these data, and comparison of observations across as broad a range of conditions as is possible given a 10-year time frame. But even after such a relatively long period of manipulation and observation, questions will likely remain about how some factors interact to affect Delta Smelt abundance.

In summary, we conclude that our new conceptual models can be used successfully to derive testable hypotheses about Delta Smelt responses to changing habitat conditions. Our hypotheses and the analyses we conducted to test them highlighted some key points as well as critical data gaps and the challenges associated with formulating and testing hypotheses in complex ecological contexts. The key points about Delta Smelt and their habitat generally agree with basic biological principles and earlier conceptual models, but warrant reinforcement because they are crucial to understanding Delta Smelt and to developing and assessing habitat management actions. Other results are less conclusive because of data limitations and the shortcomings of our largely univariate hypotheses and simple comparative analysis approach. Next steps should include addressing critical data gaps, modeling that more fully considers the effects of interacting factors on Delta Smelt, and applications of the information in this report in support of management actions. Examples of such efforts are provided in Chapter 9.

Chapter 9: Recommendations for Future Work and Management Applications

The conceptual model in this report can be viewed as a collection of hypotheses. These hypotheses are not limited to the hypotheses posed in Chapter 7 of this report; essentially, each component and linkage in the conceptual models can give rise to meaningful questions and hypotheses by itself or together with other components and linkages. This is one of the main functions of conceptual models.

Some of the hypotheses that can be derived from our conceptual model have already been addressed in the published research reviewed in Chapter 4 of this report. These results provide the knowledge base used to construct our conceptual model as well as previous conceptual models. They also provide the knowledge base for current Delta Smelt management efforts. The results and conclusions in this report add to this knowledge, but they also emphasize the need for additional monitoring, focused studies, and/or additional analysis and synthesis of existing data. These are the information gaps that can be used to guide future research activities to enhance our understanding of how factors interact to control Delta Smelt abundance.

Filling these information gaps is critically important for improving management strategies for Delta Smelt and for constantly adapting them to expected and unexpected future changes. It is clear that ecological changes due to continued growth of California’s human population, climate change, new species invasions, and other natural and anthropogenic factors will increase the challenges associated with Delta Smelt management. Moreover, as discussed in the previous Chapter, we will likely never be able to correctly detect or predict all effects of management actions and other changes in an ecosystem as complex and constantly changing as the San Francisco estuary. Science and management have to go hand in hand to constantly identify, implement, evaluate, and refine the best management options for this ever-changing system. In this Chapter, we provide examples of next steps in three major areas where additional work is needed: 1) filling critical data and information gaps; 2) mathematical modeling; and 3) applications to support adaptive management actions. We conclude this report with recommendations for future analysis and synthesis efforts.

Critical Data and Information Gaps

A short list of the most critical data and information gaps identified by the updated conceptual model is given below. It is important to note that this is not an exhaustive list of the potentially productive research questions that could be addressed for Delta Smelt. Instead, these are primary research topics that emerge as major data and information gaps in multiple places within the updated conceptual model. This indicates that additional monitoring and research on these topics may be particularly urgently needed and filling these gaps would provide immediately useful results. The list of critical data and information gaps is organized around the environmental drivers and habitat attributes identified in our conceptual models.

Contaminants and Toxicity

There is a general awareness that exposure to contaminants can impair the health of Delta Smelt and other fishes. A few studies have documented adverse effects, but little is known regarding the thresholds at which most contaminants would be toxic to or otherwise adversely affect Delta Smelt (or their prey). Even less is known about how various contaminants may interact when they co-occur, or how their effects may be enhanced or suppressed by these interactions or by other environmental factors.

1. Focused laboratory studies may provide the most efficient way to assess effects of metals, pesticides, pharmaceutical products, or mixtures of contaminants as long as field-relevant concentrations are used. However, translating results of laboratory tests to the field remains a challenging problem (Scholz et al. 2012).

2. Significant work to understand the effect of nutrient loading from municipal sources on the food web has been done (Weston et al. 2014) (e.g., Sacramento Wastewater Treatment Plant, Parker et al. 2012). A logical next step is to conduct manipulative experiments in which effluent is reduced or shut off. This type of work has recently begun (T. Kraus, USGS, personal communication), but may require multiple iterations during a variety of seasons and environmental conditions in order to understand how such manipulations or future treatment upgrades could be used to provide desired food web responses. Monitoring should continue after any such upgrades to determine if they have the expected outcomes.

Entrainment and Transport

Evaluation of differences in entrainment among years could not be critically evaluated from salvage data; better ways to estimate, monitor, and evaluate entrainment losses due to south Delta exports are needed. Such improved estimates could be derived from experimental research on Delta Smelt and other species along with hydrodynamic modeling. Besides the need to improve the estimates of direct proportional population losses due to entrainment, similarly relevant or more important needs include assessing the influence of entrainment on key population attributes (e.g., genetics, demographics, population dynamics and viability effects).

Predation Risk

The majority of the hypotheses regarding predation risk could not be fully evaluated due to a lack of data regarding co-occurring predator and prey biomass and predation rates of predators on Delta Smelt.

1. The distribution and diet of major predators with respect to the distribution of Delta Smelt needs further investigation. For some predator species, data may already be available that describe distributions over multiple years and one data synthesis effort has already begun (Mississippi Silversides, USFWS Beach Seine Survey; analysis initiated by B. Schreier, DWR). However, data are lacking for several Striped Bass and Largemouth Bass life stages and focused studies are necessary to understand how these species' distributions overlap with the distribution of larval, juvenile, sub-adult, and adult Delta Smelt.

2. The distributional overlaps of Delta Smelt with their predators need to be described over varying conditions of turbidity, salinity, temperature, and hydrology. Linking predation risk to key environmental drivers and habitat attributes will shed light on how Delta Smelt may experience varying degrees of predation across seasons and years.

Food

Food availability is a critical aspect of Delta Smelt habitat throughout the conceptual model. However, many of the hypotheses about effects of food availability in the conceptual model could not be fully evaluated with available observational data due to incomplete information on prey densities and Delta Smelt feeding behavior throughout Delta Smelt habitat.

1. An extension of the IEP EMP into the Cache Slough complex and possibly other areas around the margins of the estuary would allow a fuller regional comparison of prey densities.

2. Another option is to make concurrent zooplankton sampling a routine part of the four major surveys monitoring Delta Smelt (SKT, 20 mm, TNS, FMWT). To varying degrees, this has been ongoing since 2005, but lack of trained staff has resulted in delayed processing of many samples and concurrent zooplankton samples have never been collected during the SKT survey. Adding appropriate zooplankton sampling and sample processing capacity to the fish monitoring surveys would allow for broader and more timely comparisons of pelagic food availability between monitoring stations with and without Delta Smelt present, similar to the analysis conducted in this report for the larvae collected during the 20mm survey (Larval Hypothesis #2).

3. Studies of Delta Smelt growth (from otoliths) and feeding habits (from stomach contents) concurrent with zooplankton sampling would maximize the utility of the concurrent prey sampling by allowing the refinement of functional response models.

4. Studies of Delta Smelt feeding behavior and prey availability with regard to amphipods and other prey that are not well sampled by any of the existing monitoring surveys could help determine the importance of these types of prey to the Delta Smelt population.

Harmful Algal Blooms

While recent research has resulted in improved understanding of the factors influencing the quantity, toxicity and location of HABs, there are still many uncertainties about their direct and indirect effects on Delta Smelt relative to other factors and about what can be done to prevent them. Furthermore and in spite of their importance to ecosystem and human health, there is still no routine quantitative monitoring program in place that specifically targets harmful algae. The TNS and FMWT surveys now include qualitative, visual assessment of *Microcystis*, but more quantitative techniques and techniques that detect additional harmful species and their toxicity would likely provide greater insights. Such techniques are increasingly available (e.g., solid phase adsorption tracking; Wood et al. 2011) and some focused studies that quantify and provide distributions of HABs have been conducted or are underway. These studies should be continued in order to address hypotheses related to the effects of HABs in the conceptual model and evaluate the utility of these techniques for routine monitoring applications.

Delta Smelt Responses

To fully evaluate the interactions of various stressors on Delta Smelt population biology, a quantitative life cycle population model is needed. While such models exist, they can be refined based on research into important aspects of Delta Smelt reproductive biology, including the reproductive output of individual Delta Smelt and the population as a whole, and how it varies with environmental conditions.

In particular, fecundity data on adult female Delta Smelt caught in the SKT have only recently been collected. This is a critical parameter, necessary to assess the reproductive potential of the population in any given year. Continued collection of fecundity data over multiple years and hydrological conditions is crucial to understanding the population response to environmental conditions in the seasons preceding reproduction. In addition, an understanding of variables controlling the number of spawning events in a year for wild Delta Smelt is necessary to understand the full reproductive potential of the population. An exploration of whether spawning events are discernible on otoliths is ongoing (Hobbs group, UC Davis); if so, retrospective analyses relating multiple spawning events to concurrent conditions (e.g., tidal phase, food availability, water temperature) may be possible.

Finally, efforts to better characterize spawning habitat and habitat attributes needed for successful egg hatching should also continue. This is needed to more fully evaluate and understand linkages between environmental drivers such as hydrology and larval recruitment. Of all the life stages of Delta Smelt, we know the least about the egg stage; Delta Smelt eggs have never been found in the wild. Because of this, we were not able to construct a life stage transition conceptual model that specifically focused on eggs. More information about spawning and egg hatching habitat is needed to fill this gap in our conceptual models and to identify management actions that would promote beneficial habitat attributes.

Mathematical Modeling

As demonstrated in this report and by others, conceptual models are useful tools for identifying and understanding key ecosystem components and relationships, but they do not quantify them and cannot be used to quantitatively define functional responses to environmental drivers or make quantitative predictions. Furthermore, as discussed above, the simple univariate and comparative analysis approaches employed throughout this report cannot capture the effects of multiple and often interacting drivers on the Delta Smelt population as a whole and on specific processes such as growth, mortality, and reproduction. The influences of interspecific interactions and abiotic forcing factors on populations and communities in complex ecosystems such as estuaries are also difficult to directly measure in any practical way. Only mathematical models can deal with such complexities and provide quantitative assessments and predictions.

Fortunately, the number of scientific publications about Delta Smelt that include various types of increasingly sophisticated mathematical models is growing rapidly. Recent examples include mathematical models based on statistical approaches (e.g., Bennett 2005, Manly and Chotkowski 2006, Feyrer et al. 2007, Nobriga et al. 2008, Kimmerer 2008, Kimmerer et al. 2009, Feyrer et al. 2010, Thomson et al. 2010, Mac Nally et al. 2010, Miller et al. 2012, Sommer and Mejia 2013, Kimmerer et al. 2013). These efforts generally focused on habitat associations using presence/absence data from the various monitoring surveys or on changes in Delta Smelt abundance based on abundance indices generated by the monitoring surveys and the effects of multiple habitat attributes (covariates) on these changes.

There is also a rapidly developing body of population life cycle models for Delta Smelt and other SFE fish species (e.g., Blumberg et al. 2010, Maunder and Deriso 2011, Massoudieh et al. 2011, Rose et al. 2011, Rose et al. 2013a, b). These models use either a statistically-based “state–space” multistage life cycle modeling approach or a spatially explicit, individual-based simulation modeling approach. Both approaches allow for analysis of the importance of drivers that affect different life stages of Delta Smelt and vary in space and time.

Not surprisingly, results of mathematical modeling efforts to date agree strongly that no single factor can explain the observed Delta Smelt population dynamics and long-term changes in abundance. There is less agreement, however, about which factors are most important (see for example Rose et al. 2013b) and about the exact sequence and nature of their interactions that led to the 2002-3 Delta Smelt POD decline. It is possible, perhaps even likely, that the natural complexity of the estuarine ecosystem coupled with multiple human impacts will prevent definitive answers to these types of questions, especially when they are sought through overly rigid application of formal hypothetico-deductive reasoning and methods (Quinn and Dunham 1983). We agree with Rose et al. (2013b) that the inherent complexity of the system and the challenges it presents for scientists and managers alike “is perhaps the best reason to develop and compare alternative modeling approaches.” Even the most sophisticated modeling oversimplifies complex systems and includes many assumptions. This means that instead of a single modeling approach, multiple alternative conceptual and mathematical modeling approaches, from the simple to the complex, are needed to understand how complex systems work and to predict future changes with sufficient confidence to allow for effective management interventions. The following sections give a brief overview of some of the alternative mathematical modeling efforts currently underway or proposed for the future.

A comprehensive state-space modeling effort that takes advantage of available Delta Smelt abundance data from all monitoring surveys and the even larger monitoring data set about habitat attributes is currently underway (Ken Newman, FWS, personal communication) and future analyses using the individual-based model developed by Rose et al. (2013a) have been proposed (Rose et al. 2013b). As mentioned above, a full description or application of mathematical models is outside of the scope of this report, but to illustrate the utility of additional alternative approaches and further explore some of the linkages and interactions in our conceptual model, we give three additional examples of alternative mathematical modeling approaches that may be used to further test some of the hypotheses in the conceptual models in this report. The first is a qualitative modeling approach, the second a multivariate statistical modeling approach, and the third a numerical simulation modeling approach. Each of these approaches was explored by one of the co-authors of this report. Importantly, these approaches are meant to complement, not replace state-space, individual-based, and other modeling approaches for Delta Smelt. **Furthermore, results are preliminary and included for illustrative purposes only; peer-reviewed publications of these analyses need to be completed before they can be used to draw any conclusions.**

Qualitative Models

Qualitative modeling provides a theoretical foundation for understanding system behavior by minimizing the loss of generality and realism at the expense of model precision (Levins 1974, Levins 1975, Puccia and Levins 1991). Qualitative modeling is based on a mathematically rigorous approach that can be used to gain insight on community level process and to examine the consequences of intended or inadvertent human-induced perturbations in managed systems. Questions often addressed through qualitative modeling include the resilience and stability of the system and the direction of population change (Puccia and Levins 1991), the role of system structure on stability (Dambacher et al. 2003, Fox 2006) and the degree of predictability in the response of populations to perturbations (Montaňo-Moctezuma et al. 2007, Hosack et al. 2009). Such questions have strong implications in terms of stability-complexity relations (May 1972, Pimm 1984, Haydon 1994) and the persistence of populations and communities following regime shifts (Baxter et al. 2010, Brook and Carpenter 2010, Capitán and Cuesta 2010, Cloern and Jassby 2012).

The increased ecological understanding of the upper SFE and the potential drivers and mechanisms underlying the interannual population responses of Delta Smelt reviewed by the FLaSH and MAST syntheses provide a strong rationale to further refine and integrate our knowledge on community level interactions and ecological drivers in this highly altered system. Towards that goal, we envision qualitative modeling as a complementary approach to other types of models to evaluate the response of Delta Smelt and other populations in the upper SFE over several temporal and spatial scales. Qualitative modeling for Delta Smelt can address some relevant system-level knowledge gaps which are usually less amenable to analyses using other modeling approaches, namely, the influence of species interactions and multiple feedback levels on community stability and population changes in response to perturbations on one or more species. For example, understanding the mechanisms leading to Delta Smelt population responses under different hydrological conditions is an area of significant interest.

Signed-digraphs are a useful representation of the structure of a system, as defined by the community matrix, and have been used in qualitative models exploring food webs (Liu et al. 2010), extinction events in communities (Vandermeer 2013), and other ecological topics of theoretical and conservation relevance. Castillo (unpublished data) used this approach to evaluate the predicted response of Delta Smelt to a sustained change in fall outflow as required in the 2008 FWS Biological Opinion. Recognizing that outflows can control X2 and the size and location of the LSZ (see Chapter 4), and affect other segments of the aquatic community supporting Delta Smelt, Castillo (unpublished data) modeled the response of subadult Delta Smelt to low (5,000 cfs; X2 = 85 km), intermediate (8,000 cfs; X2 = 81 km) and high (11,400 cfs; X2 = 74 km) fall outflow scenarios. Community composition for each outflow scenario was determined relative to the geographical distribution of species expected to occupy the LSZ. The high outflow model included six community components: phytoplankton, zooplankton, Delta Smelt, predators of Delta Smelt, the overbite clam *Potamocorbula amurensis*, and outflow. The intermediate outflow scenario included two additional community components: the Asian clam *Corbicula fluminea* and the cyanobacteria *Microcystis aeruginosa*). The low outflow scenario included the same variables as in the intermediate flow scenario, except that the overbite clam was excluded and the Brazilian waterweed, *Egeria densa* was added. For each of these communities, community components could exhibit positive or negative feedbacks and positive or negative interactions with other community components. For each of the assumed flow conditions, the four alternative types of community interactions were assumed and each met the stability criteria, as defined by Puccia and Levins (1991). The predicted response of the Delta Smelt population was: 1) predominantly positive under the high outflow community scenario, 2) ambiguous under the intermediate outflow community scenario and 3) very ambiguous under the low outflow community scenario. According to these preliminary results, both outflow and outflow-induced changes in community composition and structure seem to play a critical role in determining the population response of Delta Smelt. These model predictions supported the hypothesis that a shift in the LSZ towards X2 = 74 km is a necessary condition for the fall outflow action to exert a positive influence on the Delta Smelt population. Qualitative models like these can provide useful assessments when the general direction of community interactions are understood but the data are insufficient to support a quantitative model.

Multivariate Statistical Modeling

In this report we reviewed results from many multivariate statistical modeling efforts such as the multivariate autoregressive modeling (MAR) conducted by MacNally et al (2010) to discern the main factors responsible for the POD declines and the hierarchical log-linear trend modeling by Thomson et al. (2010) that used Bayesian model selection to identify habitat attributes (covariates) with the strongest associations with abundances of the four POD fish species and determine change points in abundance and trends. The state-space life cycle modeling by Maunder and Deriso (2011) is also based on multivariate statistical modeling; an extension of this work is currently underway by Newman and others (Ken Newman, USFWS, unpublished data).

We anticipate that insight from the current conceptual model may be used to facilitate additional multivariate statistical models. As an example, we present preliminary results (Mueller-Solger, USGS, unpublished data) of univariate and multivariate statistical analyses of X2 relationships with annual Delta Smelt abundance indices that follow the approach in Jassby et al. (1995). The purpose is to further explore some of the hypotheses related to hydrology and the size and position of the LSZ included in our conceptual model and to illustrate the importance of considering more than one factor when trying to understand Delta Smelt dynamics. We include this brief exploration in this report because it serves as a useful and relevant example, but as noted above, we advise readers that these are preliminary results from an analysis that has not yet undergone peer review and should be viewed with caution. Moreover, individual and interactive effects of additional factors were not considered in this analysis, but are likely also important (see Chapter 8). As noted in Chapter 7, we recognize that “hydrology” by itself does not affect Delta Smelt, nor does the “X2” index which is used in this analysis as an index of general hydrological (outflow) conditions in the estuary. As shown in our conceptual model (Fig. 38), hydrology affects Delta Smelt through the combined effects of its interactions with other dynamic drivers and stationary landscape attributes (tier 1) on habitat attributes (tier 3). Many of these interactions have been described in this report; others should be explored further in future studies.

This analysis is intended to evaluate the effects of prior abundance, step changes, and concurrent and prior hydrological conditions in the estuary on the relative abundance of larval to early juvenile Delta Smelt (20 mm index, Fig. 3; hereafter referred to as “larval” Delta Smelt). It also considers prior hydrological conditions and the entire available abundance index time series for larval Delta Smelt provided by the 20 mm survey. The 20 mm survey, one of the newest IEP monitoring surveys, was started in 1995. Delta Smelt distribution data from this survey is heavily used to assess and manage entrainment risk. Similar to prior analyses of TNS and FMWT data (Feyrer et al. 2007, Nobriga et al. 2008), Kimmerer et al. (2009, 2013) and Sommer and Mejia (2013) used a generalized additive modeling (GAM) approach to examine the associations between Delta Smelt occurrence or catch per trawl at 20 mm survey stations and habitat attributes (salinity, temperature, turbidity, and calanoid copepod density) measured concurrently at the same stations. There have, however, been few analyses of annual abundance data from this survey. After 19 years, the 20 mm survey now provides barely enough annual abundance data points (indices) to conduct multiple regression analyses with up to two predictor variables. Clearly more years of data collection and more in-depth analyses are needed and the analyses presented here are merely a starting point.

