Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	becoming airborne in handling dusty materials to open stockpiles and mobile equipment. – Maintenance of roadways in a clean condition. o MCAPCD: – Maintaining construction vehicles and equipment according to manufacturers [sic] specifications. – Limiting equipment idling time. – Scheduling construction truck work trips to non-peak traffic hours. – Minimizing the length of construction truck trips. – Using water or chemicals to control dust from demolition, construction, or grading. – Applying asphalt, oil, water, or suitable chemicals on unpaved roads, material stockpiles or other surfaces. – Installation of hoods, fans and filters to enclose and vent the handling of dusty materials. – Using water, chemicals, chuting, venting, or other precautions when handling dusty materials in open stockpiles and mobile equipment. – Maintaining paved roadways in a clean condition. o TCAPCD (from the Tuolumne County General Plan Update EIR [Tuolumne County 2015]): – Exposed soils shall be watered as needed to control wind borne dust. – Exposed piles of dirt, sand, gravel, or other construction debris shall be enclosed, covered and/or watered as needed to control wind borne dust. – Vehicle trackout shall be minimized through the use of rubble strips and wheel washers for all trucks and equipment leaving the site. – Sweep streets once a day if visible soil materials are carried to adjacent streets (recommend water sweepers with reclaimed water). – Onsite vehicle speed shall be limited to 15 miles per hour on unpaved surfaces. – Loads on all haul/dump trucks shall be covered securely or at least 2 ft of freeboard shall be maintained on trucks hauling loads. – Construction equipment shall be maintained and tuned at the interval recommended by the manufacturers to										

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	minimize exhaust emissions. – Equipment idling shall be kept to a minimum when equipment is not in use. – Construction equipment shall be in compliance with the ARB off-road and portable equipment diesel particulate matter (DPM), regulations. – Substitute electrical equipment for diesel- and gasoline-powered equipment where practical. – Use alternatively fueled construction equipment onsite, where feasible, such as compressed natural gas (CNG), liquefied natural gas (LNG), propane, or biodiesel. – Avoid the use of onsite generators by connecting to grid electricity or utilizing solar-powered equipment. – Limit heavy-duty equipment idling time to a period of 3 minutes or less, exceeding the ARB regulation minimum requirements of 5 minutes.										
	• Apply appropriate Toxic Air Contaminants (TAC) and Hazardous Air Pollutants (HAP) mitigation measures from the applicable air district to reduce public exposure to DPM pesticides, and asbestos. These measures are documented in official rules and guidance reports; however, not all districts make recommendations for mitigation measures for TAC/HAP emissions. These measures will be applied on a project-level basis and may be tailored in consultation with the appropriate air district, depending on the severity of anticipated TAC/HAP emissions.[5]	X	—	X	X	X	X	X	X	—	X
	• Use vehicles with zero-emission or lower-emission engines.[2]	X	—	X	—	X	X	X	X	—	—
	• Limit the unnecessary idling of vehicles and equipment.[2]	X	—	X	—	X	X	X	X	—	X
	• Use low/zero carbon/alternative fuels, such as B20 biodiesel or renewable diesel.[2]	X	—	X	—	X	X	X	X	—	X
	• Control visible emissions from off-road diesel powered equipment.[2]	X	—	X	—	X	X	X	X	—	X
	• Design structural devices to minimize the frequency of maintenance trips.[2]	X	—	X	—	X	X	X	X	—	X
	• Perform necessary equipment maintenance, such as inspections and corrections, to detect failures early; keep equipment operating cleanly and efficiently. [2]	X	—	X	—	X	X	X	X	—	X
	• Use the proper sized equipment for the job during construction and operation.[2]	X	—	X	—	X	X	X	X	—	X
	• Train equipment operators in proper use of equipment during construction and operation.[2]	X	—	X	—	X	X	X	X	—	X
	• Produce concrete onsite if determined to be less emissive than transporting ready mix.[2]	X	—	X	—	X	X	X	X	—	X
	• Minimize the amount of concrete for paved surfaces or utilize a low-carbon concrete option.[2]	X	—	X	—	X	X	X	X	—	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	• Use locally sourced or recycled materials for construction materials.[2]	X	—	X	—	X	X	X	X	—	X
	• Control fugitive dust emissions during land clearing, grubbing, scraping, excavation, leveling, grading, or cut and fill operations with application of water (at least twice daily) or by presoaking.[2, 4]	X	—	X	X	X	X	X	X	—	X
	• Cover stockpiles of soil, sand, and other materials, and stabilize all disturbed areas and storage piles that are not being actively utilized for construction purposes using water, chemical stabilizers, or by covering with tarps, other suitable cover, or vegetative ground cover.[2, 4]	X	—	X	X	X	X	X	X	—	X
	• Pave, apply water, or apply soil stabilizers to unpaved areas, including all access roads and parking areas.[2, 4]	X	—	X	—	X	X	X	X	—	X
	• Sweep surrounding streets and paved areas (e.g., once per day).[2]	X	—	X	—	X	X	X	X	—	X
	• Suspend excavation and grading activity when winds (instantaneous gusts) exceed 25 miles per hour and/or greater than 20 miles per hour over a 1-hour period.[2, 4]	X	—	X	—	X	X	X	X	—	X
	• Initiate landscaping and revegetation as soon as construction tasks allow in order to minimize wind erosion.[2]	X	—	X	—	X	X	X	X	—	X
	• Encourage ride sharing and use of transit transportation for construction employees commuting to the project site.[4]	X	—	X	—	X	X	X	X	—	X
	• Use electric equipment for construction whenever possible in lieu of fossil fuel–powered equipment.4	X	—	X	—	X	X	X	X	—	X
	• Discontinue all construction activities during first stage smog alerts, first stage ozone alerts, and/or curtail construction during periods of high ambient pollutant concentrations.[4]	X	—	X	—	X	X	X	X	—	X
	• Water previously disturbed exposed surfaces (soil) a minimum of 3 times per day or whenever visible dust is capable of drifting from the site or approaches 20 percent opacity.[4]	X	—	X	X	X	X	X	X	—	X
	• Water all haul roads (unpaved) a minimum of 3 times per day or whenever visible dust is capable of drifting from the site or approaches 20 percent opacity.[4]	X	—	X	X	X	X	X	X	—	X
	• Reduce speed on unpaved roads to less than 15 miles per hour.[4]	X	—	X	—	X	X	X	X	—	X
	• Install and maintain a trackout control device that meets the specifications of regional air board requirements if needed (e.g., SJVAPCD Rule 8041 if the site exceeds 150 vehicle trips per day or more than 20 vehicle trips per day by vehicles with three or more axles).[4]	X	—	X	—	X	X	X	X	—	X
	• Cover trucks hauling debris, soil, sand, or other material to reduce dust and suspended air particles, and when transporting materials offsite, maintain a freeboard limit of at least 6 inches or effectively wet to limit visible dust emissions.[4,2]	X	—	X	X	X	X	X	X	—	X
	• Limit and remove the accumulation of mud and/or dirt from adjacent public roadways at the end of each workday.[4]	X	—	X	—	X	X	X	X	—	X
	• Remove visible trackout from the site at the end of each workday.[4]	X	—	X	—	X	X	X	X	—	X
	• Comply with applicable regional air board asphalt-concrete paving	X	—	X	X	X	X	X	X	—	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	rules such as SJVAPCD Rule 4641 (e.g., restrict use of cutback, slow-sure, and emulsified asphalt paving materials).[4]										
	• Install diesel particulate filter and utilize diesel oxidation catalyst.[6]	—	—	—	—	X	—	—	—	—	X
	• Require the pump system be electric or alternatively fueled.[6]	—	—	—	—	X	—	—	—	—	X
	• Locate pump system/emissions generating activity as far from sensitive receptors as possible.[6]	X	—	X	—	X	X	X	X	—	X
Biological Resources[b]	• Prior to land disturbance, contact USFWS and CDFW (or appropriate land management agency, such as national forests and Bureau of Land Management) and conduct all necessary pre-construction surveys for special-status plants, species, and habitat prior to construction activities. This may include the hiring of a qualified biologist to identify riparian and other sensitive vegetation communities and/or habitat for special-status plants and animals.[1,5,6]	X	—	X	X	X	X	X	X	X	X
	• Comply with local, state, and federal regulations and ordinances such as those listed below.	X	—	X	X	X	X	X	X	X	X
	○ USFWS ESA Section 7 consultation for threatened and endangered species.[2]										
	○ U.S. Army Corps of Engineers Clean Water Act Section 404 Permit and State Clean Water Act Section 401 Water Quality Certification for filling or dredging waters of the United States and other federal permitting actions.[2, 5]										
	○ CDFW California Fish and Game Code 1601 Agreement for Streambed Alteration.[2]										
	○ State Water Board WDRs (which are also permits for purposes of the Clean Water Act, if applicable).[2]										
	○ General plan or National Forest System land or Bureau of Land Management conservation requirements.[2]										
	○ City and/or county tree ordinances.[2]										
	○ Contract with qualified botanists, wildlife biologists, and arborists to develop biological assessments if a project's specific location warrants doing so. At a minimum, assessments should include project area-specific literature searches, reviews of CDFW's California Natural Diversity Database and the California Native Plant Society's Inventory of Rare and Endangered Plants of California, and field surveys of all potential project sites and their surrounding areas to identify and map existing plant communities, wildlife habitat, and heritage trees, and to identify wildlife species that currently occur, have occurred in the past (e.g., resident and migratory wildlife species that have been documented as foraging or nesting at the site), or have the potential to occur at the site due to the presence of suitable habitat. Field surveys should follow protocols established by CDFW and should be conducted during the appropriate time(s) of year (e.g., during the blooming period of potentially occurring plant species).[2,5]	X	—	X	X	X	X	X	X	X	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	• Select a project site that does not contain critical habitat if there are project site alternatives. Or locate project facilities outside the boundaries of critical habitat areas if there is only one project site available.[2, 5]	X	—	X	X		X	X	X	X	X
	• Avoid and minimize disturbance of riparian and other sensitive vegetation communities.[5]	X	—	X	X	X	X	X	X	X	X
	• Avoid and minimize disturbance of areas containing special-status plant or animal species.[5]	X	—	X	X		X	X	X	X	X
	• Where adverse effects on sensitive biological resources (including fish species) cannot be avoided, undertake additional CEQA review and develop a restoration or compensation plan to mitigate the loss of the resources.[5]	X	—	X	—	X	X	X	X	X	X
	• Where construction in areas that may contain special-status fish species cannot be avoided through the use of alternative management practices, conduct an assessment of habitat conditions and the potential for presence of special-status fish species prior to construction; this may include the hiring of a qualified fish biologist to determine the presence of special-status fish species.[5]	X	—	X	—	X	X	X	X	X	X
	• Based on the species present in adjacent waterbodies and the likely extent of construction work that may affect fish, limit construction to periods that avoid or minimize impacts on special-status fish species.[5]	X	—	X	—	X	X	X	X	X	X
	• Develop a mitigation and management plan in coordination with CDFW and USFWS to implement all appropriate measures as required by USFWS ESA Section 7 consultation and to satisfy any other local, state, and federal requirements for achieving no net loss of wetlands or other critical habitat, or take of wildlife species of concern. The plan should be submitted to the local city/county environmental planning department, USACE, USFWS, CDFW, applicable regional water quality control board (e.g., as part of a Section 401 Water Quality Certification application), and/or other oversight agencies as applicable for approval prior to its implementation if an impact on special-status species population(s) is determined to occur based on the biological assessment and evaluation of the final project site and design.[2]	X	—	X	X	X	X	X	X	X	X
	• Develop a revegetation plan if vegetation would be disturbed during construction or operation. The revegetation plan should be prepared by a qualified restoration ecologist and reviewed by the appropriate agencies. The plan should specify sites where revegetation should take place, the planting stock appropriate for the region, appropriate designs (e.g., plant arrangements that, when mature, replicate the natural structure and species composition of similar habitats in the region), planting techniques, monitoring frequency, and success criteria (e.g., sapling trees no longer require active management).[2]	X	—	—	—	X	X	X	X	X	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	• Establish temporary construction buffers for drainages, wetlands/vernal pools, and other sensitive habitat in the project area that could be affected by construction activities. The outer edges of the buffer zones will be demarcated using flagging or temporary orange mesh construction fencing before initiation of construction activities and based on site-specific conditions, seasonal restrictions for wildlife, local planning department specifications, and resource agency (e.g., USFWS and CDFW) requirements.[2,6]	X	—	X	X	X	X	X	X	X	X
	• Require a qualified biologist to perform the following construction functions if sensitive habitat or species are present. ○ Perform required preconstruction surveys to determine the current presence of, and demarcate the boundaries of construction buffers around, sensitive habitats, and submit survey reports according to CDFW and local agency guidelines for approval prior to construction.[1,2,5,6] ○ Provide USFWS-approved worker environmental awareness training that informs all construction personnel about sensitive plant and wildlife species and habitats.[2] ○ Oversee major excavation and other construction activities with the authority to stop construction activities until appropriate corrective measures have been completed.[2] ○ Report to USFWS any incidental take.[2] ○ Periodically re-inspect the project site (e.g., every week) during construction activities or whenever a there has been a substantial lapse in construction activity (e.g., more than 2 weeks).[2]	X	—	X	X	X	X	X	X	X	X
	• Locate temporary access roads and staging areas outside the boundaries of critical habitat areas, restrict movement of heavy equipment to and from the project site to established roadways and areas designated for construction and staging, and do not allow parking of vehicles or storage of potentially toxic chemicals near or up-gradient of drainages or sensitive habitats or under heritage trees.[2]	X	—	X	X	X	X	X	X	X	X
	• Implement measures to control dust, erosion, and noise (see the Air Quality, Geology and Soils, and Noise sections, respectively). [2]	X	—	X	X	X	X	X	X	X	X
	• Properly contain or remove all trash that may attract predators to the worksite during construction.[2]	X	—	X	—	X	X	X	X	X	X
	• Remove any temporary fill and construction debris and, wherever feasible, restore disturbed areas to pre-project conditions according to the before-mentioned revegetation plan after completion of construction activities.[2]	X	—	X	—	X	X	X	X	X	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	• Provide compensation for unavoidable degradation or loss of critical habitat due to project construction to ensure no net loss of that habitat as required by local, state, or federal agencies. Compensation could be provided at a minimum ratio (e.g., 3:1, 3 acres of restored wetlands for every 1 acre affected, or three native oak trees planted for every native oak tree eliminated) that ensures long-term replacement of habitat functions and values and complies with local, state, and federal requirements. Examples of compensation are as follows. ○ Construct replacement habitat as close as possible to the previous habitat location at the project site (e.g., locate replacement riparian and wetland habitats along the same drainage affected by the project construction). ○ If site limitations prevent onsite habitat replacement, construct replacement habitat as near the project site as possible. ○ Provide payment on a per-acre basis to an approved restoration or mitigation bank or other trust fund.[2]	X	—	X	—	X	X	X	X	X	X
	• Comply with measures contained within habitat conservation plans or natural community conservation plans, such as the San Joaquin Multi-Species Habitat Conservation and Open Space Plan. Consult with appropriate biologists who have training and are knowledgeable about the habitat conservation plan or natural community conservation plan. Monitoring, construction, and relocation surveys by a qualified biologist would be done as appropriate.[4]	X	—	X	X	—	X	X	X	X	X
	• Prior to implementing any management practice that would result in the permanent loss of wetlands, conduct a delineation of affected wetland areas to determine the acreage of loss in accordance with current USACE methods. For compliance with the Clean Water Act Section 404 permit and WDRs, compensate for the permanent loss (fill) of wetlands and ensure no net loss of habitat functions and values. Compensation ratios will be determined through coordination with the Central Valley Water Board and U.S. Army Corps of Engineers as part of the permitting process. Compensation may be a combination of mitigation bank credits and restoration/creation of habitat, as described below. ○ Purchase credits for the affected wetland type (e.g., perennial marsh, seasonal wetland) at a locally approved mitigation bank and provide written evidence to the resource agencies that compensation has been established through the purchase of mitigation credits. ○ Develop and ensure implementation of a wetland restoration plan that involves creating or enhancing the affected wetland type.[5]	X	—	X	X	X	X	X	X	X	X
	• Install species exclusion fencing for animal species during construction; install a temporary, plastic mesh-type construction fence at least 1.2 m tall around any established special-status plant species buffer areas to prevent encroachment by construction vehicles and personnel; a qualified biologist will determine the exact	—	—	X	X	X	—	—	—	—	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	location of the fencing.[6]										
	- Conduct pile driving with vibratory hammer.[6]	—	—	—	—	X	—	—	—	—	X
	- Implement turbidity monitoring during construction/removal.[6]	—	—	—	X	X					X
	- Implement environmental awareness program for construction personnel.[6]	—	—	—	X	X	—	—	—	—	X
Cultural Resources	- Where construction within areas that may contain cultural resources cannot be avoided through the use of alternative management practices, conduct an assessment of the potential for damage to cultural resources prior to construction; this may require the hiring of a qualified cultural resources specialist to determine the presence of significant cultural resources.[5]	—	—	X	X	X	X	X	X	X	X
	- Where the assessment indicates that damage may occur, and prior to land disturbance, submit a non-confidential records search request to the appropriate California Historic Resources Information System (CHRIS) which potentially includes the following in the plan area.[1,5]	—	—	X	—	X	X	X	X	X	X
	○ Alpine County: Central California CHRIS Information Center										
	○ Calaveras County: Central California CHRIS Information Center[5]										
	○ Contra Costa County: Central California CHRIS Information Center[5]										
	○ Madera County: Southern San Joaquin Valley CHRIS Information Center[5]										
	○ Mariposa County: Central California CHRIS Information Center[5]										
	○ Merced County: Central California CHRIS Information Center[5]										
	○ San Joaquin County: Central California CHRIS Information Center[5]										
	○ Stanislaus County: Central California CHRIS Information Center[5]										
	○ Tuolumne County: Central California CHRIS Information Center[5]										
	- Implement the recommendations provided by the CHRIS information center(s) in response to the records search request.[5]										
	- Where adverse effects on cultural resources cannot be avoided, undertake additional CEQA review and develop appropriate mitigation to avoid or minimize the potential impact(s).[5]										
	- Require a professional trained to identify evidence of cultural resources to observe major excavation and earth-moving activities if significant cultural resources are known to exist on the project site or if there is a high probability for significant cultural resources to exist.[2]	—	—	X	X	X	X	X	X	X	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	• Construction will stop within a 100-foot radius of any archaeological, paleontological, or historical resources discovered during construction activities, and treatment measures will be devised as needed. A qualified archaeologist should be brought on site within 24 hours of the discovery. If the find is determined to be significant, a full archaeological survey will take place. Construction activities in the area resume once the survey is completed and all cultural resources are recovered.[2, 6]	—	—	X	X	X	X	X	X	X	X
	• No further excavation or other site disturbance takes place if any human remains are discovered during construction activities. Notify the local coroner so that a determination can be made as to whether the remains are of Native American origin or whether an investigation into the cause of death is required. If the remains are determined to be Native American, the following actions would be taken. ○ The coroner notifies the NAHC within 24 hours. ○ The NAHC immediately notifies those persons believed to be the most likely descendant(s) (MLD) of the deceased. ○ Once the NAHC identifies the MLD, the MLD, with the permission of the landowner, inspects the site of the discovery and makes recommendations for the treatment or disposition of the remains and any associated grave items within 48 hours (per Assembly Bill 2641) of the MLD being granted access to the site. ○ The landowner is to ensure that the immediate vicinity of the remains, established according to standard professional practices, is not damaged or disturbed by further activity until the landowner has conferred with the MLD. ○ Discussion and consultation between the landowner and MLD should take into account the possibility of multiple burials and reasonable options regarding the MLD's preferences for treatment. ○ If the NAHC is unable to identify an MLD, if the MLD fails to make a recommendation, or if the NAHC is unable to mediate a dispute concerning the appropriate disposition of the remains, the landowner shall re-inter the human remains and any associated items with appropriate dignity on the property in a location not subject to further subsurface disturbance; and, to protect the remains from disturbance, the landowner must record the site with the NAHC or the appropriate CHRIS, use an open space or conservation zoning designation or easement, and/or record a document with the county in which the property is located.[2,5]	X	—	X	X	X	X	X	X	X	X
	• No further disturbance of an area, if fossils are encountered, will occur until the materials have been evaluated by a qualified paleontologist and appropriate treatment measures have been identified.[4]	—	—	X	X	X	X	X	X	X	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	• Construction workers should be aware of the following protocols for identifying cultural resources: ○ If built environment resources or archaeological resources, including chipped stone (often obsidian, basalt, or chert), ground stone (often in the form of a bowl mortar or pestle), stone tools (such as projectile points or scrapers), unusual amounts of shell or bone, historic debris (such as concentrations of cans or bottles), building foundations, or structures are inadvertently discovered during ground-disturbing activities, the land owner should stop work in the vicinity of the find and retain a qualified cultural resources specialist to assess the significance of the resources. If necessary, the cultural resource specialist also will develop appropriate treatment measures for the find. ○ If human bone is found as a result of ground disturbance, the land owner should notify the county coroner in accordance with the instructions described above. If Native American remains are identified and descendants are found, the descendants may—with the permission of the owner of the land or his or her authorized representative—inspect the site of the discovery of the Native American remains. The descendants may recommend to the owner or the person responsible for the excavation work means for treating or disposing of the human remains and any associated grave goods, with appropriate dignity. The descendants will make their recommendation within 48 hours of inspection of the remains. If the NAHC is unable to identify a descendant, if the descendants identified fail to make a recommendation, or if the landowner rejects the recommendation of the descendants, the landowner will inter the human remains and associated grave goods with appropriate dignity on the property in a location not subject to further and future subsurface disturbance.[5]	—	—	X	—	X	X	X	X	X	X
	• Develop a cultural resources monitoring and mitigation plan for cultural resources (historical, archaeological, paleontological) newly discovered during reservoir drawdown periods.	—	—	—	—	X	—	—	—	—	—
Geology and Soils	• Require a licensed geologist to evaluate county general plans and other available geologic literature for additional geological information, and conduct site-specific geologic, geotechnical, and soil investigations to evaluate the potential for the presence of an active fault or other seismic risks (strong ground shaking, liquefaction, landslides, mass wasting, or other ground failure) for site-specific projects. [2]	—	—	X	X	X	X	—	X	X	X
	• Comply with existing local, state, and federal geotechnical regulations, building codes, standards specifications, and the recommendations of geotechnical studies prepared for site-specific projects.[2, 4]	—	—	X	X	X	X	—	X	X	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	• Evaluate the project site, and up- and down-gradient areas, for erosion potential. Design the project and implement construction and maintenance activities to prevent erosion and sedimentation.[2]	—	—	X	X	X	X	—	X	X	X
	• Design storm water runoff control systems to fit the hydrology of the project area once it is fully developed, to have adequate capacity to transport the flow from all upland/upstream areas, to be non-erosive, and to conduct runoff to a stable outlet. Install systems prior to the rainy season.[2]	—	—	X	X	X	X	—	X	X	X
	• Remove vegetation only when necessary and make every effort to conserve topsoil for reuse in revegetation of disturbed areas.[2]	—	—	X	—	X	X	—	X	X	X
	• Develop land in increments of workable size such that construction can be completed during a single construction season, and coordinate erosion and sediment control measures with the sequence of grading and construction operations.[2]	—	—	X	—	X	X	—	X	X	X
	• Stabilize and revegetate all disturbed soil surfaces before the rainy season.[2]	—	—	X	—	X	X	—	X	X	X
	• Restrict stockpiling of construction materials to the designated construction staging areas and exclusive of habitats and their buffer zones.[2]	—	—	X	—	X	X	—	X	X	X
	• Employ BMPs that prevent soil or sediment from leaving construction sites, monitor them for effectiveness, and maintain them throughout the construction operations and between construction seasons. Standard measures include installation of sediment basins and traps in conjunction with grading operations; development of slope drains; stabilization of stream banks; use of hydraulic mulch, hydroseeding, straw, mulch anchored with a tackifier, polyacrylamide, rolled erosion control products (e.g., blankets and mats), earth dikes, drainage swales, and velocity dissipation devices; and installation of silt fences, fiber rolls, gravel bag berms, sandbag barriers, storm drain inlet protection, and check dams.[2]	X	—	X	—	X	X	X	X	X	X
	• Contain runoff from truck and cement equipment washdown.[2]	—	—	X	—	X	X	—	X	X	X
	• Limit to the dry season any construction activities within an area of the Ordinary High Water (OHW) line of drainages and lakes. Limit any construction activities within a floodplain, but above an OHW line, to those actions that can adequately withstand high river flows without resulting in the inundation of and entrainment of materials in flood flows.[2]	—	—	X	—	X	X	—	X	X	X
	• Have a professional hydrologist or licensed engineer develop an erosion control and water quality protection plan to avoid habitat degradation and ensure compliance with local and state erosion- and sediment-related requirements. The plan should be integrated into the construction schedule and describe how site cleanup and regrading will affect current physical conditions.[2]	—	—	X	—	X	X	—	X	X	X
	• Locate projects away from areas with unsuitable soils or steep slopes.[2]	—	—	X	X	X	X	—	X	X	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	• Depending on soil and geologic conditions, do the following. ○ Ground improvements, such as soil compaction and excavation and disposal of liquefiable soils. ○ Structural improvements, such as berms or dikes, to prevent large lateral spreading. ○ Buttress landslides. ○ Install special drainage devices and water injection wells. ○ Monitor groundwater level to ensure stable conditions.[2]	—	—	X	X	X	X	—	X	X	X
	• Comply with all provisions of the applicable codes for the county or counties in which construction of a septic system is proposed, including the design and installation of septic systems. The design of those systems will be required in accordance with applicable county code to comply with all design requirements, including for factors such as wastewater generation, soil types within the leach field, percolation testing, and slope of the leach field.	—	—	—	—	X	—	—	—	—	—
Greenhouse Gas Emissions	• Implement all requirements under Air Quality, above.	X	—	X	X	X	X	X	X	X	X
	• Implement water recycling practices or policies.[2]	—	—	X	—	X	—	—	—	—	—
	• Preserve known GHG sinks to the extent feasible and limit GHG sources as a component of project design.[2]	—	—	—	—	X	—	—	—	X	—
	• Preserve or replace onsite trees or contribute to a mitigation program providing carbon storage.[2]	—	—	—	—	X	—	—	—	X	—
Hazards and Hazardous Materials	• Provide hazardous materials and worksite safety training for construction workers in accordance with local, state, and federal requirements including, but not limited to the Occupational Safety and Health Act, Title 9 of the Code of Federal Regulations, and Title 8 of the California Code of Regulations.[2]	X	—	X	X	X	X	X	X	X	X
	• Provide hazardous materials accidental spill response plans (and/or Hazardous Materials Management Program) and training that would outline methods, materials, and responsibilities for the response to, and clean-up of, an accidental hazardous material spill during construction of the project. At a minimum, the plans should include provisions for immediate response, containment, and cleanup of a spill, including excavation and disposal of contaminated soil and notification responsibilities. Materials needed for potential cleanup activities should be kept onsite.[2]	X	—	X	X	X	X	X	X	X	X
	• Provide a health and safety plan for construction workers that is prepared by a certified industrial hygienist; comply with all appropriate local, state, and federal regulations; and identifies specific safety measures to be followed during all phases of construction and long-term operation.[2]	X	—	X	X	X	X	X	X	X	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	• Conduct careful surveys of mine sites and prepare written reports and guidance in compliance with applicable state and federal requirements before commencing cleanup actions to identify and characterize safety concerns; potential for erosion during and after cleanup actions; potentially recyclable materials (e.g., sediment/soil for fill, scrap steel, processing equipment, brick, wood, mercury, and gold); and major waste streams for disposal in onsite or offsite landfills.[2]	X	—	—	—	X	X	X	X	X	—
	• Implement dust-suppression and other measures available to prevent risks associated with inhaling dust and exhaust during construction activities.[2]	X	—	X	X	X	X	X	X	X	X
	• Label all hazardous materials onsite to inform users of potential risks and train users in appropriate handling, storage, and disposal procedures.[2]	X	—	X	X	X	X	X	X	X	X
	• Protect sites from unmonitored access with fencing and signs to prevent accidental health hazards to the nearby residents.[2]	X	—	X	—	X	X	X	X	X	X
	• To control vector (e.g., mosquito) production, design projects so they do not increase the area and/or duration of standing water, selectively install systems that are prone to standing water away from high-density areas and away from residential housing, and/or incorporate measures to mitigate vector creation (e.g., install netting over devices and/or employ vector control agencies to mitigate vector production). Design projects to comply with local vector/mosquito control agencies' requirements.[2]	—	—	—	—	X	—	—	—	X	X
	• Adhere to applicable building and safety codes and permits that would ensure construction activities would result in less-than-significant delays in response times for fire and police vehicles.[2]	—	—	X	X	X	X	X	X	—	X
	• Coordinate with local fire and police providers to establish alternative routes and traffic control during the construction activities that could cause traffic congestion or road closures.[2]	—	—	X	X	X	X	X	X	—	X
	• Review California Department of Fire's Fire Hazard Safety Zone maps, contact local fire protection agencies during early phases of project planning and, if possible, select project sites that are not in High or Very High fire severity hazard zones.[2]	—	—	X	—	X	X	X	—	—	X
	• Identify local laws, ordinances, and building codes related to fire prevention, burning, welding, and blasting, etc., to obtain any necessary permits and adhere to permit conditions.[2]	—	—	X	X	X	X	X	X	X	X
	• Maintain an adequate number of fire extinguishers and other tools and equipment that can be used for fighting fire onsite, and ensure that personnel are trained in their use.[2]	—	—	X	—	X	X	X	X	X	X
	• Maintain a water tender during extensive welding/cutting operations.[2]	—	—	X	—	X	X	X	X	X	X
	• Maintain a fire watch during hazardous operations and after the work has ceased for the day.[2]	—	—	X	—	X	—	—	—	—	—
	• Provide funding for an inspector from the local fire agency.[2]	—	—	X	—	X	—	—	—	—	—
	• Provide equipment that gives construction personnel and fire agencies the ability to communicate with one another.[2]	—	—	X	—	X	X	X	X	X	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	• Remove materials that easily ignite or contribute to an increased intensity and spread of fire from high risk areas.[2]	—	—	X	—	X	X	X	X	X	X
	• Prepare and implement an RMP for the use and storage of anhydrous ammonia that meets the requirements of California Health and Safety Code, Division 20, Chapter 6.95, Article 2 and the California Code of Regulation Title 19, Division 2, Chapter 4.5, Articles 1–11. Submit the RPM to the appropriate local or regional agency for review and approval (e.g., San Joaquin County Environmental Compliance Division).[4]	X	—	X	—	X	X	—	X	—	—
	• Identify existing underground utility lines at excavation sites prior to construction, and avoid/relocate underground utility lines in coordination with utility company/service provider; coordinate with natural gas companies and Underground Service Alert before beginning any excavation or other construction activities to ensure that pipelines are not affected.[2,6]	—	—	X	X	X	X	X	X	X	X
	• Prior to construction, perform pre-construction hazardous waste evaluations through record searches and on-site evaluations to potentially identify leaking underground storage tanks, facilities that have received CDOs or CAOs for hazardous materials, or where soil contamination may be suspected (e.g., through soil discoloration or other indicators). If soil contamination is identified, test soil prior to excavation to determine if construction site would be located in area with soil contamination. Areas to be excavated will undergo soil and/or groundwater testing (if groundwater is present in excavated area) at a certified laboratory, provided existing data cannot characterize the nature and concentration of the contamination. Where concentrations exceed applicable federal or state thresholds, contaminated areas will be avoided or soil and/or groundwater will be remediated and contained in compliance with applicable state and federal laws. If hazardous materials are encountered, consultation with DTSC will be required to establish if a permit and subsequent actions are needed to appropriately handle the materials.	X	—	X	X	X	X	X	—	—	—
Hydrology and Water Quality	• Evaluate site-specific tsunami and seiche risks, comply with local building codes that address tsunami and seiche risk, and consult with an engineer to ensure that critical structures are designed to resist strong ground motion, tsunami, and seiche wave impact if appropriate for the project site.[2]	—	—	—	—	X	—	X	X	—	X
	• Elevate and brace any project buildings if buildings are located in areas prone to flooding or tsunamis.[2]	—	—	X	X	X	X	X	X	—	X
	• Position project roads and structures to be perpendicular to potential waves so there is less resistance and erosive force.[2]	—	—	X	—	X	—	—	X	—	—
	• Ensure that project activities do not weaken nearby levees.[2]	—	—	X	X	X	X	X	X	X	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	• Prepare a SWPPP that includes specific types and sources of storm water pollutants, determines the location and nature of potential impacts, and specifies appropriate control measures to eliminate any potentially significant impacts from storm water runoff on receiving waters. The SWPPP will require treatment BMPs that incorporate, at a minimum, the required hydraulic sizing design criteria for volume and flow to treat projected storm water runoff. The SWPPP shall comply with the most current standards established by the regional water quality control board. BMPs shall be selected from the local agency's Storm water Quality Control Standards.[4,6]	X	—	X	X	X	X	X	X	X	X
	• Implement turbidity monitoring during construction/removal.[6]	—	—	X	X	X	X	X	X	X	X
	• Comply with all provisions of the applicable codes for the county or counties in which construction of a septic system is proposed, including the design and installation of septic systems. The design of those systems will be required in accordance with applicable county code to comply with all design requirements, including for factors such as wastewater generation, soil types within the leach field, percolation testing, and slope of the leach field.	—	—	—	—	X	—	—	—	—	—
Land Use	• Comply with adopted plans, policies, and regulations.	X	—	—	X	X	X	X	X	X	X
	• All actions a lead agency determines is a covered action under the Delta Plan will comply with the Delta Plan Mitigation Monitoring and Reporting Program.	—	—	—	X	—	—	X	X	X	X
	• Locate facilities consistent with land use and zoning designations.	—	—	—	X	X	X	X	X	X	X
Mineral Resources	• Design new surface water facilities to avoid displacement of active natural gas wells to the extent feasible.	—	—	—	—	X	—	—	—	—	—
	• Design new surface water facilities to maintain drilling access to natural gas fields to the extent feasible.	—	—	—	—	X	—	—	—	—	—
	• Purchase affected aggregate resource sites.	—	—	—	—	X	—	—	—	—	—
Noise	• Limit construction work to the appropriate windows of construction per the local or regional noise ordinances. Typically construction is limited to 7:00 am–6:00 pm on weekdays and permit no work on Saturdays, Sundays, or holidays unless appropriate city and county building officials grant prior approval.[2, 3]	X	—	X	X	X	X	X	X	X	X
	• Implement noise-reducing construction practices such that noise from construction does not exceed applicable local noise standards or limits specified in the applicable county ordinances and general plan noise elements.[5,6]	X	—	X	X	X	X	X	X	X	X
	• Use noise-generating equipment during periods when fewer people are present near the construction area.[2]	X	—	X	X	X	X	X	X	X	X
	• Muffle or otherwise control all construction equipment with a high noise-generating potential, including all equipment powered by internal combustion engines.[2]	X	—	X	X	X	X	X	X	X	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	• Use newer equipment with improved noise muffling, and ensure that all equipment items have the manufacturers' recommended noise abatement measures, such as mufflers, engine covers, and engine vibration isolators, intact and operational. Newer equipment will generally be quieter in operation than older equipment. All installation equipment should be inspected at periodic intervals to ensure proper maintenance and presence of noise control devices (e.g., mufflers and shrouding).[3]	X	—	X	X	X	X	X	X	X	X
	• Shroud or shield all impact tools.[2]	X	—	X	X	X	X	X	X	X	X
	• Locate all stationary noise-generating equipment, such as compressors, as far as possible from adjacent occupied offices, residents, or sensitive habitats (if they are adjacent to the project site).[2]	X	—	X	X	X	X	X	X	X	X
	• Turn off mobile equipment and machinery when not in use to reduce noise from idling equipment.[2]	X	—	X	X	X	X	X	X	X	X
	• Use temporary noise barriers or curtains along installation boundaries or partial enclosures around continuously operating equipment.[2]	X	—	X	X	X	X	X	X	X	X
	• Use the shortest possible routes from construction sites to local freeways for truck delivery routes, except when selecting routes to avoid going through residential neighborhoods.[2]	X	—	X	X	X	X	X	X	X	X
	• Establish an active community liaison program that notifies landowners within 300 ft of construction areas of the construction schedule, in writing, prior to construction to keep them informed of schedule changes, and designate a “disturbance coordinator” for the construction site.[2]	X	—	X	X	X	X	X	X	X	X
	• Develop an operations plan for specific construction activities that documents maximum noise limits and addresses the variety of available measures to limit the impacts from noise on adjacent homes, businesses, or sensitive habitats.[2]	X	—	X	X	X	X	X	X	X	X
	• Regularly inspect equipment and monitor noise and vibration to ensure that all equipment on the site is in good condition and effectively muffled and that contractors take all reasonable steps to minimize impacts, particularly when near sensitive areas.[2, 3]	X	—	X	X	X	X	X	X	X	X
	• Monitor construction noise and vibrations and modify and/or reschedule construction activities if monitoring determines that maximum limits set by local or regional noise ordinances are exceeded.[2,3]	X	—	X	X	X	X	X	X	X	X
Population and Housing	• Planned growth would be subject to growth management provisions of applicable general plans.	—	—	—	X	X	—	—	—	—	—
Public Services	• Notify local emergency and police service providers of construction activities and road closures, if any, and coordinate with the local police protection to establish alternative routes and traffic control during the installation activities.[3]	—	—	X	X	X	X	X	X	—	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
Transportation and Traffic	• Use signage, striping, fencing, barricades, and other physical structures to mark the excavated areas, promote safety, and minimize pedestrian/bicyclist accidents.[2]	X	—	X	X	X	X	X	X	—	X
	• Control traffic with signals or traffic control personnel in compliance with authorized local police or California Highway Patrol requirements.[2]	X	—	X	X	X	X	X	X	—	X
	• Develop and implement a project-specific construction traffic management plan to minimize traffic impacts on the local circulation system and ensure that construction activities adhere to local and state police and transportation requirements. A construction traffic management plan could address traffic control for any street closure, detour, or other disruption to traffic circulation; identify the routes that construction vehicles will use to access the site, hours of construction traffic, and traffic controls and detours; and include strategies for temporary traffic control, temporary signage and tripping, location points for ingestion and egress of construction vehicles, staging areas, and timing of construction activity that appropriately limits hours during which large construction equipment may be brought on or offsite and identify the need for and use of signage, striping, fencing, barricades, and other physical structures to mark minimize pedestrian/bicyclist accidents and identify public transit closures, or relocations, if needed.[2]	X	—	X	X	X	X	X	X	—	X
	• Restore public transit facilities, bicycle lanes, or pedestrian facilities (e.g., sidewalks) if closed, damaged or moved during construction, prior to the completion of construction of the entire project.	X	—	X	X	X	X	X	X	—	X
	• Limit or restrict hours of construction so as to avoid peak traffic times.[2]	X	—	X	X	X	X	X	X	—	X
Utilities and Service Systems	• Coordinate power outages and notify potentially affected utility users of temporary loss of electricity.[6]	—	—	X	X	X	X	X	X	—	X
	• Existing underground utility lines at excavation sites will be identified prior to construction and underground utility lines will be avoided or relocated in coordination with the utility company or service provider.[6]	—	—	X	X	X	X	X	X	—	X
	• Comply with all provisions of the applicable codes for the county or counties in which construction of a septic system is proposed, including the design and installation of septic systems. The design of those systems will be required in accordance with applicable county code to comply with all design requirements, including for factors such as wastewater generation, soil types within the leach field, percolation testing, and slope of the leach field.	—	—	—	—	X	—	—	—	—	—