This analysis uses annual abundance indices for larval Delta Smelt (20 mm survey, 1995-2013), adult Delta Smelt (SKT survey, 2003-2013), and subadult Delta Smelt during the previous year (FMWT survey, 1995-2013) (Fig. 3). It also uses larval recruitment indices calculated from the annual abundance indices (20 mm to SKT ratio and 20 mm to $\mathrm{FMWT}_{\mathrm{Year}-1}$ ratio, Fig. 46; see previous chapters for caveats regarding index ratios). Data from the SKT survey was only used for univariate analyses because the SKT index time series only has 11 data points at this time. Spring and fall X2 values were obtained by first calculating mean monthly X2 values calculated from daily X2 values provided by the DWR Dayflow database and then averaging the mean monthly X2 values for the “spring” months February to June and the “fall” months September to December. The 2002-2003 step decline in Delta Smelt abundance (Thomson et al. 2010) was introduced as a before/after factor (“Step”). Details about the data sources are provided in Chapter 3 of this report.

The multivariate analyses presented here were conducted with generalized linear modeling (GLM) following the approach of Jassby et al. (1995) and followed with a classical linear modeling (LM) approach guided by the GLM results. For the GLM, model parameters were estimated with a Poisson error distribution, a log link function describing the relationship between the predictor variables(s) and the mean, and a natural spline to represent non-linearities. The degrees of freedom for the splines were restricted to only 2 (i.e. one interior knot) because of the low number of available data points. Models requiring estimation of more than two independent parameters (aside from the intercept) were not considered for the same reason. Applying the GLM approach avoids the need for log-transforming the abundance data and using natural (quadratic) splines as smoothers allows a more natural representation of non-linearities than using polynomials.

The responses predicted by these models have a fairly high degree of precision as indicated by low values of SE/Mean and residuals were consistent with model assumptions. The results show significant univariate relationships at the $P < 0.05$ level (Table 7) between the 20 mm abundance index and spring X2, prior fall X2, and prior FMWT abundance index. The relationship is strongest with prior fall X2, followed by spring X2 and prior FMWT abundance index (Table

7). The relationship with spring X2 appears unimodal with maximum 20 mm indices associated with spring X2 values between about 55 and 70 km (Fig. 79a). The relationship with prior fall X2 appears negative (Fig. 79b), and the relationship with the prior FMWT abundance index (Fig. 79c) appears positive. Each of these univariate relationships was improved by the inclusion of one of the other predictor variables (Table 7). Relationships with spring and prior fall X2 were also improved by including the 2002-3 step change. As mentioned above, multivariate analyses with more than two predictor variables were not conducted because of the relatively small amount of available data (n = 19, Table 7). Based on AIC comparisons (Table 7), including the 2002 step change (introduced as a before/after factor, “Step”) somewhat improved the relationship of the 20 mm index with spring X2 (Fig. 73a) and with prior Fall X2 (Fig. 79b), but not with the prior FMWT index because that index was the basis for the analyses that detected the step change and thus already includes the step change in the actual data (Fig. 79c, model not included in Table 7). Including the prior FMWT abundance index improved the relationships with spring and fall X2 more substantially, but the model combining the effects of spring and fall X2 fit the 20 mm index data nearly as well as the model combining the effects of spring X2 and prior FMWT (Table 7).

It is interesting to note that while prior fall X2 by itself was a stronger predictor of the 20 mm index than spring X2, spring X2 was the stronger predictor when the step change or previous fall abundance were taken into account. Baxter et al. (2010) hypothesized that the shift toward higher prior fall X2 values (Fig. 17) may have contributed to an ecological “regime shift” associated with the step decline in Delta Smelt and other species. This means that prior fall X2 and the “step” factor and FMWT decline in this analysis may be related, which could explain the very similar outcomes for the two models combining spring X2 with either prior fall X2 or the prior FMWT index.

Partial residual plots show the relationship between a predictor variable and the response variable given that other independent variables are also in the model; in other words, they show the effect of one predictor variable given the effect of one or more additional predictor variables. Partial residual plots for the relationships of the 20 mm index with the combinations of spring X2 and prior fall X2 (Fig. 80 a and b) and spring X2 and prior FMWT abundance index (Fig 80 c and d) show that the general shape and direction of the relationships of the 20 mm index with each of the individual predictor variables (Fig. 79) remains intact in the models with combined predictors, but the partial residuals do not closely follow the fitted lines. This indicates that while each variable has its own, distinct effect on the 20 mm index that is maintained in the presence of the other variables, interactive effects among these variables are quite strong. In summary, low values of prior fall X2, high prior FMWT abundance, and intermediate values of spring X2 have positive associations with the abundance of larval/postlarval Delta Smelt, but the effects of individual variables are mediated by the presence of the other variables.

Because the spline degrees of freedom were strongly restricted in this GLM analysis, the results are quite similar to the results of classical linear models (LM) with log-transformed abundance data and a quadratic term to represent the unimodal non-linearity in the relationship between the 20 mm index and spring X2 (Fig. 81). We include these models here because they are more easily reproducible than the GLM models and offer simple equations for making predictions about larval abundance that can be used in adaptive management applications. As for the GLM analysis (Table 7), the best fits overall were achieved by combining spring X2 with either the step change or the prior FMWT abundance index (Table 8). All predictor combinations improved the models compared to the univariate relationships (Table 8). Based on a comparison of regression

Table 7. Summary of relationships between the 20 mm abundance index for Delta Smelt (response variable) and one or more predictor variables: n, number of observations (years); SE/Mean, model standard error (square root of mean squared residual) as proportion of mean response, P, statistical significance level for the model; R^2, coefficient of determination; adjusted R^2, R^2 adjusted for the number of predictors in the model; AIC, Akaike information criterion; Δ AIC, AIC differences; w (AIC), AIC weights. All relationships modeled with generalized linear models (GLM) with a Poisson error distribution, log link function, and a natural cubic spline with two degrees of freedom as a smoother for all predictor variables except "Step."

Predictor Variable(s)	n	SE/ Mean	P	R^2	Adjusted R^2	AIC	Δ (AIC)	w (AIC)
Spring X2, $\text{FMWT}_{\text{year-1}}$	19	0.119	<0.001	0.791	0.731	39.5	0.00	0.53
Spring X2, Fall $\text{X2}_{\text{year-1}}$	19	0.120	<0.001	0.787	0.726	40.1	0.60	0.39
Fall $\text{X2}_{\text{year-1}}$, $\text{FMWT}_{\text{year-1}}$	19	0.126	<0.001	0.764	0.697	43.2	3.78	0.08
Spring X2, Step (Factor)	19	0.143	<0.001	0.677	0.612	53.6	14.12	0.00
Fall $\text{X2}_{\text{year-1}}$, Step (Factor)	19	0.135	<0.001	0.712	0.655	55.8	16.35	0.00
Fall $\text{X2}_{\text{year-1}}$	19	0.145	<0.001	0.646	0.601	56.0	16.53	0.00
Spring X2	19	0.176	0.006	0.476	0.411	79.9	40.43	0.00
$\text{FMWT}_{\text{year-1}}$	19	0.187	0.015	0.408	0.334	89.4	49.98	0.00

coefficients and P-values, the LM relationships were statistically weaker (Table 8) than in the GLM analysis (Table 7).

Another way of including prior abundance in statistical relationships of abundance with habitat attributes and environmental drivers is to use abundance indices that are proportional to prior abundance indices, in other words, ratios of present to prior abundance indices. In this report, we used the ratios of 20 mm to SKT and 20 mm to $\text{FMWT}_{\text{Year-1}}$ abundance indices (Fig. 46; see also caveats about these indices in Chapter 3) as larval recruitment indices from adults and subadults, respectively. We found that recruitment of larvae from adults was linearly related to spring X2 for the entire available time series (2003-2013, Fig.82a and Table 9). The recruitment index for 2013 was higher than expected based on the other data points. The relationship of the recruitment index from subadults to next year's larvae with winter-spring X2 was also linear for the POD period after the abundance step decline in 2002 (Thomson et al. 2010), but with more scatter at higher X2 values. Interestingly, no relationship was apparent at all before the 2002 step decline when the proportional larval recruitment from then more abundant subadults was generally low (Fig. 82b and Table 9). In the current POD regime, larval recruitment from parental stock appears to be highest when flows through and out of the Delta are high and the interface between fresh and brackish water is located to the west (i.e. low X2), although it can occasionally also be high at lower flows, as was the case in 2013.

In late winter and spring 2013, CVP and SWP exports were reduced to comply with OMR flow requirements in the 2008 USFWS Biological Opinion aimed at reducing the risk of adult and

Figure 79. **Plots of the Delta Smelt 20 mm survey abundance index as a function of a) spring (February-June) X2, b) previous year fall (September-December) X2, and c) Delta Smelt fall midwater-trawl abundance index in the previous year. Details of general linear models (GLM) used to fit the lines are in Table 7.**

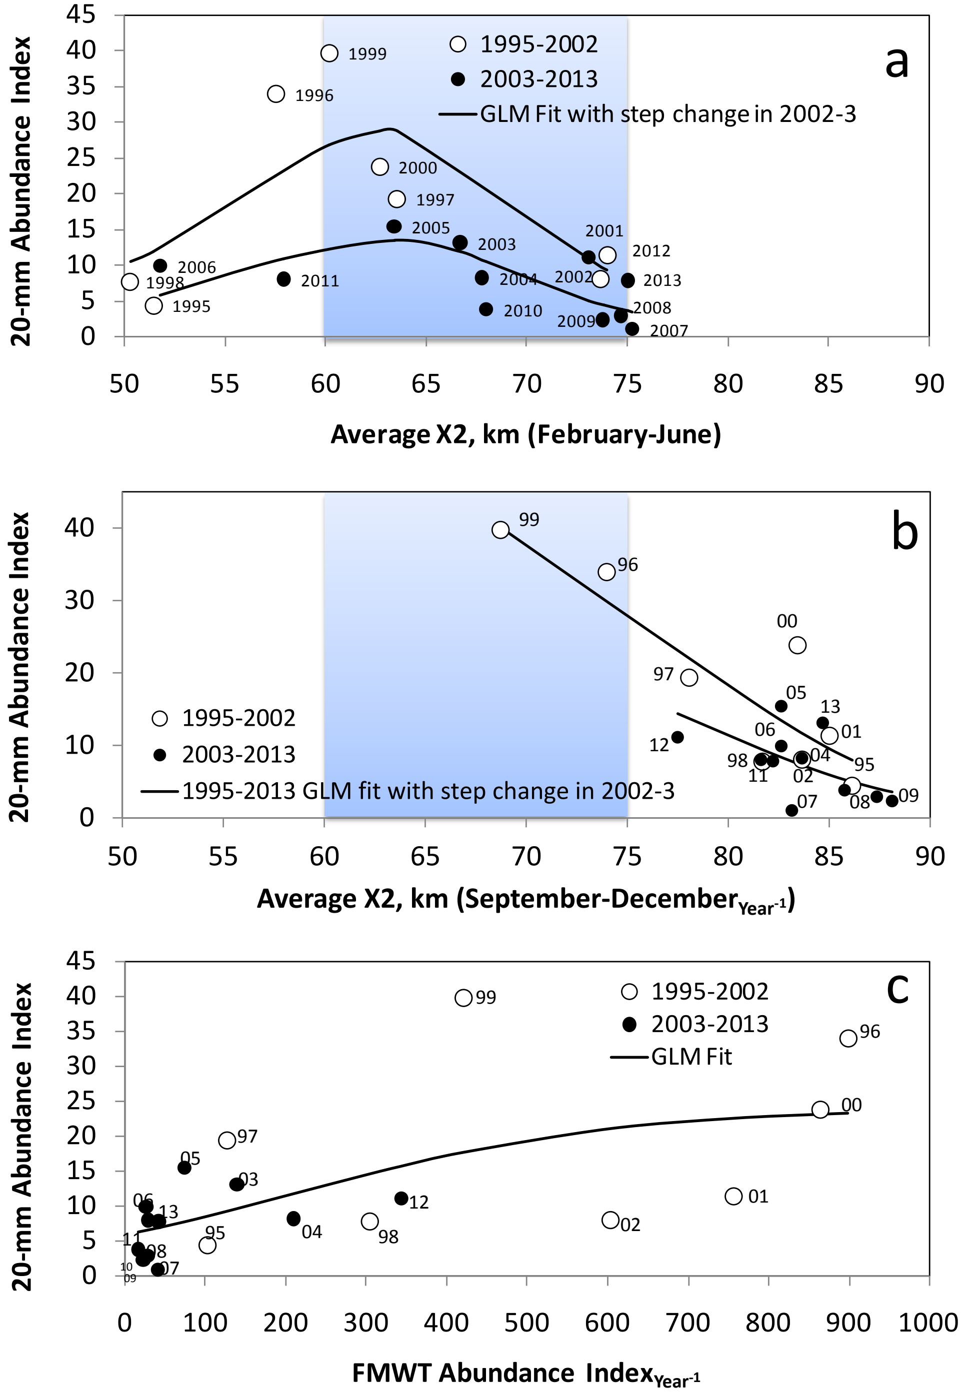


Figure 80. **Plots of partial residuals for the relationships of the 20 mm index with the combinations of spring X2, prior fall X2, and prior FMWT abundance index summarized in Table 1 (panels a, b, d, and e). The plots shown here also include partial fit lines and their 95% confidence intervals. Values for the time period of analysis are shown for: c, X2; and f, the fall midwater trawl abundance index from the previous year**

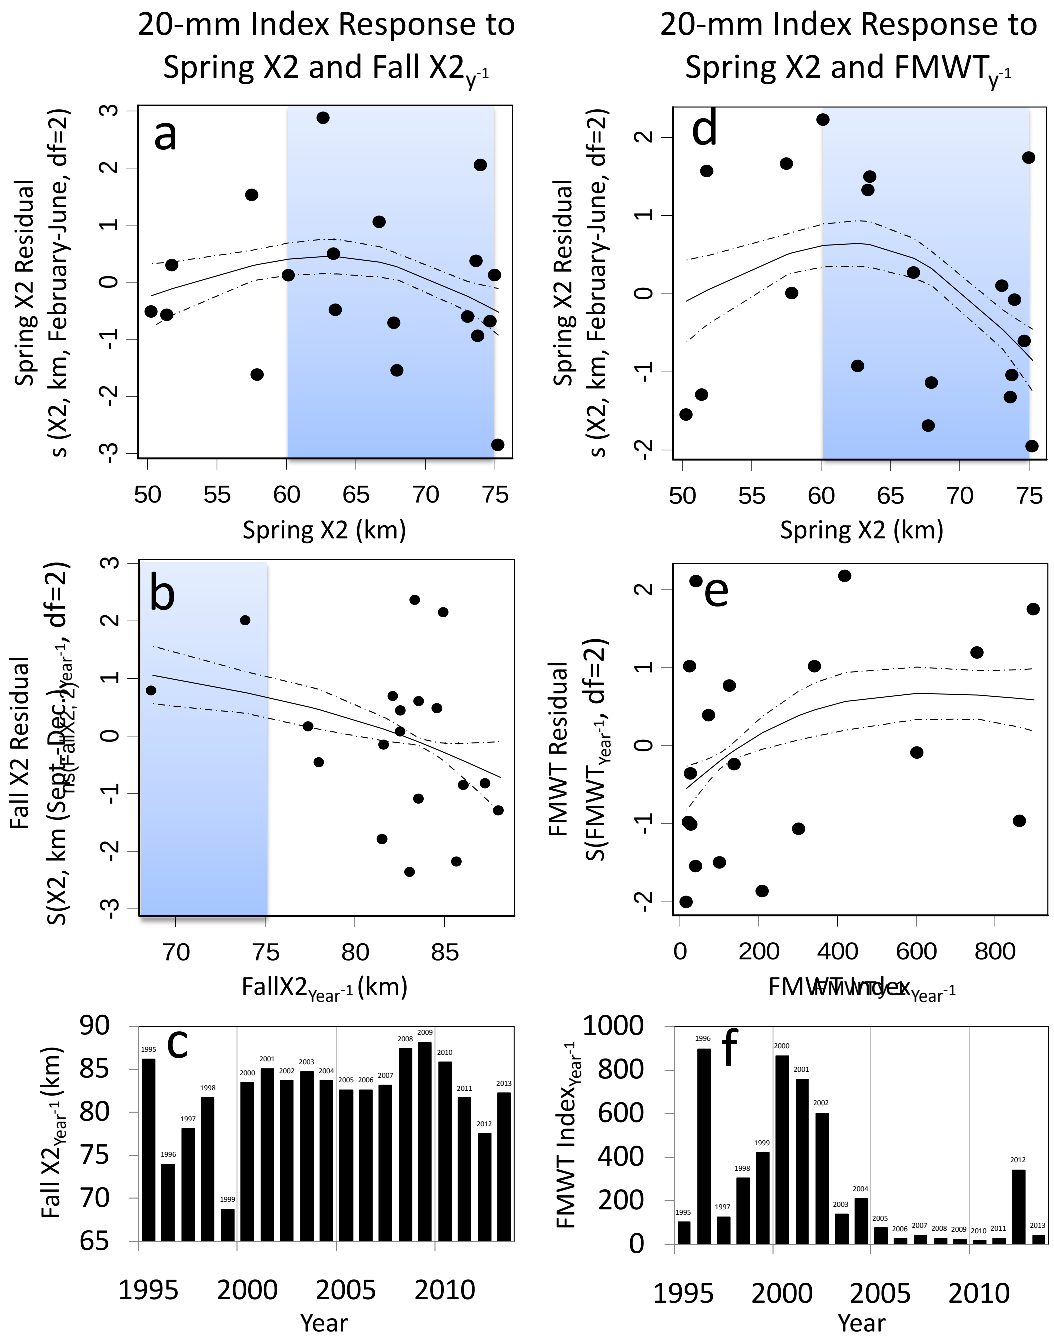

Figure 81. Plots of the Delta Smelt 20 mm survey abundance index as a function of a) spring (February-June) X2, and b) previous year fall (September-December) X2. Lines are either simple linear least squares regression (lines) or quadratic regression (curves). Details of linear models (LM) used to fit the 1995-2013 lines are in Table 8.

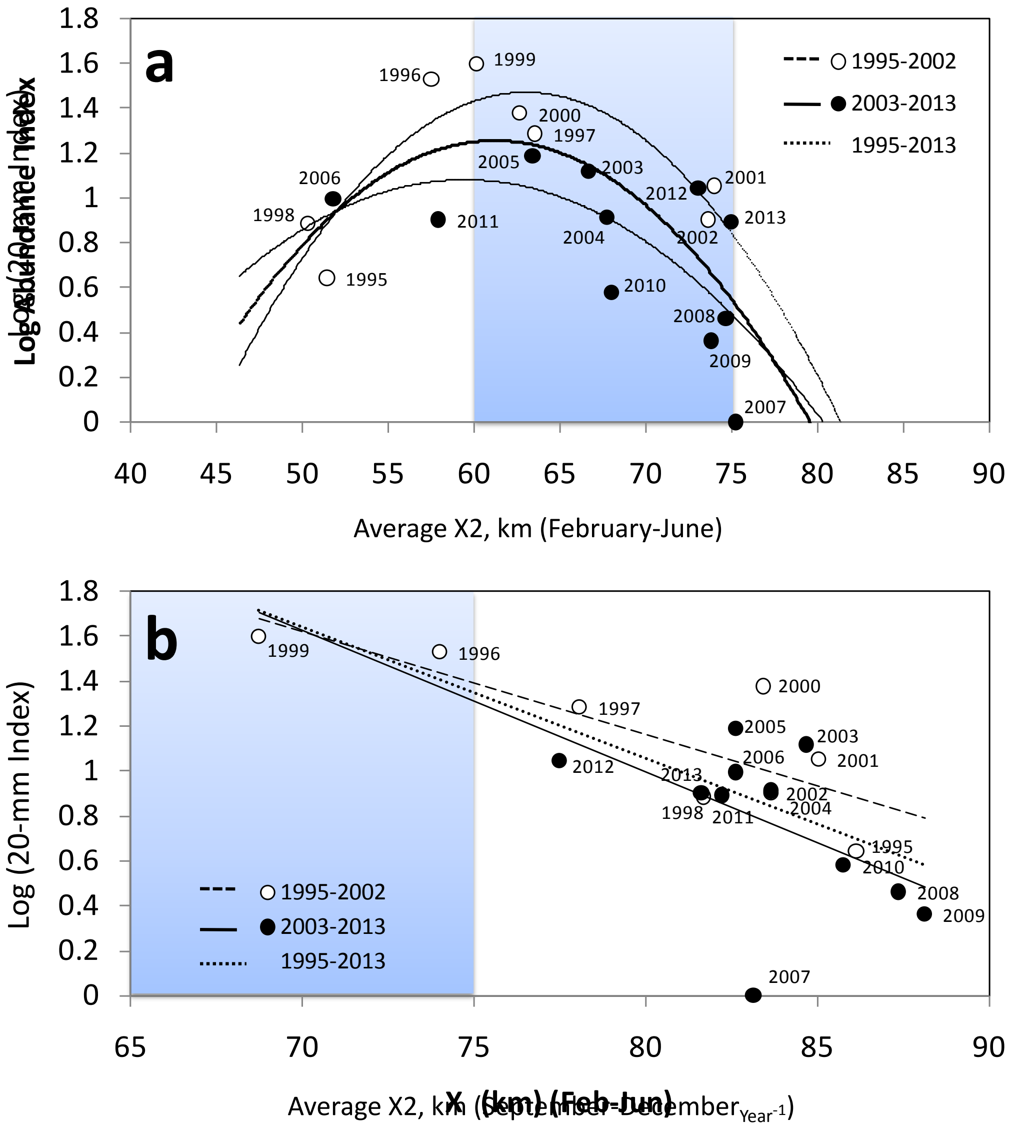

larval Delta Smelt entrainment into the water export pumps. This was the first time since the 2008 USFWS Biological Opinion was issued that exports were specifically reduced to lower Delta Smelt entrainment risk. In other years, flows were high enough to allow for higher export levels or export reductions to protect salmon were deemed sufficiently protective for Delta Smelt. It is possible that the intentional reduction in Delta Smelt entrainment risk in 2013 contributed to the high larval recruitment from adults during relatively low flow conditions, but additional years with similar conditions and targeted management actions as well as better estimates of entrainment and more in-depth analyses with other flow variables and flow averaging periods

Table 8. **Summary of relationships between the log-transformed 20 mm abundance index for Delta Smelt (response variable) and one or more predictor variables. All relationships modeled with simple least-squares linear models (LM). For explanation of column headings see Table 6.**

Predictor Variable(s)	n	SE/ Mean	P	R^2	Adjusted R^2	AIC	Δ (AIC)	w (AIC)
Spring X2, (Spring X2)^2, log FMWT$_{year-1}$	19	0.237	0.000	0.745	0.694	2.1	0.00	0.85
Spring X2, (Spring X2)^2, Fall X2$_{year-1}$	19	0.274	0.001	0.661	0.593	7.5	5.42	0.06
Fall X2$_{year-1}$, log FMWT$_{year-1}$	19	0.280	0.000	0.621	0.574	7.7	5.54	0.05
Spring X2, (Spring X2)^2, Step (Factor)	19	0.292	0.002	0.616	0.540	9.9	7.78	0.02

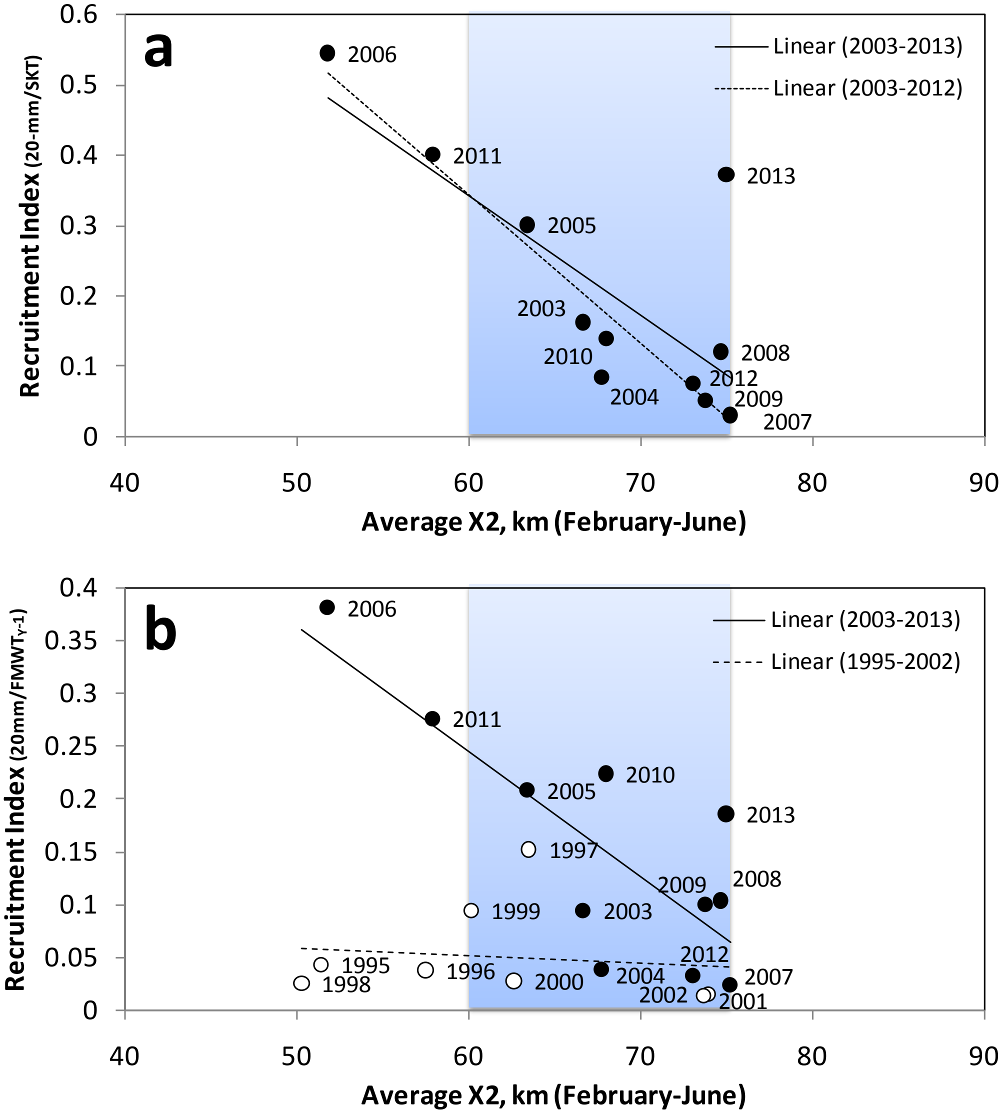
Spring X2, (Spring X2)^2	19	0.329	0.006	0.473	0.407	13.9	11.83	0.00
log FMWT$_{year-1}$	19	0.333	0.002	0.430	0.397	13.4	11.29	0.00

are needed to test this hypothesis and obtain a better understanding of flow effects on larval recruitment.

Overall, these preliminary findings suggest that abundance of the larval to early juvenile life stages of Delta Smelt may respond quite strongly to spring and prior fall outflow conditions. The relationships of the 20 mm index with spring X2 shown in this analysis were much stronger than relationships of the TNS and FMWT indices with spring X2 (Table 1, Fig. 17. Similarly, hydrological conditions in the fall seem to have a greater impact on subsequent abundance of larvae than on subsequent juvenile abundance (TNS index; Mount et al. 2013). This is consistent with the findings by Kimmerer et al. (2009) who noted more pronounced relationships of spring X2 with earlier than with later life stages of Delta Smelt and explained that this was “probably because the earlier life stages occupy areas that are fresher and therefore more responsive to changing flow than the more brackish regions.” While the size and location of the LSZ itself may be important for maturing adults in the fall, its interface with fresh water may be important to larvae and spawning adults. A more westward interface means a larger freshwater habitat for spawning and larval rearing that reaches into the shallow eastern region of Suisun Bay and is well connected with Suisun Marsh sloughs and, in wetter years, the Napa River. It also means a larger distance to the export pumps in the southern Delta and thus a reduced risk of entrainment for spawning adults and larvae. Interactions of flow with other drivers and habitat attributes as shown in the conceptual models in this report are likely also important. This suggests that at least

Figure 82. **Adult (panel a, SKT) and subadult (panel b, FMWT the previous year) to larvae (20 mm Survey) recruitment indices (abundance index ratios) as a function of spring X2 (February-June). For 20 mm/SKT a linear regression was calculated with and without 2013, which appears to be an outlier. For 20 mm/FMWT the previous year separate regressions were calculated for the POD period (2003-2013), the period before the POD (1995-2002), and the entire data record (not shown). See Table 9 for regression results.**



at present, increased Delta outflow and a more westward LSZ in fall, winter, and spring may have important beneficial effects on early life stages of Delta Smelt, but other factors (possibly including summer flows which were not included in this analysis) may be more important for their survival to adults.

Finally, similar to previously published analyses, this analysis strongly suggests that previous life stage abundance should always be taken into account in statistical explorations of habitat effects

Table 9. Summary of relationships of larval recruitment indices (abundance index ratios) for Delta Smelt (response variable) and spring X2 (predictor variable; spring: February-June): n, number of observations (years); SE/Mean, model standard error (square root of mean squared residual) as proportion of mean response, P, statistical significance level for the model; R^2, coefficient of determination. All relationships modeled with least-squares linear models (LM).

Index Ratio	Period	n	SE/Mean	P	R^2
20-mm/ SKT	2003-2013	11	0.556	0.006	0.588
20-mm/ SKT	2003-2012	10	0.270	0.000	0.918
20-mm/ $FMWT_{Year-1}$	2003-2013	11	0.469	0.003	0.648
20-mm/ $FMWT_{Year-1}$	1995-2002	8	1.012	0.771	0.015
20-mm/ $FMWT_{Year-1}$	1995-2013	19	0.981	0.321	0.058

on Delta Smelt. Prior abundance can be introduced into these relationships as actual abundance data (e.g. abundance indices or catch per trawl data), periods of relatively constant abundance (here introduced as a “step” factor), or by combining it with present abundance in proportional abundance indices such as the index ratios used here as recruitment indices. Similar to the relationships of juveniles with spring X2 discussed in Chapter 4, the overall depressed abundance of larval Delta Smelt during the POD period that started in 2002 leads to less substantial larval abundance increases with increasing outflows and decreasing X2 values than before the onset of the POD. However, the association of high larval recruitment with high spring outflow suggests that winter and spring hydrology, through its effects on habitat attributes, may be an important driver of larval recruitment during the current POD period, although it may be less important at higher abundance levels.

In summary, this preliminary analysis provides an example of how relatively simple multivariate modeling can yield intereresting insights, in this case about how prior conditions (prior fall X2), prior abundance (prior FMWT), step changes in abundance, and concurrent environmental conditions (spring X2) may all have important effects on Delta Smelt abundance in the spring. While further analyses, more sophisticated life cycle modeling, and publication in a peer-reviewed journal are needed to draw firm conclusions, these preliminary results support the idea discussed throughout this report that neither scientific understanding nor management effectiveness can be improved by only considering a single effect, or a single season or life stage. High larval recruitment is essential for setting the stage for a strong year class, but higher growth and survival through subsequent life stages are also needed to achieve and sustain higher population abundance levels.

Numerical Simulation Modeling

Quantitative simulations of the multiple factors and processes that affect Delta Smelt life stage transitions in our conceptual model are an obvious next step in the exploration and synthesis of the information presented in this report. The purpose of simulation modeling is to represent a phenomenon or process in a way that allows users to learn more about it by interacting with the simulation (Alessi and Trollip 2001). In particular, simulations allow users to easily control experimental variables and test hypotheses. Guidance from simulation model "dry runs" can make actual laboratory and field experimentation much more efficient and effective. Simulations are also valuable in visualizing outcomes, thus further promoting learning and understanding.

The individual-based Delta Smelt model by Rose et al. (2013a, b) is an example of a complex simulation model specifically created for Delta Smelt. Another simulation modeling option is to utilize "off-the-shelf" simulation software such as the "STELLA" (Structural Thinking and Experiential Learning Laboratory) simulation construction kit (http://www.iseesystems.com/softwares/Education/StellaSoftware.aspx). STELLA is designed to let users easily create their own simulations using system dynamics including positive and negative causal loops, and flows, accumulations and conversions of materials.

Culberson (USFWS, unpublished data) created a simple quantitative simulation model in STELLA that includes several life stages of Delta Smelt and is based on seasonal environmental conditions and stage to stage estimates of survival. While this simulation modeling approach appears to be feasible, it remains to be seen how such an approach will approximate actual population dynamics encountered in the field and how results compare to those of other simulation models such as the individual-based life cycle model by Rose et al. (2013a,b). A user-friendly STELLA-based model can be useful in the interim, however, to explore the relative contribution of lifecycle stage and environmental covariates to the overall status of Delta Smelt abundance from year to year and to test hypotheses derived from the conceptual model. In its fullest expression, this MAST-associated lifecycle model will be useful for illustrating how multiple suites of plausible co-variates can allow for different Delta Smelt abundance outcomes. For example, it may be possible to find high abundance under degraded conditions given low entrainment losses across successive winters and springs. Conversely, it is possible to encounter low Delta Smelt abundance given otherwise good environmental and outflow conditions with significantly warmer temperatures during fall pre-adult maturation periods. Moreover, simulated changes in survival can provide a useful frame of reference to evaluate alternative outcomes of cohort size or population size attained at different life stages. For example, given the reported levels of larva, juvenile and sub-adult Delta Smelt in IEP surveys, what levels of daily survival between life stages would be required to attain the relative abundances corresponding to each of the four years being compared? Could the small anticipated differences in assumed daily survival among those four years be attributed to some combination of habitat attributes? Or, could stage-to-stage survival (e.g., percent of individuals surviving from one stage to the next) provide a more useful frame of reference to address that question? Our proposed STELLA simulation model and associated modeling exercises will comfortably allow exploration of these questions and related ideas.

This type of modeling will best be used iteratively with emerging data and within synthesis reports to identify where important gaps exist in the Delta Smelt lifecycle understanding and demonstrate how disparate information sources might be brought together to inform our smelt population estimates through time. Importantly, our model can be used in combination with the narrative description of "a year in the life" of the Delta Smelt population from the conceptual model to more effectively describe environmental and management effects on population status in the SFE. We are especially interested in using such a model to avoid single-factor outcome discussions where smelt populations are seen as the result of "one versus another" environmental or management-related trade off, particularly when single factor analysis is aggregated over decades of data collection efforts in what we know is a constantly-changing estuary.

Figure 83 shows how output from such a model might be useful for keeping track of the variable influence of factors on overall Delta Smelt abundance across seasons within three hypothetical years. Six factors are plotted according to their sensitivity rank (their relative influence on simulated population outcomes). Specific sensitivity levels can then be identified according to the combinations of factors that emerge as important across succeeding seasons and years. Models built to simulate these influences can then be closely examined to discern how different years, year types, or management practices influence simulated abundance, and to detect where potential data gaps or inconsistencies are among the alternative conceptual models or model modes. The basis for using such an approach is a comparative one, and an absolute resolution of the size or behavior of the real Delta Smelt population is not anticipated – but remains the overall objective. Of real interest here is providing a way to interpret our emerging conceptual model within potential regime-shifts, and to capitalize on previous specifications of this model to organize our ever-improving understanding. Of additional benefit is the ability to use these models easily in “learning sessions,” where users interact with the modelers and species experts to deepen understanding of Delta Smelt biology and its relationship to Delta ecology and management.

Applications to Support Delta Smelt Management

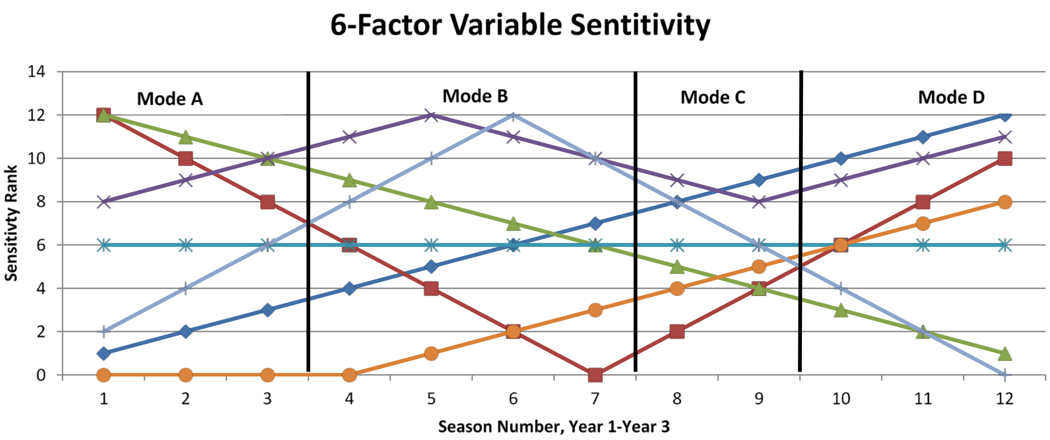
We have shown that the conceptual models in this report provide a reasonable and up to date conceptual framework that can be used to analyze and synthesize existing data and knowledge about Delta Smelt, identify critical data and information gaps, and guide new field and laboratory studies as well as mathematical modeling efforts. We have also discussed many challenges that limit our ability to reach firm conclusions and make highly confident predictions about the effects of management actions and other changes on Delta Smelt. And we have noted that science and management have to go hand in hand to constantly identify, implement, evaluate, and refine the best management options for Delta Smelt in the highly altered and ever-changing estuarine ecosystem that represents the entire range of this species.

Adaptive management is a well-established approach for systematically integrating science and management. As mentioned earlier in this report, it is increasingly required in plans for management of the San Francisco estuary, but to date, the Vernalis Adaptive Management Program (VAMP) and the Fall Ouflow Adaptive Management Plan are among the few clear examples of systematically planned and implemented adaptive management in the estuary.

We end our report with examples of how our conceptual models can be used to adaptively manage and improve Delta Smelt habitat. We conclude with several recommendations for the next analysis, synthesis, and modeling efforts. These efforts are a key ingredient for the more widespread adoption and success of adaptive management strategies; without the conceptual and mathematical models provided by these efforts adaptive management of ecosystems simply cannot proceed.

Table 10 gives examples of adaptive management goals and associated uncertainties to address habitat deficiencies (“habitat problems”) identified and discussed in this report. This table is intended as an illustration of how our conceptual models can be used to inform the first three steps of the nine-step adaptive management framework developed by the DSC Delta Science Program (DSP 2013). These three steps are: 1) definition of the problem; 2) establishment of

Figure 83. **Simulated output from a STELLA model for assessing sensitivity of the model to variation in model variables.**



management goals and actions to address the problem; and 3) modeling of linkages between management goals and actions. The third step specifically requires conceptual or quantitative models for the purpose of evaluating outcomes of alternative management actions and identification of uncertainties and data gaps. Conceptual models are also important in the other six adaptive management steps, for example to design effective adaptive management experiments and appropriate monitoring and to analyze, synthesize and evaluate results.

Table 10 is organized around the habitat attributes identified in the conceptual models. For each habitat attribute, we describe some example categories of management actions that could be considered to improve the status of Delta Smelt. In essence, these actions represent an example “tool box” for the management of Delta Smelt.