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
Operation											
Aesthetics	• Direct operational lighting away from any residential and roadway areas.[2]	X	—	—	X	X	X	X	X	—	X
	• Develop and implement a lighting plan to comply with local jurisdiction lighting requirements that may exist. The lighting plan could include stipulations such as the following. ○ Design site lighting and exterior building light fixtures to reduce the effects of light pollution and glare off of glass and metal surfaces. ○ Lighting shall be directed downward and light fixtures shall be shielded to reduce upward and spillover lighting. ○ Where it is not feasible to fully shield light fixtures from emitting light pollution, the lighting shall be directed downward and be of the minimum wattage and height suitable for illuminating the areas to be secured and the exterior work areas for worker safety.[4]	X	—	—	X	X	X	X	X	—	X
	• Apply minimum lighting standards. [6]	—	—	—	X	X	X	X	X	—	X
	• Use landscape vegetation to buffer views of new facilities if sensitive receptors are present and reduce visibility of new structures.[2,6]	X	—	X	X	X	X	X	X	—	X
	• Use building materials that do not create a source of glare if sensitive receptors are present.[2,6]	X	—	X	X	X	X	X	X	—	X
Agriculture and Forestry Resources	• Treat used municipal water and return it to the senior water right holder as recycled water for agricultural uses.	—	—	—	—	X	—	—	—	—	—
Air Quality	• Apply appropriate mitigation measures from the applicable air district to reduce operational emissions. These measures are suggested by the district or are documented in official rules and guidance reports; however, not all districts make recommendations for operational mitigation measures. Where applicable, measures will be applied on a project-level basis and may be tailored in consultation with the appropriate air district, depending on the severity of anticipated operational emissions.[5]	—	—	X	X	X	X	X	X	—	X
	• Apply appropriate TAC and HAP mitigation measures from the applicable air district to reduce public exposure to DPM, pesticides, and asbestos. These measures are suggested by the district or are documented in official rules and guidance reports; however, not all districts make recommendations for mitigation measures for TAC/HAP emissions. These measures will be applied on a project-level basis and may be tailored in consultation with the appropriate air district, depending on the severity of anticipated TAC/HAP emissions.[5]	—	—	X	X	X	X	X	X	—	X
	• Perform necessary equipment maintenance, such as inspections and corrections, to detect failures early so that the equipment operates cleanly and efficiently.[2]	X	—	X	—	X	X	X	X	—	—
	• Use maintenance vehicles with zero-emission or lower-emission engines.[2]	—	—	X	—	X	X	X	X	—	—

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	• Limit the unnecessary idling of delivery vehicles and equipment.[2]	—	—	X	—	X	X	X	X	—	—
	• Use low/zero carbon fuels, such as B20 biodiesel or renewable diesel.[2]	—	—	X	—	X	X	X	X	—	—
	• Install diesel particulate filter and utilize diesel oxidation catalyst.[6]	—	—	—	—	X	—	—	—	—	X
	• Require the pump system be electric or alternatively fueled.[6]	—	—	—	—	X	—	—	—	—	X
Biological Resources	• During maintenance activities, properly contain or remove all trash that may attract predators to the worksite. [2]	—	—	X	X	X	X	—	—	—	X
Geology and Soils	• Comply with all provisions of the applicable codes for the county or counties in which operation of a septic system is proposed, including the design and installation of septic systems. The design of those systems will be required in accordance with applicable county code to comply with all design requirements, including for factors such as wastewater generation, soil types within the leach field, percolation testing, and slope of the leach field.	—	—	—	—	X	—	—	—	—	—
Greenhouse Gas Emissions	• See measures in Air Quality, above.	X	—	X	X	X	X	X	X	—	X
	• Perform necessary equipment maintenance, such as inspections and corrections, to detect failures early so that the equipment operates cleanly and efficiently.[2]	X	—	X	X	X	X	X	X	—	X
	• Implement water recycling practices or policies.[2]	—	—	X	—	X	—	—	X	—	—
	• The California Attorney General's office report entitled, *Addressing Global Warming at the Local Agency Level*, identifies various example measures to reduce GHG emissions at the project level (California Department of Justice 2008). The following mitigation measures and project design features were compiled from the California Attorney General's Office report. These measures are not meant to be exhaustive but to provide a sample list of measures that could be incorporated into future project design. The solid waste measures and transportation measures are listed below. ○ Reuse and recycle construction and demolition waste (including, but not limited to, soil, vegetation, concrete, lumber, metal, and cardboard). ○ Provide interior and exterior storage areas for recyclables and green waste and adequate recycling containers. ○ Recover byproduct methane to generate electricity. ○ Limit idling time for commercial vehicles, including delivery and construction vehicles. ○ Use low- or zero-emission vehicles, including construction vehicles.[5]	—	—	X	X	X	X	X	X	—	X
	• Require pump system to be electric.[6]	X	—	—	—	X	—	—	—	—	X

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
Hazards and Hazardous Materials	• Provide hazardous materials and worksite safety training for workers who maintain the projects in accordance with local, state, and federal requirements, such as the Occupational Safety and Health Act, Title 9 of the Code of Federal Regulations, and Title 8 of the California Code of Regulations.[2]	X	—	X	—	X	—	X	X	—	—
	• Provide hazardous materials accidental spill response plans (and/or Hazardous Materials Management Program) and training that would outline methods, materials, and responsibilities for the response to, and clean-up of, an accidental hazardous material spill during long-term maintenance of the project. At a minimum, the plans should include provisions for immediate response, containment, and cleanup of a spill, including excavation and disposal of contaminated soil and notification responsibilities. Materials needed for potential clean-up activities should be kept onsite.[2,6]	X	—	X	X	X	—	X	X	—	X
	• Provide a health and safety plan for maintenance workers that is prepared by a certified industrial hygienist; complies with all appropriate local, state, and federal regulations; and identifies specific safety measures to be followed during long-term operation.[2]	X	—	X	X	X	—	X	X	—	X
	• Label all hazardous materials onsite to inform users of potential risks, and train users in appropriate handling, storage, and disposal procedures.[2]	X	—	X	X	X	—	X	X	—	X
	• Maintain an adequate number of fire extinguishers and other tools and equipment that can be used for fighting fire onsite, and ensure that personnel are trained in their use.[2]	X	—	X	X	X	—	X	X	—	X
	• Provide equipment that provides operations personnel and fire agencies the ability to communicate with one another.[2]	X	—	X	X	X	—	X	X	—	X
	• Maintain a defensible space around the perimeter of the project area.[2]	—	—	X	X	X	—	X	X	—	X
	• Implement dust-suppression and other measures available to prevent risks associated with inhaling dust and exhaust during maintenance activities.[2]	X	—	X	—	X	—	—	X	—	—
	• Dewater and dispose of waste brine at an appropriate landfill. If suitable, and depending on the volumes and characterization of the brine, use the brine byproduct in a solar-thermal electrical generation process to help offset electrical costs to run a desalination device.	—	—	—	—	X	—	X	X	—	—
Hydrology and Water Quality	• Actively educate project personnel about tsunami and seiche hazards, characteristics, and evacuation routes as part of site safety training.[2]	—	—	—	—	X	—	—	—	—	—
	• Develop multiple ways to receive tsunami and seiche warnings and alert site personnel.[2]	—	—	—	—	X	—	—	—	—	—
	• Develop a formal tsunami hazard plan as part of the project's site safety plan, and conduct emergency exercises.[2]	—	—	—	—	X	—	—	—	—	—

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	• Comply with all provisions of the applicable codes for the county or counties in which operation of a septic system is proposed, including the design and installation of septic systems. The design of those systems will be required in accordance with applicable county code to comply with all design requirements, including for factors such as wastewater generation, soil types within the leach field, percolation testing, and slope of the leach field.	—	—	—	—	X	—	—	—	—	—
Noise	• Employ noise-reducing operational measures; develop plans for operations and maintenance activities to address the variety of available measures to limit the impacts from noise on adjacent homes, businesses, or sensitive habitats.[2, 6]	X	—	X	—	X	X	—	X	—	X
	• Ensure all noise producing equipment under operating conditions (e.g., pumps) are enclosed or located behind barriers such that noise does not exceed applicable local noise standards or limits specified in the applicable county ordinances and general plan noise elements if sensitive receptors are present.[5]	X	—	X	X	X	X	—	X	—	X
Public Services	• Coordinate reservoir and associated recreational plans with local towns, counties, Sheriff's Department, Highway Patrol, CALFIRE, and other agencies to identify needed permit and regulatory oversight, police and fire protection and other public services for both construction and operations.	—	—	—	—	X	—	—	—	—	—
	• Coordinate reservoir development and operation plans (including associated recreation sites) with local, county, and state agencies to identify funding sources needed for increased personnel, equipment, and facilities.	—	—	—	—	X	—	—	—	—	—
Transportation and Traffic	• Follow SJCOG Regional Congestion Management Program (RCMP) policy regarding mitigation measures for capital improvement projects, which includes: mitigation measures must be adequate to allow RCMP roadway to meet RCMP LOS Standard; mitigation measures must be fully funded to be considered adequate; mitigation measures that rely on state or federal funds directed by or influenced by SJCOG must be consistent with project funding priorities established in the capital improvement plan of the RCMP and RTP or Federal TIP; and, for those mitigation measures that involve fair share contributing for mitigating cumulative impacts, the fee must be committed to funding priorities established in the capital improvement plan of the RCM, the RTP, or the Federal TIP.[8]	—	—	—	—	—	X	X	X	—	—
	• Prepare cumulative impacts on the RCMP network and reflect the most recently approved development projects from the lead agency as well as from adjacent jurisdictions (including currently programmed infrastructure improvements). [8]	—	—	—	—	—	X	X	X	X	—
	• If an RCMP intersection is projected to operate at LOS E or F after trip exemptions have been accounted for, the affected jurisdiction can choose to proactively prepare a deficiency plan in lieu of waiting for the facility to possibly fail after the development is implemented.[8]	—	—	—	—	—	X	X	X	X	—

Resource	Potential Mitigation Measure	Substituting Surface Water with Groundwater	Aquifer Storage and Recovery	Recycled Water Sources	In-Delta Diversion	New Surface Water Storage	New Source Water Supplies	Salinity Pretreatment Programs	Wastewater Treatment Plant Desalinization	Agricultural Return Flow Salinity Control	Low Lift Pump Station(s)
	• Follow the SJCOG RCMP specific mitigation fee program relative to cumulative regional impacts, if applicable, and track actual funding/implementation.[8]	—	—	—	—	—	X	X	X	X	—
Utilities and Service Systems	• Comply with all provisions of the applicable codes for the county or counties in which operation of a septic system is proposed, including the design and installation of septic systems. The design of those systems will be required in accordance with applicable county code to comply with all design requirements, including for factors such as wastewater generation, soil types within the leach field, percolation testing, and slope of the leach field.	—	—	—	—	X	—	—	—	—	—

Notes:

[a] Until such time that these potential mitigation measures are implemented, the impacts would remain significant and unavoidable, consistent with State CEQA Guidelines Section 15091. However, it is likely that impacts would be mitigated to less than significant once mitigation measures were implemented.

[b] Potential mitigation measures for conflicts with habitat conservation plans, natural community conservation plans, or other plans, policies, and regulations protecting biological species and resources that maybe attributable to land use and planning are presented in the Biological Resources sections in this table.

This page intentionally left blank.

16.6.2 Non-Flow Measures

The regulated public agencies would likely be required to comply with CEQA and perform a project-specific analysis, and engineering design should they determine the need, to approve a discretionary action associated with a non-flow measure. The project-specific analysis would be required to identify potentially significant environmental impacts. The lead agency would be required to require the implementation of all feasible mitigation measures to reduce impacts to less than significant or be responsible for providing a statement of overriding considerations for significant impacts that cannot be mitigated to a level of less than significant. Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures*, identifies the potential mitigation measures that the regulated community could implement should they determine a discretionary action they approve has significant impacts. These mitigation measures are based, in part, on mitigation measures presented in the following documents.

- *Proposed Amendment to the Water Quality Control Plan for the North Coast Region to Establish Exception Criteria to Point Source Waste Discharge Prohibition by Raising the Action Plan for Storm Water Discharges and Adding a New Action Plan for Low Threat Discharges* (North Coast Regional Water Quality Control Board 2009).
- *Amendments to the Water Quality Control Plan for the Sacramento River and San Joaquin River Basins for the Control of Methylmercury and Total Mercury in the Sacramento and San Joaquin Delta Estuary* (Central Valley Water Board 2010a).
- *Substitute Environmental Document for Toxic Pollutants in the Dominguez Chanel and Greater Los Angeles and Long Beach Waters Total Maximum Daily Load* (California Regional Water Quality Control Board, Los Angeles Region 2011).
- *Initial Study and Mitigated Negative Declaration for the Tracy Desalination and Green Energy Project* (City of Tracy 2011).
- *Irrigated Lands Regulatory Program Environmental Impact Report* (Central Valley Water Board 2010b).
- Low Head Pump Salinity Control Study Prepared to Meet Requirements of the State of California State Water Resources Control Board Water Rights Order WR 2010-0002, Condition A.7. Appendix C: Environmental Considerations for South Delta Low Head Pump Station (DWR 2011c).
- *Water Supply Options* (SFPUC 2007).
- *Biological Opinion for the 2014 Georgiana Slough Floating Fish Guidance Structure Study in Sacramento County* (NMFS 2014b).
- *Battle Creek Salmon and Steelhead Restoration Project. Environmental Implementation Plan* (ICF Jones & Stokes 2013).
- *Bay Delta Conservation Plan. Public Draft* (DWR 2013c).

An SED must identify feasible mitigation measures for each significant environmental impact identified in the SED. (Cal. Code Regs., tit. 23, § 3777, subd. (b)(d).) Feasible mitigation measures are intended to avoid, reduce, or compensate for adverse impacts on a resource and can include actions such as implementation of plans to minimize impacts. For each impact identified as significant, a mitigation measure to reduce that impact to a less-than-significant level is described, if appropriate, or the infeasibility of mitigation is discussed. One legal factor that may render a mitigation measure infeasible is the limited authority of the lead agency. CEQA does not grant agencies new, discretionary powers independent of the powers granted to the agencies by other laws. (Pub. Resources Code, § 21004; Cal. Code Regs., tit. 14, § 15040.) Accordingly, a mitigation measure may be legally infeasible if the lead agency does not have the discretionary authority to implement it. In addition, economic considerations may render mitigation measures infeasible. (Pub. Resources Code, § 21004; Cal. Code Regs., tit. 14, §§ 15040, 15041, 15126.4, 15364.) The authority to require project-level mitigation lies with the lead agencies undertaking or approving the individual projects, not the State Water Board. These agencies can and should impose the mitigation measures presented in Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures*.

Table 16-39. Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures[a]

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
Construction									
Aesthetics	• Direct construction lighting away from residential and roadway areas if sensitive receptors are present.[2]	—	—	—	X	—	X	—	—
Agriculture and Forestry Resources	• Require payment of the appropriate Agricultural Mitigation Fee, as required by local agencies consistent with applicable law, to offset the loss of Prime and Unique Farmland if construction activities disturb or destroy Prime Farmland or Unique Farmland, as defined by the California Department of Conservation.[4]	X	—	—	—	—	—	—	—
	• Avoid agricultural lands (Prime Farmland, Unique Farmland, and Farmland of Statewide Importance) to the greatest extent possible.[6]	X	—	—	—	—	—	—	—
	• Restore existing degraded habitat as a priority before converting agricultural land (Prime Farmland, Unique Farmland, and Farmland of Statewide Importance). [10]	X	—	—	—	—	—	—	—
	• Site and align project features to avoid or minimize impacts on agriculture, particularly on Prime Farmland, Unique Farmland, and Farmland of Statewide Importance. [10]	X	—	—	—	—	—	—	—
	• Focus habitat restoration efforts on developing new habitat on public lands before converting agricultural land (Prime Farmland, Unique Farmland, and Farmland of Statewide Importance). [10]	X	—	—	—	—	—	—	—
	• If public lands are not available for restoration efforts, focus restoration efforts on acquiring lands that can meet ecosystem restoration goals from willing sellers where at least part of the reason to sell is an economic hardship (for example, lands that flood frequently or where levees are too expensive to maintain). [10]	X	—	—	—	—	—	—	—
	• Use farmer-initiated and developed restoration and conservation projects as a means of reaching project goals. [10]	X	—	—	—	—	—	—	—
	• Obtain easements on existing agricultural land for minor changes in agricultural practices (such as flooding rice fields after harvest) that would increase the value of the agricultural crop(s) to wildlife. [10]	X	—	—	—	—	—	—	—
	• Include provisions in floodplain restoration efforts for compatible agricultural practices. [10]	X	—	—	—	—	—	—	—
	• Use a planned or phased habitat development approach in concert with adaptive management. [10]	X	—	—	—	—	—	—	—
	• Minimize the amount of water supply required to sustain habitat restoration acreage. [10]	X	—	—	—	—	—	—	—
	• Implement features that are consistent with local and regional land use plans. [10]	X	—	—	—	—	—	—	—
	• Involve all affected parties, especially landowners and local communities, in developing appropriate configurations to achieve the optimal balance between resource impacts and benefits. [10]	X	—	—	—	—	—	—	—

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
Air Quality	• Apply appropriate construction mitigation measures from the applicable air district (e.g., SJVAPCD) to reduce construction emissions. These measures will be applied on a project-level basis and may be tailored in consultation with the appropriate air district, depending on the severity of anticipated construction emissions.[5]	X	X	X	X	X	X	X	X
	• Apply appropriate TAC and HAP mitigation measures from the applicable air district to reduce public exposure to DPM pesticides, and asbestos. These measures are documented in official rules and guidance reports; however, not all districts make recommendations for mitigation measures for TAC/HAP emissions. These measures will be applied on a project-level basis and may be tailored in consultation with the appropriate air district, depending on the severity of anticipated TAC/HAP emissions.[5]	X	X	X	X	X	X	X	X
	• Use vehicles with zero-emission or lower-emission engines.[2]	X	X	X	X	X	X	X	X
	• Limit the unnecessary idling of vehicles and equipment.[2]	X	X	X	X	X	X	X	X
	• Use low/zero carbon/alternative fuels, such as B20 biodiesel or renewable diesel.[2]	X	X	X	X	X	X	X	X
	• Control visible emissions from off-road diesel powered equipment.[2]	X	X	X	X	X	X	X	X
	• Design structural devices to minimize the frequency of maintenance trips.[2]	X	X	X	X	X	X	X	X
	• Perform necessary equipment maintenance, such as inspections and corrections, to detect failures early keep equipment operating cleanly and efficiently.[2]	X	X	X	X	X	X	X	X
	• Use the proper sized equipment for the job during construction and operation.[2]	X	X	X	X	X	X	X	X
	• Train equipment operators in proper use of equipment during construction and operation.[2]	X	X	X	X	X	X	X	X
	• Produce concrete onsite if determined to be less emissive than transporting ready mix.[2]	—	—	—	X	X	X	—	—
	• Use locally sourced or recycled materials for construction materials.[2]	—	—	—	X	X	X	—	—
	• Control fugitive dust emissions during land clearing, grubbing, scraping, excavation, leveling, grading, or cut and fill operations with application of water (at least twice daily) or by presoaking.[2,4]	X	X	X	X	X	X	X	X
	• Cover stockpiles of soil, sand, and other materials, and stabilize all disturbed areas and storage piles that are not being actively utilized for construction purposes using water, chemical stabilizers, or by covering with tarps, other suitable cover, or vegetative ground cover.[2,4]	X	X	X	X	X	X	X	X
	• Pave, apply water, or apply soil stabilizers to unpaved areas, including all access roads and parking areas.[2,4]	X	X	X	X	X	X	X	X
	• Sweep surrounding streets and paved areas (e.g., once per day).[2]	X	X	X	X	X	X	X	X
	• Suspend excavation and grading activity when winds (instantaneous gusts) exceed 25 miles per hour and/or greater than 20 miles per hour over a 1-hour period.[2,4]	X	X	X	X	X	X	X	X
	• Initiate landscaping and revegetation as soon as construction tasks allow in order to minimize wind erosion.[2]	X	X	X	X	X	X	X	—
	• Encourage ride sharing and of use transit transportation for construction employees commuting to the project site.[4]	X	X	X	X	X	X	X	X

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
	• Use electric equipment for construction whenever possible in lieu of fossil fuel-powered equipment.[4]	X	X	X	X	X	X	X	X
	• Discontinue all construction activities during first stage smog alerts, first stage ozone alerts, and/or curtail construction during periods of high ambient pollutant concentrations.[4]	X	X	X	X	X	X	X	X
	• Water previously disturbed exposed surfaces (soil) a minimum of 3 times per day or whenever visible dust is capable of drifting from the site or approaches 20 percent opacity.[4]	X	X	X	X	X	X	X	X
	• Water all haul roads (unpaved) a minimum of 3 times per day or whenever visible dust is capable of drifting from the site or approaches 20 percent opacity.[4]	X	X	X	X	X	X	X	X
	• Reduce speed on unpaved roads to less than 15 miles per hour.[4]	X	X	X	X	X	X	X	X
	• Install and maintain a trackout control device that meets the specifications of regional air board requirements if needed (e.g., SJVAPCD Rule 8041 if the site exceeds 150 vehicle trips per day or more than 20 vehicle trips per day by vehicles with three or more axles.[4]	X	X	X	X	X	X	X	X
	• Cover trucks hauling debris, soil, sand, or other material to reduce dust and suspended air particles, and when transporting materials offsite, maintain a freeboard limit of at least 6 inches or effectively wet to limit visible dust emissions.[4,2]	X	X	X	X	X	X	X	X
	• Limit and remove the accumulation of mud and/or dirt from adjacent public roadways at the end of each workday.[4]	X	X	X	X	X	X	X	X
	• Remove visible trackout from the site at the end of each workday.[4]	X	X	X	X	X	X	X	X
	• Comply with applicable regional air board asphalt-concrete paving rules such as SJVAPCD Rule 4641 (e.g., restrict use of cutback, slow-sure, and emulsified asphalt paving materials).[4]	X	X	X	X	X	X	X	X
	• Install diesel particulate filter and utilize diesel oxidation catalyst.[6]	X	X	X	X	X	X	X	X
	• Require the pump system be electric or alternatively fueled.[6]			X		X	X	X	
	• Locate pump system/emissions generating activity as far from sensitive receptors as possible.[6]	X	X	X	X	X	X	X	X
Biological Resources[b]	• Prior to land disturbance, contact USFWS and CDFW and conduct all necessary preconstruction surveys for special-status plants, species, and habitat prior to construction activities. This may include the hiring of a qualified biologist to identify riparian and other sensitive vegetation communities and/or habitat for special-status plants and animals.[1, 5,6]	X	X	X	X	X	X	X	X

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
	• Comply with local, state, and federal regulations and ordinances such as those listed below. ○ USFWS ESA Section 7 consultation for threatened and endangered species.[2] ○ U.S. Army Corps of Engineers Section Clean Water Act 404 Permit and State Clean Water Act Section 401 Water Quality Certification for filling or dredging waters of the United States and other federal permitting actions.[2, 5] ○ CDFW California Fish and Game Code Section 1601 Agreement for Streambed Alteration.[2] ○ State Water Board WDRs (which are also permits for purposes of the Clean Water Act, if applicable).[2] ○ General plan conservation requirements.[2]	X	X	X	X	X	X	X	X
	City and/or county tree ordinances.[2] • Contract with qualified botanists, wildlife biologists, and arborists to develop biological assessments if a project's specific location warrants doing so. At a minimum, assessments should include project area-specific literature searches, reviews of CDFW's California Natural Diversity Database and the California Native Plant Society's Inventory of Rare and Endangered Plants of California, and field surveys of all potential project sites and their surrounding areas to identify and map existing plant communities, wildlife habitat, and heritage trees, and to identify wildlife species that currently occur, have occurred in the past (e.g., resident and migratory wildlife species that have been documented as foraging or nesting at the site), or have the potential to occur at the site due to the presence of suitable habitat. Field surveys should follow protocols established by CDFW and should be conducted during the appropriate time(s) of year (e.g., during the blooming period of potentially occurring plant species).[2,5]	X	X	X	X	X	X	X	X
	• Avoid and minimize disturbance of riparian and other sensitive vegetation communities.[5]	X	X	X	X	X	X	X	X
	• Avoid and minimize disturbance of areas containing special-status plant or animal species.[5]	X	X	X	X	X	X	X	X
	• Where adverse effects on sensitive biological resources (including fish species) cannot be avoided, undertake additional CEQA review and develop a restoration or compensation plan to mitigate the loss of the resources.[5]	X	X	X	X	X	X	X	X
	• Where construction in areas that may contain special-status fish species cannot be avoided through the use of alternative management practices, conduct an assessment of habitat conditions and the potential for presence of special-status fish species prior to construction; this may include the hiring of a qualified fish biologist to determine the presence of special-status fish species.[5]	X	X	X	X	X	X	X	X
	• Based on the species present in adjacent waterbodies and the likely extent of construction work that may affect fish, limit construction to periods that avoid or minimize impacts on special-status fish species.[5]	X	X	X	X	X	X	X	X

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
	• If there is a possibility of fish stranding within cofferdams, a fish rescue plan will be written and submitted to the appropriate resource agencies (NMFS, CDFW). Some of the following actions may be included:[9] ○ Fish rescue operations will occur at any project site where dewatering and resulting isolation of fish may occur, e.g., when dewatering creates pools within the stream channel or when an enclosed area within a cofferdam is dewatered. ○ Collection of fish for rescue from areas isolated by dewatering may occur by electrofishing, netting (seining or dipnetting), or a combination of these. The appropriate collection method will be determined based on site conditions. ○ The fish rescue team will include at least one person with a 4-year college degree in fisheries or biology, or a related degree. The person also must have at least 2 years of professional experience in fisheries field surveys and the use of electrofishing equipment. ○ Transfer captured fish into 5-gallon buckets filled with clean, cold creek water, supplied either with an aerator to maintain an adequate dissolved oxygen concentration or multiple small holes to provide flow-through conditions when placed on the creek bed. ○ Note the date, time, and location of collection; species; number of fish; approximate age (e.g., young-of-the-year, yearling, adult); fish condition (dead, visibly injured, healthy); approximate water depth; and water temperature. ○ Release living anadromous salmonids downstream of the project area if it is determined that they are downstream migrants, noting release date, time, and location. ○ Place dead fish in sealed zip-lock bags on ice with labels indicating species, location, date, and time of collection, and store them on ice. ○ Freeze collected dead fish as soon as possible, provide the frozen specimens to the USFWS Office for tissue analysis and run determination (if possible), and retain specimens until NMFS advises on their disposition or until 6 months after capture.	—	—	X	—	X	X	—	—
	• Develop a mitigation and management plan in coordination with CDFW and USFWS to implement all appropriate measures as required by USFWS ESA Section 7 consultation and to satisfy any other local, state, and federal requirements for achieving no net loss of wetlands, riparian habitat or other critical habitat, or take of wildlife species of concern. The plan should be submitted to the local city/county environmental planning department, U.S. Army Corps of Engineers, USFWS, CDFW, applicable regional board (e.g., as part of a Clean Water Act Section 401 Water Quality Certification application), and/or other oversight agencies as applicable for approval prior to its implementation if an impact on special-status species population(s) is determined to occur based on the biological assessment and evaluation of the final project site and design.[2]	X	X	X	X	X	X	X	X

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
	• Develop a revegetation plan if vegetation would be disturbed during construction or operation. The re-vegetation plan should be prepared by a qualified restoration ecologist and reviewed by the appropriate agencies. The plan should specify sites where revegetation should take place, the planting stock appropriate for the region, appropriate designs (e.g., plant arrangements that, when mature, replicate the natural structure and species composition of similar habitats in the region), planting techniques, monitoring frequency, and success criteria (e.g., sapling trees no longer require active management).[2]	X	X	X	X	X	X	X	X
	• Establish temporary construction buffers for drainages, wetlands/vernal pools, and other sensitive habitat in the project area that could be affected by construction activities. The outer edges of the buffer zones will be demarcated using flagging or temporary orange mesh construction fencing before initiation of construction activities and based on site-specific conditions, seasonal restrictions for wildlife, local planning department specifications, and resource agency (e.g., USFWS and CDFW) requirements.[2,6]	X	X	X	X	X	X	X	X
	• Require a qualified biologist to perform the following construction functions if sensitive habitat or species are present. ○ Perform required preconstruction surveys to determine the current presence of, and demarcate the boundaries of construction buffers around, sensitive habitats, and submit survey reports according to CDFW and local agency guidelines for approval prior to construction.[1,2,5,6] ○ Provide USFWS-approved worker environmental awareness training that informs all construction personnel about sensitive plant and wildlife species and habitats.[2] ○ Oversee major excavation and other construction activities with the authority to stop construction activities until appropriate corrective measures have been completed.[2] ○ Report to USFWS any incidental take.[2] ○ Periodically re-inspect the project site (e.g., every week) during construction activities or whenever a there has been a substantial lapse in construction activity (e.g., more than 2 weeks).[2]	X	X	X	X	X	X	X	X
	• Locate temporary access roads and staging areas outside the boundaries of critical habitat areas, restrict movement of heavy equipment to and from the project site to established roadways and areas designated for construction and staging, and do not allow parking of vehicles or storage of potentially-toxic chemicals near or up-gradient of drainages or sensitive habitats or under heritage trees.[2]	X	X	X	X	X	X	X	X
	• Implement measures to control dust, erosion, and noise (see the Air Quality, and Geology and Soils, respectively).[2]	X	X	X	X	X	X	X	X
	• Properly contain or remove all trash that may attract predators to the worksite during construction.[2]	X	X	X	X	X	X	X	X
	• Remove any temporary fill and construction debris and, wherever feasible, restore disturbed areas to pre-project conditions according to the before-mentioned revegetation plan after completion of construction activities.[2]	X	X	X	X	X	X	X	X

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
	• Provide compensation for unavoidable degradation or loss of critical habitat due to project construction to ensure no net loss of that habitat as required by local, state, or federal agencies. Compensation could be provided at a minimum ratio (e.g., 3:1, 3 acres of restored wetlands for every 1 acre affected, or three native oak trees planted for every native oak tree eliminated) that ensures long-term replacement of habitat functions and values and complies with local, state, and federal requirements. Examples of compensation are as follows. ○ Construct replacement habitat as close as possible to the previous habitat location at the project site (e.g., locate replacement riparian and wetland habitats along the same drainage affected by the project construction). ○ If site limitations prevent onsite habitat replacement, construct replacement habitat as near the project site as possible.	X	X	X	X	X	X	X	X
	• Provide payment on a per-acre basis to an approved restoration or mitigation bank or other trust fund.[2]	X	X	X	X	X	X	X	X
	• Comply with measures contained within habitat conservation plans or natural community conservation plans, such as the San Joaquin Multi-Species Habitat Conservation and Open Space Plan. Consult with appropriate biologists who have training and are knowledgeable about the habitat conservation plan or natural community conservation plan. Monitoring, construction, and relocation surveys by a qualified biologist would be done as appropriate.[4]	X	X	X	X	X	X	X	X
	• Prior to implementing any management practice that would result in the permanent loss of wetlands, conduct a delineation of affected wetland areas to determine the acreage of loss in accordance with current U.S. Army Corps of Engineers methods. For compliance with the Clean Water Act Section 404 permit and WDRs, compensate for the permanent loss (fill) of wetlands and ensure no net loss of habitat functions and values. Compensation ratios will be determined through coordination with the Central Valley Water Board and U.S. Army Corps of Engineers as part of the permitting process. Compensation may be a combination of mitigation bank credits and restoration/creation of habitat, as described below. ○ Purchase credits for the affected wetland type (e.g., perennial marsh, seasonal wetland) at a locally approved mitigation bank and provide written evidence to the resource agencies that compensation has been established through the purchase of mitigation credits. ○ Develop and ensure implementation of a wetland restoration plan that involves creating or enhancing the affected wetland type.[5]	X	X	X	X	X	X	X	X
	• Install species exclusion fencing for animal species during construction; install a temporary, plastic mesh-type construction fences at least 1.2 m tall around any established special-status plant species buffer areas to prevent encroachment by construction vehicles and personnel; a qualified biologist will determine the exact location of the fencing.[6]	X	X	X	X	X	X	X	X
	• Conduct pile driving with vibratory hammer.[6]	—	—	—	X	X	X	X	—

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
	• Monitor underwater sound generated by impact and vibratory hammers during pile installation. Monitoring shall be conducted to verify that sound level criteria are not being exceeded as calculated in the project description. If levels are exceeded, NMFS shall be notified and work halted until corrective actions are instituted to achieve sound level criteria.	—	—	—	X	X	X	X	—
	• Implement turbidity monitoring during construction/removal.[6]	X	X	X	X	X	X	—	X
	• Mitigation Measures for Hook and Line Sampling: ○ Implement environmental awareness program for construction personnel.[6] ○ Implement measures to decrease injury/mortality for predatory fish control hook and line sampling:[8] ○ Do not use soft lures or live bait. ○ For bait fishing, a circle hook will be used to minimize potential for injury, but may be barbed. ○ All listed fish (salmonids, green sturgeon) will be handled as little as possible. Remove hook from the captured fish while the fish is still in the water and release the fish as soon as possible with the minimal amount of handling required to complete the release. ○ If any deviation from this protocol occurs, the methods used to unhook the fish and release it and the reasons for the deviation from the protocol will be documented. These methods may include but are not limited to: – Cutting the fishing line outside of the mouth of deeply-hooked fish and allowing the hook to remain in the fish. A deeply-hooked fish is more likely to occur with bait and when the presentation of the bait is on a “slack line” technique rather than fished on a “tight” line technique. This reduces collateral injury and excessive bleeding of the fish through attempting to remove a deeply embedded hook. Retained hooks will eventually dissolve or will naturally be expelled from these fish. – Gently holding fish for extended periods of time in the water to ensure resuscitation and recovery by providing water flow through their mouth and gills. Fish are retained until they regain normal ventilatory movement of their gills and re-establish their equilibrium in the water prior to release.	—	—	—	—	—	—	X	—
	• Measures for Invasive Aquatic Plant Control (performed by DBW): ○ Timing restrictions based on outmigration of juvenile salmonids at specific sites (e.g., no treatment before June 1 at sites with juvenile outmigration, no treatment from October 16 to March 31) ○ Survey for elderberry shrubs and treat at low tide if any elderberry shrubs are within 100 ft of the water’s edge ○ Application window restrictions on timing between repeat applications for water hyacinth ○ An aquatic pesticide application plan including BMPs.	—	—	—	—	—	—	—	X

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
	○ A pesticide application log including specific information on each application ○ The Water Hyacinth Control Program Protocol and Procedures Manual and appendices that include requirements covering herbicide handling, treatment planning protocol, day of treatment protocols, and BMPs, plus the permit conditions of the two biological opinions and the NPDES permit (DBW 2009). ○ Environmental awareness training for all field crew members – Species identification and impact avoidance guidelines – Protocol for identification and protection of elderberry shrubs – Protocol for identification and protection of delta smelt, Chinook salmon, steelhead, green sturgeon, and associated protected habitats – Protocol for take of protected species – Use and calibration of equipment ○ Monitoring and monthly reporting of the following. – Pre- and posttreatment measurements of chemical residue, pH, turbidity levels, water temperature, and DO at selected sites – Water temperature and DO changes resulting from EDCP activities – Amounts, types, and dates of herbicide application at each site – Visual assessment of pre- and posttreatment conditions of treated sites to determine efficacy of treatment and any effects of chemical drift – Operational status of equipment and vessels ○ A water monitoring program requiring that a minimum of 10 percent of all treatment sites be sampled for each water type to collect and analyze Delta water quality data, and results of chemical residue and toxicity tests. ○ An environmental monitoring plan. ○ An approved monitoring protocol and sampling plan. ○ A quality assurance project plan for chemical residue and toxicity monitoring, describing procedures and protocols for data collection and analysis. ○ An annual report describing permit compliance and program findings and conclusions. ○ An annual data validation package to confirm the quality of environmental monitoring data.								

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
Cultural Resources	• Where construction within areas that may contain cultural resources cannot be avoided through the use of alternative management practices, conduct an assessment of the potential for damage to cultural resources prior to construction; this may require the hiring of a qualified cultural resources specialist to determine the presence of significant cultural resources.[5]	X	—	X	—	X	X	X	—
	• Where the assessment indicates that damage may occur, and prior to land disturbance, submit a non-confidential records search request to the appropriate CHRIS which potentially includes the following in the plan area.[1, 5] ○ Calaveras County: Central California CHRIS Information Center[5] ○ Mariposa County: Central California CHRIS Information Center[5] ○ Merced County: Central California CHRIS Information Center[5] ○ San Joaquin County: Central California CHRIS Information Center[5] ○ Stanislaus County: Central California CHRIS Information Center[5] ○ Tuolumne County: Central California CHRIS Information Center[5] • Implement the recommendations provided by the CHRIS information center(s) in response to the records search request.[5] • Where adverse effects on cultural resources cannot be avoided, undertake additional CEQA review and develop appropriate mitigation to avoid or minimize the potential impact(s).[5]	X	—	X	—	X	X	X	—
	• To avoid a potentially significant impact on New Melones, New Don Pedro, and New Exchequer dams due to construction and operation of water temperature control structures, a Cultural Resource Management (CRM) strategy shall be incorporated prior to the addition of any temperature controls. An appropriate CRM strategy for recording and evaluating the New Melones, New Don Pedro, and New Exchequer dams would include a records search of the area of potential effects of these projects; a field recordation of the dam and any associated historical structures on California Department of Recreation series 523 forms, specifically 523B (building, structure, or object) and/or 523E (linear resource); and the submission of these materials and any nominating materials to the State Historical Resources Commission of the California Office of Historic Preservation.	—	—	—	X	—	—	—	—
	• Require a professional trained to identify evidence of cultural resources to observe major excavation and earth-moving activities if significant cultural resources are known to exist on the project site or if there is a high probability for significant cultural resources to exist.[2]	X	—	X	—	X	X	X	—

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
	• Construction will stop within a 100-foot radius of any archaeological, paleontological, or historical resources discovered during construction activities, and treatment measures will be devised as needed. A qualified archaeologist should be brought on site within 24 hours of the discovery. If the find is determined to be significant, a full archaeological survey will take place. Construction activities in the area resumes once the survey is completed and all cultural resources are recovered.[2, 6]	X	—	X	—	X	X	X	—
	• No further excavation or other site disturbance takes place if any human remains are discovered during construction activities. Notify the local coroner so that a determination can be made as to whether the remains are of Native American origin or whether an investigation into the cause of death is required. If the remains are determined to be Native American, the following actions would be taken. ○ The coroner notifies the NAHC within 24 hours. ○ The NAHC immediately notifies those persons believed to be the most likely descendant(s) (MLD) of the deceased. ○ Once the NAHC identifies the MLD, the MLD, with the permission of the landowner, inspects the site of the discovery and makes recommendations for the treatment or disposition of the remains and any associated grave items within 48 hours (per AB 2641) of the MLD being granted access to the site. ○ The landowner is to ensure that the immediate vicinity of the remains, established according to standard professional practices, is not damaged or disturbed by further activity until the landowner has conferred with the MLD. ○ Discussion and consultation between the landowner and MLD should take into account the possibility of multiple burials and reasonable options regarding the MLD's preferences for treatment. • If the NAHC is unable to identify an MLD, if the MLD fails to make a recommendation, or if the NAHC is unable to mediate a dispute concerning the appropriate disposition of the remains, the landowner shall re-inter the human remains and any associated items with appropriate dignity on the property in a location not subject to further subsurface disturbance; and, to protect the remains from disturbance, the landowner must record the site with the NAHC or the appropriate CHRIS, use an open space or conservation zoning designation or easement, and/or record a document with the county in which the property is located.[2, 5]	X	—	X	—	X	X	X	—
	○ No further disturbance of an area, if fossils are encountered, will occur until the materials have been evaluated by a qualified paleontologist and appropriate treatment measures have been identified.[4]	X	—	X	—	X	X	X	—
	• Construction workers should be aware of the following protocols for identifying cultural resources: ○ If built environment resources or archaeological resources, including chipped stone (often obsidian, basalt, or chert), ground stone (often in the form of a bowl mortar or pestle), stone tools (such as projectile points or scrapers), unusual amounts of shell or bone, historic debris (such as concentrations of cans or bottles), building foundations, or structures are inadvertently discovered during ground-disturbing	X	—	X	—	X	X	X	—

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
	activities, the land owner should stop work in the vicinity of the find and retain a qualified cultural resources specialist to assess the significance of the resources. If necessary, the cultural resource specialist also will develop appropriate treatment measures for the find. ○ If human bone is found as a result of ground disturbance, the land owner should notify the county coroner in accordance with the instructions described above. If Native American remains are identified and descendants are found, the descendants may—with the permission of the owner of the land or his or her authorized representative—inspect the site of the discovery of the Native American remains. The descendants may recommend to the owner or the person responsible for the excavation work means for treating or disposing of the human remains and any associated grave goods, with appropriate dignity. The descendants will make their recommendation within 48 hours of inspection of the remains. If the NAHC is unable to identify a descendant, if the descendants identified fail to make a recommendation, or if the landowner rejects the recommendation of the descendants, the landowner will inter the human remains and associated grave goods with appropriate dignity on the property in a location not subject to further and future subsurface disturbance.[5]								
Geology and Soils	• Evaluate the project site, and up- and down-gradient areas, for erosion potential. Design the project and implement construction and maintenance activities to prevent erosion and sedimentation.[2]	X	X	X	—	—	X	—	—
	• An MMP, which is part of the permitting requirements and conditions by resource agencies including USFWS, CDFW, Central Valley Water Board, and U.S. Army Corps of Engineers, would be implemented to ensure erosion is minimized and the enhancing structures are functioning successfully.	X	X	X	—	—	X	—	—
	• Remove vegetation only when necessary and make every effort to conserve topsoil for reuse in re-vegetation of disturbed areas.[2]	X	—	X	—	X	X	X	—
	• Stabilize and revegetate all disturbed soil surfaces before the rainy season.[2]	X	—	X	—	X	X	—	—
	• Restrict stockpiling of construction materials to the designated construction staging areas and exclusive of habitats and their buffer zones.[2]	X	X	X	—	X	X	—	—
	• Employ BMPs that prevent soil or sediment from leaving construction sites, monitor them for effectiveness, and maintain them throughout the construction operations and between construction seasons. Standard measures include installation of sediment basins and traps in conjunction with grading operations; development of slope drains; stabilization of stream banks; use of hydraulic mulch, hydroseeding, straw, mulch anchored with a tackifier, polyacrylamide, rolled erosion control products (e.g., blankets and mats), earth dikes, drainage swales, and velocity dissipation devices; and installation of silt fences, fiber rolls, gravel bag berms, sandbag barriers, storm drain inlet protection, and check dams.[2]	X	—	X	—	X	X	—	—

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
	• Limit to the dry season any construction activities within an area of the OHW line of drainages and lakes. Limit any construction activities within a floodplain, but above an OHW line, to those actions that can adequately withstand high river flows without resulting in the inundation of and entrainment of materials in flood flows.[2]	X	X	X	—	X	X	X	—
	• Have a professional hydrologist or licensed engineer develop an erosion control and water quality protection plan to avoid habitat degradation and ensure compliance with local and state erosion- and sedimentation-related requirements. The plan should be integrated into the construction schedule and describe how site cleanup and regrading will affect current physical conditions.[2]	X	X	X	—	X	X	X	—
	• Locate projects away from areas with unsuitable soils or steep slopes.[2]	X	—	X	—	X	X		—
	• Implement all requirements under Air Quality, above.	X	X	X	X	X	X	X	X
Greenhouse Gas Emissions	• Preserve known GHG sinks to the extent feasible and limit GHG sources as a component of project design.[2]	X	X	X	X	X	X	X	X
	• Preserve or replace onsite trees or contribute to a mitigation program providing carbon storage.[2]	X	X	X	X	X	X	X	X
	• Implement local air district controls to reduce criteria pollutant emissions and help to minimize GHG emissions. Measures to reduce vehicle trips and promote use of alternative fuels, as well as clean diesel technology and construction equipment retrofits, should be considered.[5]	X	X	X	X	X	X	X	X
	• Fuel, oil, and other petroleum products will be stored only at designated sites.	X	X	X	X	X	X	X	—
Hazards and Hazardous Materials	• Hazardous materials containment containers will be clearly labeled with the identity of the hazardous materials contained therein, handling and safety instructions, and emergency contact.	X	X	X	X	X	X	X	X
	• Storage, use, or transfer of hazardous materials in or near wet or dry streams will be consistent with California Fish and Game Code (Section 5650) and/or with the permission of CDFW.	X	X	X	X	X	X	X	X
	• Material Safety Data Sheets will be made readily available to the contractor's employees and other personnel at the work site.	X	X	X	X	X	X	X	X
	• The accumulation and temporary storage of hazardous wastes will not exceed 90 days.	X	X	X	X	X	X	X	—
	• Soils contaminated by spills or cleaning wastes will be contained and removed to an approved disposal site.	X	X	X	X	X	X	X	X
	• Hazardous waste generated at work sites, such as contaminated soil, will be segregated from other construction spoils and properly handled, hauled, and disposed of at an approved disposal facility by a licensed hazardous waste hauler in accordance with state and local regulations. The contractor will obtain permits required for such disposal.	X	X	X	X	X	X	X	—
	• Provide hazardous materials and worksite safety training for construction workers in accordance with local, state, and federal requirements including, but not limited to the Occupational Safety and Health Act, Title 9 of the Code of Federal Regulations, and Title 8 of the California Code of Regulations.[2]	X	X	X	X	X	X	X	—

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
	• Provide hazardous materials accidental spill response plans (and/or Hazardous Materials Management Program) and training that would outline methods, materials, and responsibilities for the response to, and clean-up of, an accidental hazardous material spill during construction of the project. At a minimum, the plans should include provisions for immediate response, containment, and cleanup of a spill, including excavation and disposal of contaminated soil and notification responsibilities. Materials needed for potential cleanup activities should be kept onsite.[2]	X	X	X	X	X	X	X	—
	• Provide a health and safety plan for construction workers that is prepared by a certified industrial hygienist; complies with all appropriate local, state, and federal regulations; and identifies specific safety measures to be followed during all phases of construction and long-term operation.[2]	X	X	X	X	X	X	X	—
	• Label all hazardous materials onsite to inform users of potential risks and train users in appropriate handling, storage, and disposal procedures.[2]	X	X	X	X	X	X	X	—
	• Protect sites from unmonitored access with fencing and signs to prevent accidental health hazards to the nearby residents.[2]	X	X	X	X	X	X	X	—
	• Identify local laws, ordinances, and building codes related to fire prevention, burning, welding, and blasting, etc., to obtain any necessary permits and adhere to permit conditions.[2]	—	—	—	X	X	—	X	—
	• Maintain an adequate number of fire extinguishers and other tools and equipment that can be used for fighting fire onsite, and ensure that personnel are trained in their use.[2]	X	X	X	X	X	X	X	—
	• Maintain a water tender during extensive welding/cutting operations.[2]	—	—	—	X	X	X	—	—
	• Identify existing underground utility lines at excavation sites prior to construction, and avoid/relocate underground utility lines in coordination with utility company/service provider; coordinate with natural gas companies and Underground Service Alert before beginning any excavation or other construction activities to ensure that pipelines are not affected.[2, 6]	X	—	X	—	X	—	X	—
	• Ensure that project activities do not weaken nearby levees.[2]	X	X	X	—	X	X	X	—
	• Prior to construction, perform pre-construction hazardous waste evaluations through record searches and on-site evaluations to potentially identify leaking underground storage tanks, facilities that have received CDOs or CAOs for hazardous materials, or where soil contamination may be suspected (e.g., through soil discoloration or other indicators). If soil contamination is identified, test soil prior to excavation to determine if construction site would be located in area with soil contamination. Areas to be excavated will undergo soil and/or groundwater testing (if groundwater is present in excavated area) at a certified laboratory, provided existing data cannot characterize the nature and concentration of the contamination. Where concentrations exceed applicable federal or state thresholds, contaminated areas will be avoided or soil and/or groundwater will be remediated and contained in compliance with applicable state and federal laws. If hazardous materials are encountered, consultation with DTSC will be required to establish if a permit and subsequent actions are needed to appropriately handle the materials.	X	X	X	—	X	—	X	X

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
Hydrology and Water Quality	• Prepare a SWPPP that includes specific types and sources of storm water pollutants, determines the location and nature of potential impacts, and specifies appropriate control measures to eliminate any potentially significant impacts from storm water runoff on receiving waters. The SWPPP will require treatment BMPs that incorporate, at a minimum, the required hydraulic sizing design criteria for volume and flow to treat projected storm water runoff. The SWPPP shall comply with the most current standards established by the regional water quality control board. BMPs shall be selected from the local agency's Storm Water Quality Control Standards.[4,6]	X	X	X	X	X	X	X	X
	• Implement turbidity monitoring during construction/removal.[6]	X	X	X	X	X	X	X	X
	See Agriculture and Forestry Resources in this table for additional applicable mitigation measures.								
Noise	• Implement noise-reducing construction practices such that noise from construction does not exceed applicable local noise standards or limits specified in the applicable county ordinances and general plan noise elements. Typically construction is limited to 7:00 am–6:00 pm on weekdays and permit no work on Saturdays, Sundays, or holidays unless appropriate city and county building officials grant prior approval.[2, 3, 5, 6]	—	—	—	X	X	X	X	X
	• Use noise-generating equipment during periods when fewer people are present near the construction area.[2]	—	—	—	X	X	X	X	X
	• Muffle or otherwise control all construction equipment with a high noise-generating potential, including all equipment powered by internal combustion engines.[2]	—	—	—	X	X	X	X	X
	• Use newer equipment with improved noise muffling, and ensure that all equipment items have the manufacturers' recommended noise abatement measures, such as mufflers, engine covers, and engine vibration isolators, intact and operational. Newer equipment will generally be quieter in operation than older equipment. All installation equipment should be inspected at periodic intervals to ensure proper maintenance and presence of noise control devices (e.g., mufflers and shrouding).[3]	—	—	—	X	X	X	X	X
	• Shroud or shield all impact tools.[2]	—	—	—	X	X	X	X	X
	• Locate all stationary noise-generating equipment, such as compressors, as far as possible from adjacent occupied offices, residents, or sensitive habitats (if they are adjacent to the project site).[2]	—	—	—	X	X	X	X	X
	• Turn off mobile equipment and machinery when not in use to reduce noise from idling equipment.[2]	—	—	—					
	• Use temporary noise barriers or curtains along installation boundaries or partial enclosures around continuously operating equipment.[2]	—	—	—	X	X	X	X	X
	• Use the shortest possible routes from construction sites to local freeways for truck delivery routes, except when selecting routes to avoid going through residential neighborhoods.[2]	—	—	—					
	• Establish an active community liaison program that notifies landowners within 300 ft of construction areas of the construction schedule, in writing, prior to construction to keep them informed of schedule changes, and designate a "disturbance coordinator" for the construction site.[2]	—	—	—	X	X	X	X	X

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
	• Regularly inspect equipment and monitor noise and vibration to ensure that all equipment on the site is in good condition and effectively muffled and that contractors take all reasonable steps to minimize impacts, particularly when near sensitive areas.[2, 3]	—	—	—	X	X	X	X	X
	• Monitor construction noise and vibrations and modify and/or reschedule construction activities if monitoring determines that maximum limits set by local or regional noise ordinances are exceeded.[2, 3]	—	—	—	X	X	X	X	X
Recreation	• Navigational buoys, lights, and signage will be installed in sloughs upstream and downstream from the barriers to advise boaters about the presence of the barriers and maintain navigation along waterways. The project proponent will coordinate with the U.S. Coast Guard on signage and buoys.	—	—	—	—	—	X	—	—
Transportation and Traffic	• Use signage, striping, fencing, barricades, and other physical structures to mark the excavated areas, promote safety, and minimize pedestrian/bicyclist accidents.[2]	X	X	X	X	X	X	X	X
Operation									
Biological Resources	• Develop a mitigation and management plan (MMP) in coordination with CDFW and USFWS to implement all appropriate measures as required by USFWS ESA Section 7 consultation and to satisfy any other local, state, and federal requirements for achieving no net loss of wetlands, riparian habitat or other critical habitat, or take of wildlife species of concern. The plan should be submitted to the local city/county environmental planning department, U.S. Army Corps of Engineers, USFWS, CDFW, applicable regional board (e.g., as part of a Clean Water Act Section 401 Water Quality Certification application), and/or other oversight agencies as applicable for approval prior to its implementation if an impact on special-status species population(s) is determined to occur based on the biological assessment and evaluation of the final project site and design.[2]	X	X	X	X	X	X	—	—
	• Properly contain or remove all trash that may attract predators to the worksite during operation.[2]	X	X	X	X	X	X	X	X
Geology and Soils	• As discussed under Biological Resources above, an MMP, which is part of the permitting requirements and conditions by resource agencies including USFWS, CDFW, Central Valley Water Board, and U.S. Army Corps of Engineers, would be implemented to ensure erosion is minimized and all structures are functioning successfully.	X	X	X	—	—	X	—	—
Greenhouse Gas Emissions	• Implement local air district controls to reduce criteria pollutant emissions and help to minimize GHG emissions. Measures to reduce vehicle trips and promote use of alternative fuels, as well as clean diesel technology and construction equipment retrofits, should be considered.[5]	X	X	X	X	X	X	—	X
	• Use vehicles with zero-emission or lower-emission engines.[2]	X	X	X	X	X	X	X	X
	• Limit the unnecessary idling of vehicles and equipment.[2]	X	X	X	X	X	X	X	X
	• Use low/zero carbon/alternative fuels, such as B20 biodiesel or renewable diesel.[2]	X	X	X	X	X	X	X	X
	• Control visible emissions from off-road diesel powered equipment.[2]	X	X	X	X	X	X	X	X
	• Encourage ride sharing and use of transit transportation for construction employees commuting to the project site.[4]	X	X	X	X	X	X	X	X

Resource	Potential Mitigation Measure	Floodplain and Riparian Habitat Restoration	Gravel Augmentation	Enhanced In-Channel Complexity	Improve Temperature Conditions	Fish Screens	Physical Barriers in Southern Delta	Predatory Fish Control	Invasive Aquatic Vegetation Control
	• Use electric equipment for construction whenever possible in lieu of fossil fuel-powered equipment.[4]	X	X	X	X	X	X	X	X
Hydrology and Water Quality	• As discussed under Biological Resources above, an MMP, which is part of the permitting requirements and conditions by resource agencies including USFWS, CDFW, Central Valley Water Board, and U.S. Army Corps of Engineers, would be implemented to ensure no erosion is occurring, water quality remains the same or is improved, any changes in hydraulics are what is expected, and the project is functioning successfully.	X	X	X	X	X	X	—	X

Notes:

[a] Until such time that these potential mitigation measures are implemented, the impacts would remain significant and unavoidable, consistent with State CEQA Guidelines Section 15091. However, it is likely that impacts would be mitigated to less than significant once mitigation measures were implemented.

[b] Potential mitigation measures for conflicts with habitat conservation plans, natural community conservation plans, or other plans, policies, and regulations protecting biological species and resources that maybe attributable to land use and planning are presented in the Biological Resources sections in this table.

This page intentionally left blank.

16.7 Cumulative Impacts

This section evaluates the cumulative impacts associated with other indirect actions, additional actions, and methods of compliance described in Sections 16.2, *Lower San Joaquin River Alternatives—Other Indirect Actions*, 16.3, *Lower San Joaquin River Alternatives— Non-Flow Measures,* and 16.4, *Southern Delta Water Quality Alternatives— Reasonably Foreseeable Methods of Compliance*. Cumulative impacts are defined in the State CEQA Guidelines (Cal. Code Regs., tit. 14, § 15355) as "two or more individual effects which, when considered together, are considerable or which compound or increase other environmental impacts." A cumulative impact occurs from "the change in the environment which results from the incremental impact of the project when added to other closely related past, present, and reasonably foreseeable probable future projects. Cumulative impacts can result from individually minor but collectively significant projects taking place over a period of time." (Cal. Code Regs., tit. 14, § 15355, subd. (b).) State CEQA Guidelines recommend either a list or projection approach, the use of which must be guided by the standards of practicality and reasonableness. The State Water Board has decided to prepare a cumulative impact discussion for all actions presented in this chapter to disclose potential cumulative effects. However, given the lack of specificity for the actions described in this chapter over time, and in particular geographies, the analysis is necessarily general and broad. Furthermore, while lead agencies or other entities could take one or more of the actions described in this chapter, the combination of indirect actions, non-flow measures, and other actions in response to the alternatives is speculative and unknowable and, as such, the number of actions taken over time and in different locations cannot be identified. For example, not any one non-flow measure alone could fully inform adaptive implementation and, as such, various actions and measures may be combined. Specific combinations of measures cannot be predictably aligned with the alternatives because entities could take one or more of these non-flow measures and the combination of measures that entities would take under each alternative is speculative and unknowable. Because of the unknown location, scope, timing, and magnitude of potential impacts described in Sections 16.2 through 16.4, projects or programs adequately similar in nature, location, and type cannot be identified that would result in a meaningful comparative analysis. As such, to the extent feasible, possible impacts on each resource area are considered cumulatively in this section in combination with similar possible impacts in the plan area and the extended plan area, without reference to specific contributing projects.

Potential mitigation measures identified in Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* and Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures*, are also incorporated and discussed, if appropriate. In some circumstances, the effects prior to implementing the mitigation measures would not be cumulatively considerable because of the localization of potential effects or the possible separation in time and space of potential effects. In these cases, the mitigation measures would serve to further reduce potential cumulatively considerable effects. In other circumstances, the mitigation measures may reduce cumulative effects to less than cumulatively considerable; however, the potential mitigation measures cannot be enforced by the State Water Board because they require actions by lead agencies or third parties over which the State Water Board has no decision-making authority. As such, the discussion identifies whether mitigation may help to reduce cumulatively considerable impacts. However, it necessarily concludes if impacts cannot be mitigated because they are beyond the enforcement of the State Water Board, cumulative impacts would be significant and unavoidable.

Aesthetics

Construction of activities described in this chapter could have temporary effects on aesthetics and the visual character and quality of an area due to the location of construction equipment, personnel, or modifying landscape features under construction. Because construction typically does not permanently alter the aesthetic quality of an area, it is unlikely that aesthetic impacts during construction would result in substantial cumulative effects in association with other construction activities and the visual character and quality in a given area. As such, impacts would not be cumulatively considerable.

Construction could create temporary light and glare during potentially needed nighttime construction periods. Given the potential location of these and the low likelihood of other sources of nighttime light and glare, this likely would not result in a cumulatively considerable impact if mitigation measures identified in Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures,* are employed. If mitigation measures are not incorporated by lead agencies or third-parties, impacts would be cumulatively considerable when considered in combination with other similar impacts in a given area.

The potential cumulative aesthetic effects depend on the location of the action, how intact and complete the visual character is of the location, and the types of sensitive viewers (e.g., recreationists) that may experience a change in the view. New facilities or structures could affect the visual character and quality of the surrounding area depending on the presence or absence of other permanent structures the type (e.g., size, bulk) of the permanent structures. If actions occur in primarily urban areas and result in new facilities or infrastructure, impacts likely would not be cumulatively considerable. If actions occur in areas without existing infrastructure, and in existing natural landscapes, the size and scale of new infrastructure could result in a substantial degradation of the surrounding visual character or quality. As such, impacts would be cumulatively considerable. Operation of the facilities could result in new sources of light or glare, that, when in combination with proximity to existing facilities could result in substantial increases in light or glare and result in cumulatively considerable impacts. Implementation of mitigation measures identified in Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* and Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures,* with respect to light and glare would likely reduce cumulative effects. If mitigation measures are not incorporated by lead agencies or third-parties, impacts would be cumulatively considerable.

Operations that do not require new facilities and do not permanently and substantially alter a landscape that is intact with scenic views, or designations of scenic highways or wild and scenic rivers generally lack the potential to affect the visual character and quality of the surrounding area when considered with other projects in the general vicinity that may affect aesthetics. Impacts would not be cumulatively considerable. However, operations that permanently convert large landscapes that contain scenic views, scenic highways, or wild and scenic rivers would result in cumulative impacts because of the expected substantial change in the unique visual landscape in which the change was occurring. Permanent changes of this nature and magnitude could not be mitigated, and impacts would be cumulatively considerable.