Note that the tool box identified in Table 10 is not meant to be exhaustive. Rather, the list is intended as an example set of adaptive management actions suggested by the conceptual models. As such, the list provides no insight into the cost-effectiveness or feasibility of any of the potential actions. Moreover, we acknowledge that there is substantial uncertainty about the potential benefits of actions in the tool box. As mentioned above, identification of uncertainties about the feasibility and benefits of proposed management actions is an important step in adaptive management that can only be accomplished with the help of conceptual or quantitative models. A key point is that these studies are somewhat different than the critical data and information gaps presented earlier in this Chapter. Specifically, Table 10 emphasizes information gaps that are most relevant to specific management questions, while the earlier list focuses on needs to improve the overall scientific understanding that provides the basis for our conceptual models for Delta Smelt. Clearly, efforts to resolve uncertainties and gaps in understanding are needed in both categories. Overlapping uncertainties may highlight especially urgent data and information needs. For Delta Smelt, this includes uncertainties related to contaminants, predation, and entrainment along with interactions of physical habitat attributes with other factors.

Table 10. **Example tool-box for applying the conceptual model to Delta Smelt management.**

Habitat Attribute	Management Actions	Example Study Efforts
Physical Features	Increase habitat area & quality	-Identification of key microhabitats for each life stage and attributes. -Effects of flow/LSZ position on habitat quality, particularly key biotic habitat elements (access to prey, evasion of predators). -Approaches to maintain & expand high turbidity habitat (e.g. supply, habitat design, SAV management). -Approaches to maintain and expand habitat with moderate temperatures (e.g. channel configuration, water depth and velocity). -Evaluation of whether targeted restoration meets habitat needs (e.g. temperature, substrate, turbidity)
Chemical Features	Reduce toxicity	-Identification of chronic effects of contaminants. -Identification of effects of Harmful Algal Blooms. -Approaches to reduce toxicity from contaminants and HABs
Food	Increase pelagic production Increase access to alternative foods (e.g. epibenthic). Reduce sources of loss Manage towards higher quality foods Prevention and control of non-native species	-Role of tidal wetlands as subsidy habitats (not necessarily occupied by smelt) -Ammonia-bivalve interactive effects on diatom, copepod, mysid, amphipod production. -Relative importance (contribution to smelt growth) of epibenthic foods (e.g., mysids, amphipods, aquatic insects). -Effect of bathymetry, vegetation type (and density) on access to epibenthic and pelagic foods. -Role of tidal wetlands and wetland/open-water complexes. -Approaches to reduce losses to benthic grazing (e.g. invasive clams) and/or to the suppression of bivalve populations -Value of different food types to Delta Smelt nutrition. -Effects of habitat conditions (e.g. ammonia, flow) on food quality. -Identification of nutrient sources and sinks. -Improved detection methods for invasive species -Studies to evaluate alternative control methods.
Entrainment	Avoid entrainment region Adjustments to timing and magnitude of exports	-Identification of factors that lead to increased occupancy of South Delta. -Improved measurement of entrainment and its environmental correlates -Effects of exports and entrainment on viability (e.g. abundance, genetics, demographics). -Approaches to reduce entrainment and enhance emigration success.
Predation risk	Reduction of predator population Reduction of predation rate	-Studies on delta smelt responses (behavior, distribution, abundance) to variation in predator abundance. -Identify habitat features that reduce predation rate (e.g. depth, turbidity, food, lower water temperatures).

Recommendations for future analysis and synthesis

Efforts to resolve the management issues listed in Table 10 or carry out the modeling and fill the critical science gaps discussed earlier in this Chapter will not succeed without an organizational commitment to continued systematic and long-term collection, synthesis and evaluation of data and information about Delta Smelt, its habitat, and important drivers of habitat and abundance changes. The importance of Delta Smelt for ecosystem and water supply management in and far beyond the SFE is widely recognized. The impressive rate at which we are learning about Delta Smelt and the estuarine ecosystem and the large amount of existing information about them is less widely recognized by many managers and even by many scientists. Part of the reason for this is that it is difficult to track the large quantity of new (since 2010) information documented in this report and even more difficult to integrate it with the previously existing information in a meaningful way. But without this integration, identification of priorities for additional scientific investigations is ad hoc and piecemeal at best and the value of new information cannot be fully realized in management applications such as those listed in Table 10.

Moreover, comprehensive adaptive management efforts simply cannot succeed without adequate conceptual and mathematical models and important science and management opportunities will be missed. Such efforts currently include the ongoing fall outflow adaptive management for Delta Smelt and new efforts called for by the new “Collaborative Science and Adaptive Management Program” (CSAMP), the California Delta Stewardship Council’s Delta Plan, and the multi-agency Bay Delta Conservation Plan (BDCP). The fact that even the incomplete draft version of our report released for public review in June 2013 already played a central role in CSAMP work planning, court documents, and elsewhere bears clear testimony to the fact that there is a great and urgent policy and management need for analysis, synthesis and conceptual models such as those provided in this report.

In consequence, we strongly recommend that there be a continued management, analysis, and synthesis effort, whether carried out by the IEP, the Delta Science Program, or some other scientist, group or agency. While it is possible for individual scientists to take on such efforts (e.g., Bennett 2005), the amount, diversity, and rapid growth of pertinent data and information suggests that team efforts may usually be a more feasible and possibly also a more effective option. Collaborative, multidisciplinary analysis and synthesis teams are also at the core of the National Center for Ecological Analysis and Synthesis in Santa Barbara, CA (NCEAS, http://www.nceas.ucsb.edu/), the newer National Socio-Environmental Synthesis Center in Annapolis, MD (SESYNC, http://www.sesync.org/) and the Delta Collaborative Analysis and Synthesis (DCAS) approach promoted by the Delta Science Program’s Delta Science Plan (DSP 2013). Important IEP POD and MAST lessons for future synthesis teams are that the role and responsibilities of all team members need to be very clear, that lines of communication need to always be open and available to all, and that there needs to be strong and fully engaged team leadership with a clearly dedicated lead author and/or lead editor for all major team products. In addition, to complete analyses and reports on schedule, it is necessary for team members to prioritize synthesis efforts for sustained periods of time, without being tasked with additional projects that may be urgent for short-term needs.

Another consideration is the type of publication that results from analysis and synthesis efforts. The IEP MAST and POD teams have written comprehensive agency reports, but would have preferred writing peer-reviewed books or monographs (e.g., published by the American Fisheries Society or by U.C. Press) had the time and resources been available to do so. Such books would be considered better scientific products with greater scientific standing and a longer life span and would reach a much larger audience. Another approach would be to write a series of shorter articles that could be published in a special issue of a peer-reviewed scientific journal. This too would take more time and effort and would also somewhat restrict the types of topics that could be covered. Journal articles are, however, the main target for national analysis and synthesis centers such as NCEAS and SESYNC because they have the greatest scientific standing and are the most widely accepted and well established method of written science communication.

Regardless of which analysis, synthesis, and communication approach is chosen, none of these efforts can succeed without commitment of adequate funding, staffing, and other resources. The IEP MAST team that developed and wrote this report was formed in 2012 for IEP science synthesis and work planning, but it has remained a pilot-level effort that was never adequately supported. MAST work remained a part-time effort for all co-authors of this report, and for most it was an “on the side” task compared to their “regular” agency duties. There is no doubt that completion of this report could have proceeded much more rapidly with greater allocation of resources. Public and independent peer reviews of a draft version of this report (see http://www.water.ca.gov/iep/pod/mast.cfm) greatly improved the structure and content, but were not an original part of the MAST planning. Preparing and conducting the reviews as well as responding to the 355 specific and many more general review comments took considerable time (see also Appendix A). Other MAST tasks also added to the delays. In addition to this report, the MAST completed a synthesis report for the Fall Low Salinity Habitat (FLaSH) investigation component of the Fall Outflow Adaptive Management Program (Brown et al. 2014) and prepared a solicitation package for research proposals, which it then also reviewed.

We strongly recommend that adequate, long-term support for these types of efforts be among the highest science and adaptive management priorities for the region and the entire State of California. Given its pivotal role in adaptive management and the increasingly large amounts of new scientific data and information that are produced every year, the authors of this report, individually and as a team, cannot think of any science activity that is more urgently in need of greater support than analysis, synthesis, and communication of scientific results.

For additional analysis and synthesis efforts about Delta Smelt, we recommend that the next individual or team to take this on should:

- Build on this report by evaluating the conceptual model with more rigorous analyses that include more years of data, developing lifecycle and numerical models as discussed above, and/or using the conceptual model to develop a comprehensive list of data and information gaps and approaches to addressing these gaps in order to inform management strategies;
- Early in the process, make clear decisions about the analytical/modeling approaches to be used, the scope of the synthesis to be done, and approaches for review and communication of results;
- Evaluate additional data and information needs concerning Delta Smelt;
- Consider approaches to understand the effects of the wide variety of management actions targeting Delta Smelt, including adaptive management of fall outflow, entrainment, habitat restoration, etc (e.g., Table 10);
- Develop key “indicator” variables that can be used to track and predict the status of Delta Smelt and its habitat and serve as “performance metrics” to evaluate the success of management actions. Such variables, and a “report card” to summarize them, were considered for this report, but the MAST decided that developing them was beyond the scope of

this report and would require a fairly substantial effort that could be the main focus of an additional effort.

An additional recommendation is that an ultimate goal of these efforts should be the integration of conceptual and mathematical models such as those described in the previous section of this Chapter and the routine use of both types of models in adaptive management. Neither the recently published mathematical models nor existing conceptual models for Delta Smelt have been applied to management issues in a consistent manner. This is likely at least partially due to unfamiliarity of managers with the models and the need for specialists (model developers) to apply the mathematical and in some cases even the conceptual models to management issues in the absence of easy to use and understandable model interfaces and specifications. We also recommend a comprehensive biological modeling forum and/or more specific biological modeling teams and "summits" as recommended by the IEP Science Advisory Group (2010, available at http://www.water.ca.gov/iep/docs/IEPModelWorkshopReview.pdf) and, more recently, the Delta Science Plan (DSP 2013). Such groups would not only facilitate communication among modelers, but could also help make the connection from model development to model applications of interest to managers and policy makers. They would complement and could (and likely should) be integrated with the existing, California Water and Environmental Modeling Forum (CWEMF, see http://www.cwemf.org), which tends to focus on modeling physical processes. As with the overall analysis and synthesis teams, these groups could be implemented by the IEP, The Delta Science Program, CWEMF, or others. The chosen organizational umbrella is less important than actual implementation and involvement of appropriate local and outside scientific and management expertise. Some possible topics for these groups include:

1. Reviews and updates to existing conceptual and mathematical models

2. Further development of mathematical models of Delta Smelt population abundance drawn specifically from the conceptual models described in this report; applications and extensions of recently published models to help make management decisions and guide new modeling efforts; additional modeling efforts and future research projects to improve resolution and understanding of the particular factors identified as critical to reproduction, recruitment, survival, and growth.

3. Review and refinement of new models such as the emerging comprehensive state-space population model (Newman, personal communication); development of additional models or modules of models specifically aimed at estimating effects of inadequately monitored or difficult to measure and evaluate habitat attributes such as predation risk and toxicity; development of new "nested" and/or "linked" mathematical modeling approaches that can accommodate multiple drivers and their interactive effects across temporal and spatial scales.

4. Collaboration among physical and biological modelers, experimental and other scientists, managers, and stakeholders to develop and model management scenarios and strategies that move beyond the current focus on relatively crude distinctions among "water year types" toward a more integrative ecosystem and landscape-based management approach.

We end this report with the hope that the conceptual models and information presented will be used for achieving better management outcomes for Delta Smelt and the estuarine ecosystem on which it depends. These precious natural resources are owned by no one, but are held in public trust by the California and U.S. governments for the benefit of all the people. We are grateful for the opportunity to serve our State and nation in the collaborative manner afforded by working under the interagency umbrella of the Interagency Ecological Program for the San Francisco Estuary.

Appendix A: How the Delta Smelt MAST Report was Written

The report titled “An updated conceptual model for Delta Smelt: our evolving understanding of an estuarine fish” (hereafter referred to as Delta Smelt MAST report) was written in 2013-2014 by the IEP Management, Analysis, and Synthesis Team (MAST). The Delta Smelt MAST report was developed through a series of report drafts and a public technical review and followed a set of general report guidelines. This report appendix describes the Delta Smelt MAST report guidelines, the report review and revisions, and report milestones.

Delta Smelt MAST Report Guidelines

Report Purpose and Approach

The Delta Smelt MAST report is a technical report intended to synthesize the latest scientific data and information on Delta Smelt, a topic of particularly high relevance to agency managers and decision makers in California. Specifically, it provides an up to date assessment and conceptual model of factors affecting Delta Smelt throughout its primarily annual life cycle and demonstrates how the conceptual model can be used in science and management. The Delta Smelt MAST report updates and redesigns previous conceptual models for Delta Smelt with new data and information since the release of the last synthesis report about the “Pelagic Organism Decline” (POD) by the Interagency Ecological Program (IEP) in 2010. It then uses the conceptual model to generate hypotheses about the factors that may have contributed to the 2011 increase in

Delta Smelt abundance and evaluate them using a simple comparative approach. The Delta Smelt MAST report ends with key conclusions, a discussion of our hypothesis testing approach, and recommendations for future work and adaptive management applications, with examples.

1. **Report Development.** The 2014 MAST report is a synthesis report developed and written by the IEP Management, Analysis, and Synthesis Team (MAST). The MAST is co-chaired by the IEP Lead Scientist and IEP Program Manager and includes senior scientists from IEP member agencies tasked with data analysis, synthesis, and work planning. The MAST report is the collective product of a dynamic and collaborative interagency team process involving focused team discussions at monthly MAST meetings, intensive conceptual model and report development at additional multi-day off-site meetings, presentations and discussions with other scientists, stakeholders, and the public (e.g., at the annual IEP workshop, meetings of the IEP Stakeholder Group and IEP Project Work Teams), and data analysis and synthesis as well as writing, integration, and revisions of report sections by MAST members with written communication via email and the MAST wiki. MAST report authors were expected to follow the MAST report guidelines described here. They were also expected to consider all internal review comments by other MAST members and members of the IEP Management and Coordinators teams as well as external technical review comments received during a 40-day public review period. Details about the public review process are given in II.

2. **Report Authorship.** The “author of record” for the 2013 MAST report is the entire IEP MAST, and the responsibility for authorship lies with the entire MAST as well. Individual authorship of report sections is not credited; the report is a product of the IEP MAST and not of any individual author or an individual IEP member agency. All current MAST members are MAST report authors and are listed alphabetically in the initial pages of the report (see III. below). Former MAST members will not be listed as authors, but will be noted as contributors. Each report section had a lead author who had primary responsibility for writing and revising the section. One designated MAST member (Larry Brown, USGS) functioned as report lead editor who compiled and integrated all sections and sent full draft report versions to the MAST for review by all MAST members. All MAST members sent their edits and comments back to Larry Brown and the section authors for revisions. The report went through multiple draft versions before its finalization.

3. **Report Organization.** The 2014 MAST report is an IEP technical report and follows the same basic organization as other IEP technical reports, including a title page, list of all authors, acknowledgements, table of contents, executive summary, an introductory section with background information and report objectives, and concise sections detailing the analysis and synthesis approach, models and hypotheses, findings, and conclusions as well as illustrative tables, figures, and full references for all citations. In response to reviewer recommendations received during the public technical review (see II.), the report was restructured and expanded from originally six to nine Chapters.

4. **Supporting Evidence.** The 2014 MAST report follows the conventions of IEP and other technical reports regarding supporting evidence, which includes the following. The rationale for any findings, conclusions, and recommendations should be fully explained in the report. Whenever possible, conceptual models and hypotheses should be evaluated through analysis of the available data. Additional supporting information should be obtained from the peer-reviewed literature or from publicly accessible reports. Related or competing hypotheses and models that have been previously published in the peer-

reviewed literature should be acknowledged and discussed in the report and conclusions should be based on even-handed, dispassionate consideration of all available evidence. Sources for all supporting data and information should be clearly identified and cited. Citation of personally communicated unpublished results (e.g. emails, memos) is permissible, but should be used sparingly.

Delta Smelt MAST Report Review and Revisions

1. **What was the purpose of the review?** The purpose of the public technical review of the draft Delta Smelt MAST report was to ensure its scientific credibility, relevance to managers and decision makers, and a transparent and legitimate process that welcomed and considered input and recommendations from other scientists, managers, stakeholders, and the public.

2. **What was expected of draft Delta Smelt MAST report reviewers?** MAST report reviewers were asked to provide written comments on any and all technical aspects of the draft report, but to pay particular attention to review criteria outlined in the MAST report review guidelines.[1]

3. **Who reviewed the draft Delta Smelt MAST report?** The draft Delta Smelt MAST report released for public review on July 23, 2014, was reviewed by invited IEP staff and colleagues as well as by invited external peer reviewers and other scientists who submitted comments during the 40-day public review period, as follows.

   a. IEP Coordinators (1 Reviewer, IEP management review)

   b. Former MAST Members (2 Reviewers, IEP colleague scientific peer review)

   c. Invited Subject Area Expert (1 Reviewer, IEP colleague review of contaminants sections)

   d. Independent Scientific Peer Reviewers (3 Reviewers, external independent scientific peer review facilitated by the Delta Science Program)

   e. Other Scientists, Stakeholders and the Public (7 Reviewers, external public review)

   In addition, the IEP Coordinators were asked to review the revised, near-final version of the Delta Smelt MAST report and the executive summary and to approve the final version. The IEP Directors were briefed and invited to comment on the direction and progress of the Delta Smelt MAST report on a quarterly basis.

4. **How were external draft Delta Smelt MAST report reviewers identified, invited, and informed?** Independent Scientific Peer Reviewers for the draft Delta Smelt MAST report were identified by the Delta Stewardship Council's Delta Science Program (DSP) and Delta Lead Scientist. In accordance with the DSP "Procedures for Independent Scientific Peer Review,"[2] the Delta Lead Scientist determined and invited the independent scientific peer reviewers using the following selection criteria: standing in the scientific community, expertise relevant to the documents being reviewed, and free of conflict of interest.

---

[1] http://www.water.ca.gov/iep/docs/mast_report_process_july2013.pdf

[2] http://deltacouncil.ca.gov/docs/2012-11-06/delta-science-program-procedures-conducting-independent-scientific-peer-review

All other review was invited by email and in a notice posted on the IEP website.[3] A draft of the 2013 MAST report, associated figures, and MAST report review guidelines were posted on July 23, 2013, for public technical review. The draft report release for review did not include an executive summary and conclusions. The public review period closed on August 31, 2013.

5. **How many review comments were received and where can they be accessed?** The MAST received 14 sets of review comments on the July 2013 draft MAST report. They included many general comments as well as 355 comments that referred to specific lines in the report, see table A1. All comments by external reviewers (public review comments and the review comments by the three independent scientific peer reviewers) were posted on the IEP website.[4]

6. **How were the review comments addressed?** All review comments received during the 40-day review period were compiled in an Excel spreadsheet and summarized numerically (Table A1). Review comments and procedures for addressing them were discussed by the MAST at its regular monthly meetings and during a one-day offsite meeting in November 2013. The process for addressing review comments included the following:

    a. The lead author for each report section had the primary responsibility for addressing review comments pertaining to that section and for revising the section.

    b. Secondary revision leads were also assigned and assisted the primary revision lead.

    c. For each review comment in the Excel spreadsheet, it was noted whether the comment: (1) Did not suggest a revision and no revision was made; (2) Suggested a revision and a revision was made; or (3) Suggested a revision, but no revision was made, for example because it was outside of the report scope, explained elsewhere, or the lead author did not agree with the recommended revision.

    d. Revised sections and the annotated excel spreadsheet were sent by email to the entire MAST. MAST members were alerted to all major revisions.

    e. Major revisions were discussed with all MAST members during MAST meetings and via email.

    f. Decisions about major revisions were made by the whole MAST; no comment implied consent.

    g. Decisions about more minor revisions were made by the section revision leads and the report lead editor, often in consultation with some or all other MAST members.

    h. The report lead editor (Larry Brown, USGS) compiled, further revised, and integrated all revised report sections and sent full draft report versions to the MAST for review by all MAST members. The final draft versions of the report and executive summary were also sent to the IEP coordinators for their review and approval.

7. **What major changes were made to the draft report in response to review comments?** The draft Delta Smelt MAST report underwent several major changes in response to review comments. Changes include the following:

   a. The report purpose and goals were reconsidered, clarified, and somewhat expanded. Specifically, the four-year comparison of factors that may have contributed to the Delta Smelt abundance increase in 2011 was deemphasized in favor of a broader assessment and conceptual model of factors affecting Delta Smelt throughout its primarily annual life cycle and demonstrations of how the conceptual model can be used in science and management.

   b. The report structure was substantially changed to better fit the revised report purpose and goals and to improve the organization of the large amount of information included in the report. Four new Chapters were added to describe the updated conceptual model (Chapter 5), provide a more thorough overview of Delta Smelt life history and population dynamics (Chapter 6), summarize and discuss findings and conclusions (Chapter 8), and provide recommendations and examples of future work and management applications (Chapter 9). An executive summary was also added, along with this appendix.

   c. The content of the report was expanded to accomplish the somewhat expanded report purpose and goals, reflect previously missing information pointed out by reviewers as well as new information from the latest scientific publications, and provide conclusions and recommendations for future work and management applications.

   d. Several reviewers commented that the simple four-year comparative approach that was used to evaluate factors that may have contributed to the Delta Smelt abundance increase in 2011 was too limited and that more years of data and more in-depth analyses and modeling were needed for this evaluation. The MAST agreed, but decided that these types of analyses would require additional time and resources and were outside the scope of this report which emphasized synthesis of existing information over new data analyses. Instead, the MAST decided to discuss some of the benefits and limitations of analysis and synthesis approaches used in the report in Chapter 8 and existing and ongoing analyses and modeling efforts along with additional, analysis, synthesis, modeling, and other science needs and potential management applications in Chapter 9. Three examples of additional mathematical modeling approaches are also included in Chapter 9. These approaches were explored by individual co-authors of this report. Preliminary results of these analyses are given for illustrative purposes only; peer-reviewed publications of these analyses need to be completed before they can be used to draw firm conclusions.

Delta Smelt MAST Report Milestones

Note: The time line for the development, review, revision and completion of the Delta Smelt MAST report had to be adjusted repeatedly because of numerous new work assignments for individual MAST members, the large number and depth of review comments, the federal government shut-down, personnel changes, etc.

2012

March 13-16	Initial MAST off-site meeting (Marconi Center, CA) to discuss MAST products and direction and start MAST work on the 2012 IEP proposal solicitation[5], the “FLaSH” report[6], and the Delta Smelt MAST report (hereafter MAST report)
Sep 13-14	MAST off-site meeting (Yolo Wildlife Area, CA)
Dec 4-5	MAST off-site meeting (Clarksburg, CA)

2013

March 29	First draft MAST report completed
April 24	MAST presentation (talk) at annual IEP Workshop (Larry Brown, USGS)
May 20	Second draft MAST report completed
June 6	Third draft MAST report completed
July 23 – Aug 31	Fourth draft MAST report completed and posted on the IEP website for a 40-day review period
August 14	Draft MAST report discussion with IEP Stakeholder Group
Sep 11	Special IEP Stakeholder Group meeting about the draft MAST report
Oct 30	MAST report poster presentation at 2013 State of the Estuary Conference
Nov 14	MAST off-site meeting (UC Davis, CA)
Dec 8	Fifth draft MAST report completed

[6] http://deltacouncil.ca.gov/science-program/fall-low-salinity-habitat-flash-studies-and-adaptive-management-plan-review-0

2014

Feb 3	Sixth draft MAST report completed
Feb 11	MAST presentation (talk) at DSP-SWRCB “Delta Outflows” workshop (Larry Brown, USGS)
Feb 20	MAST presentation (talk) at a meeting of the IEP Resident Fishes Project Work Team (Larry Brown, USGS)
Feb 26	MAST presentation (talk) at annual IEP Workshop (Larry Brown, USGS)
April 16	Seventh draft MAST report completed
April 17	First draft MAST report executive summary completed
April 24	Second draft MAST report executive summary completed and sent to IEP Coordinators for review
May 15	Eight draft MAST report completed and sent to IEP Coordinators for a one-week “red flag” review. This draft includes the executive summary and a description of how the MAST report was written and revised with a list of major report revisions in response to review comments (Appendix A)
June 2	Ninth draft MAST report completed and sent to IEP Coordinators for review and IEP Directors briefings
June 11	IEP Coordinators briefed on MAST report including a review of the major changes.
June 17	Agencies and stakeholders of the CAMT Delta Smelt Scoping Team briefed about the MAST report including major findings and changes since 2013.
July 2	IEP Stakeholder Group meeting to discuss MAST report revisions and completion
July 3	Coordinators approve the final draft MAST report for publication as an IEP Technical Report; when ready the draft final report will be posted on the MAST webpage[7] until the IEP Technical Report publication is completed and report is posted on the IEP Technical Reports webpage[8]
July 14	MAST model presented to IEP Wetlands Conceptual Model Team.
July 29	IEP Directors meeting with presentation and discussion of final MAST report
July 30	MAST model presented to IEP Wetlands Project Work Team.
August 6	MAST briefing to Drought Operations Plan Team

Appendix B: Calculation of Annual Abundance Indices

This Appendix describes the data and methods used by 4 long-term fish monitoring surveys for calculating annual abundance indices for Delta Smelt (*Hypomesus transpacificus*). Descriptions are arranged sequentially beginning with the Spring Kodiak Trawl, which calculates an index of abundance for adult Delta Smelt, followed by the 20 mm Survey, which calculates an index

---

[7] http://www.water.ca.gov/iep/pod/mast.cfm
[8] http://www.water.ca.gov/iep/products/technicalrpts.cfm

for late-stage larvae and small juveniles; the Summer Townet Survey calculates an index for juveniles and the Fall Midwater Trawl Survey calculates an index for sub-adults. As mentioned in the main document, abundance indices are not population estimates, but they are believed to increase monotonically with increases in true population size.

Spring Kodiak Trawl

The Department of Fish and Wildlife (DFW) initiated the Spring Kodiak Trawl Survey (SKT) in 2002. The SKT replaced the Spring Midwater Trawl and provided a more effective means to monitor the distribution and reproductive status of adult Delta Smelt. Survey results provide near real-time information on the proximity of adult Delta Smelt to south Delta export facilities and can provide an indication of likely spawning areas.

The SKT includes 5 monthly Delta-wide surveys, January through May (Figure 84). Only the first 4 surveys contribute to the annual abundance index. No index exists for 2002, when only 3 surveys were conducted. The index is calculated after all data have been verified for accuracy.

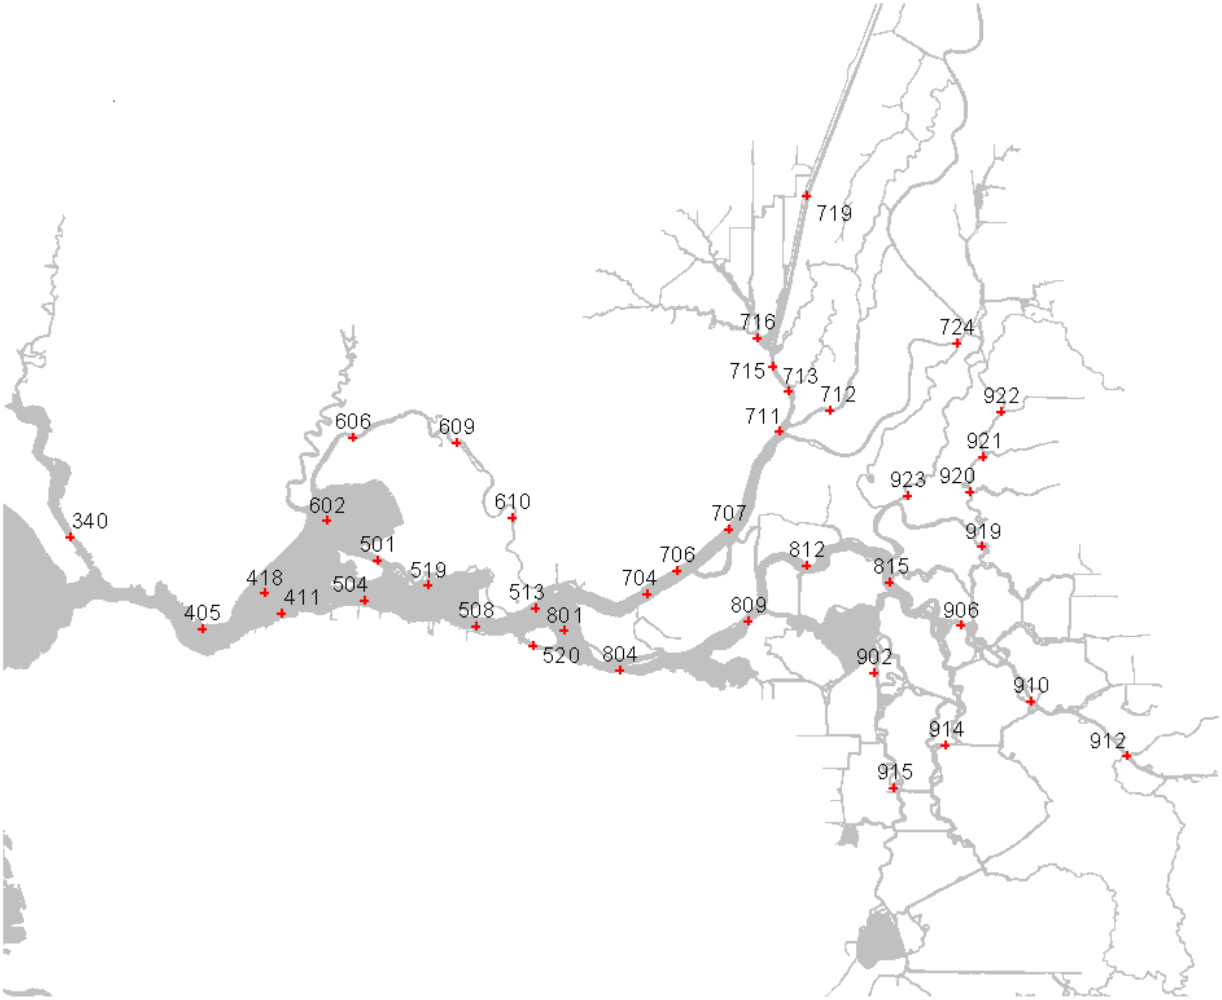
Field crews tow the net at the surface between 2 boats once for 10-min at each station per survey; 5-min surface tows are used at stations with historically high catch to limit excessive Delta Smelt take; a second 5-min surface tow is completed if Delta Smelt catch in the first tow did not exceed 50. A flow meter deployed at the start of the tow and retrieved at the end provides information on distance towed through the water. To calculate fish density, survey personnel assume that the SKT net fishes with the mouth fully opened, an area of 13.95 m^2 (7.62 m wide by 1.83 m deep). Volume filtered is the product of distance towed and mouth area. Volume filtered varies and by convention researchers expand catch per volume filtered (number per m^3) for juvenile and adult fish to catch per 10,000 m^3.

Annual abundance index calculations use adult Delta Smelt data from 39 of the 40 stations (Fig. 84). For each of the first 4 monthly surveys, adult catch per 10,000 m^3 values from each station are grouped into 3 distinct regions based on geographic location: 1) the confluence and Suisun region (sites 340, 405, 411, 418, 501, 504, 508, 513, 519, 520, 602, 606, 609, 610, 801); 2) the Sacramento River and Cache Slough region (sites 704, 706, 707, 711, 712, 713, 715, 716, 719, 724); and 3) the San Joaquin River and Delta region (804, 809, 812, 815, 902, 906, 910, 912, 914, 915, 919, 920, 921, 922, 923). A monthly mean is calculated for each region and the sum of the regional means is the monthly or survey index. The sum of the 4 survey indices is the annual index.

20 mm Survey

DFW initiated the 20 mm Survey in 1995 to monitor the distribution and relative abundance of larval and juvenile Delta Smelt throughout their historical spring range in the upper San Francisco Estuary (Fig. 85), and provide near real-time information on the relative densities and proximities of these young fish to south Delta export pumps. The 20 mm Survey includes sampling on alternate weeks from mid-March through early July, typically resulting in 9 surveys per year. During each survey, field crews complete 3 oblique tows at each of the 47 stations (Fig. 85). The 20 mm Survey added stations over time, but not all contribute to annual abundance index calculation. The survey added 5 Napa River stations in 1996 for a total of 41 core stations, which are included in the annual abundance index calculations (Fig. 85, circles). In 2008, 6 non-

Figure 84. **Map of Spring Kodiak Trawl Survey stations showing all currently sampled stations. Data from all stations except 719 are used in abundance index calculation.**

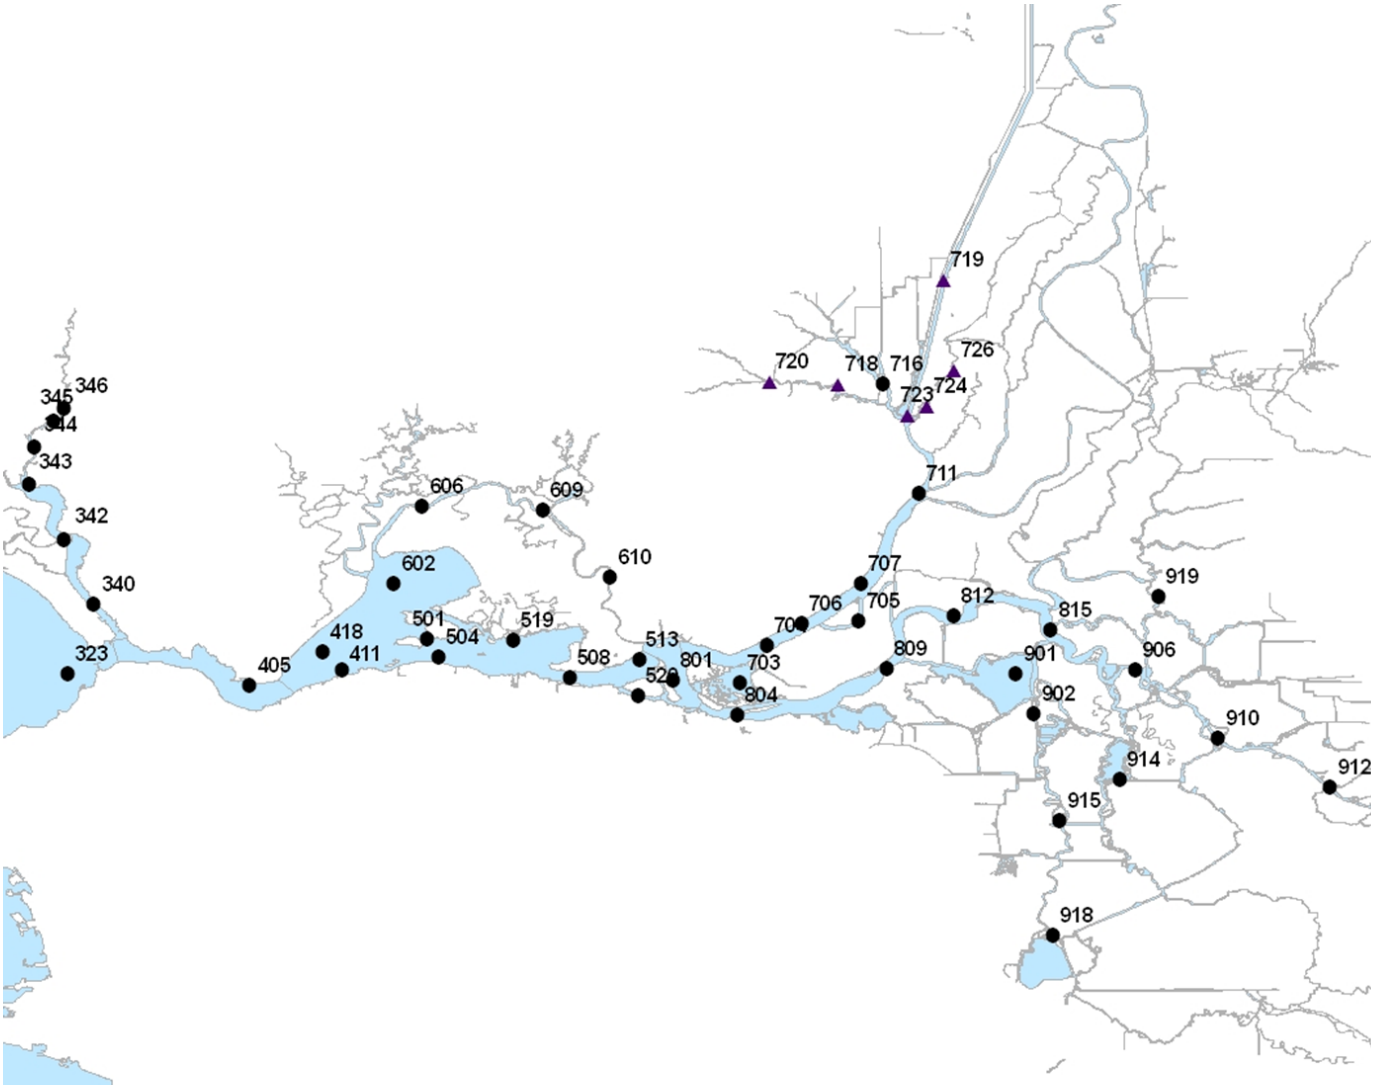


core stations were added, which are not included in the annual abundance index calculations, including Barker Slough (site 720), Lindsey Slough (site 718), Miner Slough (sites 724 and 726), and the Sacramento Deep Water Shipping Channel (n = 2; sites 719 and 723) (Fig. 85, triangles).

The 20 mm net includes a flow meter located within the mouth of the net to measure distance traveled by the net during the tow. This value is then multiplied by the fixed mouth area of the net (1.51 m^2) to provide total volume filtered. The tows are then standardized to catch of Delta Smelt per 10,000 m^3.

As already noted, the annual abundance index calculation uses only catch per 10,000 m^3 values from the 41 index stations. For each survey, the mean fork length of Delta Smelt is calculated from measurements of the fish captured during each survey. The two surveys just before the average fork length reached 20 mm and the 2 surveys just after the average fork length reached 20 mm are included in the annual abundance index calculation. For these 4 surveys the geometric

Figure 85. **Map of 20 mm survey stations showing all currently sampled stations. Data from all core stations are used in abundance index calculation.**



mean of the catch of Delta Smelt per 10,000 m^3 is calculated across the 41 core stations. The geometric mean for each survey is calculated as the arithmetic mean of $\log_{10}(x+1)$-transformed values of Delta Smelt catch per 10,000 m^3 across the 41 core stations. The resulting value is then back-transformed (including subtraction of 1) for the calculation of the annual abundance index. The annual abundance index is calculated as the sum of the geometric means of the 4 selected surveys.

Summer Townet Survey

The Summer Townet Survey (TNS) was started by DFW in 1959 to produce an annual index of summer abundance for age-0 Striped Bass (*Morone saxatilis*). In the mid-1990s, DFW staff developed an abundance index calculation for Delta Smelt. Annual abundance indices for Delta Smelt have been calculated for the period 1959 through the present, except for 1966-1968. The

TNS Survey samples 32 historic stations, 31 of which contribute to index calculation (labeled as “core stations,” Fig. 86). Currently sampled TNS stations range from eastern San Pablo Bay to Rio Vista on the Sacramento River and to Stockton on the San Joaquin River (Fig. 86). In 2011, TNS added 8 supplemental stations in the Cache Slough and the Sacramento River Deepwater Ship Channel region to increase spatial coverage and better describe Delta Smelt range and habitat (Fig. 86). Historically, TNS sampling began when age-0 Striped Bass achieved a mean fork length of 20 mm based on larval sampling, typically in mid-June to early July, and ended when age-0 Striped Bass surpassed a mean size of 38.1 mm fork length. Since 2003, TNS has consistently included 6 surveys annually, running on alternate weeks from early June through mid- to late August.