Agricultural Resources

Agricultural land has been converted to nonagricultural uses in the Central Valley, including the plan area, due to urbanization and changing landscape. The California Department of Conservation

(CDC) indicates that since 1984 the average annual net conversation of Prime Farmland, Farmland of Statewide Importance and Unique Farmland has been approximately 38,000 (CDC 2015a). While urbanization accounts for the majority of the total loss of agricultural lands (approximately 1.1 million) between 1984 and 2010, there are other causes for farmland loss including ecological restoration projects that totaled a loss of more than 291,000 acres between 1984 and 2010 (CDC 2015a). Trends in San Joaquin, Stanislaus, and Merced Counties generally show a decline in agricultural lands as supported by the statewide trend (CDC 2015b). However, there are also tradeoffs between Prime, Unique, and Farmland of Statewide Importance where Prime Farmland may annually decrease but Unique Farmland increase (CDC 2015b). The construction and operation of most of the activities described in this chapter would not result in temporary or permanent impacts on agricultural resources. This is because either the location of the activity would not be in or adjacent to agricultural uses or because the activity would support agricultural uses. However, if the activities result in the permanent removal of agricultural lands because of the conversion of agricultural lands to nonagricultural uses significant and unavoidable cumulative impacts could occur. While potential mitigation measures identified in Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* and Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures*, identify mitigation, if permanent loss occurs because significant acreage is converted to nonagricultural use (e.g., restoration projects), impacts would be cumulatively considerable, when considering the larger context for the loss of designated agricultural lands.

Forests are typically managed in California for multiple purposes including recreation and resource extraction. Trees are periodically harvested and replanted depending on a particular forest management plan and projected demand for timber within an area. It is unlikely that there would be another project similar to that of new surface water reservoirs that would completely and permanently remove forestland. As such, while the impact is significant, it would not be cumulatively considerable because no other project is expected to have a similar type of impact.

Air Quality

Construction emissions associated with actions described in this chapter would be short term. Because cumulative impacts, by definition, are long-term, construction emissions are not anticipated to result in cumulatively considerable impacts on air quality. Additionally, implementation of potential mitigation measures identified in Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* and Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures*, for air quality emissions generated during construction would serve to further reduce, or minimize, or eliminate air quality emissions for actions identified in this chapter. Air quality emissions from vehicle trips used for either monitoring or maintenance, or from back-up generators could result. Vehicle trips would be limited in duration and would occur discretely over time and in many different locations. As such, these emissions would not be cumulatively considerable.

The air basins where potential actions could be located (i.e., SJVAB, MCAB, GBVAB) are in nonattainment for a variety of emissions (e.g., ozone, PM2.5, PM10). As such, air quality emissions from regularly operating new equipment could generate long-term emissions that contribute to nonattainment because of the daily operation of different facilities, in different locations over the lifetime of the facility. In addition, if numerous truck trips are required under operating conditions to transport or dispose of materials, the number of trucks, duration of the trips generated, and travel routes could result in cumulative air quality impacts within these air quality basins or others that are in nonattainment. Although implementation of mitigation measures identified in Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* and Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures*, could reduce the generation of emissions during operating conditions, impacts would be cumulatively considerable. If mitigation measures are not incorporated by lead agencies or third parties, impacts would be cumulatively considerable.

Biological Resources

The plan area, and to a lesser extent, the extended plan area, has been subjected to extensive changes due to land conversion to agricultural and urban uses, water development, population growth, and recreation. These changes have altered the physical and biological integrity of the Central Valley, causing loss of native riparian vegetation along river systems, loss of wetlands, and loss of native habitat for plant and wildlife species. Many of the biological impacts from the actions evaluated in this chapter can be mitigated, due to the temporary nature (short duration in time and location) of construction, with potential mitigation measures identified in Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* and Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures*. If, depending on the project-specific construction timeline and type of construction, the impacts are short in duration, temporary, and localized and do not result in *take* of a species, then impacts would not be cumulatively considerable. However, if mitigation measures are not incorporated by lead agencies or third parties, impacts would be cumulatively considerable.

Construction may permanently remove or substantially degrade sensitive habitat, remove species, and result in *take* because of the potential mechanisms needed for construction (e.g., building cofferdams). As such, the potential mitigation measures may not be sufficient to reduce effects during construction. The cumulative impact of the significant reduction in quality habitat and the take of individual listed plants or wildlife species would be cumulatively considerable when viewed in combination with similar impacts in the area.

Operation could result in effects on biological species if they represent a continual degradation or on-going effect on existing special-status species or habitat. While monitoring, or potentially adaptive management, could be done to assess the effects of the operation on biological resources, and adjustments of operation could be made, impacts would be cumulatively considerable when viewed in combination with similar impacts in the area.

Cultural

Ground-disturbing activities associated with most of the actions evaluated in this chapter could result in cumulatively considerable effects on cultural resources if performed in combination with other ground-disturbing activities. Effects would be localized and primarily related to construction because ground-disturbing during construction tends to result in discovery of cultural resources and can result in the potential destruction of those resources. Implementation of potential mitigation measures for cultural resources identified in Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* and Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures*, during construction would reduce the contribution to this impact to a level that is not cumulatively considerable. The potential mitigation measures would ensure identification of cultural resources and minimization of impacts on identified resources either through removal and preservation or modification of project location or construction methods. If mitigation measures are not incorporated by lead agencies or third-parties, impacts would be cumulatively considerable when viewed in combination with similar impacts in the area. In addition, even with mitigation, due to the potential expansive and large scale ground disturbing activities associated with the construction of new surface water reservoirs, impacts would remain cumulatively considerable because they could result in the complete destruction of known or unknown cultural resources.

Geology and Soils

Geology and soils could be affected during construction activities associated with the actions evaluated in this chapter because of disturbance of soil. Construction effects on geology and soils would generally be localized and temporary. In many instances, it would also be relatively short in duration. As such, it is unlikely that cumulatively considerable effects on geology and soils would occur in association with other construction activities in any given area. Therefore, the impacts would not be cumulatively considerable. In addition, potential mitigation measures identified in Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* and Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures*, would serve to further reduce impacts during construction associated with geology and soils.

Once facilities are in place, operating conditions would not bring or expose people to significant risk of earthquakes, landslides, unstable soils, or other geologic hazards, and therefore could not result in a continued disturbance of soils or geology. However, if operations result in continued or increased groundwater pumping at levels that would lead to overdraft conditions in the groundwater basin, they could result in a continued disturbance of soils or geology.

Greenhouse Gases/Climate Change

Unlike other air quality emissions (e.g., criteria pollutants), GHG emissions occur at a global level. The relatively long lifespan and persistence of GHGs require that climate change be considered a cumulative and global impact. While it is unlikely that increases in global temperature or sea level could be attributed to the emissions resulting from a single project, it is appropriate to conclude the GHG emissions from the actions described in this chapter (if they were to occur) would combine with GHG emissions in California, the United States, and the globe to cumulatively contribute to global climate change. In addition, given the ZEL standard recently implemented by the SJVAPCD, GHG impacts from implementation of these activities may not be negligible. Because it is unknown to what extent climate change would be affected by the incremental GHG emissions produced, the impact on GHG and climate change would be cumulatively considerable. Implementation of potential mitigation measures identified in Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* and Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures*, for the actions identified above, would result in lower GHG emissions levels than had they not been incorporated. However, these mitigation measures would not completely eliminate GHG emissions. As such, impacts would be cumulatively considerable.

Hydrology and Water Quality

Urbanization and the development of agriculture has led to significant alteration of hydrology and water quality in the plan area and extended plan area over time. The alteration has led to surface water resources that are fully managed in accordance with a complex set of existing laws, regulations, and policies and by multiple dams and diversions. Groundwater resources have been less managed than surface water resources; however, they, too, have been greatly altered and substantially reduced through urbanization and the development of agriculture.

During construction of some of the actions evaluated in this chapter, the disturbance of soil and working within or adjacent to rivers and water ways could result in localized and temporary effects on hydrology and water quality. As such, it is unlikely that cumulatively considerable effects would on hydrology and water quality would occur in association with other construction activities or projects in any given area, and impacts would not be cumulatively considerable. In addition, potential mitigation measures identified in Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* and Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures*, would serve to reduce impacts during construction associated with hydrology and water quality.

Impacts would not be cumulatively considerable if there are no substantial and permanent effects on hydrology or water quality under operating conditions because of small operating footprints of the facilities, limited generation of substantial amounts of runoff or discharges, or the purpose of the activity is to treat water or wastewater prior to discharge or use. Substantial and permanent effects on hydrology and water quality could occur due to the alteration of a river through the development and operation of substantial infrastructure (e.g., new surface water reservoirs). While potential mitigation measures, alternative locations, or alternative project designs (currently unknown) could reduce cumulative effects, given the potential size and scale of infrastructure projects, impacts would be cumulatively considerable and significant.

Hazards and Hazardous Materials

Within the plan area and extended plan area, projects must comply with all existing hazardous material regulations through the local, state, and federal government. These regulations are in place to reduce the potential of accidental releases, spills, or explosions of hazardous materials and to minimize the environmental and public health impacts should one occur. Although projects cannot completely eliminate the probability associated with an accidental release, explosion, or spill, the existing regulations reduce the overall probability and minimize the impacts during a release.

Hazardous materials are typically used during construction (e.g., fuels and lubricants) of the actions evaluated in this chapter. However, the transport of significant quantities of hazardous materials or waste would not occur and would not involve the handling or disposal of significant quantities of hazardous materials or waste. In addition, the use would be temporary and localized within the area of construction. Because the hazardous material use and disposal would be intermittently located, it is unlikely that use during construction activities would result in a substantial cumulative effect in association with other uses in any given area. As such, no cumulatively considerable hazardous impacts would occur as a result of construction activities. In addition, implementation of potential mitigation measures associated with the handling of hazardous materials during construction identified in Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* and Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures*, would serve to further reduce, or minimize, hazardous impacts.

Construction could result in disrupting existing underground utility lines during ground-disturbing activities. However, this would be highly localized and infrequent in time and, as such, would not result in impacts that are cumulatively considerable. In addition, mitigation measures identified in Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* and Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures,* of identifying utilities prior to ground-disturbing activities would further reduce impacts. Construction activities may also disturb known or unknown hazardous materials in soil or groundwater depending on the type of ground disturbing activity and the type of activity; however, mitigation measures identified in Table 16-38 would reduce impacts to less than cumulatively considerable because materials would be remediated and removed if they were discovered. However, if mitigation measures are not incorporated by lead agencies or third-parties, impacts would be cumulatively considerable.

Activities that involve the regular handling and transport of hazardous materials could result in a cumulatively considerable impact if they do so in conjunction with many other projects that also handle and transport hazardous materials. The mitigation measures identified in Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures,* would reduce impacts to less-than-significant levels; however, given the use of hazardous materials application in the waterways and use at existing facilities, until the mitigation was implemented, impacts would be cumulatively considerable and significant.

Noise

Noise from construction activities associated with actions evaluated in this chapter would be highly localized. Because noise-sensitive land uses are intermittently located, it is unlikely that noise from construction activities would result in a substantial cumulative effect associated with other noise sources, particularly related to construction, in any given area. As such, no cumulatively considerable noise impacts would occur as a result of construction activities. In addition, implementation of potential mitigation measures associated with noise identified in Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* and Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures*, generated during construction would serve to further reduce or minimize noise levels associated with construction.

Noise from operating activities could result primarily from either vehicle trips, used for monitoring or maintenance, or from operation of new equipment. Noise from vehicle trips would be spread throughout the roadway system and may contribute to traffic noise. However, monitoring or maintenance trips would be limited in duration and spread over time. As such, impacts would not be cumulatively considerable. Operation of equipment could produce permanent noise. Some of the noise generated would occur in areas with existing facilities that generate noise. While it is anticipated that noise generated by these facilities would be reduced and dampened through the use of walls, structures, or other facilities as described in Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* and Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures*, unless these measures are implemented, impacts would be cumulatively considerable, given the proximity to other permanent noise-generating facilities.

Mineral Resources

Projections indicate mineral resources, particularly aggregate, is decreasing overall as population increases, which is putting pressure on existing mineral sources along the Stanislaus, Tuolumne, and Merced Rivers (Clinkenbeard 2012a; Smith and Clinkenbeard 2012). Construction and operation of the following could result in temporarily or permanently removing mineral resources from use: floodplain and riparian habitat restoration, gravel augmentation, and enhancing in-channel complexity and new surface water supplies. There is a low potential for floodplain and riparian habitat restoration and enhancing in-channel complexity to permanently remove mineral resources from use given how they would be constructed and the conditions needed for construction. However, removal of additional mineral resources, particularly under gravel augmentation and new surface water supplies, would be cumulatively considerable when considered with other similar impacts in the area. Although mitigation measures identified in Table 16-39, *Potential Mitigation Measures for Construction and Operation Activities Related to Non-Flow Measures,* could reduce impacts, until the mitigation was implemented, impacts would be cumulatively considerable and significant.

Land Use and Planning, Population and Housing, and Public Services

General and specific plans and zoning codes allow for the construction and operation of different land uses in designated areas within the jurisdiction of local agencies. Local agencies have the discretion to modify or conditionally approve uses that may not be specifically approved for a particular area. Construction and operation involving public infrastructure or facilities evaluated in this chapter are typically allowed in multiple land use designations and zoned areas (e.g., public facilities, residential, industrial, open space overlays) and, as such, have a limited potential to affect land use and planning or conflict with local policies and plans when considered with other projects that may also involve infrastructure or facilities. In addition, there would be limited potential for effects on land use and planning where construction and operation of new facilities would be at existing infrastructure or facility locations already allowed by local policies and plans. Construction and operation that does not involve infrastructure or facilities also has a limited potential to affect land use and planning. Some of these actions may occur adjacent to or within waterways, and frequently these areas are designated natural resource or open space areas by land use plans. If inconsistencies were identified, they would not result in cumulatively considerable impacts because amendments would be processed, as required, to reduce impacts. Given the above, there would be no cumulative impacts.

Construction and operation would likely not result in an increase in population, the need for housing or public services, because many of the activities would either be restoration-type activities that have no effect on population, housing, or public services or because the activities would provide replacement water supplies and, as such, would not provide a supply to meet a new or an increase in demand. As such, cumulative impacts would not occur and impacts would not be cumulatively considerable. However, new surface water reservoirs would likely require public services, depending on the size and location of the reservoir. The ability to satisfy the needed services depends on the types of services currently in place and their ability to absorb additional demand; however, this would be highly localized and as such is not expected to result in cumulatively considerable impacts. In addition, mitigation measures identified in Table 16-38 would be expected to further reduce impacts.

Construction could impair the implementation of or physically interfere with an existing emergency response or emergency preparedness plan, or require the preparation of a new emergency response or emergency preparedness plan. However, projects would be required to coordinate with all law enforcement agencies during construction of all roadway improvements to establish emergency vehicular access, ensuring continuous law enforcement access to surrounding areas. Furthermore, police and fire stations are generally distributed to facilitate quick emergency response throughout the plan area and extended plan area, as applicable. If emergency plans are affected, they would only affect emergency plans during construction. Given the infrequent of activities over time and geography and the limited nature of potential impacts, impacts would not be cumulatively considerable.

Recreation

If construction is located near recreation facilities, and facilities may be indirectly affected by construction, cumulative impacts could occur as discussed under other resources (e.g., noise). However, these impacts would last during the construction period only and would return to levels comparable to those that existed prior to construction once construction is complete. Furthermore, in the event that patrons do visit other facilities due to project construction activities, it is not expected that patrons would use facilities in a manner that would cause or accelerate substantial physical deterioration of those facilities. It is expected that the demand for alternative recreation resources would be distributed among the large number of parks and recreational facilities in the area and region, and would likely return to original recreation resources once construction activities cease.

Activities that permanently alter or remove highly specialized or designated recreational resources (e.g., white water rafting) could have cumulative impacts (e.g., new surface water reservoirs). Depending on the type of existing activity and whether it is relatively limited in time and geography, the loss of that opportunity may be cumulatively considerable and could not be mitigated given the potential complete loss of the recreational resource.

Transportation and Traffic

Construction of the actions evaluated in this chapter has a limited potential to affect level of service on existing roads given that construction would be relatively temporary in duration and because typically, roadways return to preconstruction levels of service once the construction is completed. In addition, construction that occurs in remote areas away from other construction or operating projects would not result in cumulatively considerable impacts.

Transportation and traffic impacts from operational activities could result primarily from vehicle trips used for monitoring or maintenance. However, monitoring or maintenance trips would be limited in duration and spread over time. In addition, for those that would be located within proximity to existing facilities or infrastructure maintenance or monitoring likely would not result in any additional trips beyond what currently may be needed for existing facilities. As such, impacts would not be cumulatively considerable.

Transportation and traffic impacts from operating activities that result in a permanent and regular increase of traffic on roadways depends on frequency of trips, designated haul routes, and final destination. If haul routes are located in urban areas, on heavily traveled roads, they may result in a decrease of levels of service on existing roadways. Transportation and traffic impacts that result from the use of new amenities (e.g., recreation at a reservoir) would depend on the location of the amenity, the service provided, and the season of operation. This could be a highly localized effect. Furthermore, regional and local plans typically project traffic levels over time to accommodate increases in traffic within planning frameworks. As such, impacts would not be cumulatively considerable.

Utilities and Service Systems (Service Providers)

Construction and operation of the actions evaluated in this chapter would not be expected to exceed wastewater treatment requirements of the Central Valley Water Board either because the action would not involve the discharge of wastewater or because the action would improve wastewater discharge entering a receiving water. Additionally, most actions would not result in the discharge of wastewater and, therefore, would not require the construction or operation of wastewater treatment facilities. Most actions do not result in an increased demand for wastewater treatment and, as such, would not result in the determination by a wastewater treatment provider that it has inadequate capacity to serve the action. Accordingly, impacts would not be cumulatively considerable.

Where construction and operation of new septic or closed vault toilet systems would be required, design requirements would be followed. In addition Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* includes mitigation measures. Since the construction and operation of septic tanks or close vaulted toilet systems are relatively localized, the implementation of these mitigation measures would reduce impacts on the environment such that the construction of these facilities for new surface water storage facilities would not be cumulatively considerable when considered in combination with other projects with similar impacts.

Solid waste generated during construction of actions would be a temporary increase in the generation of solid waste and would not result in a cumulatively considerable impact on existing solid waste disposal locations. Actions that require regular disposal of waste could generate a reoccurring volume of waste depending on the generation requirements. However, disposal of all solid waste (including brine from desalination actions) would be done in accordance with all applicable federal, state, and local regulations and guidelines. Therefore, impacts would not be cumulatively considerable.

Construction or operation of new wastewater or water treatment facilities could occur. Implementation of these actions could result in impacts on multiple resources (e.g., air quality, noise, biological resources), and would be cumulatively considerable when considered with other similar impacts in the area. Although mitigation measures identified in Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* could serve to reduce impacts, until the mitigation was implemented, impacts would be cumulatively considerable and significant.

Construction and operation of the actions evaluated in this chapter would likely not require new stormwater infrastructure or the expansion of existing infrastructure. Where construction of new stormwater drainage facilities would be required, surface water drainage design would be required to be followed. In addition Table 16-38, *Potential Mitigation Measures for Construction and Operation Activities Related to Other Indirect and Additional Actions,* includes mitigation measures that require stormwater runoff control systems to fit the hydrology of the plan area, have adequate capacity, and be non-erosive. Since the construction and operation of stormwater drains are relatively localized and occur within an existing area of service, the implementation of these mitigation measures would reduce impacts on the environment such that the construction of these facilities for new surface water storage facilities would not be cumulatively considerable when considered in combination with other projects with similar impacts.

Chapter 17
Cumulative Impacts, Growth-Inducing Effects, and Irreversible Commitment of Resources

17.1 Introduction

This chapter describes the cumulative impacts associated with the Lower San Joaquin River (LSJR) and southern Delta water quality (SDWQ) alternatives together with other projects (and programs) that could cause related impacts. In accordance with the California Environmental Quality Act (CEQA) Guidelines (California Code of Regulations [Cal. Code Regs.], tit. 14, § 15130) requirements, this chapter discusses the cumulative impacts of the LSJR and SDWQ alternatives in conjunction with other past, present, and reasonably foreseeable probable future projects. Present and reasonably foreseeable probable future projects are projects that are currently under construction, approved for construction, have submitted a request for approval or review by an agency, or are in the final stages of formal planning.

This chapter provides an analysis of the potential cumulative impacts, organized by resource area, which would result from the implementation of the proposed project (the LSJR and SDWQ alternatives, or plan amendments) and the other projects, described in Section 17.2.1, *Projects Considered*, of this chapter. The resource areas correspond with the resource chapters (Chapters 5–14) of this recirculated substitute environmental document (SED). The cumulative impacts associated with the No Project Alternative (LSJR/SDWQ Alternative 1) are discussed in Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*. The cumulative impacts associated with other indirect and additional actions are discussed in Chapter 16, *Evaluation of Other Indirect and Additional Actions*.

This chapter also fulfills the CEQA requirement to describe the growth-inducing impacts of a proposed project. This chapter discusses the ways in which the LSJR and SDWQ alternatives could directly or indirectly foster economic or population growth or the construction of additional projects. (Cal. Code Regs., tit. 14, §15126.2, subd. (d).)

Finally, this chapter fulfills the CEQA requirement to disclose any significant irreversible environmental changes that could potentially result from implementation of the LSJR and SDWQ alternatives. (Cal. Code Regs., tit. 14, § 15126.2, subd. (c).)

17.2 Cumulative Impacts

17.2.1 Projects Considered

Cumulative impacts are defined in the State CEQA Guidelines as “two or more individual effects which, when considered together, are considerable or which compound or increase other environmental impacts.” (Cal. Code Regs., tit. 14, § 15355.) A cumulative impact from several projects is “the change in the environment which results from the incremental impact of the project when added to other closely related past, present, and reasonable foreseeable probable future projects. Cumulative impacts can result from individually minor but collectively significant projects taking place over a period of time." (Cal. Code Regs., tit. 14, § 15355, subd. (b).)

Overall, the LSJR alternatives would generally increase the instream flow requirements above baseline conditions. The principal potential impacts of the LSJR alternatives stem from the following factors.

- Reduced availability of surface water for agricultural, municipal, and other uses that result from requiring unimpaired flows[1] to remain in the stream system for the protection of fish and wildlife.
- Changes in timing and magnitude of flows in the plan area and reduced surface water availability for diversion that in turn have effects on groundwater.
- Changes in the timing and magnitude of flows that affect reservoir levels and riverine systems.

The cumulative analysis considers adverse effects of the project identified in the resource chapters that are significant or less than significant. If an impact has been determined to have no effect, then it would not contribute to any cumulative effects and it is not discussed in this chapter.

As described in the respective resource chapters (Chapters 5–14), LSJR Alternatives 3 and 4, with or without adaptive implementation, would have a significant and unavoidable impact on the following resources in the plan area.

- Groundwater resources
- Recreational resources and aesthetics
- Agricultural resources
- Service providers
- Energy and greenhouse gases

LSJR Alternative 2 with adaptive implementation would have a significant and unavoidable impact on groundwater, agriculture, and service providers in the plan area. LSJR Alternatives 2, 3, and 4 with or without adaptive implementation would have a less-than-significant effect on the other resources addressed in this SED, each of which is also evaluated in this chapter.

SDWQ Alternative 2 would have a significant and unavoidable impact on service providers. SDWQ Alternatives 2 and 3 would have a less-than-significant impact on surface hydrology and water quality, agricultural, and energy and greenhouse gases. SDWQ Alternatives 2 and 3 would have no impact on the other resources evaluated in Chapters 5–14 this SED.

The principal effect of SDWQ Alternative 2 would stem from the potential need of wastewater treatment plant operators to construct new wastewater treatment facilities or expand existing facilities to comply with salinity objectives. The construction of new wastewater treatment facilities or expansion of existing facilities or infrastructure could cause significant environmental effects and, thus, have a significant and unavoidable impact on service providers. The indirect environmental effects, cumulative and otherwise, of these new or expanded facilities or infrastructure are

---

[1] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.

separately evaluated in Chapter 16, *Evaluation of Other Indirect and Additional Actions*. Statements in this chapter that an SDWQ alternative will have no impact pertains to the impact questions evaluated in Chapters 5–15 of the SED.

As described in the respective resource chapters, LSJR Alternatives 2 with adaptive implementation and LSJR Alternatives 3 and 4 with or without adaptive implementation would have a significant and unavoidable impact on the following resources within the extended plan area.

- Aquatic biological resources
- Terrestrial biological resources
- Recreational resources and aesthetics
- Service providers
- Energy and greenhouse gases

LSJR Alternatives 2, 3, and 4 with or without adaptive implementation would have a less-than-significant effect on the other resources in the extended plan area.

The SDWQ alternatives would not have impacts in the extended plan area because (1) flows in the extended plan area are not expected to change in response to the SDWQ alternatives, and (2) the extended plan area is far upstream from the southern Delta, which means that any change in the salinity conditions in the southern Delta would not affect the water quality in the extended plan area. As such, no cumulative impact is associated with the SDWQ alternatives in the extended plan area and, therefore, are not discussed further in this chapter.

As discussed in Chapter 15, the No Project Alternative (LSJR/SDWQ Alternative 1) would have significant and unavoidable impacts on the following resources.

- Surface hydrology and water quality
- Aquatic biological resources
- Terrestrial biological resources
- Recreational resources and aesthetics
- Agricultural resources
- Cultural resources
- Service providers
- Energy and greenhouse gases

The No Project Alternative would have a less-than-significant effect on the other resources addressed in this SED.

The proposed plan amendments are analyzed at a programmatic level of detail in this cumulative effects analysis. Responsibility for implementing the objectives will be assigned in future proceedings and evaluated on a project-level basis in accordance with CEQA. Where information is not sufficient for a detailed cumulative effects analysis, or there is a high level of uncertainty as to what actions would occur and how they would affect resources, this is noted in the text and no attempt at speculation is made.

Projects with Potential Cumulative Impacts

Table 17-1 lists and describes specific projects, or categories of projects, that could have a cumulative impact and why. The description of the potential impacts of the LSJR and SDWQ alternatives on each resource is in the respective resource chapter (Chapters 5–14). Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*, describes the impacts of the No Projects Alternative, including cumulative impacts.

This cumulative impact evaluation considers past projects, present projects, and reasonably foreseeable probable future projects with related effects in the San Joaquin River (SJR) Basin (including the three eastside tributary watersheds—the Stanislaus, Tuolumne, and Merced Rivers), the southern Delta, and Delta. *Present and reasonably foreseeable probable future projects* are those projects that currently exist or are sufficiently certain to allow for a meaningful analysis, such as projects that are currently under construction, approved for construction, have submitted a request for approval or review by an agency, or are in the final stages of formal planning. Cumulative effects from past projects are generally reflected in the existing environmental conditions described in the resource chapters and provide context for the geographic area of environmental effects that are included in the cumulative impact analysis.

A number of past and present projects which affect flows in the LSJR and Delta are included in baseline. However, due to their dynamic nature all possible future effects may not be fully represented by the baseline. Given their potential to have different effects due to changing conditions, the cumulative effects of the following projects, described in Table 17-1, are also considered.

- National Marine Fisheries Service (NMFS) Biological Opinion and Conference Opinion on the Long-Term Operations of the Central Valley Project (CVP) and State Water Project (SWP) (NMFS BO)
- United States Fish and Wildlife Service (USFWS) Biological Opinion on the Long-Term Operations of CVP and SWP (USFWS BO) (delta smelt)

Table 17-1 also includes categories of projects, with examples, so that the cumulative effects of a general class of projects can be determined. For example, water transfers are included as a general category of past, present, and reasonably foreseeable probable future projects that could have a cumulative effect. While water transfers are considered reasonably foreseeable, they are temporary in nature and can vary widely year-to-year. Historically, 1–2 water transfers of approximately 4–25 thousand acre-feet (TAF) occur annually within the plan area, as defined in Chapter 1, *Introduction*. These historical water transfers can be used to estimate the frequency and volumes of transfers that may occur in the future.

Table 17-1. Cumulative Project List

Project: California High Speed Rail Project

Status: Future—project development is ongoing

Location: San Francisco Peninsula, Santa Clara Valley, San Joaquin Valley, Antelope Valley, San Fernando Valley, and Los Angeles Basin

Project description: This project would involve the planning, design, construction, and operation of a high speed rail system connecting major population centers across California. Phase 1 of the project would run from San Francisco to the Los Angeles Basin (to be completed by 2029). Phase 2 of the project would extend the system to Sacramento and San Diego (no scheduled completion date). Once completed, the system would have up to 24 stations covering 800 miles. Construction of the system could create thousands of jobs and boost economic development across the state, encouraging population growth. Once completed, the project would improve environmental quality by reducing greenhouse gas (GHG) emissions from other forms of transportation.

Resource areas with potential cumulative effects:

- Groundwater resources
- Agricultural resources
- Service providers
- Energy and greenhouse gases

This project is expected to encourage population growth. This could increase water use in the region, which has historically relied on groundwater supplies. Therefore, it can be presumed that increased water demand would increase groundwater pumping, thereby affecting groundwater resources, reducing water availability for agricultural uses, and requiring service providers to meet the increased water demand. In addition, while the completed project is expected to reduce GHG emissions, construction would rely on considerable use of heavy equipment and construction vehicle trips, which could lead to increased GHG emissions. Thus, the project could have a related effects as the plan amendments on groundwater, agriculture, service providers, and energy and greenhouse gases.

Project: California WaterFix

Status: Future—project development is ongoing

Location: Delta

Project description: This project is proposed by the California Department of Water Resources (DWR) as a new State Water Project (SWP) Delta facility that would include three new screened intakes on the Sacramento River in the northern Delta, each capable of diverting up to 3,000 cubic feet per second (cfs) of water. This project would make physical and operational improvements to the SWP system in the Delta necessary to restore and protect ecosystem health, water supplies of the SWP and the Central Valley Project (CVP) south of the Delta, and water quality within a stable regulatory framework, consistent with statutory and contractual obligations. The Draft Bay Delta Conservation Plan (BDCP) and BDCP Draft Environmental Impact Report/Environmental Impact Statement (EIR/EIS) were made available by DWR and the U.S. Bureau of Reclamation (USBR) for public review and comment in 2013. After consideration of the public comments, which included concerns regarding the effectiveness of certain habitat restoration measures and the level of scientific uncertainty regarding future conditions associated with climate change, DWR and USBR proposed a modified preferred alternative, Alternative 4A (i.e., “California WaterFix”), in 2015.

Alternative 4A includes the water conveyance facilities originally proposed but does not include the habitat conservation plan. It also uses a different regulatory approach for obtaining the permits and authorizations needed for implementation under the federal Endangered Species Act (ESA) and the California Endangered Species Act (CESA). Alternative 4A is evaluated, along with other proposed alternatives, in the Recirculated Draft EIR/Supplemental Draft EIS (RDEIR/SDEIS) that was released on July 10, 2015 for public review and comment. On August 26, 2015, DWR and USBR filed an application with the State Water Resources Control

Board (State Water Board) for changes to their water rights permits that are needed to implement Alternative 4A. The water rights process will include public participation and the opportunity to comment; the evidentiary hearing on the petition began in July, 2016.

Resource areas with potential cumulative effects:

- Surface hydrology and water quality
- Aquatic biological resources
- Agricultural resources
- Service providers

This project could affect hydrodynamics (i.e., flow paths) and water quality in the Delta, including the southern Delta. If surface water is diverted in the northern Delta, in lieu of at the SWP Clifton Court Forebay and the CVP Jones Pumping Plant in the southern Delta, it could reduce the reverse flow effect that occurs when Sacramento River and San Joaquin River (SJR) flows are drawn south instead of moving west, as they would naturally, towards the San Francisco Bay. Reducing reverse flows would generally result in improved hydrologic conditions for aquatic species as both fish and food production are not drawn towards the southern Delta where chances of survival for at-risk native fish species diminish. However, drawing less Sacramento River water to the southern Delta could also result in increased salinity and generally reduced water quality in the southern Delta as Sacramento River water is less saline. In general, increased salinity could have a cumulative effect on surface hydrology and water quality, aquatic biological resources, agricultural resources, and service providers. Additionally, there could be construction-related impacts associated with the installation of new gates at Clifton Court Forebay in the southern Delta. However, specific cumulative effects of this project cannot be determined because the project will be affected by other projects, described in this table, which could also affect flows paths in the Delta and could have similar effects. These other projects include: National Marine Fisheries Service (NMFS) Biological Opinion and Conference Opinion on the Long-Term Operations of the Central Valley Project and State Water Project (NMFS BO); United States Fish and Wildlife Service (USFWS) Biological Opinion on the Long-Term Operations of CVP and SWP (USFWS BO) (delta smelt); and, the update to the 2006 *Water Quality Control Plan for the San Francisco/Sacramento-San Joaquin Delta Estuary* (2006 Bay-Delta Plan), Phase II.

Project: Central Valley Salinity Alternatives for Long-Term Sustainability (CV-SALTS) and Central Valley-Wide Salt and Nitrate Management Plan (SNMP)

Status: Future—project development is ongoing

Location: Central Valley

Project description: This project would address salinity and nitrate problems in the Central Valley and develop long-term solutions that would lead to enhanced water quality and economic sustainability.
In 2006, the State Water Board and Central Valley Regional Water Quality Control Board (Central Valley Water Board) initiated this stakeholder effort. Near-term projects include developing the first phase of a conceptual model for salt and nitrate conditions in the Central Valley and a comprehensive and robust geographic information systems (GIS) framework to support the salt management planning effort.
The overarching goals of CV-SALTS include protecting and enhancing the environment and maintaining reliable, high-quality urban water supply, while also retaining the agricultural economy and supporting economic growth. The specific goal is to develop a salt-management plan in compliance with the state's recycled water policy. The Central Valley Water Board held a series of California Environmental Quality Act (CEQA) scoping meetings in October, 2013 for the development of an SNMP for incorporation into the Water Quality Control Plan for the Sacramento and San Joaquin River Basins (Sacramento–San Joaquin Basin Plan) and the Water Quality Control Plan for the Tulare Lake Basin (Tulare Lake Basin Plan). Additional stakeholder meetings regarding the development of the SNMP and possible amendments to the Sacramento–San Joaquin Basin Plan and Tulare Lake Basin Plan were held in June and August, 2016. The draft SNMP is expected to be completed in late 2016. This project also includes the development of new water quality objectives for salinity for the lower San Joaquin River (LSJR) upstream of Vernalis, which will be proposed as a future basin plan amendment to the Sacramento–San Joaquin River Basin Plan.