Field crews perform at least two 10-min oblique tows at most stations. A third tow is conducted when any fish were caught during either of the first 2 tows. At least 1 tow is completed at each of the new Cache Slough and Sacramento River Deepwater Ship Channel stations. To reduce Delta Smelt take, field crews only perform a second tow at these stations if Delta Smelt catch from the first tow is less than 10. Delta Smelt catch per tow data are used for index calculation.

The annual abundance index for Delta Smelt is the arithmetic mean of the abundance indices from the first 2 surveys conducted each year. Delta Smelt abundance indices for each biweekly survey are calculated by summing catch across all tows for each index station, multiplying the summed catch by a station weighting factor representing the water volume of that station (Table B1); then the volume-weighted catches are summed across all 31 index stations and the sum divided by 1000.

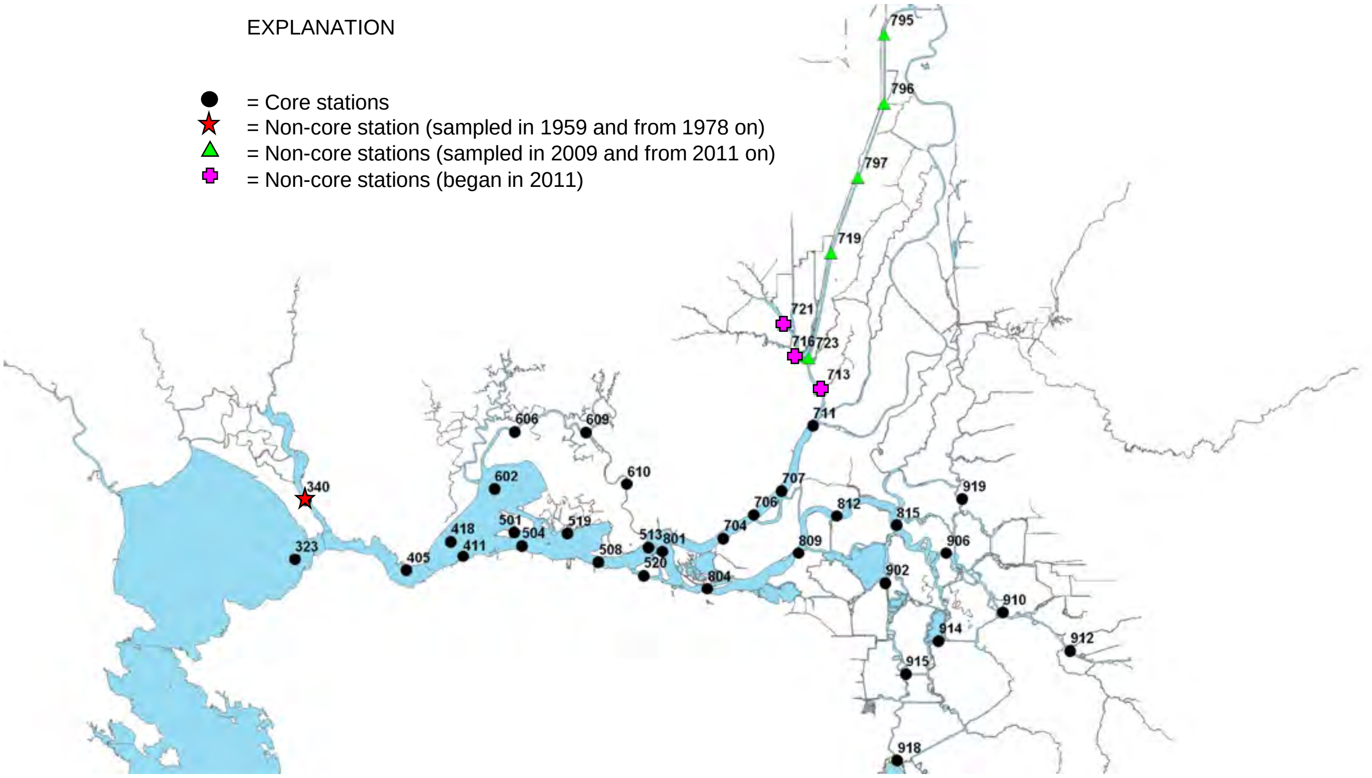
The annual abundance index for age-0 Striped Bass is calculated using similar methods, except the first two surveys are not used. Instead, abundance indices from the 2 surveys that bound the date when the fish reach a mean fork length of 38.1 mm are used; this frequently occurs after several surveys have been completed in a field season.

Fall Midwater Trawl Survey

DFW began the Fall Midwater Trawl Survey (FMWT) in 1967 to provide an annual index of relative abundance and information on the distribution of age-0 Striped Bass for the fall period. Later, DFW staff developed abundance and distribution information for other upper-estuary pelagic fishes, including Delta Smelt. Surveys have been conducted in all years from 1967 to present, except 1974 and 1979. The FMWT survey currently samples 122 stations monthly (Fig. 87), from September through December. Station locations range from San Pablo Bay to Hood on the Sacramento River, and from Sherman Lake to Stockton on the San Joaquin River (Fig. 87). Currently, annual abundance index calculations use catch data from 100 of the 122 stations sampled monthly, but the number of stations used for the index has varied through time. Table 12 contains the complete list of stations used for abundance index calculation for FWMT (n = 117), including historical stations (underlined) that must be included for proper calculation of past indices, but are not included in calculations for recent years. The remaining 22 stations were added in 1990, 1991, 2009, and 2010 to improve our understanding of Delta Smelt habitat use (Fig. 87). At each sampling station, field crews perform a single, 12-min oblique tow monthly.

Delta Smelt catch per tow data are used for calculation of the annual abundance index. Individual survey indices are calculated by first grouping the 100 core stations (Fig. 87) into 14 regions based on their location (Table 12). Survey indices are calculated by averaging Delta Smelt catch

Figure 86. **Map of summer townet survey stations showing all currently sampled stations. Data from all core stations are used in abundance index calculation.**



across index stations within each region, multiplying these regional means by their respective weighting factors (i.e. a scalar based on water volume; Table 12), and summing the weighted values. Annual abundance indices are calculated as the sum of the 4 survey abundance indices (i.e. September through December).

Feds scramble to avoid another mass salmon die-off in the Sacramento River

By Phillip Reese and Ryan Sabalow preese@sacbee.com

A year ago, California lost nearly an entire generation of endangered salmon because the water releases from Shasta Dam flowed out warmer than federal models had predicted. Thousands of salmon eggs and newly hatched fry baked to death in a narrow stretch of the Sacramento River near Redding that for decades has served as the primary spawning ground for winter-run Chinook salmon.

Earlier this year, federal scientists believed they had modeled a new strategy to avoid a similar die-off, only to realize their temperature monitoring equipment had failed and Shasta's waters once again were warming faster than anticipated.

In the months since, in what is essentially an emergency workaround, they've revised course, sharply curtailing flows out of Shasta. The hope is that they reserve enough of the reservoir's deep, cold water pool to sustain this year's juvenile winter-run Chinook. But it's meant sacrificing water deliveries to hundreds of Central Valley farmers who planted crops in expectation of bigger releases; and draining Folsom reservoir – the source of drinking water for much of suburban Sacramento – to near-historic lows to keep salt water from intruding on the Delta downstream.

In spite of all this, another generation of wild winter-run Chinook salmon could very well die.

For all the focus on fallowed farm fields and withered lawns in California's protracted drought, native fish have suffered the most dire consequences. The lack of snowmelt, warmer temperatures and persistent demand for limited freshwater supplies have left many of the state's reservoirs – and, by extension, its streams and rivers – hotter than normal. The changing river conditions have threatened the existence of 18 native species of fish, the winter-run Chinook among them.

Chinook are called king salmon by anglers for a reason. They can grow to more than 3 feet in length, and the biggest can top more than 50 pounds. Decades ago, before dams were built blocking their traditional spawning habitat, vast schools of these silver-sided fish with blue-green backs migrated from the ocean to spawn and die in the tributaries that feed the Sacramento River in runs timed with the seasons.

The largest run that remains in the Sacramento River system is the fall run, which survives almost entirely due to hatchery breeding programs below the Shasta, Oroville and Folsom dams. The winter run, in contrast, is still largely reared in the wild, laying its eggs in the gravel beds below Shasta's concrete walls. Their numbers have dwindled in the face of predators and deteriorating river conditions. The federal government declared the run endangered in 1994, and it has flirted with extinction ever since.

Following last year's failed federal efforts, only about 5 percent of the winter-run Chinook survived long enough to begin to migrate out to sea. The species has a three-year spawning cycle, meaning that three consecutive fish kills could lead to the end of the winter run as a wild species. One hatchery below Lake Shasta breeds winter-run Chinook in captivity.

Officials with the U.S. Bureau of Reclamation, which operates both Shasta and Folsom dams, say they believe their emergency efforts at Shasta are working and they anticipate "some" winter-run Chinook will survive this year.

"We believe that we are on track," said bureau spokesman Shane Hunt. "We are sitting in a much better place today than we were a year ago today."

Several biologists interviewed remain dubious. They note that preserving more cold water in Shasta has meant many stretches of the Sacramento River are warmer than they were last year. They worry that salmon eggs and fry will still die – only gradually instead of suddenly.

“We stand a pretty good chance of losing the wild cohort again this year, like we did last year,” said Peter Moyle, a UC Davis researcher and one of the nation’s leading fisheries biologists. “If we get lucky some of those fish will survive. We’re definitely pushing the population to its limits.”

Agricultural leaders, meanwhile, say there’s good reason to suspect the government models will again prove flawed and the fish will die despite the sacrifices farmers have made.

Rep. Jim Costa, a Democrat and third-generation farmer who represents a wide swath of the San Joaquin Valley, is among those who think there’s a good chance farmers have been punished for no benefit to the fish.

“That begs the question: What are we accomplishing?” Costa said. “We are in extreme drought conditions. ... The water districts that I represent in the San Joaquin Valley have had a zero – zero – water allocation. ... Over half a million acres have been fallowed ... It just seems to defy common sense and logic.”

Some members of California’s fisheries industry also have lost confidence in the bureau, arguing the government has badly mismanaged its rivers. Beyond the very existence of a wild population of fish, they say, the government is risking millions of dollars for California’s economy and hundreds of fishing jobs – and a key source of locally caught seafood for markets and restaurants.

Two consecutive fish kills involving an endangered species could lead to more stringent regulation of commercial and recreational fishing. It’s a real possibility, state and federal fisheries regulators said, that salmon fishing could be severely restricted along much of California’s central coast and in the Sacramento River system next year.

Larry Collins, a commercial fisherman operating out of Pier 45 in San Francisco, said that in the fight over water, the fishing industry – and wild fish – lack the political clout compared with municipal and agricultural interests.

“I’ve been around a long time, and I’ve fought the battle for a long time, and I’ve watched the water stolen from the fish,” he said. “The fish are in tough shape because their water is growing almonds down in the valley. To me, it’s just outright theft of the people’s resource for the self-aggrandizement of a few, you know?”

“You got money you can buy anything,” he added. “You can buy extinction.”

Federal models prove faulty

On paper, the requirements for salvaging the winter-run Chinook seem fairly basic. The winter-run Chinook spawn from April to August. Juvenile fish swim downriver from July to March. If the water in the Sacramento River is too hot as the fry emerge from their eggs, they die. Warm water also makes it more difficult for the juveniles to survive their swim downstream to the ocean.

But in practice, there are broad variables to keeping the river cool, involving snowmelt, heat waves, water depths and the temperatures of the tributaries entering the reservoir, as well as conditions in the river downstream.

A year ago, federal and state officials had a plan to keep temperatures in key portions of the Sacramento River below 56 degrees; temperatures above 56 can trigger a die-off. The models built by the Bureau of Reclamation indicated operators could release large amounts of water from Lake Shasta while still maintaining a cool temperature, easing the pressure on farms and cities. According to their calculations, the water would be cold enough at key points in the Sacramento River to ensure survival of 30 percent of the salmon run.

But the models were wrong. The Bureau of Reclamation essentially ran out of cold water reserves in Lake Shasta, limiting its ability to control temperatures in the Sacramento River. Average daily river temperatures rose well above levels needed by salmon to survive. The 5 percent that did transition from eggs to fry were left to navigate to the ocean in tough conditions.

“That 5 percent – I guarantee you they didn’t make it down through the Delta,” said Bill Jennings, executive director of the California Sportfishing Protection Alliance.

Fast forward to this year, and another plan gone awry.

During the spring, government officials again said they would keep winter-run Chinook alive by maintaining water temperatures below 56 degrees. The State Water Resources Control Board signed off on their plan in mid-May.

Only weeks later, Bureau of Reclamation officials told the state that their temperature monitoring equipment wasn’t working. In fact, they said, temperatures in Shasta were warmer than anticipated – and dramatic intervention would be needed to keep winter-run Chinook alive. They asked the board to consider a new plan and immediately restricted flows from Shasta.

The state water board took up the issue at a meeting on June 16. Members of the board bemoaned their lack of good choices and later adopted a plan that left no one happy. Water releases would be curtailed out of Lake Shasta. Folsom Lake would be drawn to historic lows. Deliveries to farmers would be reduced.

And, despite those measures, the average daily temperature in the Sacramento River would rise to 57 degrees on most days and 58 degrees on some days, according to the government models. That’s too high a temperature for all winter-run Chinook to survive, but the Bureau of Reclamation, in documents supporting the change, said its modeling predicted roughly 20 percent of the fish would survive to early adulthood. That would be lower than a typical year – but not a disaster.

But are this year’s models more accurate? Already this summer, average daily temperatures at a key point in the Sacramento River have risen above 58 degrees on seven separate occasions, including several times in late August, state data show.

Federal officials said their models anticipated some temperature spikes, and noted that on each occasion so far, they were able to release cold water into the river and bring temperatures back down.

“It can have an effect” on fish, said Hunt, the bureau spokesman, of river temperatures above 58 degrees. But, he added, “That temperature is not a lethal temperature immediately.”

Jon Rosenfield, a biologist with the Bay Institute, disagreed, saying that many winter-run salmon likely were doomed by the temperature spikes. He offered the analogy of a chicken egg: “If you take an egg and dip it in boiling water, you are jeopardizing its ability to develop into a chick,” he said. “The longer you do that and the hotter the temperatures, the less likely it is to develop.”

Another concern is whether there is still enough cold water in Shasta to keep river temperatures low into the fall. Hunt says yes – that the government projects that Shasta will contain 350,000 acre-feet of cold water, below 56 degrees, at month’s end, far more than in 2014.

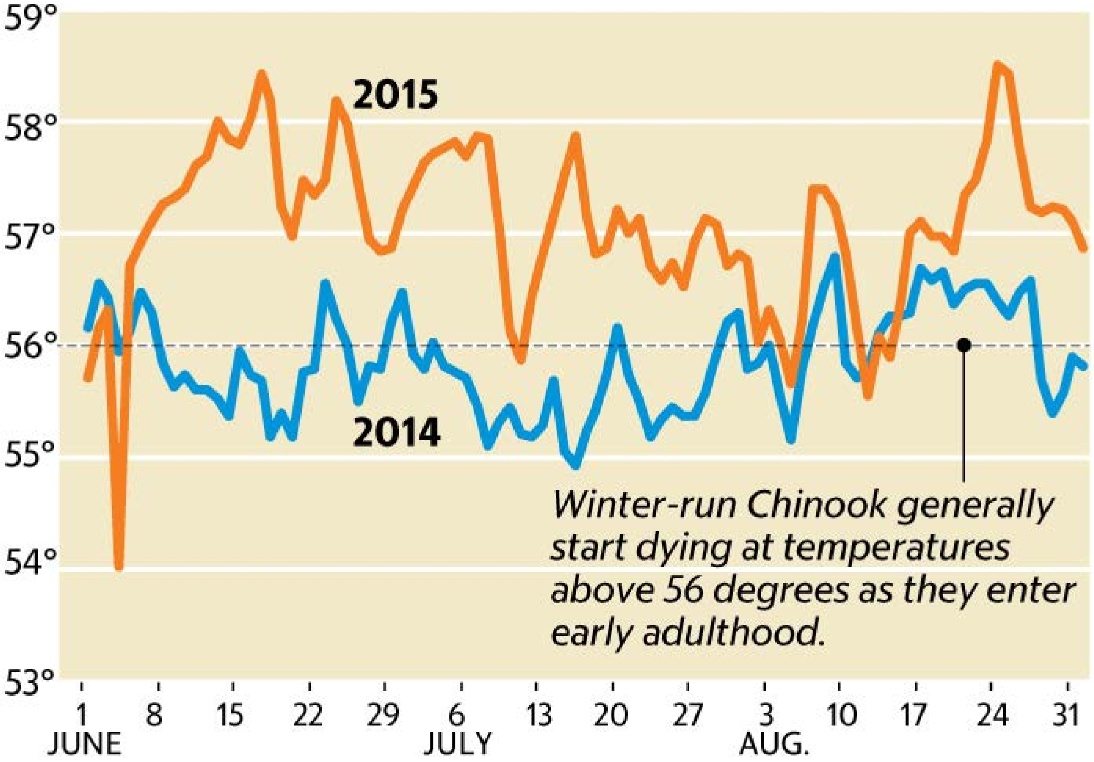
Rosenfield expressed doubts that the bureau is in position to do detailed calculations on its cold water supply. “They are way behind in anything using modern technology in measuring how much cold water they have,” Rosenfield said.

Scientists won’t know whether this year’s plan worked until fish surveys are completed in the winter. In a worst-case scenario, the government could rely even more heavily on its hatchery to sustain winter-run Chinook. Rosenfield called that option a “Band-Aid,” noting it would not preclude the loss of the fish as a wild species. Hatchery fish, he said, tend to come from a limited gene pool and may also have difficulty surviving in warm water.

Higher river temperatures; low lake levels

Under a new plan, federal officials have allowed temperatures in the Sacramento River in Shasta County to rise above 56 degrees consistently throughout the summer. They predict the warmer temperatures will not cause a mass salmon die-off; some biologists are dubious.

Average daily water temperatures in the Sacramento River above Clear Creek



One consequence of the temperature plan to keep winter-run Chinook alive has been increased flows out of Folsom Lake.

Daily Folsom Lake storage (in acre-feet)

Looking to the future

Jeff Gonzales worries about the ripple effects of another bad salmon season. Gonzales, a retired fire captain from Durham who guides clients on river-fishing trips, remembers when fisheries managers shut down the season for the fall-run Chinook in 2008 and 2009.

In those years, officials closed the fall-run fishing season in response to an unprecedented decline in the numbers of Chinook that had returned to the Sacramento, American and Feather rivers to spawn. The run plummeted amid poor ocean conditions and environmental problems in the Sacramento-San Joaquin Delta.

Gonzales thinks a similar scenario could be well underway, and that this year's fall run is also in danger. He's troubled by photos his fellow guides have sent him of fully-grown fall-run salmon floating dead in southern stretches of the Sacramento River. He attributes the deaths to warm water.

On Thursday morning, he was guiding clients on the river near Los Molinos, between Chico and Red Bluff, in search of fall-run salmon. The river is so warm, he said, that it's been tough to find fish in his normal spots. The fish, he said, have either raced upstream seeking colder water, or are holding off the entrance to the Delta in the Pacific, waiting for a cold water flow.

That means slow-going for him and other guides.

On Thursday, his four clients, all firefighters enjoying an off-day, spent a four-hour stretch watching ospreys, wood ducks and herons glide by as their lures wriggled in the swift current. Every so often, a Chinook would breach the water and slap the surface with its tail, almost tauntingly. That morning, just one client saw his rod bend under the weight of a lunging 15-pound, silver-sided king.

Some clients have canceled trips because of the paltry catches, Gonzales said, and business will only get worse if the salmon seasons get shut down due to yet another winter-run die-off.

Maneuvering through the currents, the river rippling out before him, he lamented not just the loss of the fish but of a cultural heritage.

“You’ve gotta think about our future here, you know?” Gonzales said. “Our children and our grandchildren may not be able to see what we’re seeing here.”

Key Points:
- Warming since 1901 caused a significant trend toward drought in California
- Recent drought was naturally driven and modestly intensified by warming
- Warming has rapidly amplified the probability of severe drought

Abstract A suite of climate data sets and multiple representations of atmospheric moisture demand are used to calculate many estimates of the self-calibrated Palmer Drought Severity Index, a proxy for near-surface soil moisture, across California from 1901 to 2014 at high spatial resolution. Based on the ensemble of calculations, California drought conditions were record breaking in 2014, but probably not record breaking in 2012–2014, contrary to prior findings. Regionally, the 2012–2014 drought was record breaking in the agriculturally important southern Central Valley and highly populated coastal areas. Contributions of individual climate variables to recent drought are also examined, including the temperature component associated with anthropogenic warming. Precipitation is the primary driver of drought variability but anthropogenic warming is estimated to have accounted for 8–27% of the observed drought anomaly in 2012–2014 and 5–18% in 2014. Although natural variability dominates, anthropogenic warming has substantially increased the overall likelihood of extreme California droughts.

1. Introduction

During 2012–2014, drought in California (CA) caused water use restrictions, rapid drawdown of groundwater reserves [*Famiglietti*, 2014; *Harter and Dahlke*, 2014], fallowed agricultural fields [*Howitt et al.*, 2014], and ecological disturbances such as large wildfires and tree mortality [e.g., *Moore and Heath*, 2015; *Worland*, 2015]. The ultimate cause of the recent drought was a persistent ridge of high atmospheric pressure over the Northeast Pacific that blocked cold-season storms from reaching CA and stifled precipitation totals [e.g., *Seager et al.*, 2015]. Tree ring reconstructions from CA indicate that the resultant 3 year precipitation shortfall of 2012–2014 has been matched less than once per century over the past several hundred years [*Griffin and Anchukaitis*, 2014; *Diaz and Wahl*, 2015]. Dynamical studies agree that the Northeast Pacific ridge that caused the precipitation shortfall was part of an atmospheric wave train originating from the western tropical Pacific due to warm sea surface temperatures (SSTs) in that region [*Funk et al.*, 2014; *Seager et al.*, 2014a, 2015; *Wang and Schubert*, 2014; *Wang et al.*, 2014; *Hartmann*, 2015]. The observed ridging anomaly was stronger than the modeled response to tropical SST forcing [e.g., *Wang and Schubert*, 2014; *Seager et al.*, 2015], however, and leaves room for contributions from internal atmospheric variability or anthropogenic climate change. Although it has been suggested that anthropogenic emissions enhance the probability of *extreme* Northeast Pacific ridging events without necessarily affecting the long-term mean state [*Swain et al.*, 2014; *Wang et al.*, 2014, 2015], model projections of increased extremes in cold-season precipitation totals do not emerge as relevant until the second half of this century [*Berg and Hall*, 2015]. Furthermore, observed CA precipitation totals indicate no long-term trend despite cooccurring increases in western tropical Pacific SSTs [*Seager et al.*, 2015], climate models do not produce negative CA precipitation trends when forced by observed SST trends [*Funk et al.*, 2014], and future anthropogenic climate change is projected to result in slight *positive* trends in CA precipitation totals [*Neelin et al.*, 2013; *Seager et al.*, 2014b, 2015; *Simpson et al.*, 2015], all arguing against the likelihood of an anthropogenic role in the recent CA precipitation shortfall.

Importantly, there is widespread consensus that warmth has intensified the effects of the recent precipitation shortfall by enhancing potential evapotranspiration (PET) [*AghaKouchak et al.*, 2014; *Griffin and Anchukaitis*, 2014; *Diffenbaugh et al.*, 2015; *Mann and Gleick*, 2015; *Shukla et al.*, 2015]. Because warming is a well-understood and robustly modeled response to anthropogenic emissions of greenhouse gases, it is expected that warming-induced drying will continue for centuries to come [e.g., *Cook et al.*, 2015; *Diffenbaugh et al.*, 2015]. However, the degree to which anthropogenic warming and resultant increases in PET were responsible for the recent drought severity in CA is unknown.

Griffin and Anchukaitis [2014] used the Palmer Drought Severity Index (PDSI), a proxy for near-surface soil moisture [*Palmer*, 1965], to investigate the role of temperature in the recent drought, but they did not separate the influence of anthropogenic warming from natural temperature variability and their employed version of PDSI (from the National Oceanic and Atmospheric Administration (NOAA)) uses a simplified formulation of PET. *Mao et al*. [2015] attempted to isolate the anthropogenic component of warming using a more physically based PET calculation but focused only on the Sierra Nevada Mountain region and spring snowpack, and simply characterized anthropogenic warming as the observed linear trend in daily minimum temperatures. Other studies investigate the effect of warming on the likelihood of severe drought events in CA [e.g., *AghaKouchak et al*., 2014; *Diffenbaugh et al*., 2015; *Shukla et al*., 2015] but do not directly address the anthropogenic contribution to recent drought severity. Each study noted above considers only a single climate data product without addressing the structural uncertainty across different data products.

Here we quantify the severity of recent CA drought using an ensemble of data products and multiple PDSI formulations, determine the relative roles of individual components of the water balance, and determine the proportion of recent drought severity that can be attributed to increases in PET due to anthropogenic warming.

2. Methods

2.1. Palmer Drought Severity Index

We calculate monthly PDSI to characterize temporal and spatial variations in CA drought from 1901 to 2014: most humidity, wind speed, and insolation data sets do not extend prior to 1901. The PDSI is based on a simple two-layer soil moisture model and is locally normalized to reflect moisture anomalies relative to long-term mean conditions. PDSI is a primary tool used for drought monitoring in the United States [*Heim*, 2002; *Svoboda et al*., 2002] and generally agrees well with modeled and observed soil moisture anomalies [*Dai et al*., 2004; *Cook et al*., 2015; *Smerdon et al*., 2015; *Zhao and Dai*, 2015] and tree ring records [*Cook et al*., 2007]. While some recent studies have taken more complex modeling approaches to investigate the recent CA drought [*Mao et al*., 2015; *Shukla et al*., 2015], we use the PDSI because it allows efficient calculations of centennial-length records at high spatial resolution, which can be computed many hundreds of times with different climate variables, input data sets, and methodological schemes. The PDSI only reflects drought variability from a climatological perspective. Our results therefore do not explicitly reflect human water demand, stream flow and reservoir storage, or accessibility of groundwater. The PDSI also considers all precipitation to occur as rain, neglecting snow storage and subsequently delayed inputs to soil moisture and runoff. To assess implications of this latter simplification, PDSI is compared to modeled soil moisture by *Mao et al*. [2015] for the snow-dominated Sierra Nevada mountains.

Other studies also have used the PDSI to examine recent CA drought [*Griffin and Anchukaitis*, 2014; *Diffenbaugh et al*., 2015; *Robeson*, 2015]. A key difference between these studies, which use data developed by NOAA, and our study is the formulation of PET. The NOAA calculations involve the simplified Thornthwaite formula [*Thornthwaite*, 1948] that considers monthly mean temperature to be the only climatological driver of PET variability. This approach can overemphasize the influence of warmth when temperatures are high, and further inaccuracies are introduced by ignoring the nontemperature components of PET [e.g., *Hobbins et al*., 2008; *Hoerling et al*., 2012; *Sheffield et al*., 2012]. The more physically based Penman-Monteith (PM) formula [*Penman*, 1948; *Monteith*, 1965] considers the suite of variables affecting PET: mean daily maximum temperature (T_{max}), mean daily minimum temperature (T_{min}), humidity, wind speed, and net radiation. We use the PM formula and repeat calculations using Thornthwaite in some cases for comparison. Additionally, we use the newer self-calibrated PDSI ($\mathrm{PDSI}_{\mathrm{sc}}$), developed to make drought severity comparable among locations [*Wells et al*., 2004].

Consistent with several prior studies [e.g., *Cook et al*., 2004, 2007, 2010; *Griffin and Anchukaitis*, 2014], we focus on June–August (JJA). $\mathrm{PDSI}_{\mathrm{sc}}$ is an integration of hydroclimate over multiple months to several years [*Guttman*, 1998] and summer is the ideal season for characterizing drought intensity in CA for two reasons: (1) it is when drought effects tend to be most critical; and (2) it is when $\mathrm{PDSI}_{\mathrm{sc}}$ is most accurate in mountain regions because snowpack has melted or is at a minimum [e.g., *Dai et al*., 2004]. To facilitate interpretation, each grid cell's annual record of JJA $\mathrm{PDSI}_{\mathrm{sc}}$ is normalized so that two $\mathrm{PDSI}_{\mathrm{sc}}$ units equal a 1 standard deviation departure from the 1931–1990 mean, retaining a similar variance in the records of JJA $\mathrm{PDSI}_{\mathrm{sc}}$ as is in the monthly records. Again for interpretability, we renormalize statewide mean JJA $\mathrm{PDSI_{sc}}$ records. We use a 1931–1990 calibration interval in all $\mathrm{PDSI_{sc}}$ calculations to be consistent with NOAA methodology.

2.2. Climate Data

We calculate $\mathrm{PDSI_{sc}}$ records for all 432 combinations of four precipitation, four temperature, three vapor pressure, three wind speed, and three insolation data sets. Data sets are listed with references in Table S1 in the supporting information and described in Text S1. We bilinearly interpolate each monthly climate field for each data set to the spatial resolution of the PRISM data set (0.04167°) [*Daly et al*., 2004]. For each climate variable, data sets were calibrated so that climatological means and variances match during 1961–2010 (see Text S1). Uncertainties are high for humidity, wind speed, and insolation because they are largely based on models or observations of other variables [e.g., *Dai*, 2011]. Although consideration of multiple data products helps to characterize some of this uncertainty, data products are not all produced independently. Errors therefore may be recurrent in multiple data products (see Text S1).

2.3. Decomposition of PET and $\mathrm{PDSI_{sc}}$

We calculate the influence of a given variable, or subset of variables, on PET as the PET anomaly calculated while holding all other variables at their mean annual cycles [e.g., *Cook et al*., 2014; *Scheff and Frierson*, 2014; *Zhao and Dai*, 2015]. Mean annual cycles were always defined over 1961–2010. For $\mathrm{PDSI_{sc}}$, the contribution of precipitation was defined as $\mathrm{PDSI_{sc\_P}}$, calculated by holding PET at its mean annual cycle and only allowing precipitation to vary. The contribution of PET was calculated as the difference between $\mathrm{PDSI_{sc\_P}}$ and a recalculation of $\mathrm{PDSI_{sc}}$ in which both precipitation and PET vary. We isolated the influences of the temperature and nontemperature components of PET by applying versions of PET in which only the component of interest varies. Contributions of subcomponents of PET and $\mathrm{PDSI_{sc}}$ anomalies were nearly perfectly additive, but all relative anomalies were rescaled to sum to exactly 100% of the total anomaly.

2.4. Effect of Anthropogenic Warming

Anthropogenic warming was isolated from that of natural temperature variability by considering four warming scenarios that are described in detail in the next two paragraphs. For each scenario, natural temperature variability is calculated as the observed temperature minus the anthropogenic trend. All records of anthropogenic warming and natural variability were calculated independently for T_{max} and T_{min}, each grid cell, and each month. For each warming scenario, we recalculated PET twice: once considering only the anthropogenic warming record and once considering the residual record of natural temperature variability. Methods were repeated from above to assess $\mathrm{PDSI_{sc}}$ anomalies caused by anthropogenic warming and natural temperature variability.

The four anthropogenic warming scenarios are defined as follows: (1) linear trend, (2) 50 year low-pass filter (using a 10-point butterworth filter), (3) unadjusted mean trend from an ensemble of climate models, and (4) an adjusted version of #3. The first two warming scenarios represent empirical fits to the observed temperature records during 1895–2014. Although a linear trend is commonly used to represent the anthropogenic effect, a linear fit to a centennial temperature record may underestimate the human effect on temperature in recent decades because radiative forcing during this period has increased relatively rapidly [e.g., *Myhre et al*., 2013]. The 50 year low-pass filter partially addresses this issue, but multidecadal natural temperature variability inhibits complete isolation of the anthropogenic effect with either the linear trend or the 50 year filter. Additionally, trends toward the end of the 50 year filter record are affected by boundary constraint assumptions. Although continued warming is likely, we pad the end of the temperature record with a repetition of the last 25 years in reverse order, likely leading to an underestimation of anthropogenic warming in the most recent years.

In the third and fourth warming scenarios, we use modeled records of T_{min} and T_{max} produced for the Coupled Model Intercomparison Project Phase 5 (CMIP5) [*Taylor et al*., 2012] to represent anthropogenic warming trends for each month. Thirty-six models in the CMIP5 archive are used, based on the availability of T_{max} and T_{min} data for the historical (1850–2005) and future (2006–2099, RCP 8.5 [*van Vuuren et al*., 2011]) simulations. For each model, T_{min} and T_{max} are each averaged across all available runs for the historical and future periods, bilinearly interpolated to the geographic resolution of PRISM, and bias corrected for each grid cell so that monthly means during 1961–2010 matched observational means. We calculate 50 year low-pass filtered time series for each month during 1850–2099 and average across the 36 models. The resultant ensemble mean records for 1895–2014 represent the CMIP5 records of anthropogenic warming used in the

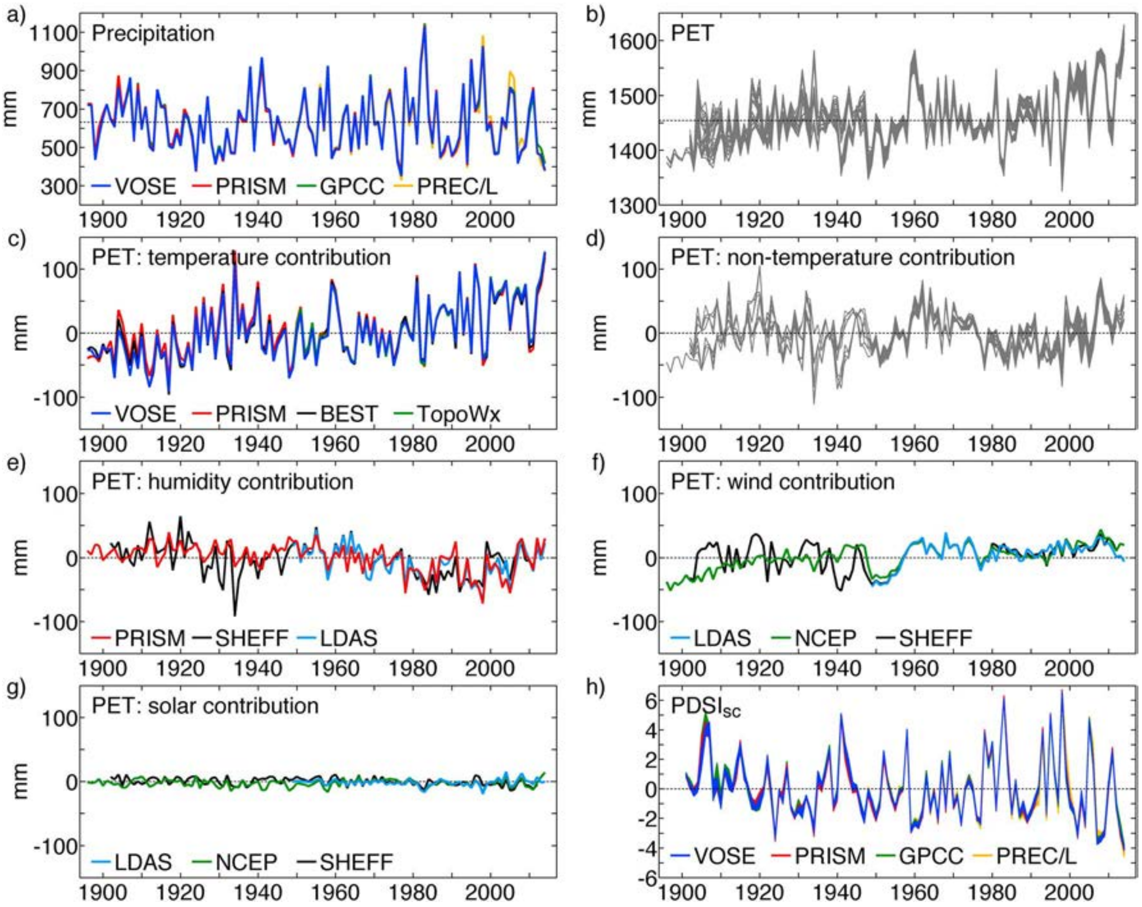

Figure 1. Contributors to interannual (water year) drought variability in CA, calculated from multiple data sets. (a) Precipitation. (b) PET totals, calculated using the PM equation for all combinations of four temperature, three humidity, three wind velocity, and three insolation data sets. (c) Temperature contribution to PET anomalies. Contributions of (d) all nontemperature variables, (e) humidity, (f) wind velocity, and (g) insolation to PET anomalies. (h) JJA PDSI$_{\mathrm{SC}}$ calculated with all 432 combinations of the climate-variable data sets. Horizontal black lines: 1931–1990 means. Colors distinguish data products.

third warming scenario. For the fourth scenario, we linearly adjust these records to best fit the observations from 1895 to 2014. This approach reduces biases in the modeled trends but carries the implicit assumption that observed temperature trends are entirely anthropogenic in origin, which is a questionable assumption. For example, *Johnstone and Mantua* [2014a] indicate that some of the observed warming trend may be due to warming in the Northeast Pacific that is not linked to anthropogenic climate change, but also see *Abatzoglou et al.* [2014] and *Johnstone and Mantua* [2014b].

3. Results and Discussion

3.1. Recent Drought Conditions

Figure 1a shows annual water year (WY: October–September) CA precipitation totals for 1896–2014 and demonstrates general agreement among the four gridded data sets. The WY 2014 precipitation total was the third lowest (fourth lowest for Global Precipitation Climatology Centre (GPCC) [*Schneider et al.*, 2014]) on record (behind WYs 1977 and 1924) and WY 2012–2014 precipitation was the lowest (third lowest for GPCC) 3 year running average on record (Figure S1a). The effects of the recent precipitation deficit have been amplified by positive PET anomalies. Figure 1b shows the 108 records of WY PET, calculated from all combinations of temperature, humidity, wind, and insolation data sets. Among the PET records, 32 include data for 2014. WY 2014 PET was 9–12% above average and the highest on record in every case. PET for WY 2012–2014 was 7–9% above average and either the highest or second highest (behind WY 2007–2009) on record (Figure S1b).

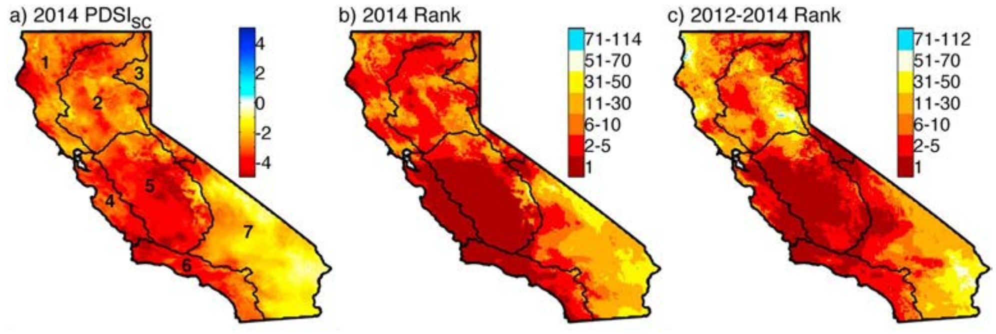

Figure 2. Maps of (a) JJA PDSI$_{sc}$ and ranking for (b) 2014 and (c) 2012–2014. Rankings are based on all years between 1901 and 2014, and a ranking of 1 indicates record-breaking drought. PDSI$_{sc}$ in this figure is based on VOSE precipitation and temperature, PRISM humidity, and LDAS [*Mitchell et al*., 2004; *Rodell et al*., 2004] wind speed and insolation. Polygons bound the seven NOAA climate divisions (division numbers shown in Figure 2a).