Resource areas with potential cumulative effects:

- Surface hydrology and water quality
- Service providers

CV-SALTS would balance the use of assimilative capacity and the implementation of management measures. Therefore, it could change the timing and magnitude of salt discharges to the LSJR and southern Delta channels, which could affect water quality conditions in the LSJR, including salt loading. Thus, CV-SALTS could have a related effects as the plan amendments on surface hydrology and water quality and service providers.

Project: County General Plan Updates

Status: Ongoing

Location: Merced, San Joaquin, and Stanislaus Counties

Project description: General plans for counties identify land use designations, land use changes, and plans for growth. Following is a list of plans and the status of updates for the counties that can cause similar impacts as the plan amendments.

Merced—The 2030 *Merced County General Plan* was adopted on December 10, 2013. The plan is an overarching policy document that guides land use, housing, transportation, infrastructure, community design, and other policy decisions.

- San Joaquin—The draft 2035 *General Plan for San Joaquin County* was released for public comment in October, 2014. Many of the existing policies of the county's 2010 General Plan remain unchanged, but the comprehensive update reflects a new vision for future growth and development within the county. It also reflects recent state law requirements, including: Delta protection and use; flood risk protection; water and energy conservation; and GHG emissions reductions.
- Stanislaus—Revises the Land Use, Circulation, Conservation/Open Space, Noise, and Safety Elements. The update will incorporate changes in legislation, code, and local standards on a 20-year planning horizon (to 2035). There will be no changes to the Land Use map designations. The draft EIR was released for public review in April 2016.

Resource areas with potential cumulative effects:

- Agricultural resources
- Groundwater resources
- Service providers

The San Joaquin Valley is one of the fastest-growing areas in California, with urban expansion often resulting in the conversion of land from agricultural uses to nonagricultural uses. Although county general plans regulate land use conversions (e.g., Stanislaus County requires a majority of county voters to approve rezoning land designated as agricultural or open space to residential), urban expansion efforts that prioritize the implementation of water supply projects and other construction, could result in the removal of land from agricultural use in the plan area, including Important Farmland. The final EIR for the Merced 2030 General Plan and the draft EIR for the Stanislaus General Plan Update state that buildout under the plans could result in significant impacts related to groundwater depletion and recharge. The draft EIRs for the San Joaquin 2035 General Plan and the Stanislaus General Plan Update state that there would be significant impacts related to the construction of new water supply or treatment facilities or the expansion of existing facilities. Thus, these county general plans could have related an effects as the plan amendments on agricultural resources, groundwater resources, and service providers.

Project: Delta Stewardship Council (DSC) Delta Plan

Status: Future

Location: Delta

Project description: The Delta Plan addresses a range of challenges facing the Delta, including water supply reliability and Delta ecosystem health concerns. The Sacramento–San Joaquin Delta Reform Act of 2009 (California Water [Cal. Wat.] Code, § 85000 et seq.) provides for the establishment of an independent state agency, the DSC, to achieve the coequal goals of providing a more reliable water supply for California and protecting, restoring, and enhancing the Delta ecosystem. The DSC is charged with the development and implementation of a legally enforceable, long-term comprehensive management plan for the Sacramento–San Joaquin Delta to achieve the coequal goals. The Delta Plan was unanimously adopted by the DSC on May 16, 2013 and became effective on September 1, 2013. On June 23, 2016, a Sacramento Superior Court judge issued a ruling setting aside the Delta Plan because parts of it were not consistent with the Delta Reform Act and ordering the DSC to revise the Delta Plan. The decision has been appealed. Any revised Delta Plan would likely be similar to the existing plan because many aspects of the plan were upheld and are required to fulfill the statutory mandates of the Act.

The Delta Plan is intended to provide a comprehensive, long-term management plan for the Delta, and it establishes regulatory policies that would be binding on certain covered actions (as defined in Cal. Wat. Code § 85057.5) and non-binding recommendations to further the state's coequal goals for the Delta. DSC does not exercise direct review and approval over covered actions. Covered actions are plans, programs, or projects that (1) will occur, in whole or in part, within the boundaries of the Delta or Suisun Marsh; (2) will be carried out, approved, or funded by the state or a local public agency; and (3) is covered by one or more of the Delta Plan policy areas (reliable water supply; delta ecosystem restoration; water quality improvement; flood risk reduction; and, protection and enhancement of the Delta as an evolving place).

The Delta Plan will be implemented through requiring the statutorily defined covered actions of other public agencies to be consistent with the Delta Plan and providing recommendations to other public agencies regarding future actions they may take. While the State Water Board's regulatory actions are not covered actions subject to the Delta Plan, the Delta Plan contains recommendations for State Water Board's development of flow objectives and criteria for the Delta and major tributary streams in the Delta watershed. The State Water Board identified the Stanislaus, Tuolumne, and Merced Rivers as high priority tributaries for these actions. While the Delta Plan could result in other agencies or entities taking future actions, it would not directly result in regulatory approvals or actions, or other projects. The EIR for the Delta Plan explains that it evaluates potential actions as part of its proposed project, even though the Delta Plan would not directly cause, and the DSC would not have regulatory authority over, most actions (Delta Stewardship Council 2013).

Resource areas with potential cumulative effects:

- Surface hydrology and water quality
- Flooding, sediment, and erosion
- Agricultural resources
- Energy and greenhouse gases

While the Delta Plan would not directly result in regulatory approvals, actions, or other projects, it could result in other agencies or entities taking future actions. The Delta Plan could recommend and require consistency determinations for projects that could affect circulations patterns in the southern Delta. These projects could reduce circulation of water in the southern Delta, which could reduce dilution of locally saline water and increase salinity in the southern Delta channels. This could increase the number of months with EC above the water quality objective for salinity at the southern Delta compliance locations, thereby potentially affecting the surface hydrology and water quality resources. Additionally, if the Delta Plan recommends projects that involve habitat restoration or flow augmentation, it could have a cumulative effect on flooding, sediment, and erosion. Or, if the Delta Plan recommends projects that could convert agricultural land to nonagricultural uses (e.g., habitat restoration), it could have a cumulative effect on agricultural resources. Lastly, construction of projects recommended by the Delta Plan could rely on considerable use of heavy equipment and construction vehicle trips, which could lead to increased GHG emissions and could have an effect on energy and greenhouse gases.

Project: **Federal Energy Regulatory Commission (FERC) Relicensing of the Don Pedro Hydroelectric Project (FERC Project No. 2299)**

Status: Future—project development is ongoing

Location: Tuolumne County, Tuolumne River

Project description: This project would relicense the Don Pedro Hydroelectric Project so it can continue to operate under new license conditions. The current FERC license expired on April 30, 2016. Modesto and Turlock Irrigation Districts filed their application for a new license on April 28, 2014. FERC relicensing of the New Don Pedro Project may affect the operations of the CCSF's Hetch Hetchy system if CCSF contributes water supply to meet instream flows imposed as a condition of water quality certification associated with the relicensing or otherwise imposed through the relicensing process. Currently, however, there is no specific action to alter Hetch Hetchy operations. Some studies remain to be completed before agencies and other stakeholders can file recommended terms and conditions with FERC. State Water Board staff are engaged in the FERC process and will provide input at the appropriate time regarding new streamflow recommendations and other measures for the projection of beneficial uses in the Tuolumne River. The State Water Board also has mandatory conditioning authority due to the required water quality certification under Clean Water Act (CWA) Section 401.

Resource areas with potential cumulative effects:

- Flooding, sediment, and erosion
- Aquatic biological resources
- Terrestrial biological resources
- Recreation resources and aesthetics
- Agricultural resources
- Cultural resources
- Energy and greenhouse gases

The operation of this project was considered in the effects analysis for the LSJR alternatives, including a wide range of potential flow releases. As such, the cumulative effects for the resources listed above are not expected to be significantly different from those identified for the LSJR and SDWQ alternatives, as discussed in the respective resource chapters (Chapters 5–14). However, localized changes resulting principally from re-operation of the reservoir could occur as other agencies have mandatory conditioning authority and because there could be project-specific operational and infrastructure changes. While there are currently no specific action to alter Hetch Hetchy operations any change in CCSF's operations could result in potential cumulative effects to the resources listed above. Localized changes at Don Pedro Reservoir or upstream within the CCSF systems could have a related effects as the plan amendments on the resource areas listed above.

Project: **FERC Relicensing of Merced River Hydroelectric Project (FERC Project No. 2179) and Merced Falls Hydroelectric Project (FERC No. 2467)**

Status: Future—project development is ongoing

Location: Mariposa County, Merced River

Project description: This project would relicense the Merced River and Merced Falls hydroelectric projects (owned by Merced Irrigation District [ID] and Pacific Gas and Electric Company [PG&E], respectively) so they can continue to operate under new license conditions. The original licenses for both projects expired on February 28, 2014. However, both projects continue to operate under FERC-issued annual licenses, which include the conditions of the original licenses, until the relicensing proceedings are completed and new licenses are issued. The participants in the FERC relicensing process filed recommended terms and conditions for inclusion in a new FERC license, and FERC issued a draft EIS for the relicensing of the Merced River Project and the Merced Falls Project on March 30, 2015. Comments on the draft EIS were due to FERC on May 29, 2015 and FERC will address those comments in a final EIS. Merced ID has begun the process to purchase the Merced Falls Hydroelectric Project from PG&E, and so will be the licensee for both projects.

Resource areas with potential cumulative effects:

- Flooding, sediment, and erosion
- Aquatic biological resources
- Terrestrial biological resources
- Recreation resources and aesthetics
- Agricultural resources
- Cultural resources
- Energy and greenhouse gases

The operation of this project was considered in the effects analysis for the LSJR alternatives, including a wide range of potential flow releases. As such, the cumulative effects for the resources listed above are not expected to be significantly different from those identified for the LSJR and SDWQ alternatives, as discussed in the respective resource chapters (Chapters 5–14). However, localized changes resulting principally from re-operation of the reservoir could occur as other agencies have mandatory conditioning authority and because there could be project-specific operational and infrastructure changes. These localized changes could have related effects as the plan amendments on the resource areas listed above.

Project: **FERC Relicensing of Lyons Reservoir**

Status: Planned/ongoing

Location: Upper Stanislaus River (south fork)

Project description: This project would relicense the Lyons Reservoir Hydroelectric Project and allow PG&E continued operation under the facility under new license conditions. The current FERC license expires in August of 2022. PG&E will begin the FERC relicensing process around August of 2017 with their final license application due in the summer of 2020. Studies of the reservoir and system (including the transfer of water to Tuolumne Utilities District (TUD) via the Main Tuolumne Canal to a penstock that connects to PG&E's Phoenix Powerhouse; between 4 to 30 cfs is regularly passed through the powerhouse and discharged to Power Creek) remain to be completed before agencies and other stakeholders can file recommended terms and conditions with FERC. State Water Board staff will be engaged in the FERC process and will provide input at the appropriate time regarding new streamflow recommendations and other measures for the projection of beneficial uses in the Stanislaus River. The State Water Board also has mandatory conditioning authority due to the required water quality certification under CWA Section 401.

Resource areas with potential cumulative effects:

- Aquatic biological resources
- Terrestrial biological resources

- Cultural resources
- Recreation resources and aesthetics
- Cultural resources
- Hydropower
- Energy and greenhouse gases

Localized changes resulting principally from re-operation of the reservoir could occur as other agencies have mandatory conditioning authority and because there could be project-specific operational and infrastructure changes. Localized changes at Lyons Reservoir could have related effects as the plan amendments on the resource areas listed above.

Project: Groundwater recharge projects

Status: Ongoing

Location: Eastern San Joaquin, Modesto, Turlock, and Merced Groundwater Subbasins

Project description: These projects are intended to replenish groundwater resources to prevent or minimize groundwater overdraft and subsidence issues, and are used as part of a conjunctive management approach to ensure a reliable, drought-tolerant regional water supply by banking water in wet years for use in dry years. An example of a groundwater recharge project is the Farmington Groundwater Recharge Program in San Joaquin County. The Stockton East Water District (SEWD), United States Army Corps of Engineers, and other local water agencies launches the project to partner with local landowners, businesses, growers, and ranchers to save the region's water supply by recharging an average of 35 thousand acre-feet (TAF) of water annually into the Eastern San Joaquin Subbasin, in the eastern part of San Joaquin County. The goal of the program is to directly recharge the groundwater basin and increase surface water deliveries in-lieu of groundwater pumping to reduce overdraft and establish a barrier to saline water intrusion.

Resource areas with potential cumulative effect:

- Surface hydrology and water quality
- Aquatic biological resources
- Agricultural resources

Water diverted from the Stanislaus, Tuolumne, and Merced Rivers and the SJR upstream of Merced for these projects could result in decreased inflow of low salinity water into the southern Delta, possibly resulting in higher concentration of pollutants in the SJR and increased salinity in the southern Delta. These projects could also reduce the quality and quantity of water that remains in the rivers and is available for agriculture irrigation, and therefore could have related effects as the plan amendments on surface hydrology and water quality, aquatic biological resources, and agricultural resources. However, as discussed in Chapter 7, *Aquatic Biological Resources*, stream flows are expected to remain within the historic range.

Project: Habitat restoration projects

Status: Planned/ongoing

Location: Merced, Stanislaus, and Tuolumne Watersheds

Project description: Habitat restoration projects may address aquatic habitat (e.g., the Habitat Restoration Plan for the Lower Tuolumne River Corridor and the Gravel Mining Reach Floodway Restoration Projects), or terrestrial habitat (e.g., the Grayson River Ranch Conservation Easement). Restoration projects may include (1) physical activities to address gravel-dominated reaches of the tributaries, where past in-channel and channel-adjacent gravel mining have simplified the channel configuration and aquatic habitat and reduced gravel transport; or (2) re-establishing native plant species and restoring floodplains. Projects considered are as follows.

- Central Valley Project Improvement Act—Mandate to balance competing demands for a limited supply of water, which include: meeting the requirements of fish and wildlife protection, restoration and enhancement; agriculture; and municipal, industrial, and power uses. The 1992 legislation includes mandates that change the management of the CVP and measures that are likely to reduce the amount of water available for irrigation and municipal use. Continued implementation actions include habitat restoration actions in the plan area.
- California EcoRestore (A California Natural Resources Agency initiative)—Help coordinate and advance habitat restoration in the Sacramento–San Joaquin Delta. A broad range of habitat restoration projects will be pursued, including projects to address aquatic, sub-tidal, tidal, riparian, floodplain, and upland ecosystem needs.
- Dos Rios Ranch—Restore land to provide wildlife habitat and flood control in Central Valley on 1,600 acres of biologically rich floodplain in the Central Valley, including along the SJR and Tuolumne River.
- Gravel Mining Reach Floodway Restoration—Restore 7 miles of Tuolumne River actively gravel mined area to increase floodway capacity to convey 15,000 cfs, increase salmon spawning and rearing habitat, protect dikes and off-channel pits from future flood damage, and restore riparian forests on floodplains.
- Habitat Restoration Plan for the Lower Tuolumne River Corridor—Provide an integrated and long-term restoration strategy for the Lower Tuolumne River to maximize anadromous fish habitat improvements, minimize channel restoration project costs, and streamline project evaluation and monitoring. The plan's development process is intended to (1) propose general types of inventoried preservation and restoration sites, (2) evaluate fluvial geomorphic processes, (3) evaluate geomorphic-salmonid relationships and develop restoration strategy, (4) finalize restoration site list and designs, and (5) integrate into a comprehensive river corridor habitat restoration plan.

  Knights Ferry Floodplain and Side-Channel Restoration—Restore existing side-channel and floodplain habitat to benefit Chinook salmon and steelhead.
- Lower Tuolumne River Big Bend Project—Improve forest, river, and wildlife habitats along the Tuolumne River. When completed, over 25,000 native trees and shrubs will have been planted, and over 150 acres of native grasses and forbs will have been seeded throughout the 240,250-acre project area.
- Restoration of the Ruddy Mining Reach—Restore and increase salmonid spawning and rearing habitat along the lower Tuolumne River in the Ruddy Mining area. The project covers a 6.1-mile length of channel and is located approximately 23 miles east of Modesto.
- Proposed Expansion of the San Joaquin River National Wildlife Refuge—Expand the refuge and acquire up to 22,156 acres along the LSJR and Tuolumne and Stanislaus Rivers to protect and restore riparian habitat to benefit the birds of the Pacific Flyway and numerous other wildlife species.

- Spawning Gravel Supplementation (Stanislaus County, Tuolumne River)—Mechanically place large volumes of gravel followed by periodic augmentation and maintenance of gravel supply, as needed, for river restoration.
- Tuolumne River Restoration Projects including Warner Deardorff Segment, Mining Reach Project No. 3—Return a 6.1-mile reach of the Tuolumne River to a more natural, dynamic channel morphology to improve, restore, and protect instream and riparian habitat for fall-run Chinook salmon survival, including restoring hydrological and geomorphic processes.

Resource areas with potential cumulative effects:

- Flooding, sediment, and erosion
- Terrestrial biological resources
- Agricultural resources

Habitat restoration projects are typically not expected to result in a change to levee stability, flooding potential, or sediment and erosion potential. However, if the projects involve construction in or adjacent to channels, the projects may alter the course of a stream or river such that substantial erosion or siltation on- or offsite may result. Additionally, habitat restoration projects typically not expected to result in an impact on terrestrial biological resources as they are meant to recover wildlife species and habitat. However, projects may have short-term impacts (e.g., construction noise or temporary removal of habitat) on sensitive terrestrial species and habitat. Habitat restoration projects could reduce water availability from the Stanislaus, Tuolumne, and Merced Rivers and the SJR, which could reduce the number of irrigated acres, thereby potentially resulting in related effects as the plan amendments on agricultural resources.

Project: Merced County's Castle Airport Master Plan (AMP) for Development of Castle Airport

Status: Future—project development is ongoing

Location: Merced County

Project description: Adopted by Merced County in 2011, the AMP lays out the plan for ultimate development of the airport and its operations. The project would convert the former U.S. Air Force base into a civilian use airport that would include an air cargo facility, a corporate and private aircraft service center, a charger operation, modern hangers, and a cold storage facility for produce. The AMP functions as a tool for the implementation of the aviation elements, and is consistent with the planned airport facilities and operations are specified in the 1996 Castle Air Force Base Reuse Plan. The completed project would include office and commercial development, and is expected to promote new jobs to area residents, air cargo and airline operations, stimulate investment and new growth, and create employment opportunities and commercial development. The project's initial study found that this project would result in increased water demand and is likely to deplete groundwater supplies (County of Merced Department of Commerce 2011).

Resource areas with potential cumulative effects:

- Groundwater resources
- Service providers
- Energy and greenhouse gases

This project is expected to encourage population growth, which could increase water use in the region, which has historically relied on groundwater supplies. Increased water demand could increase groundwater pumping, thereby affecting groundwater resources and the service providers who would need to meet the increased water demand. Additionally, this project could have construction-related impacts that could lead to increased GHG emissions. Thus, the project could have related effects as the plan amendments on groundwater, service providers, and energy and greenhouse gases.

Project: Modesto Regional Water Treatment Plant (MRWTP) Phase Two Expansion Project

Status: Ongoing

Location: Tuolumne River and SJR Watersheds in Stanislaus County

Project description: The Modesto Irrigation District (MID) and the City of Modesto expansion of the City's water treatment plant doubles the plant's capacity. The project also involves the construction of multiple downstream facilities (including storage reservoirs, pump stations, transmission and distribution pipelines, and regulating values) to provide adequate municipal and industrial water supply within the City's service area. The project is intended to ensure reliable water supplies, and meet increased water demands associated with projected population growth in the region. Lastly, the project's Final Subsequent Environmental Impact Report states that the City of Modesto is also building additional water supply wells to make up for well capacity that has been lost due to contamination (MID 2005).

Resource areas with potential cumulative effects:

- Groundwater resources
- Agricultural resources
- Energy and greenhouse gases

This project would improve the quality of drinking water sources and therefore would not result in cumulatively considerable or significant effects on service providers. This project is partially in response to projected population growth and the associated increases in total water use demands. As this area has historically relied on groundwater supplies, increased water demand could increase groundwater pumping, thereby affecting groundwater resources. Increasing the plant's capacity allows the City to receive more water for domestic use, which could result in reduced water availability for agricultural uses, thereby reducing the number of acres that could be irrigated. Additionally, this project could have construction-related impacts that could lead to increased GHG emissions. Thus, the project could have related effects as the plan amendments on groundwater, agricultural resources, and energy and greenhouse gases.

Project: NMFS Biological Opinion and Conference Opinion on the Long-Term Operations of the CVP and SWP

Status: Present

Location: SJR, tributaries, southern Delta, Delta

Project description: A 2009 BO in which NMFS concluded that continued operations of the CVP and SWP would likely jeopardize several listed species, including Sacramento River winter-run Chinook salmon, Central Valley spring-run Chinook salmon, Central Valley steelhead, the southern distinct population segment of North American green sturgeon, and southern resident killer whales. The 2009 BO identifies the following actions to be taken by USBR and/or DWR.

- Limit the magnitude of reverse flows in Old and New Rivers to reduce entrainment of juvenile fish into state and federal export facilities in the southern Delta.
- Implement facility improvements at state and federal export facilities to increase fish survival.
- Implement measures, including a fish study using acoustic tags, to increase survival of juvenile steelhead migrating from the SJR Basin.
- Implement a year-round minimum flow regime that improves conditions for steelhead in the Stanislaus River.
- Issue a BO effective through December 31, 2030.
- Propose a reasonable and prudent alternative (RPA) that, if implemented, is believed to avoid the likelihood of jeopardizing the continued existence of these listed species.

Resource areas with potential cumulative effects:

- Surface hydrology and water quality
- Aquatic biological resources
- Terrestrial biological resources
- Agricultural resources
- Cultural resources
- Energy and greenhouse gases

This project places limits on SWP and CVP exports and reverse flows on Old and Middle Rivers. These changes to hydrodynamics in the Delta, including limits on Old and Middle River flows, could affect circulation patterns in the southern Delta and could result in different salinity conditions in the southern Delta. Through elevated salinity levels in the southern Delta, the ongoing project, therefore, has the potential to have a cumulative effect on surface hydrology and water quality, aquatic biological resources, terrestrial biological resources, and agricultural resources. Additionally, this project could result in the re-operation of the reservoirs which could lead to a change in the amount and timing of water surface elevation fluctuations in the reservoirs. A change in the rates of flows downstream of the reservoirs could have a cumulative effect on the cultural resources. These changes could also change the timing of, or reduce, hydropower generation from the dams, which, in turn, could have an effect on energy resources.

Project: Recreation management and improvement projects

Status: Planned/ongoing

Location: Merced, Stanislaus, and Tuolumne Watersheds, and SJR up to Friant Dam

Project description: These long-term management plans implement projects to improve and increase recreation facilities and establish a visitor use capacity program that addresses the kinds and amounts of public use that can be sustained while protecting and enhancing the resource. Projects considered include the following.

- Tuolumne Wild and Scenic River Comprehensive Management Plan—Long-term management plan for the 54-mile stretch of the Tuolumne Wild and Scenic River corridor within Yosemite National Park to ensure a high-quality visitor experience. The plan includes projects that would expand recreational opportunities in the riparian zone and improve conditions that pose localized risks to scenic vistas. Located within the extended plan area.
- Merced Wild and Scenic River Final Comprehensive Management Plan—Long-term management plan for the Merced River corridor to ensure a high-quality visitor experience. The plan includes projects that would increase camping opportunities, diversity recreation options, and restore the riverbank, which would improve in-water recreation activities. Located within the extended plan area.
- Central Valley Vision—A 20-year roadmap for improving state parks in the Central Valley. Includes improving and increasing recreation facilities at existing parks (e.g., new boating trails, increasing the number of campsites and picnic sites, and improving river access for swimming, boating, and other water sports) along the Stanislaus, Merced, and Tuolumne Rivers and the SJR.
- San Joaquin River Blueway Plan—A plan that provides the public opportunities to explore and enjoy the SJR from its headwaters to the Delta via a network of parks, wildlife refuges, and other publicly accessible places. The long-term vision plan, released in 2011, proposes improved access to the Upper SJR by creating a blueway—a boating trail to camping, fishing, bird watching, and other kinds of recreation. The plan would provide additional shore-based recreation opportunities, which may result in increased opportunities for water-enhanced recreation. The plan would expand recreational opportunities and use of the SJR without degrading the condition or visual character of the resource.

Resource areas with potential cumulative effects:

- Recreation resources and aesthetics

These types of projects are typically not expected to result in a change to levee stability, flooding potential, or sediment and erosion potential. And, unrelated to flow and water levels, these and similar projects would be expected to modify and enhance on-bank and in-water recreational opportunities. However, the development of recreation facilities around the reservoirs and urbanization of the watersheds could impact the views and viewsheds (i.e., aesthetics) experienced by recreationists. Thus, the projects could have related effects as the plan amendments on recreation resources and aesthetics.

Project: San Francisco Public Utilities Commission (SFPUC) Hetch Hetchy Repair and Rehabilitation Program and Lower Cherry Aqueduct Emergency Rehabilitation

Status: Present

Location: Tuolumne River and Lower Cherry Aqueduct

Project description: The Lower Cherry Aqueduct (LCA) consists of a small diversion dam on Cherry Creek and a 3.6-mile-long aqueduct comprised of alternating segments of tunnel, canal, and above-ground and buried pipelines that convey water from Cherry Creek Diversion Dam (CCDD) to Early Intake Reservoir on the Tuolumne River. At Early Intake Reservoir, Mountain Tunnel head gates can be opened to allow water to flow into the SFPUC's tunnel and pipeline system that carries water to the San Francisco Bay Area. The reliable function of this facility is critical for providing a backup water supply for SFPUC customers. The proposed improvements, to be implemented in two phases, would initially replace open canal sections with large-diameter buried pipe; restore and replace deteriorated fire-damage structures at CCDD, and restore the access path to the CCDD. In the future, one section of elevated pipeline that constricts the flow of the aqueduct would be replaced with a larger-diameter pipeline to restore the facility's historical design capacity of 200 cfs.

Resource areas with potential cumulative effects:

- Aquatic biological resources
- Terrestrial biological resources

Streamflows within Eleanor and Cherry Creeks would be directly affected by operation of LCA. Operation of the LCA also would have an indirect streamflow effect within Cherry Creek downstream of Holm Powerhouse and on the mainstem of the Tuolumne River during reservoir storage recovery years. As such, implementation could have an effect on habitat conditions for aquatic and biological species.

Project: Sustainable Groundwater Management Act (SGMA)

Status: Present

Location: Groundwater basins underlying the LSJR, Delta, and tributaries

Project description: SGMA establishes a framework requiring local agencies to sustainably manage groundwater resources. SGMA imposes deadlines for local agencies to form groundwater sustainability agencies, draft groundwater sustainability plans, and implement those plans to achieve groundwater sustainability within 20 years of plan adoption. SGMA authorizes state intervention in groundwater basin management if local managers are unable or unwilling to meet SGMA requirements. Given the directive to local agencies, and the backstop of state intervention if needed, it is anticipated that SGMA, along with other groundwater recharge, conjunctive use, and management projects, would not adversely impact groundwater resources and would actually benefit groundwater resources.

Resource areas with potential cumulative effects:

- Agricultural resources

SGMA would improve groundwater resources and provide service providers tools to prevent and/or mitigate domestic well drinking water supply impacts and therefore are not expected to result in a cumulative impact on groundwater resources and service providers. However, the initial implementation of SGMA could result in limits on groundwater supply for agricultural uses during the transition from current practices to sustainable groundwater management and, thus, could affect agricultural resources. Therefore, implementation of SGMA could potentially have a cumulative effect on agricultural resources.

Project: Tuolumne Utilities District (TUD) Phoenix Lake Preservation and Restoration Project

Status: Present and Future, -On-going Phased Project

Location: Tuolumne River, Tuolumne County

Project description: Phoenix Lake is an 88-acre water storage reservoir located approximately 3 miles east of the City of Sonora. Phoenix Lake water rights and facilities, as well as portions of the lake, are owned by the TUD. The TUD uses the lake as a primary drinking water source for the communities of Sonora, Jamestown, Scenic View and Mono Village. While the allowable storage capacity of the lake is approximately 900 acre-feet (AF), the current capacity is only 600 AF.

Phase III project will improve the water quality and restore storage capacity in Phoenix Lake and the Phoenix Lake watershed. Phase III will provide access to approximately 170 AF of water that currently does not exist. The construction of the sediment forebay will remove a majority of the sediments transported to the lake via the Sullivan Creek watershed.

Resource areas with potential cumulative effects:

- Surface hydrology and water quality
- Aquatic biological resources
- Terrestrial biological resources
- Recreational resources and aesthetics
- Cultural resources
- Energy and greenhouse gases

Depending on the historical diversions of TUD, the diversions could increase by up to 170 AF, given that Phase III would increase storage capacity up to that amount. This diversion could occur during the summer when water is typically used by TUD. As such, the on-going project also has the potential to have a cumulative effect on aquatic biological resources in the reservoir, terrestrial biological resources around the reservoir, and recreational resources and aesthetics in and around the reservoir depending on the drawdown experienced by the reservoir under the new storage capacity. The project is intended to improve water quality conditions in the lake and the long term health of the lake and its storage capacity, and as such is expected to have a beneficial effect on surface hydrology and water quality.

Project: USFWS Biological Opinion on the Long-Term Operations of CVP and SWP (delta smelt)

Status: Present

Location: SJR, tributaries, southern Delta, Delta

Project description: USFWS issued an opinion on December 15, 2008, to USBR on the effects of the continued operation of CVP and SWP on delta smelt and its designated critical habitat. It identified an RPA intended to protect each life stage and the critical habitat of the federally protected delta smelt and its designated critical habitat that includes flow components.

Resource areas with potential cumulative effects:

- Surface hydrology and water quality
- Aquatic biological resources
- Agricultural resources

This project places limits on SWP and CVP exports and reverse flows on Old and Middle Rivers. The NMSF biological opinion is meant to protect fish listed under ESA from being jeopardized by the adverse effects of SWP and CVP export water operations. While the required reservoir releases and pumping reductions could reduce direct impacts on fish, thereby not resulting in an impact on aquatic biological resources, less Sacramento River water could be drawn into the southern Delta, which could increase salinity. These changes to hydrodynamics in the Delta, including limits on Old and Middle River flows, could affect circulation patterns in the southern Delta resulting in different salinity conditions in the southern Delta. Through elevated salinity levels in the southern Delta, the on-going project also has the potential to have a cumulative effect the surface hydrology and water quality, and agricultural resources.

Project: University of California (UC) Merced 2020 Project

Status: Future—project development is ongoing

Location: Merced County

Project description: The project will double the size of the UC Merced campus to accommodate up to 10,000 students by 2020. The project would add approximately 1.2 million gross square feet of classroom, laboratory, student life, housing, and administrative and faculty space on 219 acres, including 136 acres of undeveloped land adjacent to the existing campus.

Resource areas with potential cumulative effects:

- Groundwater resources
- Service providers
- Energy and greenhouse gases

This project is expected to encourage population growth, which could increase water use in the region, which has historically relied on groundwater supplies. Therefore, it can be presumed increased water demand could increase groundwater pumping, thereby affecting groundwater resources and the service providers who would need to meet the increased water demand. Additionally, although the completed project is expected to reduce GHG emissions, the construction of the project would rely on considerable use of heavy equipment and construction vehicle trips, which could lead to increased GHG emissions. Thus, the project could have related effects as the plan amendments on groundwater, service providers, and energy and greenhouse gases.

Project: Update to the 2006 Bay-Delta Plan, Phase II

Status: Future—project development is ongoing

Location: Delta

Project Description: The comprehensive update of the 2006 *Water Quality Control Plan for the San Francisco/Sacramento-San Joaquin Delta Estuary* (2006 Bay-Delta Plan) by the State Water Board will evaluate and potentially amending existing water quality objectives that protect beneficial uses and the program of implementation to achieve those objectives. The elements of the Phase II update are: (1) Delta outflow objectives, (2) export/inflow objectives, (3) Delta Cross Channel Gate closure objectives, (4) Suisun Marsh objectives, (5) potential new reverse flow objectives for Old and Middle Rivers, (6) potential new floodplain habitat flow objectives, (7) potential changes to the monitoring and special studies program, and (8) other potential changes to the program of implementation. The State Water Board will also consider other potential changes to the Bay-Delta Plan during Phase II, including issues identified through the scoping process and information that is produced as part of California WaterFix.