All PET data sets indicate positive and significant trends during WY 1949–2014, ranging from 8.2 to 13.7 mm/decade when considering linear trends. These trends are almost entirely due to warming. Since WY 1949, warming positively forced PET by 10–12 mm/decade (65–82 mm total), equivalent to 10–13% of the mean WY precipitation (Figure 1c). The VOSE [*Vose et al*., 2014], BEST [*Rohde et al*., 2013], and TopoWx (which only goes back to 1948 [*Oyler et al*., 2015]) data sets indicate that the temperature contribution to PET was highest on record in 2014 while PRISM indicates that the temperature contribution was higher in 1934. All four data sets agree that the temperature contribution to PET during WY 2012–2014 was substantially higher than that of any other 3 year period on record (Figure S1c).

Nontemperature variables account for approximately one third of WY PET variability (Figure 1d), although much uncertainty exists among the nontemperature data sets. Nearly all interannual variability and inter–data set spread in nontemperature PET (Figure 1d) are due to contributions from vapor pressure and wind speed (Figures 1e–1g). According to the data sets considered, positive wind speed trends contributed positively to PET (4.5 to 4.8 mm/dec), positive humidity trends contributed negatively (−3.5 to −4.0 mm/dec), and insolation had a minimal influence due to very low interannual variability in warm-season insolation relative to the mean. Prior to 1948, trends in the nontemperature components of PET are much less certain due to a nearly complete lack of pre-1948 observational data [e.g., *Dai*, 2011].

Within CA, PET trends were spatially heterogeneous, with much of the Central Valley experiencing reduced PET during the second half of the twentieth century due to suppressed daytime warming and increased humidity, consistent with the effects of increased irrigation [*Lobell and Bonfils*, 2008]. These results are broadly consistent with observed decreases in warm-season pan evaporation at sites in the Central Valley during 1951–2002 [*Hobbins et al*., 2004]. These agricultural trends appear distinct from the well-known global declines in pan evaporation that appear to have been caused by pollution-induced solar dimming during the 1950s–1980s and reductions in wind speed [*Roderick et al*., 2009]. While long-term records of insolation and wind speed are sparse in CA, those that exist indicate insignificant wind trends of inconsistent sign [*Pryor et al*., 2009; *Pryor and Ledolter*, 2010] and twentieth century insolation decreases that were too small to substantially affect statewide mean PET, similar to prior findings in Australia [*Roderick et al*., 2007].

Figure 1h shows all 432 records of JJA PDSI$_{sc}$ for 1901–2014 (128 records extend through 2014). Colors in Figure 1h indicate the precipitation product; spread among colors reflects disagreement among precipitation products and spread within colors reflects disagreement among PET products. All records indicate that 2014 JJA PDSI$_{sc}$ was the lowest on record (−4.64 to −3.67), with 25–37% of CA experiencing record-breaking drought locally. The year 2014 had the highest proportion of record-breaking drought area on record for all data sets, with the most severe anomalies centered in the southern Central Valley and the central and southern CA coasts (Figures 2a and 2b).

Considering 3 year running average PDSI$_{sc}$, 2012–2014 JJA drought intensity was found to be similar to, but generally not as severe as, that of 2007–2009 when averaged across CA, regardless of data sets used (Figure S1h). The similarity of mean PDSI$_{sc}$ during these two periods is interesting given that WY 2012–2014 had the lowest precipitation total on record and PET levels were comparable during each period. The difference

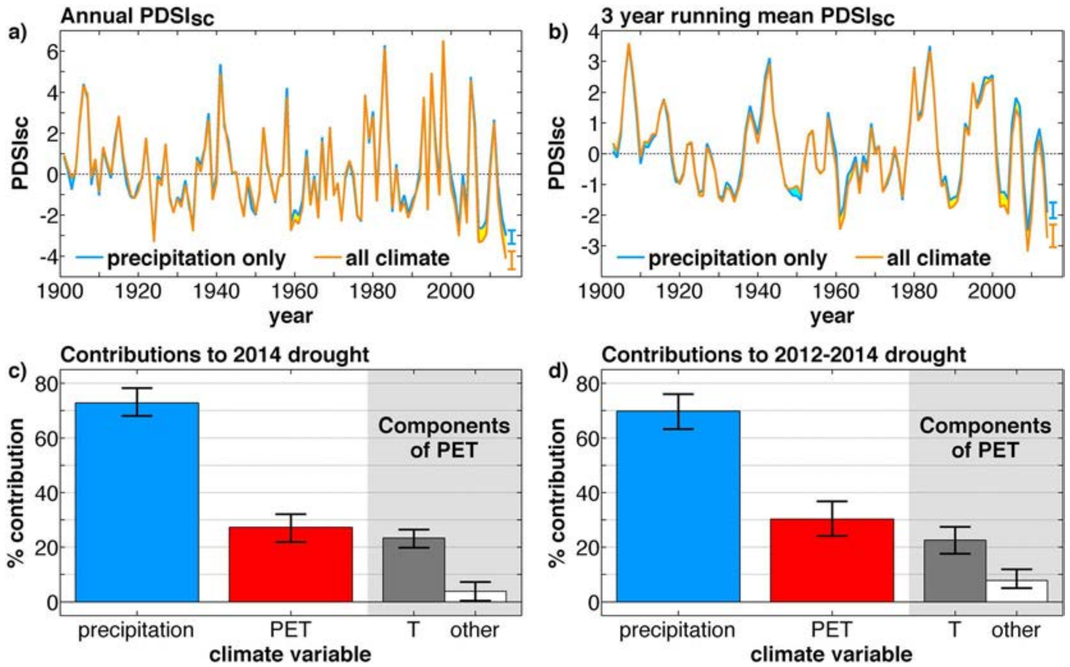

Figure 3. Contributions of precipitation and PET to drought variability. (a) Annual and (b) 3 year running mean JJA $\mathrm{PDSI}_{\mathrm{sc}}$ records calculated when (blue) only precipitation is allowed to vary from the climatological mean and (orange) when both precipitation and PET vary. Thus, departures of the blue line from zero are due to precipitation variability and departures of the orange line from the blue line are due to PET variability. Shading between lines in Figures 3a and 3b indicate periods when (cyan) low PET reduces drought and (yellow) high PET intensifies drought. Percent contributions of precipitation and PET to the (c) 2014 and (d) 2012–2014 $\mathrm{PDSI}_{\mathrm{sc}}$ anomalies. The bars in the shaded area of Figures 3c and 3d break the contribution of PET into contributions from temperature (*T*) and nontemperature (other: humidity, wind, and solar). Time series and bars represent mean conditions across all combinations of climate data products and whiskers bound all values from all combinations of data products.

was in the timing of precipitation. Unlike the 2012–2014 drought, which intensified over time, the 2007–2009 drought was most intense at the onset and the moisture deficit established in 2007 partially propagated into 2008 and 2009. Additionally, spring months for WY 2012-2014 were generally wetter than WY 2007–2009, contributing to soil moisture at a critical time immediately prior to summer (Figure S2).

The finding that the 2012–2014 $\mathrm{PDSI}_{\mathrm{sc}}$ was not as severe as that of 2007–2009 conflicts with prior findings based on NOAA PDSI (which is based on VOSE precipitation and temperature) that 2012–2014 was the most severe 3 year drought on record in CA [*Griffin and Anchukaitis*, 2014; *Robeson*, 2015]. This is attributable to the NOAA calculation of PDSI, which amplifies the effect of extreme heat anomalies in 2014 via the Thornthwaite PET equation (Figures S3 and S4). Importantly, while our calculations indicate that 2012–2014 was probably not a record-breaking drought event when averaged across CA, 2012–2014 drought severity *was* record breaking in much of the agriculturally important Central Valley (Figure 2c). In contrast, drought in 2007–2009 was most severe in the sparsely populated and already dry desert region of southeastern CA.

$\mathrm{PDSI}_{\mathrm{sc}}$ does not account for snowpack effects, which are important for human water supply, and our calculations of statewide $\mathrm{PDSI}_{\mathrm{sc}}$ may therefore not always accurately reflect drought from the perspective of human water supply, which is disproportionately linked to the Sierra Nevada Mountains. For that region, *Mao et al.* [2015] used the Variable Infiltration Capacity (VIC) hydrologic model [*Liang et al.*, 1994] to simulate hydrological dynamics during 1920–2014. Using the *Mao et al.* [2015] meteorological forcing to calculate $\mathrm{PDSI}_{\mathrm{sc}}$ for the Sierra Nevada Mountains, we find strong agreement ($r = 0.93$) with VIC JJA soil moisture (Figure S5). VIC soil moisture nevertheless indicates slightly more severe drought than $\mathrm{PDSI}_{\mathrm{sc}}$ during the most extreme drought years, likely due to early disappearance of snowpack [e.g., *Mote*, 2006; *Mankin and Diffenbaugh*, 2015] and subsequently reduced spring and summer melt-driven soil moisture inputs (Figure S6). Given that the calculation of $\mathrm{PDSI}_{\mathrm{sc}}$ neglects snowpack and therefore cannot capture the effect of early snowmelt on summer soil moisture, the warming effect on summer $\mathrm{PDSI}_{\mathrm{sc}}$ presented in the next section is likely conservative for snow-dominated areas.

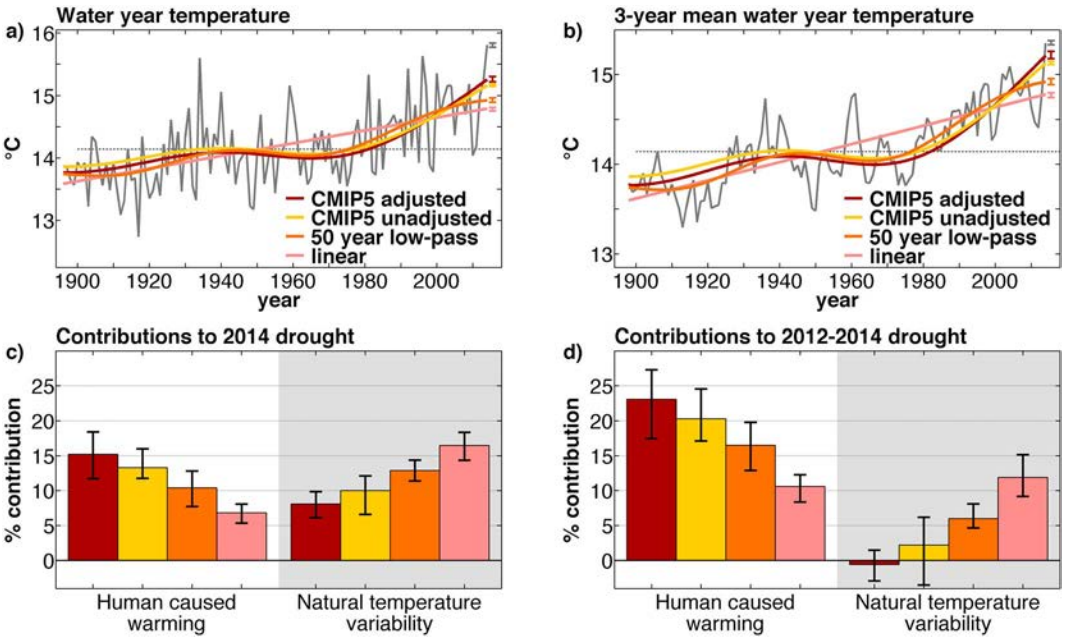

Figure 4. Contributions of anthropogenic warming and natural temperature variability to recent temperature and drought. (a) Annual and (b) 3 year running water year temperature records with four alternate scenarios of anthropogenic warming. Contributions of anthropogenic warming versus natural temperature variability to (c) 2014 and (d) 2012–2014 JJA $\mathrm{PDSI}_{\mathrm{SC}}$ anomalies, where bar colors correspond to the colors of the four anthropogenic warming trends in Figures 4a and 4b. For each of the anthropogenic warming scenarios, natural temperature variability is calculated as the observed temperature minus the warming trend. All time series and bars represent mean conditions across all combinations of climate products. Whiskers bound all values for all combinations of data products.

3.2. Effect of Warming on Recent Drought

Figures 3a and 3b compare $\mathrm{PDSI}_{\mathrm{SC}}$ (orange) to an alternate calculation in which only precipitation varies and PET is held at its mean annual cycle (blue). While there is no long-term trend in precipitation-driven $\mathrm{PDSI}_{\mathrm{SC}}$ since 1948 or 1901, trends in actual $\mathrm{PDSI}_{\mathrm{SC}}$ are significant and negative ($p < 0.05$ according to Spearman's Rho and Kendall's Tau) due to increasing PET. During 2014 and 2012–2014, PET anomalies accounted for 22–32% and 24–37% of the JJA $\mathrm{PDSI}_{\mathrm{SC}}$ anomalies, respectively (Figures 3c and 3d). Recalculating $\mathrm{PDSI}_{\mathrm{SC}}$ considering the temperature and nontemperature components of PET separately, we find that the intensifying effect of high PET on recent drought was nearly entirely caused by warmth (Figures 3c and 3d). High temperatures accounted for 20–26% and 18–27% of the JJA $\mathrm{PDSI}_{\mathrm{SC}}$ anomalies in 2014 and 2012–2014, respectively (Figures 3c and 3d).

The contribution of temperature is further separated into contributions from natural temperature variability and anthropogenic warming in Figure 4. Figures 4a and 4b show the WY temperature record and the four anthropogenic warming scenarios, which indicate an anthropogenic warming contribution in WY 2014 of 0.61–1.27°C relative to the 1931–1990 mean. The empirically derived trends suggest a weaker anthropogenic warming contribution in recent years than the CMIP5 trends because (1) the linear trend does not account for the nonlinear increase in anthropogenic forcing and (2) the 50 year low-pass filter trend indicates slowed warming in the past two decades that is partly due to our conservative smoothing approach and partly due to decadal climate variability. The CMIP5 trends represent the nonlinear increase in radiative forcing without being affected by decadal climate variability or smoothing artifacts. The similarity between the adjusted and unadjusted CMIP5 warming trends suggest that the CMIP5 provides a reasonable representation of the anthropogenic warming influence in CA despite having stronger warming trends than the conservatively designed empirical trends.

Breaking the temperature contributions to $\mathrm{PDSI}_{\mathrm{SC}}$ into anthropogenic and natural components, the four anthropogenic warming trends account for 5–18% of the JJA $\mathrm{PDSI}_{\mathrm{SC}}$ anomaly in 2014 and 8–27% of the anomaly in 2012–2014 (Figures 4c and 4d). Despite differences in these relative contributions of warming to drought during 2014 versus 2012–2014, the *absolute* contributions of anthropogenic warming to drought during these two periods were virtually identical. The absolute anthropogenic contribution does not change much interannually but instead acts as a gradually moving drought baseline upon which the effects of natural climate variability are superimposed (Figure S7a).

As of 2014, the anthropogenic warming forcing accounted for approximately -0.3 to -0.7 standardized PDSI_{sc} units, depending on the anthropogenic warming scenario and combination of climate data sets considered (Figure S7a). To illustrate how this trend in background drought conditions affected the probability of severe drought as of 2014, we compare the probability distribution of 1901–2014 PDSI_{sc} values calculated in the absence of anthropogenic warming to the same distributions shifted negative by 0.46, the 2014 PDSI_{sc} forcing by the 50 year low-pass filter warming trend (Figure S7b, based on VOSE temperature and precipitation data). Comparing the two distributions, we find that severe summer droughts with $\text{PDSI}_{sc} \leq -3$ were approximately twice as likely under 2014 anthropogenic warming levels (Figure S7c). Although uncertainty in probabilities of extreme events is large when based on observed records [e.g., *Swain et al*., 2014], and the anthropogenic trend may not result in a perfectly uniform shift in the PDSI_{sc} distribution, this analysis illustrates the general fact that the anthropogenic drying trend, while still small relative to the range of natural climate variability, has caused previously improbable drought extremes to become substantially more likely, consistent with the conclusions of other recent studies [e.g., *AghaKouchak et al*., 2014; *Cook et al*., 2015; *Diffenbaugh et al*., 2015; *Shukla et al*., 2015; *Williams et al*., 2013, 2014, 2015].

Regarding anthropogenic contributions, there are some important caveats. First, anthropogenic climate change has potentially affected more than just temperature in CA [e.g., *Swain et al*., 2014; *Wang et al*., 2014, 2015]. Lack of long-term observational data on wind speed and humidity in CA, and uncertainties in existing data, make it difficult to quantify anthropogenic influences on these variables. For CA precipitation, current models project a weak overall increase [*Neelin et al*., 2013; *Seager et al*., 2014b, 2015; *Simpson et al*., 2015], but no such precipitation trend has emerged. Hence, we only characterize anthropogenic effects on temperature in this study. Second, observed warming trends are affected by processes not related to greenhouse gas emissions such as land use (e.g., agriculture, urbanization) and natural low-frequency climate variability. While climate models provide a definition of anthropogenic warming that should be unbiased by observations, the accuracy of this approach, as in other attribution studies [e.g., *Bindoff et al*., 2013], is confined by the accuracy of climate models. Finally, our analyses do not account for snowpack, making our results a likely underestimation of the contribution of heat anomalies to recent drought in snow-dominated mountain areas and should be interpreted conservatively regarding the effects of warming on water resources for systems strongly affected by the timing of seasonal runoff from mountains.

4. Conclusions

Anthropogenic warming has intensified the recent drought as part of a chronic drying trend that is becoming increasingly detectable and is projected to continue growing throughout the rest of this century [e.g., *Cook et al*., 2015]. As anthropogenic warming continues, natural climate variability will become increasingly unable to compensate for the drying effect of warming. Instead, the soil moisture conditions associated with the current drought will become increasingly common. Impacts of drought on society may be increasingly intensified due to declining availability of groundwater reserves [e.g., *Famiglietti*, 2014]. The Central Valley may be particularly vulnerable to warming-driven drought if reductions in water supply cause reductions in irrigation, as irrigation has slowed warming in this region [*Lobell and Bonfils*, 2008]. The dramatic effects of the current drought in CA, combined with the knowledge that the background warming-driven drought trend will continue to intensify amidst a high degree of natural climate variability, highlight the critical need for a long-term outlook on drought resilience, even if wet conditions soon end the current drought in CA.

Acknowledgments
We thank Y. Mao for sharing VIC meteorological forcing and soil moisture data from *Mao et al.* [2015]. We thank J. Sheffield for making the SHEFF data set available at http://hydrology.princeton.edu. We thank R. Vose for providing the VOSE data set. PRISM data were obtained from the PRISM Climate Group, Oregon State University (http://www.prism.oregonstate.edu, created 4 February 2004). PRISM dew point data were obtained from http://oldprism.nacse.org. TopoWx data were obtained from ftp://mco.cfc.umt.edu/resources/TopoWx-source/. LDAS data were obtained from http://disc.sci.gsfc.nasa.gov/hydrology/data holdings. GPCC data through 2013 come from ftp://ftp.dwd.de/pub/data/gpcc/html/fulldata_v7_-doi_download.html. PREC/L, NCEP2, NCEP/NCAR, NOAA twentieth century reanalysis, and GPCC for 2014 were accessed from http://www.esrl.noaa.gov. A spatially continuous map of soil moisture holding capacities for the United States came from the Web Soil Survey data set (http://websoilsurvey.nrcs.usda.gov). This work was supported by NSF award AGS-1243204 and NOAA award NA14OAR4310232. Lamont–Doherty publication number 7924. Thanks to K.J. Anchukaitis and two anonymous reviewers for comments that improved this manuscript. The climate and PDSI_{sc} data sets compiled for this study are available at http://www.ldeo.columbia.edu/~williams/ca_drought_2015_grl.html.

The Editor thanks two anonymous reviewers for their assistance in evaluating this paper.