Resource areas with potential cumulative effects:

- Surface hydrology and water quality
- Aquatic biological resources

- Agricultural resources
- Service providers

The principal elements of the Phase II update that could have potential cumulative effects are changes in export/inflow objectives and reverse flow objectives for Old and Middle River. The export/inflow objectives could change the timing and magnitude of exports from SWP and CVP pumping facilities, and other diversions, in the southern Delta in order to protect migrating salmon and other species. New reverse flow objectives for Old and Middle River could affect the quantity and timing of high quality Sacramento River flows across the Delta from the Sacramento River to the SWP and CVP export facilities in the southern Delta. Both of these elements have the potential to change salinity conditions, including elevated salinity, in the southern Delta, which could have a cumulative effect on surface hydrology and water quality. Elevated salinity in the southern Delta channels would reduce assimilative capacity in southern Delta channels, and that could have an effect on aquatic biological resources, agricultural resources, and service providers.

Project: Upper San Joaquin River Restoration Program (SJRRP), including Water Year 2010 Interim Flows Project

Status: Present

Location: Fresno and Madera Counties, Upper SJR

Project description: This program is a comprehensive long-term effort to restore flows to the SJR from Friant Dam to the confluence of Merced River and restore a self-sustaining Chinook salmon fishery in the river while reducing or avoiding adverse water supply impacts from restoration flows. The first water releases from Friant Dam in support of the SJRRP, called interim flows, began October 1, 2009. Restoration flows began January 1, 2014. The program includes provisions to reduce or avoid water supply impacts by recapturing water. This element of the program may include modifications to existing facilities or the construction of new facilities to deliver water directly back to the Friant Division Contractors, or may be made available to others through transfers, exchanges or sales. This may include operational changes and the construction of facilities in the LSJR and the Delta.

Resource areas with potential cumulative effects:

- Flooding, erosion, and sediment
- Aquatic biological resources

This project will increase flows in the SJR upstream of the plan area, and so it has the potential to improve conditions for fish and increase groundwater recharge in the southeastern boundary of the plan area. To the extent that any of the flows continue downstream of the Merced River confluence, the project has the potential to increase LSJR flows, thus benefitting fish and wildlife. Most of the potential effects of the project occur in areas that have not recently had any flow in most years. These areas are in the LSJR upstream of the Merced River confluence and are outside of the plan area. While there is potential for the project to result in flooding and seepage effects in the SJR and have effects on terrestrial, recreational, and agricultural resources, these effects would occur outside the plan area. To the extent that the Upper SJRRP flows contribute to increased flows in the LSJR at and below the Merced River confluence, the project could increase the movement of contaminants into the LSJR and affect temperatures. Thus, there is a potential for a cumulative significant effect on aquatic biological resources.

Environmental documents prepared for the project identify that there could be increases of temperature in the SJR downstream of the Merced River, but these are at times of very low Merced River flows. The LSJR alternatives would increase Merced River flows overall, thus reducing any such temperature effect. The Upper SJRRP environmental documents conclude that surface water effects in the SJR from the Merced River to the Delta would be less than significant and that there would be a less-than-significant effect on fall-run Chinook salmon and other native fishes in the Stanislaus, Tuolumne, and Merced Rivers. The adaptive implementation element of the LSJR alternatives allows the timing of flows to be optimized to

achieve the flow objectives while allowing for consideration of other beneficial uses, thus further reducing or eliminating any possible temperature effect.

Project: Water transfers

Status: Future

Location: Sacramento River and SJR Watersheds

Project description: Water transfers are likely to occur in the future and may involve transfers of water between entities within the project area, transfers from outside the project area to users within the project area, or transfers from entities within the project area to users outside the project area. Water transfers would occur beyond those that would occur in response the LSJR alternatives. Water transfers that involve changes in point of diversion, place of use, or purpose of use to a post-1914 water right most often require the approval of the State Water Board. Transfers of water between CVP contractors or SWP contractors do not require action by the State Water Board unless the point of diversion, purpose of use, or place of use under the CVP's or SWP's water right needs to be changed to accomplish the transfer. Transfers that require the use of state, regional, or a local public agency's conveyance facilities require the owner of the conveyance facilities (e.g., DWR, USBR) to determine that the transfers will not harm any other legal user of water, will not unreasonably affect fish and wildlife, and will not unreasonably affect the overall economy of the county from which the water is transferred. The most common forms of water transfers involve reservoir reoperation, substitution of groundwater for surface water, and crop acreage idling.

Resource areas with potential cumulative effects:

- Surface hydrology and water quality
- Flooding, sediment, and erosion
- Aquatic biological resources
- Terrestrial biological resources
- Groundwater resources
- Recreational resources and aesthetics
- Agricultural resources
- Energy and Greenhouse Gases

Water transfers have the potential to change or increase flows, which could alter the hydrodynamics in the southern Delta, and could have a cumulative effect on surface hydrology and water quality. Because any increases in flows resulting from the transfers would be well within normal channel capacities, water transfers are typically not expected to result in a change to levee stability, flooding potential, or sediment and erosion potential. However, transfers that include a flow shifting component could reduce flows outside the transfer period and could result in reduced surface water availability, both of which could have a cumulative effect on aquatic biological resources; terrestrial biological resources; groundwater resources; and agricultural resources. Energy and greenhouse gases could also be affected if reservoir releases are substantially changed such that hydropower is not produced when it may be needed. Lastly, transfers could alter reservoir levels, which could have an impact on recreational resources and aesthetics. As such, transfers could have an effect on the resource areas listed above.

Projects with No Potential Cumulative Impacts

In considering other projects that may contribute to related impacts in combination with the LSJR and SDWQ alternatives, this SED identified categories of projects that may have beneficial impacts on environmental resources, or would otherwise not have related adverse effects and are, therefore, not expected to contribute to significant cumulative impacts. This section identifies such categories of projects.

Projects with Beneficial Effects

Some projects will generally improve water quality conditions, and have a beneficial effect on surface hydrology and water quality in the plan area. As such, these projects are not expected to contribute to significant adverse effects in the plan area or extended plan area. Examples of such projects include the following.

- Agricultural Drainage Selenium Management Program—Reduce agricultural drainage containing elevated levels of selenium (through land and irrigation management practices) and limit where and when drainage water can be discharged.
- Conditional Waiver of Waste Discharge Requirements for Irrigated Lands—Central Valley Regional Water Quality Control Board (Central Valley Water Board) will use conditional waivers to develop new and additional information to establish a more reasonable basis for adoption of individual or general waste discharge requirements in the future. A conditional waiver is a regulatory process under California's nonpoint source program designed to meet requirements of the California Water Code. Discharges from irrigated agricultural lands are regulated to prevent the agricultural discharges from impairing the waters that receive the discharges.
- Grasslands Bypass Project (U.S. Bureau of Reclamation [USBR] and San Luis Delta Mendota Water Authority discharges of salt, selenium, and boron)—This project in Merced and Fresno Counties prevents discharge of subsurface agricultural drainage water into wildlife refuges and wetlands in central California and reduces the discharge of selenium, boron, and salt into the SJR.
- Tuolumne Utilities District (TUD) Phoenix Lake Preservation and Restoration Project—The project is intended to improve water quality conditions in the lake and the long-term health of the lake and its storage capacity by removing sediment and creating a sediment forebay and, as such, is expected to have a beneficial cumulative effect on surface hydrology and water quality.

Some projects will generally improve water supply conditions and have a beneficial effect on the surface hydrology and water quality and groundwater resources in the plan area. As such, these projects are not expected to contribute to significant effects in the plan area. Examples of such projects include the following.

- Bay Area Water Quality and Supply Reliability Program—This program identifies regional opportunities for the participating Bay Area water agencies to improve water supply and water quality for the benefit of the entire Bay Area.
- City of Stockton Delta Water Supply Project (DWSP)—Completed in 2012, this project pumps water from the Delta through miles of underground pipeline, along Eight Mile Road to a surface water treatment plant, to provide a new supplemental, high-quality water supply for Stockton.

- City of Tracy Connection to the South San Joaquin Irrigation District (SSJID)—Completed in 2009, the City of Tracy's second connection to the SSJID water line allows the City to receive additional potable water.
- Eastern San Joaquin Integrated Conjunctive Use (ICU) Program—This project would develop approximately 140–160 TAF per year of new surface water supply for the basin to directly and indirectly support conjunctive use by Northeastern San Joaquin County Groundwater Banking Authority (GBA) member agencies. This amount of water would support groundwater recharge consistent with the GBA's objectives for conjunctive use and the underlying groundwater basin. The GBA approved the ICU Program in February, 2011.
- New Exchequer Spillway Modification—This project on the Merced River would increase the height of the existing spillway gates and un-gated spillway by 8 to 10 feet, which would increase the storage capacity of Lake McClure.

Projects with No Significant Adverse Effects

Certain plans and policies like the California Water Plan establish policy and direction for the management of the state's water resources. As discussed below, the plan would not result in environmental effects and, therefore, would not contribute to any cumulative effects.

- California Water Plan—This strategic plan for managing and developing the state's water resources provides a planning framework for water managers, elected officials, agencies, tribes, businesses, stakeholders, and the public to develop findings and recommendations and make decisions regarding California's water future. The water plan is updated every 5 years.
  The water plan does not mandate action or authorize spending for actions. It also does not include environmental review and documentation as would be required under CEQA. Because the water plan does not cause environmental impacts, it would not contribute to cumulative effects.

17.2.2 Cumulative Impact Analysis

This section describes, analyzes, and determines the potential cumulative impacts of the LSJR and SDWQ alternatives within the plan area, as appropriate for each resource area, which could result from the implementation of the proposed plan amendments and the projects summarized in Table 17-1. This section also describes, analyzes, and determines the potential cumulative impacts of the LSJR alternatives in the extended plan area, as appropriate for each resource area. As discussed previously, the SDWQ alternatives would not have impacts in the extended plan area because (1) flows in the extended plan area are not expected to change in response to the SDWQ alternatives, and (2) the extended plan area is far upstream from the southern Delta, which means that any change in the salinity conditions in the southern Delta would not affect the water quality in the extended plan area. As such, no cumulative impact is associated with the SDWQ alternatives in the extended plan area and, therefore, the SDWQ alternatives in relation to the extended plan area are not discussed further in this section. The resource areas in this section correspond with the resource chapters (Chapters 5–14) of this SED. As stated above, the cumulative impacts associated with the No Project Alternative (LSJR/SDWQ Alternative 1) are discussed in Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*.

Surface Hydrology and Water Quality

As stated in Chapter 5, *Surface Hydrology and Water Quality*, LSJR Alternatives 2, 3, and 4 and SDWQ Alternatives 2 and 3 would have a less-than-significant impact on the surface hydrology and water quality resources in the plan area and extended plan area.

The impacts considered in Chapter 5 are as follows.

- Impact WQ-1: Violate water quality standards by increasing the number of months with electric conductivity (EC) above the water quality objectives for salinity at Vernalis or southern Delta compliance stations
- Impact WQ-2: Substantially degrade water quality by increasing Vernalis or southern Delta salinity (EC) such that agricultural beneficial uses are impaired
- Impact WQ-3: Substantially degrade water quality by increasing pollutant concentrations caused by reduced river flows

Overall, the LSJR alternatives would cause flows to increase, which would reduce pollutant concentrations and improve any current chronic water quality problems. Higher flows would also result in an overall decrease in salinity concentrations in the southern Delta. However, flows would be variable and would sometimes be lower than under baseline. Other projects that could result in cumulative effects have the potential to degrade water quality either through the reduction of dilution flows, changing hydrodynamic conditions in the Delta, or through the addition of pollutants. As discussed in Chapter 5, upstream of the rim dams,[2] river flows would also increase and reduce pollutant concentrations under the LSJR alternatives, and reservoir level changes would not change or increase pollutant concentrations. There would be no cumulative water quality impacts upstream of the rim dams. In the plan area, the SDWQ alternatives would only have an effect on WQ-1 by changing the EC standard, thereby reducing the number of exceedances of the standard. Otherwise, the SDWQ alternatives would have no impact. Therefore, the SDWQ alternatives would not cause a significant cumulative impacts and are not discussed further in this section.

Projects could result in a cumulative effect on water quality if they violate water quality standards by increasing the number of months with salinity (EC) above the water quality objectives for salinity at Vernalis or southern Delta compliance stations (Impact WQ-1) or substantially degrade water quality by increasing Vernalis or southern Delta EC such that agricultural beneficial uses are impaired (Impact WQ-2). Accordingly, with respect to these impacts, the geographic scope of this cumulative analysis focuses on projects within the area comprising Vernalis and the southern Delta and that have the potential to increase EC through the reduction of dilution flows, changes in hydrodynamic conditions in the Delta, or the addition of pollutants elsewhere in the plan area. The geographic scope also includes the Stanislaus, Tuolumne and Merced Rivers in the plan area and the extended plan area because these are the areas where water quality degradation impacts could occur (Impact WQ-3).

EC values in the southern Delta are primarily affected by the salinity of water flowing into the southern Delta from the SJR at Vernalis, salt discharged back into southern Delta channels that was previously diverted for irrigation, the combined CVP and SWP pumping influencing salinity in the

---

[2] In this document, the term *rim dams* is used when referencing the three major dams and reservoirs on each of the eastside tributaries: New Melones Dam and Reservoir on the Stanislaus River; New Don Pedro Dam and Reservoir on the Tuolumne River; and New Exchequer Dam and Lake McClure on the Merced River.

southern Delta, and tidal mixing of inflow from the Pacific Ocean. Municipal treated wastewater discharges have some effect on the southern Delta salinity. The LSJR flow at Vernalis has a large effect on the LSJR salinity at Vernalis. Following a dilution relationship in which salinity is inversely proportional to the flow, higher flows generally reduce salinity. Increased CVP and SWP pumping could also affect southern Delta salinity by bringing more low-salinity Sacramento River water across the Delta to the export pumps. However, periods of low Delta outflow (in the fall months) could cause increased seawater intrusion and higher EC at the southern Delta export intakes for the CVP and SWP.

Past and present cumulative projects that have contributed to elevated salinity in the southern Delta are discussed in more detail in the environmental setting section of Chapter 5. Examples of such projects that affect salinity in the southern Delta include the operation of the SWP and CVP, which alter the hydrodynamics in the southern Delta, development of irrigated agricultural lands, water diversions, and discharges from publicly owned treatment works (POTWs) in the southern Delta and in the LSJR upstream of Vernalis.

In general, future actions that could cumulatively affect water quality in the southern Delta resulting in elevated salinity are similar to the past and present projects and include new water diversions, water transfers, changes to SWP and CVP pumping, and changes to discharges from POTWs and agricultural lands. Past, present, and reasonably foreseeable probable future projects, described in Table 17-1, may have effects on surface hydrology and water quality resources through the following mechanisms.

- Change in circulation patterns in the southern Delta such that the mixture of low and high salinity water changes, resulting in higher salinity in the southern Delta (this is limited to an analysis of projects in the southern Delta).
- Change in flow and salt discharges into the southern Delta (this is limited to projects in the southern Delta and projects in the SJR Watershed that increase salt discharges).
- Degradation of water quality by increasing pollutant concentrations caused by reduced river flows in the plan area.

Projects, described in Table 17-1, that could change circulation patterns in the southern Delta include the following.

- California WaterFix
- Central Valley Salinity Alternatives for Long-Term Sustainability (CV-SALTS) and Central Valley-wide Salt and Nitrate Management Plan (SNMP)
- Delta Stewardship Council (DSC) Delta Plan
- NMFS BO (for salmon)
- USFWS BO (for delta smelt)
- Update to the 2006 Bay-Delta Water Plan, Phase II

These projects could directly reduce circulation of water in the southern Delta, and thereby reduce dilution of locally saline water, which could result in increased salinity in southern Delta channels. For example, California WaterFix, which calls for the construction of facilities to divert water from the Delta at a location on the Sacramento River, could result in increased salinity in southern Delta channels if less low salinity water is pumped at the existing export facilities in the southern Delta.

Additionally, projects intended to protect endangered species (e.g., salmon and delta smelt) could also increase salinity in the southern Delta. The NMFS BO and the USFWS BO (collectively the "BOs") would place constraints on the future operation of the SWP and CVP and could reduce the quantity of low salinity water pumped across the Delta into the southern Delta, thereby resulting in increased salinity in the southern Delta. Similarly, future updates to the 2006 Bay-Delta Water Plan, Phase II could place conditions on the CVP and SWP that would reduce exports at the facilities operated by the California Department of Water Resources (DWR) and USBR, or other conditions on DWR, USBR, and other water right holders that would change the quantity of low salinity water flowing into southern Delta channels, and thereby increase salinity in the southern Delta. Additionally, although the Delta Plan would not directly result in regulatory approvals, actions, or other projects, it could result in other agencies or entities taking future actions. For example, the Delta Plan could recommend and require consistency determinations for projects that may affect circulations patterns in the southern Delta, thereby indirectly affecting the surface hydrology and water quality resources.

Projects, described in Table 17-1, that change flow and salt discharges into the southern Delta include the following.

- CV-SALTS

As described in Table 17-1, CV-SALTS includes the development of new salinity objectives for the LSJR upstream of Vernalis and a program of implementation to achieve these objectives. It could affect the timing of salt discharges to the LSJR, which could result in increased salinity in the SJR and increased salinity in the southern Delta.

Projects that reduce river flows could result in significant cumulative impacts by substantially degrading water quality by increasing pollutant concentrations caused by reduced river flows (Impact WQ-3). Projects, described in Table 17-1, that could change flow patterns and degrade water quality by increasing pollutant concentrations caused by reduced river flows include the following.

- Groundwater recharge projects
- Water transfers

Groundwater recharge projects would typically operate at times of high flows. However, if they were to operate during relatively low flow periods, the projects could result in lower flows. The resulting decreased inflow of low salinity water into the southern Delta could result in higher concentration of pollutants in the SJR and increased salinity in the southern Delta. While water transfers would tend to increase flows, the transfers could include a flow shifting component that would reduce flows outside the transfer period. In such cases, salinity would be improved as a result of increased low salinity water at the time of the transfer; however, salinity may increase at other times due to lower flows outside of the transfer period. Additionally, wastewater change petitions could result in lower flows during already low flow periods.

Of those projects discussed above where the State Water Resources Control Board (State Water Board) has approval authority (e.g., California WaterFix, WWCPs, and groundwater recharge projects), it would be required to consider and implement water quality objectives for salinity and other pollutants such that objectives are not exceeded. Notwithstanding this, given the condition of the surface hydrology and water quality in the plan area, the impacts of past, present, and reasonably foreseeable probable future projects on water quality are cumulatively significant.

However, the LSJR alternatives would generally increase river flows on the three eastside tributaries, as compared to baseline conditions for February–June, and there are only small changes in flow expected outside of these months. Increases in flow typically result in lower salinity levels, and therefore would not cause an increase in exceedances of existing (or proposed) water quality objectives nor result in an impact on the agricultural beneficial use, as discussed for Impacts WQ-1 and WQ-2, respectively, in Chapter 5. Additionally, as discussed for Impact WQ-3, the general increase in flow would typically result in lower concentrations of pollutants.

Therefore, LSJR Alternative 2, 3, and 4 would not result in a cumulatively considerable[3] incremental contribution to cumulative impacts or significant cumulative impacts related to salinity and water quality degradation, and cumulatively adverse impacts would be less than significant.

In the extended plan area, surface hydrology and water quality would not be degraded and violation of water quality standards would not occur as a result of the LSJR alternatives. As described in Chapter 5, Section 5.4.4*, Impacts and Mitigation Measures: Extended Plan Area,* water quality in the upstream Stanislaus, Tuolumne, and Merced Rivers is generally high quality and there is a relatively small volume of water that could be affected by LSJR Alternatives 2, 3, and 4 in the extended plan area on the three eastside tributaries. In general these alternatives would cause flows to increase, which would reduce concentrations and improve any chronic water quality problems. In addition, upstream reservoirs in the Stanislaus and Tuolumne Watersheds is generally high quality (there are no substantial reservoirs upstream on the Merced River). Furthermore, reservoir volume reductions would have minimal effects on most water quality constituents (e.g., mercury) because the reduction in storage would result from water (and the constituent) flowing out of the reservoir. In other words, the concentrations of water quality constituents would not change or increase relative to baseline and it is unlikely that the water quality would be degraded. Past, present and reasonably foreseeable probable future projects identified in Table 17-1 that could affect surface hydrology and water quality in the extended plan area include the Phoenix Lake Preservation and Restoration Project and the Lyons Reservoir Modification. The Phoenix Lake Preservation and Restoration project is expected to result in an overall benefit to surface hydrology and water quality by controlling and capturing sediment. Therefore, LSJR Alternative 2, 3, and 4 would not result in a cumulatively considerable incremental contribution to cumulative impacts or significant cumulative impacts related to surface hydrology and water quality degradation.

Flooding, Sediment, and Erosion

As stated in Chapter 6, *Flooding, Sediment, and Erosion*, LSJR Alternatives 2, 3, and 4 would have a less-than-significant impact on flooding, sediment, and erosion in the plan area and extended plan area. Under the SDWQ alternatives, salinity would generally remain the same as baseline conditions; furthermore, change in water quality does not affect flooding, sedimentation, or erosion. As such, SDWQ Alternatives 2 and 3 would have no impact on the flooding, sediment, and erosion and, therefore, are not considered further in this section.

The impacts considered in Chapter 6 are as follows.

---

[3] *Cumulatively considerable* means that the incremental effects of an individual project are significant when viewed in connection with the effects of past, current, and probably future projects. (Cal. Code Regs., tit 14, § 15065, subd. (a)(3).)

- Impact FLO-1: Substantially alter the existing drainage pattern of the site or area, including through the alteration of the course of a stream or river, in a manner that would result in substantial erosion or siltation on- or offsite
- Impact FLO-2: Substantially alter the existing drainage pattern of the site or area, including through the alteration of the course of a stream or river, or substantially increase the rate or amount of surface runoff in a manner that would result in flooding on- or offsite

The geographic scope of this cumulative analysis focuses on projects within the plan area and the extended plan area since it is where impacts could occur, in addition to the larger SJR Basin, because activities within the larger basin could affect sedimentation and flooding.

The LSJR alternatives would change flow patterns in rivers throughout the plan area and extended plan area. However, the range of flows would be similar to flows that occur under baseline conditions. Therefore, the amount of sediment and gravel transported at higher flows and flows that exceed channel capacities are expected to be similar to baseline conditions.

Past, present, and reasonably foreseeable projects, described in Table 17-1, may have effects on flooding, sediment, and erosion through the following mechanisms.

- Alteration of drainage patterns, including through the alteration of the course of a stream or river, in a manner that would result in substantial erosion or siltation on- or offsite.
- Alteration of existing drainage patterns, including through the alteration of the course of a stream or river, or substantially increase the rate or amount of surface runoff in a manner that would result in flooding.

Habitat restoration or other projects that involve construction in or adjacent to channels may alter of the course of a stream or river, through changes in floodplain geometry, such that substantial erosion or siltation on- or off-site may occur. Following is a list of such projects, which are described in Table 17-1.

- California EcoRestore
- Central Valley Project Improvement Act projects
- Dos Rios Ranch
- Gravel Mining Reach Floodway Restoration
- Habitat Restoration Plan for the Lower Tuolumne River Corridor
- Knights Ferry Floodplain and Side-Channel Restoration
- Lower Tuolumne River Big Bend Project
- Restoration of the Ruddy Mining Reach
- Spawning Gravel Supplementation (Stanislaus County, Tuolumne River)
- Tuolumne River Restoration projects, including Warner Deardorff Segment—Mining Reach Project No. 3

California EcoRestore will include many smaller habitat restoration projects that are mostly outside the plan area, but some projects may be implemented in the southern Delta portion of the plan area. The Central Valley Improvement Act includes a suite of habitat restoration projects and actions in the Central Valley, including within the plan area. Other projects, such as Dos Rios Ranch, Habitat

Restoration Plan for the Lower Tuolumne River Corridor, Knights Ferry Floodplain and Side-Channel Restoration, and other listed projects, will restore habitat in floodplains, add sinuous reaches similar to natural channels, and add gravel that can be moved by moderate to high flows. These projects could alter the course of water flowing in a river or stream, but the changes would be similar to existing natural channels, as would sedimentation levels. To the extent that these projects occur in floodplains within the plan area, the projects could also have short-term construction-related impacts that could result in erosion. However, these effects would likely be less than significant because the projects would employ standard construction practices (e.g., erosion control and best management practices). Moreover, the floodplain restoration projects would allow water to spread across a wider area, thus relieving constricted channels of flow that cause erosion or siltation. The gravel added by these projects would move more often, particularly under LSJR Alternatives 3 and 4 (Chapter 6, Tables 6-10, 6-11, and 6-12). However, the amount of gravel (in the upper reaches) and sand (in the mid- to lower reaches) movement and bank erosion would not be any greater than analyzed in Chapter 6, Section 6.4.3, *Impacts and Mitigation Measures*, and, therefore, would not result in significant impacts on flooding, erosion, or sedimentation. Additionally, these restoration activities are not expected to result in a change to levee stability, flooding potential, or sediment and erosion potential. Therefore, the incremental contribution of LSJR Alternatives 2, 3, and 4 would not be cumulatively considerable, and impacts would be less than significant.

Other projects, described in Table 17-1, that may involve both habitat restoration and changes in flows that could result in substantial erosion or siltation on- or offsite or flooding include the following.

- DSC Delta Plan
- Federal Energy Regulatory Commission (FERC) Relicensing of the Don Pedro Hydroelectric Project (FERC Project No. 2299)
- FERC Relicensing of the Merced River Hydroelectric Project (FERC Project No. 2179) and Merced Falls Hydroelectric Project (FERC No. 2467)
- Upper San Joaquin River Restoration Project (SJRRP), including Water Year 2010 Interim Flows Project
- Water transfers

As mentioned previously, the Delta Plan would not directly result in regulatory approvals, actions, or other projects, but could result in other agencies or entities taking future actions. The Delta Plan could affect the flooding, sedimentation, and erosion resources by recommending projects that involve habitat restoration or flow augmentation that are similar, in nature and effect, to the habitat restoration and flow augmentation projects described above. However, these restoration activities and flow augmentation projects are not expected to result in a change to levee stability, flooding potential, or sediment and erosion potential.

The FERC projects would include the flows associated with the LSJR alternatives and any other flow adopted by FERC. Specifically, FERC projects undergoing relicensing must comply with conditions of water quality certification, such as the LSJR flow requirements, and any other minimum or bypass flows imposed through the relicensing process. However, these flows on the Tuolumne and Merced Rivers are not expected to increase peak flows in a way that would cause sufficient gravel transport to erode and undermine river levees. As such, the effects would not be substantially different from those analyzed in Chapter 6. While the FERC projects could include habitat restoration elements, the projects would focus on the upper gravel-bedded portions of these tributaries and, therefore, are not expected to result in levee instability or exceedance of existing channel capacities. Ongoing physical salmon habitat restoration activities located in the upper, gravel-dominated reaches on the tributary generally take place where past in-channel and channel-adjacent gravel mining has simplified the channel configuration and aquatic habitat, and reduced gravel transport. As such, these restoration activities are not expected to result in a change to levee stability, flooding potential, or sediment and erosion potential.

Through the augmentation of flows in reaches of the SJR that have not recently had such levels of flow, the Upper SJRRP could increase the seepage and flooding potential. However, these effects would occur in the SJR upstream of the Merced River confluence and, thus, the LSJR alternatives would not contribute to these impacts. Additionally, the restoration flows expected on the SJR downstream of the Merced River confluence would be well below the channel capacities along the LSJR and in the southern Delta (Figure 6-3 in Chapter 6), and, thus, are not expected to result in a change to levee stability, flooding potential, or sediment and erosion potential.

Water transfers could increase flows; however, the increases would be well within normal channel capacities of the three eastside tributaries and the LSJR. As such, the transfers are not expected to result in a change to the levee stability, flooding potential, or the sediment and erosion potential. Consequently, even if expected levee improvements do not occur, these flows would not significantly impact flood flows, channel stability, or levees (DWR 2012).

Flows in the three eastside tributaries and LSJR are controlled by reservoir operations except during the highest flood flows in large storm events and occasionally when levees are breached (Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*; McBain and Trush 2002; DWR 2010, 2011, 2012). Furthermore, dams, irrigation water use, river bank protection, and levees maintain the rivers within their banks and reduce sediment transport and channel migration. Consequently, past, present, and reasonably foreseeable probable future projects would not result in cumulatively significant impacts on flooding, sediment, and erosion resources.

Cumulatively considerable impacts would not occur as a result of the LSJR alternatives. Flows would generally remain within existing flood channels and would not result in substantial alterations of the existing drainage patterns, substantial erosion or siltation, or substantial increases in bank erosion or mobilization of sediment. Also, flows would not result in a substantial increase in the rate or amount of surface runoff in a manner that would result in flooding. Flows imposed through the FERC process, which would include the flows associated with the LSJR alternatives and any other flow adopted by FERC, are not expected to increase peak flows in a way that would cause sufficient gravel transport to erode and undermine river levees. Therefore, the effects would not be substantially different from those analyzed in Chapter 6, Section 6.4.3, *Impacts and Mitigation Measures*.

Similarly, the restoration flows on the SJR below Friant Dam combined with the LSJR alternatives on the three eastside tributaries would generally be well below the channel capacities along the LSJR and in the southern Delta (Figure 6-3 in Chapter 6). The SJR restoration flows would increase average river flows but not peak flows associated with flood control releases during storm events. Consequently, even if expected levee improvements do not take place, these flows would not significantly impact flood flows, channel stability, or levees (DWR 2012). Projects implementing flood control measures, channel widening, or flood bypass would all reduce the potential for large flows to affect flooding.

Therefore, LSJR Alternatives 2, 3, and 4 would not result in a cumulatively considerable incremental contribution to cumulative impacts or significant cumulative impacts related to flooding, sedimentation, and erosion, and cumulatively adverse impacts would be less than significant.

In the extended plan area, flooding, sedimentation, and erosion would not occur as a result of the LSJR alternatives. As described in Chapter 6, Section 6.4.4*, Impacts and Mitigation Measures: Extended Plan Area*, there could potentially be more storage capacity under these alternatives on the Stanislaus and Tuolumne Rivers, which would help reduce flooding. Furthermore, the river channels on the Stanislaus, Tuolumne, and Merced Rivers are primarily contained in bedrock and would have minimal potential for increased sediment transport, erosion, or flooding under the LSJR Alternatives 2, 3, and 4. Past, present, and reasonably foreseeable probable future projects identified on Table 17-1 that could affect flooding, sediment, and erosion include the FERC Relicensing of Lyons Reservoir and the FERC Relicensing of the Don Pedro Hydroelectric Project, which could potentially affect operations of the CCSF/Hetch Hetchy reservoir system, upstream of New Don Pedro Reservoir in the extended plan area. FERC projects undergoing relicensing must comply with conditions of water quality certification, such as the LSJR flow requirements, and any other minimum or bypass flows imposed through the relicensing process. However, similar to the FERC relicensing in the plan area, the flows on the Stanislaus and Tuolumne Rivers are not expected to increase peak flows in a way that would cause sufficient gravel transport to erode and undermine existing river banks. Under the new licenses, these reservoirs would be operated consistent with flood control standards and rules. Therefore, LSJR Alternative 2, 3, and 4 would not result in a cumulatively considerable incremental contribution to cumulative impacts or significant cumulative impacts related to flooding, sedimentation and erosion.

Aquatic Biological Resources

As stated in Chapter 7, *Aquatic Biological Resources*, LSJR Alternatives 2, 3, and 4 would have a less-than-significant impact on aquatic biological resources in the plan area and would have significant and unavoidable impacts in the extended plan area. Under the SDWQ alternatives, salinity would generally remain the same as baseline conditions. As such, SDWQ Alternatives 2 and 3 would have no impact on aquatic biological resources and, therefore, are not considered further in this section.

The impacts considered in Chapter 7 are as follows.

- Impact AQUA-1: Changes in spawning success and habitat availability for warmwater species resulting from changes in reservoir water levels
- Impact AQUA-2: Changes in availability of coldwater species reservoir habitat resulting from changes in reservoir storage
- Impact AQUA-3: Changes in quantity/quality of physical habitat for spawning and rearing resulting from changes in flow
- Impact AQUA-4: Changes in exposure of fish to suboptimal water temperatures resulting from changes in reservoir storage and releases
- Impact AQUA-5: Changes in exposure to pollutants resulting from changes in flow

- Impact AQUA-6: Changes in exposure to suspended sediment and turbidity resulting from changes in flow
- Impact AQUA-7: Changes in redd dewatering resulting from flow fluctuations
- Impact AQUA-8: Changes in spawning and rearing habitat quality resulting from changes in peak flows
- Impact AQUA-9: Changes in food availability resulting from changes in flow and floodplain inundation
- Impact AQUA-10: Changes in predation risk resulting from changes in flow and water temperature
- Impact AQUA-11: Changes in disease risk resulting from changes in water temperature
- Impact AQUA-12: Changes in southern Delta and estuarine habitat resulting from changes in SJR inflows and export effects

In general, the LSJR alternatives would increase flows and decrease reservoir levels in both the plan area and the extended plan area. This could affect reservoir operations on the Stanislaus, Tuolumne, and Merced Rivers, flows in each of these tributaries, and flows in the LSJR and Delta, which could result in impacts on aquatic habitat and aquatic biological communities, including native and nonnative fish species. Reservoir operations of the major rim dams and flows in the three eastside tributaries downstream of these dams would generally fall within the ranges observed under baseline, and there would be general improvement (increase) in stream flows under the LSJR alternatives, relative to baseline. Therefore, the LSJR alternatives would have a less-than-significant impact on aquatic biological resources in the plan area. However, the LSJR alternatives could have a significant and unavoidable impact in the extended plan area because reservoirs upstream of the major rim dams in the extended plan area are smaller than the downstream rim reservoirs, potentially magnifying individual changes. Furthermore, required bypass flows may reduce the opportunity for these reservoirs to refill once they are drawn down. Reservoir drawdown could reduce the area and volume of water available for in-reservoir aquatic habitat, thereby affecting aquatic species, including fish. In addition, lower storage in the upstream reservoirs could result in increased water temperatures.

The LSJR alternatives could also affect flows in the southern Delta. The southern Delta is part of the larger Bay-Delta system and provides habitat for resident and migratory fish species. Essential habitats for salmonids and other fish species rely upon suitable water quality and water quantity conditions. For salmonids, these conditions must support juvenile and adult physiological transitions between fresh water and saltwater (NMFS 2009). Changes to estuarine habitat that degrade any of these conditions could have a negative effect on aquatic biological resources. Therefore, stressors similar to those described above for the three eastside tributaries and LSJR could influence the abundance and presence of fish in the southern Delta and Bay-Delta. In addition, conditions in the southern Delta are influenced by river inflow, tidal action, SWP and CVP water export facilities, local pump diversions, and agricultural and municipal return flows (Moyle 2002). Therefore, the geographic scope of this cumulative analysis focuses on projects within the three eastside tributaries in the plan area and the extended plan area, the three rim reservoirs, and the southern Delta.

Past, present, and reasonably foreseeable projects, described in Table 17-1, may have effects on aquatic biological resources through the following mechanisms.

- Reduction of flows or change in reservoir operations in a manner that could change aquatic habitat availability and water temperatures and expose indicator species to pollutants and suspended sediments.
- Have an effect on habitat quality in the southern Delta by changing flows and circulation patterns in the southern Delta.

Projects, described in Table 17-1, that may reduce flows or change reservoir operations in a manner that could change habitat availability, water temperatures, and exposure to pollutants and suspended sediments for indicator species in the plan area and extended plan area include the following.

- FERC Relicensing of the Don Pedro Hydroelectric Project (FERC Project No. 2299)
- FERC Relicensing of the Merced River Hydroelectric Project (FERC Project No. 2179) and Merced Falls Hydroelectric Project (FERC No. 2467)
- Groundwater recharge projects
- NMFS BO (salmon, steelhead, sturgeon)
- Upper SJRRP, including Water Year 2010 Interim Flows Project
- Water transfers

The FERC projects would include the flows associated with the LSJR alternatives and any other flow adopted by FERC. However, these flows on the Tuolumne and Merced Rivers are not expected to change flows and reservoir storage in a way that would have effects substantially different from those analyzed in Chapter 7. NMFS BO actions include implementation of a year-round minimum flow regime that improves conditions for steelhead in the Stanislaus River, which has the potential to change reservoir storage levels in New Melones Reservoir on the Stanislaus River. However, reservoir storage is not expected to vary in a way that would have effects substantially different from those analyzed in Chapter 7. While groundwater recharge projects and water transfers have the potential to reduce the quantity of water that remains in the three eastside tributaries and the LSJR, the unimpaired flow requirements under the LSJR alternatives would still have to be maintained. Thus, flows are not expected to vary in a way that would have effects substantially different from those analyzed in Chapter 7. Lastly, although augmented flows in reaches of the SJR under the Upper SJRRP could increase the movement of contaminants into the LSJR and affect temperatures, these changes would have a less-than-significant impact on fall-run Chinook salmon and other native fishes. The increased flows would dilute existing levels of pollutants from agricultural runoff currently found in the river (e.g., Upper SJR to the confluence of the Merced) and modeling results of the Upper SJRRP determined little difference between baseline and the interim and restoration flow conditions. In addition, mobilization of pollutants is not expected because certain areas along the river would receive delivery of interim and restoration flows instead of existing CVP supplies. Furthermore, the increased flows under the LSJR alternatives would reduce any increased temperature effect that may occur as a result of the Upper SJRRP.

Projects, described in Table 17-1, that may have an effect on aquatic biological resources by changing flows and circulation patterns in the southern Delta include the following.

- California WaterFix
- NMFS BO

- USFWS BO (delta smelt)
- Update to the 2006 Bay-Delta Water Plan, Phase II

The NMFS and USFWS BOs are meant to protect fish listed under ESA from being jeopardized by the adverse effects of SWP and CVP export water operations by, at times, requiring reservoir releases, pumping reductions, or both, as well as habitat restoration and other actions. While reservoir releases and pumping reductions would reduce direct impacts on fish, less Sacramento River water could be drawn into the southern Delta, which could increase salinity. California WaterFix proposes new SWP Delta facilities, including three new screened intakes in the northern Delta that could be operated at least partially in lieu of existing SWP and CVP southern Delta pumping. California WaterFix could reduce entrainment and impingement of estuarine species in the southern Delta from existing SWP and CVP operations but could also change south Delta water circulation and salinity by reducing the amount of Sacramento River water drawn into the southern Delta compared to baseline. Furthermore, the update to the 2006 Bay-Delta Water Plan, Phase II could require greater Delta inflows, greater Delta outflows, or both, which could change south Delta water circulation and salinity.

The operations of the SWP and CVP are conditioned to meet the criteria in the 2006 *Water Quality Control Plan for the San Francisco/Sacramento-San Joaquin Delta Estuary* (2006 Bay-Delta Plan), and would continue to be conditioned to meet any updates to the Bay-Delta Plan, including through future State Water Board water right actions. As new points of diversion for the SWP, California WaterFix must seek permits from the State Water Board. Such permits would be conditioned to ensure that aquatic biological resources are protected consistent with Bay-Delta Plan requirements. The update to the 2006 Bay-Delta Water Plan, Phase II must reasonably protect fish and wildlife beneficial uses. Therefore, the range of salinity levels and circulation patterns in the southern Delta are not expected to be substantially different from those analyzed in Chapter 7. Moreover, indicator species are historically adapted to much greater fluctuations in salinity than those required under the Bay-Delta Plan to protect southern Delta agricultural beneficial uses. Considering the combined impacts of past, present, the above-discussed projects and the LSJR alternatives, there would not be a significant cumulative impact on aquatic biological resources in the plan area. The combined effects on flow, which are necessary for habitat, temperature, water quality and circulation, and on reservoir levels at the rim dams are not expected to vary in a way that would have effects substantially different from those analyzed in Chapter 7. Moreover, there will be an overall increase in stream flows under LSJR alternatives. Therefore, LSJR Alternative 2, 3, and 4 would not result in a cumulatively considerable incremental contribution to significant cumulative impacts related to aquatic biological resources in the plan area.

However, significant cumulative impacts in the extended plan area could occur as a result of the LSJR alternatives. Similar to the plan area, past, present, and reasonably foreseeable projects, described in Table 17-1, may have effects on aquatic biological resources if they reduce flows or change reservoir operations in a manner that could change aquatic habitat availability and water temperatures and expose indicator species to pollutants and suspended sediments. Projects, described in Table 17-1, that may result in these types of impacts include the following.

- FERC Relicensing of the Don Pedro Hydroelectric Project (FERC Project No. 2299)
- FERC Relicensing of Lyons Reservoir
- San Francisco Public Utilities Commission (SFPUC) Hetch Hetchy Repair and Rehabilitation Program and Lower Cherry Aqueduct Emergency Rehabilitation

- TUD Phoenix Lake Preservation and Restoration project

These projects have the ability to modify the flow regime in the extended plan area on the Stanislaus and Tuolumne Rivers. Changes in the storage requirements or operation of the reservoirs under FERC relicensing, reservoir modifications, or as a result of increased diversions could significantly affect aquatic biological species in the Stanislaus and Tuolumne Rivers. These past, present, and reasonably foreseeable future projects could store and then divert water in the summer and fall, when the LSJR alternatives may result in reduced flows, particularly in the fall, as a result of earlier bypasses in the year. If this were to occur, there would likely be increases in temperature and reductions in overall available aquatic habitat. As such, the incremental contribution to aquatic biological resource impacts from LSJR Alternative 2, with adaptive implementation, or LSJR Alternatives 3 or 4, with or without adaptive implementation, would be cumulatively considerable when viewed in connection with the potential changes to aquatic habitat, temperature, and flow on the Stanislaus and Tuolumne Rivers as a result of the projects identified above. Cumulative impacts on aquatic biological resources in the extended plan area would be significant. There is no other feasible mitigation measure beyond what is proposed in Section 7.4.3, *Impacts and Mitigation Measures*, to reduce this impact to less-than-significant levels and, therefore, the cumulative impact would remain significant and unavoidable.

Terrestrial Biological Resources

As stated in Chapter 8, *Terrestrial Biological Resources*, LSJR Alternatives 2, 3, and 4 would have a less-than-significant impact on terrestrial biological resources in the plan area, and would have significant and unavoidable impacts on terrestrial biological resources in the extended plan area. Under the SDWQ alternatives, salinity would generally remain the same as baseline conditions. As such, SDWQ Alternatives 2 and 3 would have no impact on terrestrial biological resources and therefore are not considered further in this section.

The impacts considered in Chapter 8 are as follows.

- Impact BIO-1: Have a substantial adverse effect on any riparian habitat or other sensitive natural terrestrial communities identified in local or regional plans, policies, or regulations or by the CDFW or USFWS
- Impact BIO-2: Have a substantial adverse effect on federally protected wetland as defined by Section 404 of the Clean Water Act (including, but not limited to, marsh, vernal pool, coastal, etc.) through direct removal, filling, hydrologic interruption, or other means
- Impact BIO-3: Facilitate a substantial increase in distribution and abundance of invasive plants or nonnative wildlife that would have a substantial adverse effect on native terrestrial species
- Impact BIO-4: Have a substantial adverse effect, either directly or through habitat modifications, on any terrestrial animal species identified as a candidate, sensitive, or special-status species in local or regional plans, policies, or regulations or by CDFW or USFWS
- Impact BIO-5: Conflict with the provisions of an adopted habitat conservation plan, natural community conservation plan, or other approved local, regional, or state habitat conservation plan or conflict with any local policies or ordinances protecting biological resources

Overall, the LSJR alternatives would increase flows and decrease reservoir levels in both the plan area and the extended plan area. This could affect reservoir operations on the Stanislaus, Tuolumne, and Merced Rivers, flows in each of these tributaries, and flows in the LSJR and Delta, which could result in potential impacts on terrestrial habitat and terrestrial biological communities, including native and invasive species. The geographic scope of this cumulative analysis focuses on projects within affected areas (i.e., the riparian habitat adjacent to river channels and reservoir shorelines and the areas subject to surface water level fluctuations around the three rim reservoirs) along the three eastside tributaries in the plan area and the extended plan area, the three rim reservoirs, and the southern Delta.

Past and present cumulative effects of projects that have contributed to a decline in the diversity and abundance of terrestrial species and their habitats are discussed in the environmental setting section of Chapter 8. In general, future actions that could cumulatively affect terrestrial biological resources are similar to past and present projects. Past, present, and reasonably foreseeable projects, described in Table 17-1, may have effects on terrestrial biological resources through the following mechanisms.

- Change in reservoir levels on the three eastside tributaries.
- Increase in the variability of changes to river flow volumes and timing.
- Physical modification of areas within and adjacent to the river channels such that there could be a substantial adverse effect on habitat or species of interest.

Projects, described in Table 17-1, that could change reservoir water surface elevations or increase the variability of changes to river flow volumes and timing include the following.

- FERC Relicensing of the Don Pedro Hydroelectric Project (FERC Project No. 2299)
- FERC Relicensing of the Merced River Hydroelectric Project (FERC Project No. 2179) and Merced Falls Hydroelectric Project (FERC No. 2467)
- NMFS BO (for salmon)
- Water transfers

The FERC projects would include the flows associated with the LSJR alternatives and any other flow adopted by FERC. However, these flows on the Tuolumne and Merced Rivers are not expected to change flows and reservoir storage in a way that would have effects substantially different from those analyzed in Chapter 8. NMFS biological opinion actions include implementation of a year-round minimum flow regime in the Stanislaus River, which has the potential to change reservoir storage levels in New Melones Reservoir. Additionally, while water transfers have the potential to reduce the quantity of water that remains in rivers in the plan area, the unimpaired flow requirements under the LSJR alternatives would still have to be maintained. Thus, flows are not expected to vary in a way that would have effects substantially different from those analyzed in Chapter 8.

Habitat restoration projects, habitat conservation plans, and other projects that involve construction in or adjacent to channels may alter the course of a stream or river or the adjacent habitat. In general, these projects are intended to benefit terrestrial biological resources by replacing riparian habitat that has been lost. Following is a list of such projects, which are described in Table 17-1.

- California EcoRestore
- Central Valley Project Improvement Act projects
- Dos Rios Ranch

- Gravel Mining Reach Floodway Restoration
- Habitat Restoration Project for the Lower Tuolumne River Corridor
- Knights Ferry Floodplain and Side-Channel Restoration
- Lower Tuolumne River Big Bend Project
- Merced River Ranch Floodplain Restoration
- Proposed expansion of the SJR National Wildlife Refuge

Habitat restoration projects, habitat conservation plans, and other similar types of projects are meant to recover wildlife species and habitat (including some riparian, floodplain, and adjacent terrestrial habitats). These efforts would work in conjunction to support terrestrial species and replace habitat that has been lost that could benefit terrestrial species. Such projects may have some short-term impacts on sensitive terrestrial species and habitat, such as indirect effects associated with construction noise or temporary removal of habitat. However, any disturbance that may take place would be in accordance with best management practices and applicable laws and regulations, and would be temporary and localized. Furthermore, such projects likely would be implemented in drier periods when the LSJR alternatives are less likely to contribute to related impacts. Overall, the LSJR alternatives would generally result in higher flows in the SJR and the three eastside tributaries below the rim reservoirs during the February–June period and could change rim reservoir storage levels. However, these additional flows are not expected to have significant impacts on riparian habitat, wetlands, or other sensitive natural terrestrial communities (Impacts BIO-1 and BIO-2) along river channels because the plants located in these areas can survive inundation, are resistant to the effects of scouring and deposition, and are growth-limited by water availability. Furthermore, the fluctuations of water elevation in the three rim reservoirs would be minimal under the LSJR alternatives and are not expected to affect riparian habitat or wetlands surrounding the reservoirs. Because a substantial change in riparian habitat would not be expected, special-status animal species would not be adversely affected (Impact BIO-4). In addition, because the impacts on riparian habitat and the special-status animal species that are dependent on it would be less than significant, the LSJR alternatives would not conflict with any plans protecting these biological resources (Impact BIO-5). Lastly, while flow changes and fluctuations in reservoir elevations could cause alteration of vegetation patterns in specific locations, there is no basis to suggest that increased flows would substantially increase the distribution and abundance of invasive plant species (Impact BIO-3). The incremental contribution of the LSJR alternatives' impacts when viewed in connection with past, present and probable future projects, such as those discussed above, is not cumulatively considerable. As such, LSJR Alternatives 2, 3, and 4 would not result in significant cumulative impacts related to terrestrial biological resources.

As discussed in Chapter 5, *Surface Hydrology and Water Quality*, the LSJR alternatives would result in an overall slight reduction in salinity in the southern Delta. This impact would not be significant for riparian habitats and terrestrial wildlife and plant species which regularly tolerate fluctuation in salinity and experience tidal influences and salinity inputs from other sources. For example, native plant species in the southern Delta have adapted to brackish water and salinity levels that have historically existed in the southern Delta. Therefore, the incremental contribution of the LSJR alternatives would not be cumulatively considerable, and cumulative impacts would be less than significant in the southern Delta.

The area of potential effects for the extended plan area is similar to that of the plan area—it includes areas affected by fluctuations in reservoir levels and areas adjacent to the stream channels. However, in the extended plan area on the Stanislaus and Tuolumne Rivers, impacts of the LSJR alternatives for terrestrial biological resources would be potentially more significant than below the rim dams because the upstream reservoirs are smaller and the effects of potential changes in reservoir storage could be magnified. In particular, under LSJR Alternative 2 with adaptive implementation and LSJR Alternatives 3 and 4, with or without adaptive implementation, the upstream reservoirs could experience substantial changes in reservoir volumes and surface water elevations that would not be experienced in the downstream rim reservoirs. In addition, channel flows in the extended plan area could decrease during the fall relative to baseline conditions since reservoirs have more open storage to fill. These changes could potentially result in reduced habitat conditions for terrestrial species along channel banks and reservoirs. Thus, as discussed in Chapter 8, the impacts associated with lower reservoir levels under LSJR Alternative 2 with adaptive implementation and LSJR Alternatives 3 and 4, with or without adaptive implementation are significant and unavoidable.

Past, present, and reasonably foreseeable projects, described in Table 17-1, may have effects on terrestrial biological resources in the extended plan area if they reduce flows or change reservoir operations in a manner that could change habitat availability adjacent to existing reservoirs on the Stanislaus and Tuolumne Rivers or adjacent to these rivers. In general, if projects lower reservoir elevations or river flows such that vegetation is reduced and wildlife habitat is reduced, significant impacts could occur. A reduction of river flows or reservoirs could occur if diversions were increased or operations changed to release more or less water during different times of the year. Projects, described in Table 17-1, that may result in these types of impacts include the following.

- FERC Relicensing of the Don Pedro Hydroelectric Project (FERC Project No. 2299)
- FERC Relicensing of Lyons Reservoir
- San Francisco Public Utilities Commission (SFPUC) Hetch Hetchy Repair and Rehabilitation Program and Lower Cherry Aqueduct Emergency Rehabilitation
- TUD Phoenix Lake Preservation and Restoration project

If these projects result in potentially lower flows in the summer or fall, when there may be effects associated with LSJR Alternatives 2, with adaptive implementation, or LSJR Alternatives 3 or 4 with or without adaptive implementation, the incremental cumulative contribution would be cumulatively considerable when considered with past, present, and reasonably foreseeable projects, such as those discussed above. This would result in a significant cumulative impact upstream in the extended plan area. There is no other feasible mitigation measure beyond what is proposed in Chapter 8, Section 8.4.4, *Impacts and Mitigation Measures: Extended Plan Area,* to reduce this impact. Therefore, the cumulative impacts related to terrestrial biological resources in the extended plan area would remain cumulatively significant and unavoidable.

Groundwater Resources

As stated in Chapter 9, *Groundwater Resources*, LSJR Alternative 2 with adaptive implementation and LSJR Alternatives 3 and 4, with or without adaptive implementation, would have significant and unavoidable impacts on the groundwater resources in the plan area, while LSJR Alternative 2 without adaptive implementation would have a less-than-significant impact on groundwater resources in the plan area. LSJR Alternatives 2, 3, and 4 would have a less-than-significant impact on groundwater resources in the extended plan area. The SDWQ alternatives would not result in a change in groundwater pumping or groundwater recharge from surface water that currently takes place. As such, SDWQ Alternatives 2 and 3 would have no impact on groundwater resources and, therefore, are not discussed further in this section.

The impacts considered in Chapter 9 are as follows.

- Impact GW-1: Substantially deplete groundwater supplies or interfere substantially with groundwater recharge
- Impact GW-2: Cause subsidence as a result of groundwater depletion

Overall, the LSJR alternatives would reduce the amount of surface water available to those entities that currently divert surface water. To replace reduced surface water supplies, these entities could increase their reliance on groundwater, thereby increasing groundwater pumping and reducing groundwater recharge, relative to the baseline water balance, in the four groundwater subbasins underlying the plan area (the Eastern San Joaquin, Modesto, Turlock, and Extended Merced[4] Subbasins). Increased groundwater pumping could also result in groundwater quality impacts due to the potential for the migration of contamination and subsidence due to groundwater depletion. Other projects that could result in cumulative effects on groundwater resources would have the potential to deplete groundwater supplies either through increased groundwater pumping or interference with groundwater recharge.

Projects could result in a cumulative effect on groundwater resources if they increase reliance on groundwater, thereby depleting groundwater supplies or potentially interfering with groundwater recharge (Impact GW-1), which could also result in a potential migration of groundwater contamination, or if the increased groundwater pumping causes groundwater levels to decline such that there is an increased risk of subsidence (Impact GW-2). Accordingly, the geographic scope of this cumulative analysis on groundwater impacts focuses on projects within the four groundwater subbasins that underlie the plan area, as well as the extended plan area.

Groundwater levels in the four subbasins are primarily affected by inflows (i.e., natural and artificial recharge) and outflows (e.g., pumping and other discharges). Groundwater pumping has the greater impact on groundwater levels, especially as the subbasins have a long history of pumping more groundwater than the basins naturally recharge (i.e., overdraft). Reducing surface water availability could increase reliance on groundwater, as suppliers and groundwater users increase pumping to replace the lost surface water, thereby reducing groundwater levels. Lowering groundwater levels also has an effect on the risk of subsidence, especially in the Merced Subbasin, where there is evidence of subsidence (Sneed and Brandt 2015; Farr et al. 2015).

Past and present cumulative projects and activities that have contributed to declining groundwater levels in the four subbasins are discussed in the environmental setting section of Chapter 9. Examples of such activities that affect groundwater resources in the four groundwater basins include groundwater pumping for municipal, domestic, and agricultural uses (which has increased in recent decades), and the associated effects on groundwater quality by altered movement of groundwater contaminants towards wells.

---

[4] As defined in Chapter 9, *Groundwater Resources*, the Extended Merced Subbasin is the Merced Subbasin plus the small area of the Chowchilla Subbasins that is between the Merced Subbasin and the Chowchilla River.

In general, future actions that could cumulatively affect groundwater resources in the four groundwater subbasins underlying the plan area are similar to past and present projects and include new municipal, domestic, and agricultural development, including infrastructure. Past, present, and reasonably foreseeable projects, described in Table 17-1, may have effects on groundwater resources through the following mechanisms.

- Increase reliance on groundwater resources to meet increased potable water supply demands, thereby reducing groundwater levels or reducing groundwater recharge (both of which could also increase the migration of contaminants) or increasing subsidence.
- Reduce surface water availability, thereby increasing reliance on groundwater and thus reducing groundwater levels or reducing groundwater recharge (both of which could also increase the migration of contaminants) or increasing subsidence.

Several of the projects described in Table 17-1 are expected to encourage population growth, which could increase total municipal and industrial water use demands in a region that has historically relied on groundwater supplies. The projected population growth associated with these projects could increase total water demand and could increase reliance on groundwater resources to meet increased potable water supply demands. These projects include the following.

- California High Speed Rail Project
- Merced County's Castle Airport Master Plan (AMP) for development of Castle Airport
- Modesto Regional Water Treatment Plant (MRWTP) Phase Two Expansion Project
- University of California (UC) Merced 2020 Project
- Proposed Merced County 2030 General Plan
- Proposed Stanislaus County General Plan Update

Due to varied responses to reduced surface water deliveries and differences in groundwater conditions in the subbasins, the impacts of these projects cannot be determined with certainty. However, because municipalities and suppliers within the subbasins have historically relied on groundwater for all or a portion of their water supply, it is reasonable to conclude that reliance on groundwater would increase as the total water demand increases. The increased reliance could result in increased groundwater pumping, which could lead to an overall decline in groundwater levels in the subbasins and the potential for contaminants to move towards wells. Additionally, because lowered groundwater levels is associated with an increased risk of subsidence, these and similar projects could also increase the risk of subsidence in the subbasins.

Similarly, projects that reduce surface water availability could also result in significant cumulative impacts by increasing dependence on groundwater, which, again, could lead to an overall decline in groundwater levels and the associated potential for contaminant movement and subsidence. Projects that reduce surface water availability could also interfere with groundwater recharge activities, as recharge typically only occurs when there is excess surface water. Projects, described in Table 17-1, that could reduce surface water availability include the following.

- Water transfers

Although water transfers would tend to increase flows, there could be a flow shifting component that reduces flows at other times outside the transfer period. Increased flows would not increase natural instream groundwater recharge as the transfers do not increase the surface area from which recharge occurs. However, water transfers, which could involve transfers of water between entities within the plan area, transfers from outside the plan area to users within the plan area, or transfers from entities within the plan area to users outside the plan area, could result in a lowering of groundwater levels if groundwater is pumped in substitution for transferred water. Transfers could also reduce the availability of surface water for recharge activities if water that is transferred would otherwise have been injected into the aquifer or applied to spreading grounds where it could have percolated into the aquifer. Alternatively, water transfers could affect in-lieu groundwater recharge activities. Under in-lieu recharge programs, water users increase their surface water deliveries in order to temporarily decrease the amount of groundwater they pump from the aquifer. Decreased pumping allows natural recharge to accumulate in the underground aquifer for use during dry years. If water that otherwise would have been used to facilitate in-lieu recharge were to be transferred, then groundwater would still be pumped, which could result in a lowering of groundwater levels. The incremental contribution to groundwater resource impacts from LSJR Alternative 2 with adaptive implementation or LSJR Alternatives 3 or 4 with or without adaptive implementation would be cumulatively considerable when viewed in connection past, present, and probable future projects like the California High Speed Rail Project, the Castle AMP, the Modesto MRWTP Phase Two Expansion Project, the UC Merced 2020 Project, buildout under the proposed general plan updates for Merced and Stanislaus Counties, and water transfer projects. Cumulative impacts on groundwater resources in the plan area would be significant. There is no other feasible mitigation measure beyond what is proposed in Section 9.4.3, *Impacts and Mitigation Measures*, to reduce this impact to less-than-significant levels and, therefore, the cumulative impact would remain significant and unavoidable.

As discussed in Chapter 9, the geology in the extended plan area produces relatively small, localized, and isolated groundwater aquifers. This geology means that there is only one designated groundwater basin within the extended plan area, in Yosemite National Park, which has a relatively small amount of consumptive use. Given the small amount of consumptive use in the extended plan area, the LSJR alternatives would not significantly increase reliance on groundwater within the extended plan area, meaning that groundwater pumping is not anticipated to increase such that groundwater levels or recharge activities would be affected. Moreover, given the extended plan area geology and that groundwater pumping is not expected to significantly affect groundwater levels, there would be no significant risk of subsidence in the extended plan area or water quality impacts. The past, present, and reasonably foreseeable future projects identified in Table 17-1 do not have the potential to affect groundwater resources in the extended plan area because they are not expected to use existing groundwater resources in the extended plan area. As such, the LSJR alternatives' incremental contribution to cumulative impacts related to groundwater resources in the extended plan area would not be cumulatively considerable when viewed in connection with the effects of other past, present, and probable future projects

Recreational Resources and Aesthetics

As stated in Chapter 10, *Recreational Resources and Aesthetics*, LSJR Alternatives 2 and LSJR Alternative 3 without adaptive implementation would have a less-than-significant impact on recreation resources and aesthetics in the plan area, while LSJR Alternatives 3 with adaptive implementation and LSJR Alternative 4 with or without adaptive implementation would have significant and unavoidable impacts on recreational resources and aesthetics in the plan area. Within the extended plan area, LSJR Alternative 2 without adaptive implementation would have less-than-significant impacts on recreation resources and aesthetics, while LSJR Alternative 2 with adaptive implementation and LSJR Alternatives 3 and 4 with or without adaptive implementation would have significant and unavoidable impacts on recreational resources and aesthetics in the extended plan area. Under the SDWQ alternatives, water quality in the southern Delta is expected to remain within historical ranges; furthermore, any changes in salinity levels within historical ranges are expected to be imperceptible to recreationists. As such, SDWQ Alternatives 2 and 3 would have no impact on these resources and, therefore, are not considered further in this section.

The impacts considered in Chapter 10 are as follows.

- Impact REC-1: Substantially physically deteriorate existing recreational facilities on the rivers or at the reservoirs
- Impact REC-2: Substantially degrade the existing visual character or quality of the reservoirs

Overall, the LSJR alternatives would increase flows in the three eastside tributaries and decrease reservoir levels. Increases in flows may physically deteriorate the condition of existing recreation facilities at reservoirs or rivers. Because many recreation activities are limited to a range of flows (e.g., swimming, use of boat put-ins, access to picnic areas and campgrounds), a substantial increase in flows during the recreation season (May–September) could result in recreationists being unable to use the river for certain types of in-water and on-bank activities. The reductions in reservoir levels could increase the distance between established facilities and the water, which could reduce use of existing recreation facilities (e.g., as reservoir levels decline boat ramps become less accessible which could result in fewer boaters on the water). Reductions in reservoir levels could also increase the frequency with which the non-vegetated ring around the perimeter of the reservoir would be exposed, thereby affecting visual aesthetics. As discussed in Chapter 10, the LSJR alternatives would have greater impacts on recreational resources and aesthetics within the extended plan area than the plan area.

The geographic scope of this cumulative analysis focuses on projects within the plan area and the extended plan area because this is where recreational and visual effects could occur. The geographic scope also includes the SJR up to Friant Dam, as changes upstream could impact in-water recreation along the SJR within the plan area. The southern Delta is not included within the geographic scope, as the salinity water quality objectives would have no impact on visual and recreational resources.

Past, present, and reasonably foreseeable projects, described in Table 17-1, may have effects on recreation resources and aesthetics through the following mechanisms.

- Drawdown of reservoir levels on the three eastside tributaries.
- Increase in the variability of changes to flow volumes and timing.

Projects, described in Table 17-1, that could draw down reservoir levels on the three eastside tributaries include the following FERC projects.

- FERC Relicensing of the Don Pedro Hydroelectric Project (FERC Project No. 2299)
- FERC Relicensing of the Merced River Hydroelectric Project (FERC Project No. 2179) and Merced Falls Hydroelectric Project (FERC No. 2467)
- FERC Relicensing of Lyons Reservoir
- TUD Phoenix Lake Preservation and Restoration project

The Don Pedro and Merced River and Merced Falls FERC Hydroelectric Projects would include the flows associated with LSJR alternatives and any other flow adopted by FERC. Specifically, FERC projects undergoing relicensing must comply with conditions of water quality certification, such as the LSJR flow requirements, and any other minimum or bypass flows imposed through the relicensing process. However, these flows on the Tuolumne and Merced River are not expected to increase peak flows in a way that would cause substantial physical deterioration of on-bank recreation facilities. The proposed relicensing of New Don Pedro Reservoir and Lake McClure would include the maintenance of recreational facilities and potential changes to the release of water from the reservoir for power generation. In addition, the proposed relicensing could include actions, such as: increased flow, changes in timing of flow within a month or flows at different times of the year, fish passage, and, temperature control devices. If New Don Pedro Reservoir and Lake McClure are managed to include these types of actions, it is expected that the reservoirs could experience drawdown conditions, which could impact recreation resources and aesthetics. However, these conditions would be similar to historic conditions, and recreational amenities could be managed to provide continued access to recreationists. Furthermore, viewers typically anticipate the change in water elevation that results in the bathtub-ring effect with little vegetation and sediment. As such, the effects would not be substantially different from those analyzed in Chapter 10 for the plan area. The Lyons Reservoir FERC relicensing and the Phoenix Lake Preservation and Restoration Project are also not expected to result in a change in peak flows. However, depending on the drawdown that may occur at these reservoirs under the restoration and new FERC license, recreational and aesthetic resources may be affected, particularly in the summertime during prime recreation periods. In addition, diversions under the relicensing could occur in the summer or fall, which could potentially reduce the volume of water in the reservoir or river, depending on the scheduled release of water and the need for it downstream. These types of impacts could also occur under the FERC relicensing of the Don Pedro Hydroelectric Project as it may affect the operations of the CCSF's Hetch Hetchy system if CCSF contributes water supply to meet instream flows imposed as a condition of water quality certification associated with the relicensing or otherwise imposed through the relicensing process.

Other projects, described in Table 17-1, that could increase the variability of changes to flow volumes and timing include the following.

- Water transfers

Water transfers have the potential to increase flows, but the increases would be well within normal channel capacities of the three eastside tributaries and the LSJR and so are not expected to result in an increase in inundation of on-bank recreation facilities or result in physical deterioration of the facilities. Additionally, the transfers are unlikely to result in reductions of reservoir levels to such an extent that recreation facilities would be affected or the visual aesthetics be degraded. Therefore, these flows would not significantly impact recreation resources and aesthetics. Lastly, the effects of water right actions that implement the LSJR alternatives are accounted for in the effects associated with the LSJR alternatives and, therefore, would not result in additional impacts.

Additionally, some recreation management and improvement projects that are unrelated to flow and water levels may nevertheless have related impacts on recreation. Following is a list of such projects, which are described in Table 17-1.

- Tuolumne Wild and Scenic River Comprehensive Management Plan
- Merced Wild & Scenic River Final Comprehensive Management Plan

- Central Valley Vision
- SJR Blueway Plan

While unrelated to flow and water levels, these and similar projects would be expected to modify and enhance on-bank and in-water recreational opportunities. Similar types of past and present projects have gradually increased pressure on recreational resources, extracted water from the LSJR and three eastside tributaries, and altered the natural environment, including through urbanization of the viewshed. However, the projects also increased the number of recreational opportunities for the general public along the three eastside tributaries, the LSJR, and at the reservoirs by developing trails, boat launches, campsites, and other recreational amenities. The above-listed projects are expected to increase the number of recreational facilities and opportunities along the rivers and reservoirs, and implement other actions to ensure flows on the rivers suitable for recreation purposes and to preserve scenic views. Because similar projects have generally developed and promoted recreation, they have not had significant impacts on recreational amenities. However, development around the reservoirs and urbanization of the watersheds have had significant impacts on the views and viewsheds experienced by recreationists.

LSJR Alternative 2 would continue to support flows that are optimal for all types of recreation on the three eastside tributaries for the majority of the recreational season (May–September) and on the LSJR and would not substantially physically deteriorate existing recreational facilities at the reservoirs. Additionally, LSJR Alternative 2 with or without adaptive implementation would not substantially decrease May–September reservoir elevations, resulting in visual impacts. The incremental cumulative contribution of LSJR Alternative 2 with or without adaptive implementation to impacts on recreational resources on the rivers and reservoirs would not be significant when considered in combination with the past, present, and reasonably foreseeable probable future projects such as those described above. Therefore, under LSJR Alternative 2 with or without adaptive implementation, cumulative impacts would not be significant.

Under LSJR Alternatives 3 and 4 without adaptive implementation, the seasonal average frequency of flows conducive to swimming and wading (i.e., flows less than 500 cubic feet per second [cfs]) would decrease more than 10 percent on the Merced and Tuolumne Rivers, primarily due to reductions in May and June. There would be little change in high flows on these rivers from July–September, during the warmest months in the San Joaquin Valley, when swimming and wading are most popular. Thus, in-water recreation conditions are not expected to be substantially reduced. Flows may increase over the baseline in the extended plan area due to bypass flows, affecting in-river recreation. However, as described above, reasonably foreseeable probable future projects in the plan area and extended plan area are expected to increase recreation opportunities. Therefore, under LSJR Alternatives 3 and 4 without adaptive implementation, the incremental contribution of these impacts would not be cumulatively considerable and would not result in a significant cumulative impact on in-river recreation.

River flows greater than 2,500 cfs would increase in frequency on the Tuolumne River in May and June, and could result in an increase in the frequency of inundation of on-bank recreation areas under LSJR Alternative 3 without adaptive implementation (specifically, method 1). This inundation is not anticipated to substantially physically deteriorate these recreation facilities because they are capable of withstanding periodic inundation. Under LSJR Alternative 3 with adaptive implementation and LSJR Alternative 4 with or without adaptive implementation, modeled frequencies of flows greater than 2,500 cfs would substantially increase in the three eastside tributaries. Similar recreation impacts from increased river flows may occur in the extended plan area during bypass periods. Although on-bank recreation facilities on all of these rivers are purposefully built adjacent to, and within close proximity of, rivers and are able to withstand periodic inundation by higher flows, the frequency of flows predicted under these alternatives would likely result in much more frequent inundation of adjacent on-bank recreational facilities along these rivers relative to baseline, which is expected to contribute to substantial physical deterioration over time. Thus, the incremental contribution of LSJR Alternative 3 with adaptive implementation or LSJR Alternative 4 with or without adaptive implementation to the substantial physical deterioration of recreation facilities in the plan area and extended plan area over time would be cumulatively considerable when viewed in connection with the effects of the projects discussed above. As discussed in Chapter 10, Section 10.4.3, *Impacts and Mitigation Measures*, reducing flows could reduce this impact; however, such a reduction would directly contradict the purpose of these alternatives. In addition, the State Water Board has limited authority to impose mitigation measures on specific construction, operation, and maintenance of local recreational facilities to mitigate for the physical deterioration of recreation facilities. There are no other feasible mitigation measures the State Water Board can impose to reduce this impact to less–than-significant levels. As such, cumulative impacts related to recreational resources in the plan area and extended plan area would remain significant and unavoidable.

LSJR Alternative 3 without adaptive implementation and LSJR Alternative 4 without adaptive implementation are expected to cause a substantial decrease in May–September reservoir elevations at New Don Pedro Reservoir at the 30 percent cumulative distribution level for which increases in minimum reservoir elevations during the same period would not compensate. However, it is expected that this decrease would not substantially physically deteriorate existing recreation facilities at the reservoir, and all boat ramps would remain operable. Effects associated with reduced reservoir elevations at New Don Pedro Reservoir would be offset by increases in elevations under dry year conditions. Additionally, given the Class III designation of the views at New Don Pedro Reservoir (discussed in Chapter 10) and the typical fluctuations and the land-water interface experience of recreationists, the decrease in reservoir elevation is not expected to substantially degrade the visual quality. The incremental contribution of reduced elevations at New Don Pedro Reservoir would not be considered significant when considered with past, present, and reasonably foreseeable projects, such as those discussed above. Therefore, under LSJR Alternatives 3 and 4, the cumulative impact related to recreation and aesthetics in the plan area would not be significant. Elevations at New Melones Reservoir and Lake McClure would increase at the 30 percent cumulative distribution elevations under LSJR Alternatives 3 and 4, which would improve views such that there would be no significant cumulative impact.

In contrast to the discussion above, reduced reservoir elevations under LSJR Alternative 2, with adaptive implementation, and LSJR Alternatives 3 and 4 with or without adaptive implementation would potentially result in significant impacts on views and recreation and aesthetics, as discussed in in Chapter 10, Section 10.4.4, *Impacts and Mitigation Measures: Extended Plan Area,* in the extended plan area. The incremental cumulative contribution would be significant when considered with past, present, and reasonably foreseeable projects, such as those discussed above, and there would be a significant cumulative impact upstream of the rim dams. Reservoirs upstream of the rim dams are much smaller such that impacts would be more pronounced and cumulatively considerable than in downstream reservoirs, even considering increased recreational opportunities from other projects. There is no other feasible mitigation measure beyond what is proposed in Section 10.4.4 to reduce this impact and, therefore, the cumulative impact related to recreational resources in the extended plan area would remain significant and unavoidable.

Drawdown in upstream reservoir storage particularly under LSJR Alternatives 3 and 4, with or without adaptive implementation, but also under LSJR Alternative 2 with adaptive implementation, in the extended plan area could result in reduced flows in the fall on the Stanislaus and Tuolumne Rivers. If flows are reduced such that sensitive viewers (e.g., recreationists) cannot see water in the river, the river becomes less of a defining feature of the overall landscape. This could substantially degrade the visual character and quality of views of the Tuolumne River, many parts of which have been designated wild and scenic, and the Stanislaus River, which can be viewed from Scenic Highways 108 and 4. The incremental contribution would be cumulative considerable when viewed in connection with the effects of the projects discussed above, especially considering the sensitivity of the area. Therefore, the cumulative impact on aesthetics would be significant, even though higher spring flows and lower fall flows are reflective of what would occur in a natural system. Providing more flows in the fall would mitigate this impact; however, it is counter to the LSJR alternatives' purpose to provide additional flows during February–June to more closely mimic the natural hydrograph for the protection of fish and wildlife beneficial uses, and is therefore infeasible. There are no other feasible mitigation measures that the State Water Board may impose. As such, impacts related to the aesthetics in the extended plan area would remain cumulatively significant and unavoidable.

Agricultural Resources

As stated in Chapter 11, *Agricultural Resources*, LSJR Alternative 2 with adaptive implementation and LSJR Alternatives 3 and 4 with or without adaptive implementation would have significant and unavoidable impacts on the agricultural resources in the plan area, while LSJR Alternative 2 without adaptive implementation would have a less-than-significant impact on the agricultural resources in the plan area. LSJR Alternatives 2, 3, and 4 would have a less-than-significant impact on the agricultural resources in the extended plan area. Under the SDWQ alternatives, water quality within the southern Delta would generally remain the same as baseline conditions such that even salt-sensitive crops would not be considered significantly affected. As such, SDWQ Alternatives 2 and 3 would have a less-than-significant impact on agricultural resources.

The impacts considered in Chapter 11 are as follows.

- Impact AG-1: Potentially convert Prime Farmland, Unique Farmland, or Farmland of Statewide Importance (Important Farmland) to nonagricultural use
- Impact AG-2: Involve other changes in the existing environment which, due to their location or nature, could result in a conversion of farmland to nonagricultural use
- Impact AG-3: Conflict with existing zoning for agricultural use or a Williamson Act contract
- Impact AG-4: Conflict with any applicable land use plan, policy, or regulation related to agriculture of an agency with jurisdiction over a project (including, but not limited to the general plan, specific plan, local coastal program, or zoning ordinance) adopted for the purpose of avoiding or mitigating an environmental effect

In general, the LSJR alternatives would increase flows and decrease reservoir levels, which would reduce the amount of surface water available for irrigation districts in the plan area to supply to agricultural acreage. A reduction in surface water for irrigation could lead to the potential conversion of Important Farmland to nonagricultural uses. As discussed in Chapter 11, there are many factors affecting whether or not farmland is ultimately converted to nonagricultural uses, particularly whether or not it is urbanized, but it is reasonable to assume that a portion of the

Important Farmland losing irrigation could be converted to nonagricultural uses. The LSJR alternatives do not require land purchases, grading, or construction of buildings or infrastructure. Therefore, the LSJR alternatives do not require conditional use permits; make zoning changes; cancel or rescind Williamson Act contracts; update general plans; or make changes to agricultural land use plans, policies, or regulations that could affect agricultural resources.

Past, present, and reasonably foreseeable projects, described in Table 17-1, may have effects on agricultural resources through the following mechanisms.

- Urbanization of agricultural land or otherwise remove it from agricultural use.
- Reduction or limitation of the availability of surface water or groundwater for irrigation in the plan area such that agricultural land is potentially removed from agricultural use.
- Changes in the water quality of existing irrigation water supplies in the plan area such that agricultural land is potentially removed from agricultural use.

The geographic scope of this cumulative analysis focuses on projects within the irrigated agricultural acreage in the LSJR and SDWQ areas of potential effects as defined in Chapter 11, Agricultural Resources. There are more than 1 million acres of agricultural lands in California's San Joaquin Valley, which includes 527,793 acres of Important Farmland (65 percent of the agricultural acreage) in the LSJR area of potential effects, and 111,532 acres of Important Farmland (76 percent of the agricultural acreage) in the southern Delta. Important Farmland that is either Prime Farmland or Farmland of Statewide Significance is designated as such because of certain positive qualities, such as good soil characteristics like drainage, and the availability, amount, and frequency of irrigation. To maintain this status these lands must be irrigated 8 out of every 10 years and there must be adequate depth to the water table to support commonly cultivated crops..

Urban expansion, including infrastructure, habitat restoration efforts, and regional planning efforts that prioritize the implementation of water supply projects and other construction, could result in the removal of land from agricultural use in the plan area, including Important Farmland. Projects, described in Table 17-1, that would urbanize agricultural land or could otherwise remove it from agricultural use in the plan area, include the following.

- Urban growth in San Joaquin, Stanislaus, and Merced Counties (i.e., Proposed San Joaquin County 2035 General Plan, Merced County 2030 General Plan, Proposed Stanislaus County General Plan Update)
- Infrastructure projects (i.e.,., California High Speed Rail Project)
- Habitat restoration projects (i.e., Dos Rios Ranch and California EcoRestore)
- Regional planning efforts (i.e., DSC Delta Plan)

The San Joaquin Valley is one of the fastest-growing areas in California. For example, San Joaquin County converted 15,924 acres of Important Farmland to urban uses between 2000 and 2010 and estimates that an additional 12,133 acres of county land currently in agricultural/open space uses would be designated for nonagricultural/open space uses by 2035, mostly around existing urban centers, including 5,968 acres of Important Farmland. In Stanislaus County, between 2010 and 2012, urban and built-up land increased 293 acres and agricultural land decreased by 893 acres overall. However, Stanislaus County restricts growth under Measure E, passed in November 2007, which requires that land designated as agricultural or open space in the Land Use Element of the proposed *Stanislaus County General Plan* cannot be amended to residential or rezoned to residential without the approval of a majority of county voters. Measure E will remain in effect until December 31, 2036, unless it is otherwise amended by a future voter initiative. Merced County predicts that future growth resulting from implementation of its *Merced County 2030 General Plan* would result in both direct and indirect conversion of Important Farmland to urban or nonagricultural uses such as energy facilities, surface mining, the construction of infrastructure, and scattered rural residences. For example, total buildout of urban land uses designated in the *Merced County 2030 General Plan* could result in the new development of 14,683 acres by 2030.

Infrastructure and transportation projects, including roads and rail, could contribute to the conversion of Important Farmland. Transportation projects could be built upon Important Farmland and may also spur growth by creating new transportation hubs. For example, the California High Speed Rail Project calls for a high-speed rail system to be built and operated by 2029 with links between San Francisco and Los Angeles, as well as Sacramento and San Diego. The system would cover 800 miles with up to 24 stations, including several in the planned segment that traverses the LSJR area of potential effects. The project estimates that, for all statewide segments, a total of between 2,445 and 3,860 acres of farmland could be needed for railroad rights-of-way. New corridor alignments could also have the potential impact of severing existing parcels of farmland, potentially causing some to be converted to nonagricultural uses. Although the project connects existing urban areas, like many infrastructure projects, it may encourage some urbanization in currently undeveloped areas near project facilities.

Although habitat restoration projects maintain the open-space character of land, river and floodplain restoration efforts may require agricultural land along river corridors to be converted to nonagricultural uses, including to provide room for construction activities or for additional riparian habitat to complete the restoration projects. These changes could be permanent or temporary, and some of the land removed may be classified as Important Farmland. Examples of habitat restoration include Dos Rios Ranch and California EcoRestore. Dos Rios Ranch would restore land to provide wildlife habitat and flood control in the Central Valley on 1,600 acres of biologically rich floodplain, including 3 miles of riverfront on the SJR and 3 miles on the Tuolumne River. The plan area includes 119 acres of former agricultural land that was prone to flooding and planted in tomatoes, corn, alfalfa, and mixed row crops. California EcoRestore would help coordinate and advance at least 30,000 acres of critical habitat restoration in the Sacramento–San Joaquin Delta, mostly in the northern and central Delta, although some could occur in the southern Delta. Approximately 25,000 acres of the planned EcoRestore habitat is already required by the NMFS BO discussed in greater detail below. Another 5,000 acres are potential enhancements over and above the restoration required by the BOs. While some restored lands could remain in agricultural use, a significant portion is likely to be converted to nonagricultural use, including some lands that are Important Farmland.

Like general plans, regional plans do not direct construction of specific projects but may encourage certain types of activities and where they should be located. For example, the DSC was charged with developing and implementing a legally enforceable, long-term comprehensive management plan for the Delta. The Delta Plan must be designed to achieve the coequal goals of providing a more reliable water supply for California and protecting, restoring, and enhancing the Delta ecosystem while protecting and enhancing the unique cultural, recreational, natural resource and agricultural values of the Delta as an evolving place. As mentioned previously, the Delta Plan would not directly result in regulatory approvals, actions, or other projects, but could result in other agencies or entities taking future actions; however, the Delta Plan does encourage water supply reliability, habitat restoration, and other types of projects that could convert agricultural land to nonagricultural use.

On June 23, 2016, a Sacramento Superior Court judge issued a ruling setting aside the Delta Plan because parts of it were not consistent with the Delta Reform Act and ordering the DSC to revise the Delta Plan. However, any revised Delta Plan will continue to encourage water supply reliability and habitat restoration to fulfill the statutory mandates of the Delta Reform Act.

Development in the plan area, including residential, commercial, and industrial growth, is subject to local land use policies for agricultural mitigation that are designed to compensate for the premature and unnecessary conversion of agricultural land to urban uses, discourage noncontiguous urban development patterns, and promote the conservation, preservation, and continued existence of open space lands. These policies can include agricultural mitigation fees and agricultural conservation easement requirements based on acres of land converted. However, conversions of agricultural lands due to urban and rural development, including infrastructure, are still considered significant and unavoidable after mitigation (Merced County 2013; San Joaquin County 2014). The Delta Plan adopts policies that encourage certain types of projects including, but not limited to: potential surface water and groundwater storage facilities; water intakes; conveyance facilities (canals, pipelines, tunnels, siphons, and pumping plants); groundwater wells; water transfers; hydroelectric generation; ecosystem restoration; and development that could potentially affect agricultural resources. The DSC environmental review for the Delta Plan states that temporary project impacts on agricultural resources are likely to be fully mitigated. For projects that will result in the permanent conversion of agricultural land, depending on the nature of the conversion and the characteristics of the farmland to be converted, mitigation such as agricultural conservation easements, or contributing funds to a land trust or other entity qualified to preserve farmland in perpetuity, may be feasible. Nevertheless, the Delta Plan environmental review concludes that there will be permanent impacts on agricultural resources that are significant (Delta Stewardship Council 2013).

The High Speed Rail Project includes mitigation strategies to avoid or reduce impacts on agricultural land by sharing existing rail rights-of-way to the maximum extent possible, avoiding alignment options in established farmlands, and considering farmland preservation strategies. However, the High Speed Rail Project concludes impacts on farmland are still considered potentially significant and unavoidable, even after mitigation (California High-Speed Rail Authority and USDOT Federal Railroad Administration 2012).

Habitat projects retain land in open space use and do not destroy the chemical and biological integrity of soils; therefore, the differences between agricultural uses and habitat uses are largely economic and not environmental. Nevertheless, while many habitat projects, like EcoRestore, strive to adopt strategies (e.g., restoring degraded habitat as a priority before converting agricultural land or focusing habitat restoration efforts on developing new habitat on public lands before converting agricultural lands) in order to minimize impacts on agriculture, it is likely that agricultural land will still be converted (USBR et al. 2013).

The LSJR alternatives would allocate more water for instream flow requirements, as compared to baseline, which would reduce the amount of surface water available for irrigation districts in the plan area to supply to agricultural acreage, which could lead to the potential conversion of Important Farmland to nonagricultural uses. As discussed in Chapter 11, Section 11.4.3, *Impacts and Mitigation Measures*, while a reduction in water supply availability for agricultural purposes could potentially lead to a reduction in crop acreage and a potential conversion of Important Farmland to nonagricultural use, it is not a linear relationship. Non-irrigated lands could continue to be used for agricultural use through dry land farming, fallowing, grazing, dairy, and animal husbandry practices, and agricultural producers could mitigate reduced water availability for consumptive use by increasing irrigation efficiency, which would allow the amount of water currently applied to serve more acres. However, the State Water Board has limited authority to impose agricultural mitigation measures, and irrigation efficiencies and cropping decision would be the decisions of local farmers and local irrigation districts. While reducing flows could reduce the impacts of the LSJR alternatives, such a reduction would directly contradict the purpose of the LSJR alternatives. Thus, the incremental contribution of LSJR Alternative 2 with adaptive implementation or LSJR Alternatives 3 or 4, with or without adaptive implementation would be cumulatively considerable when viewed in connection with the effects of past, present, and future projects discussed above that could urbanize agricultural land or could otherwise remove it from agricultural use. There are no other feasible mitigation measures beyond what is proposed in Section 11.4.3, *Impacts and Mitigation Measures*, to reduce this cumulative impact to less-than-significant levels. As such, cumulative impacts related to agricultural resources in the plan area are significant and unavoidable.

The impacts of SDWQ Alternatives 2 or 3 on agricultural resources in the southern Delta are considered to be less than significant because water quality would not be degraded such that agricultural uses would be affected. Furthermore, these alternatives are meant to protect agricultural beneficial uses in the southern Delta. Therefore, the incremental contribution of SDWQ Alternatives 2 or 3 would not be cumulatively considerable, and cumulative impacts would not be significant.

Projects, described in Table 17-1, that could change water availability in the LSJR area of potential effects and potentially reduce irrigation to Important Farmland, thus increasing the likelihood that it could be converted to nonagricultural uses, include the following.

- Groundwater recharge projects
- FERC Relicensing of the Don Pedro Hydroelectric Project (FERC Project No. 2299)
- FERC Relicensing of the Merced River Hydroelectric Project (FERC Project No. 2179) and Merced Falls Hydroelectric Project (FERC No. 2467)
- Habitat restoration projects
- MRWTP Phase Two Expansion Project
- SGMA
- Water transfers

Groundwater recharge projects could take water that would otherwise remain in the Stanislaus, Tuolumne, and Merced Rivers and divert it to spreading basins that allow it to percolate into the ground or could capture it for direct injection into the groundwater aquifer. Water transfers from the three eastside tributaries could involve changes in the timing and flow of water as water is transferred between entities within the plan area, from outside the plan area to users within the plan area, or from entities within the plan area to users outside the plan area. FERC hydropower relicensing could require project-specific operational and infrastructure changes that could affect the timing and availability of water for irrigation. Habitat restoration projects could also divert surface water from the three eastside tributaries to restore and support natural habitat. The MRWTP would double the capacity of Modesto Irrigation District's (MID) water treatment plant allowing the City of Modesto to receive more water from MID for domestic use. SGMA requires sustainable management of the groundwater basins in the plan area by locally-created groundwater sustainability agencies (GSAs) that must adopt and implement groundwater sustainability plans

(GSPs) by 2020, if the basin is currently in chronic overdraft, or by 2022 for all other basins. GSPs utilize a 50-year planning horizon but must meet 5-year milestones and achieve sustainability within 20 years.

If a groundwater recharge project diverted water supply that was to otherwise be used for irrigation, there could be reductions in the number of irrigated acres, including acres of Important Farmland, which could lead to conversions to nonagricultural uses. Water transfers from the three eastside tributaries could reduce the availability of irrigation water availability and lead to reductions in irrigated acres, including acres of Important Farmland, which could lead to conversions to nonagricultural uses. In addition, farmers themselves may choose to fallow or idle their agricultural land in order to transfer water. Land that is temporarily fallowed is still considered to be in agricultural use. However, if land were permanently fallowed, that could be a direct conversion to nonagricultural uses. The FERC relicensing of the Don Pedro Hydroelectric Project, the Merced River Hydroelectric Project, and the Merced Falls Hydroelectric Project were considered in the effects analysis for the LSJR alternatives, including a wide range of potential flow releases. As such, these projects are expected to have effects similar to those identified for the LSJR alternatives, and the cumulative effects on agricultural resources are not expected to be significantly different from the analysis in Chapter 11. However, because other agencies have mandatory conditioning authority, and there may be project-specific operational and infrastructure changes required under these FERC projects, there may be localized changes in water availability in the Tuolumne and Merced Rivers resulting principally from re-operation of the reservoirs. If the water supply is reduced, there could be reductions in the number of acres that can be irrigated, which could lead to conversions of agricultural land, including Important Farmland, to nonagricultural uses. Habitat restoration projects could divert surface water from the three eastside tributaries, which could reduce surface water availability for agricultural uses. With reduced water supply, there could be reductions in the number of acres that can be irrigated. With irrigation reductions, there could be conversions, including conversions of Important Farmland, to nonagricultural uses. The MRWTP could transfer water from MID to the City of Modesto, which could reduce water availability for agricultural uses, which could in turn reduce the number of acres that can be irrigated and, therefore, potentially result in conversion to nonagricultural uses. Finally, SGMA requires sustainable groundwater management which, in the near term, could result in limits on groundwater supply for irrigation water. Historically, groundwater has been used for both direct irrigation and for surface water replacement, especially under drought conditions when surface water supplies are low. A reduced groundwater supply could result in a reduced number of acres that can be irrigated and could result in the conversion of agricultural land, including Important Farmland, to nonagricultural uses.

LSJR Alternatives 2 with adaptive implementation or LSJR Alternatives 3 and 4 with or without adaptive implementation would allocate more water for instream flow requirements, which would reduce the amount of surface water available for irrigations districts in the plan area to supply to agricultural acreage, which could lead to the potential conversion of Important Farmland to nonagricultural use. These impacts are considered cumulatively significant when considered in combination with past, present, and future projects described above that could reduce the water supply available for agricultural use, which could in turn lead to the conversion of agricultural land, including Important Farmland, to nonagricultural uses. There are no other feasible mitigation measures beyond what is proposed in Section 11.4.3, *Impacts and Mitigation Measures*, to reduce this cumulative impact to less-than-significant levels. As such, cumulative impacts would remain significant and unavoidable.

No reduction of agricultural acreage is likely under SDWQ Alternatives 2 and 3 because water quality within the southern Delta is expected to remain within the historic range. Under the program of implementation, the USBR would still be responsible for complying with the existing Vernalis salinity requirements established in the 2006 Bay-Delta Plan. Accordingly, the SDWQ alternatives would not degrade salinity conditions such that agricultural resources would be significantly affected. Projects, described in Table 17-1, that could cause changes in the water quality of existing irrigation water supplies in the plan area such that agricultural land is potentially removed from agricultural use include the following.

- California WaterFix
- NMFS BO (Chinook salmon, steelhead, sturgeon, and southern resident killer whales)
- USFWS BO (delta smelt)
- Update to the 2006 Bay-Delta Water Plan, Phase II
- Water transfers

The BOs are meant to protect fish listed under ESA from being jeopardized by the adverse effects of SWP and CVP export water operations by, at times, requiring reservoir releases, pumping reductions and other actions. Increased salinity concentrations could reduce crop yield or cause some crops to be removed from production. California WaterFix proposes new SWP Delta facilities, including three new screened intakes in the northern Delta, that could be operated at least partially in lieu of existing SWP and CVP southern Delta pumping. While California WaterFix could reduce entrainment and impingement of estuarine species in the southern Delta from existing SWP and CVP operations, it could also change south Delta water circulation and salinity by reducing the amount of Sacramento River water drawn into the southern Delta, thereby increasing salinity in the southern Delta. Transfers of water from the three eastside tributaries and SJR upstream of Merced could change the magnitude and timing of flows in the SJR and southern Delta. For example, WWCPs, such as the pending WWCP for the City of Turlock, could result in decreased flows in the LSJR during already low flow periods. Additionally, the update to the 2006 Bay-Delta Water Plan, Phase II could require greater Delta inflows, greater Delta outflows, or both. This could change southern Delta water circulation and salinity levels for agricultural resources.

The operations of the SWP and CVP are conditioned to meet the criteria in the Bay-Delta Plan and would continue to be conditioned to meet any updates to the Bay-Delta Plan, including through future State Water Board water right actions. As new points of diversion for the SWP, California WaterFix must seek permits from the State Water Board. Such permits would be conditioned to ensure that water for agricultural beneficial uses are protected consistent with Bay-Delta Plan requirements. Water transfers could change flow patterns, which could affect salinity concentrations in the southern Delta. Transfers that must pass through the Delta would generally improve south Delta salinity by increasing river water levels and inflow into the Delta and export pumping of transferred water would be subject to State Water Board conditions, including Bay-Delta Plan objectives for agricultural beneficial uses. Finally, the update to the 2006 Bay-Delta Plan, Phase II, must reasonably protect agricultural beneficial uses. Therefore, the range of salinity levels and circulation patterns in the southern Delta are not expected to be substantially different from those analyzed in Chapter 11. Consequently, past, present, and reasonably foreseeable probable future projects would not change the water quality of existing irrigation water supplies in the plan area such that agricultural land is potentially removed from agricultural use.

Considering the above limitations to adverse changes to water quality that could affect agriculture, LSJR Alternatives 2, 3, and 4 with or without adaptive implementation and SDWQ Alternatives 2 and 3 would not result in a cumulatively considerable incremental contribution to significant cumulative impacts related to changes in the water quality of existing irrigation water supplies such that agricultural land is potentially removed from agricultural use.

As discussed in Chapter 11, there are limited agricultural resources in the extended plan area and no designated Prime, Unique, or Farmland of Statewide Importance. Any effects on agricultural resources that result from reduced water supply would be similar to that described for the plan area but much smaller in magnitude and extent given the limited agricultural resources in the extended plan area. As discussed in Chapter 5, *Surface Hydrology and Water Quality*, projects in the extended plan area upstream of the rim dams would have very small effects on flows downstream of the rim dams and would not change surface water or groundwater availability for the irrigation districts. The past, present, and reasonably foreseeable future projects identified on Table 17-1 do not have the potential to affect agricultural resources in the extended plan area because they are not expected to convert designated agricultural uses to non-agricultural uses in the extended plan area. As such, the LSJR alternatives' incremental contribution to cumulative impacts related to agricultural resources in the extended plan area would not be cumulatively considerable when viewed in connection with the effects of other past, present, and probable future projects and would not result in a significant cumulative impact.

Cultural Resources

As stated in Chapter 12, *Cultural Resources*, LSJR Alternatives 2, 3, and 4 would have a less-than-significant impact on the cultural resources in the plan area and extended plan area. Under the SDWQ alternatives, salinity would generally remain the same as baseline conditions such that the baseline water quality conditions would not change. As such, SDWQ Alternatives 2 and 3 would have no impacts on cultural resources in the southern Delta and, therefore, are not considered further in this section.

The impacts considered in Chapter 12 are as follows.

- Impact CUL-1: Cause a substantial adverse change in the significance of a historical or archaeological resource
- Impact CUL-2: Disturb any human remains, including those interred outside formal cemeteries
- Impact CUL-3: Directly or indirectly destroy a unique paleontological resource or site or unique geologic feature

In general, the LSJR alternatives would change the rates of flow of the three eastside tributaries and the LSJR, the maximum and minimum surface elevations of the three reservoirs, and the timing these surface water elevation, which could affect cultural resources. Other projects in the plan area that are considered in this cumulative impact assessment have the potential to result in changes in river flows and changes in reservoir water surface elevations. As discussed in Chapter 12, changes in flow upstream of the rim dams would be small and would not change flows downstream of the rim dams or in the southern Delta. Therefore, projects in the extended plan area would not impact on cultural resources in the plan area.

Projects could result in a cumulative effect on cultural resources if they cause a substantial adverse change in the significance of a historical or archaeological resource (Impact CUL-1); disturb any human remains, including those interred outside formal cemeteries (Impact CUL-2); or directly or indirectly destroy a unique paleontological resource or site or unique geologic feature (Impact CUL-3) within the fluctuation zones of the reservoirs and along the rivers. Accordingly, the geographic scope of this cumulative analysis focuses on projects within the areas of fluctuation in surface water elevation around the channels of the three eastside tributaries and the LSJR and the reservoirs within the plan area and the extended plan area that have the potential for significant known and unknown cultural resources.

Past and present cumulative projects that have contributed to cultural resource impacts are discussed in more detail in the environmental setting section of Chapter 12. These projects include ground-disturbing construction activities that have resulted in the disturbance of archaeological resources and demolition of built environment resources. Development for agricultural, transportation, mining, or urban purposes has resulted in the conversion of raw land and the associated disturbance of archaeological resources, buried human remains and fossils, and, in some cases, demolition of existing built environment structures and residences.

In general, reasonably foreseeable probable future actions that could cumulatively affect cultural resources include FERC relicensing projects and restoration programs. These projects may increase exposure or inundation of the resource through re-operation of reservoirs and associated downstream flows in areas with the potential for significant known and unknown cultural resources to exist. The projects, described in Table 17-1, may have effects on cultural resources through the following mechanisms.

- Changes in the rates of flow of the three eastside tributaries and the LSJR.
- Alteration of the maximum and minimum surface elevations in the three reservoirs.
- Alteration of the timing that fluctuations in surface water elevations occur in the three reservoirs.

Projects, described in Table 17-1, that could result in changes through any of the three mechanisms stated above include the following.

- FERC Relicensing of the Don Pedro Hydroelectric Project (FERC Project No. 2299)
- FERC Relicensing of the Merced River Hydroelectric Project (FERC Project No. 2179) and Merced Falls Hydroelectric Project (FERC No. 2467)
- NMFS BO (for salmon)

These and similar projects could result in the re-operation of the reservoirs, which could lead to a change in the amount and timing of water surface elevation fluctuations in the reservoirs and a change in the rates of flows downstream of the reservoirs. While the FERC projects would include the flows associated with the LSJR alternatives and any other flow adopted by FERC, the projects could result in project-specific operational and infrastructure changes and re-operation of the reservoir that could result in localized changes to reservoir elevations. Similarly, the NMFW biological opinion identified actions included the implementation of a year-round minimum flow regime in the Stanislaus River, which has the potential to change reservoir storage levels in New Melones Reservoir on the Stanislaus River.

Significant known and unknown cultural resources along the river channel margins within the fluctuation zones of the reservoirs could be affected by increased exposure or inundation. However, given previous natural and anthropogenic disturbances, and that the expected changes from the

LSJR alternatives and these projects are within historical fluctuations, there is a low potential for undocumented cultural resources to exist along the rivers or within the fluctuation zone of the reservoir.

There is generally a high potential for currently known and unknown significant historic or archaeological resources (Impact CUL-1) to exist at the three reservoirs. Under the LSJR alternatives, the historic or archaeological resources in the fluctuation zones of the reservoirs could experience variation in their physical environment due to changes in water level or siltation. However, these variations have an extremely low potential to cause a substantial adverse change in the characteristics that convey the historical significance of the resource. In addition, any significant historical and archaeological resources are protected and managed under the Historic Properties Management Plans (HPMPs) as part of the FERC hydropower water quality certifications for the Don Pedro Hydroelectric Project (FERC Project No. 2299) on the Tuolumne River and the Merced River Hydroelectric Project (FERC Project No. 2179), including Lake McClure, and by the resource management plan (RMP) administered by USBR at New Melones Reservoir on the Stanislaus River. These management plans would include standard unanticipated discovery and treatment measures should any previously unknown significant or potentially significant cultural resources be discovered during continued operation of the reservoirs.

There is a low potential for significant unknown historic or archaeological resources (Impact CUL-1) to be located within and adjacent to the three eastside tributaries and LSJR due to past anthropogenic and natural modifications within and adjacent to the river channels. Under the LSJR alternatives, average and seasonal flows are expected to remain within the existing channels that have been previously disturbed by natural flows and anthropogenic activities.

The potential for human remains (Impact CUL-2) to exist within the fluctuation zone of the reservoirs is low. Under LSJR alternatives, there would be a low potential for a change in reservoir elevation to disturb documented or currently undocumented human remains. In addition, documented or currently undocumented sites with human remains would be protected under federal and state laws and under the HPMPs prepared as part of the FERC hydropower water quality certifications for the Don Pedro Hydroelectric Project (FERC Project No. 2299) on the Tuolumne River and the Merced River Hydroelectric Project (FERC Project No. 2179), including Lake McClure, and by the RMP administered by USBR at New Melones Reservoir. Similarly, the potential for the presence of undocumented human remains within and adjacent to the three eastside tributaries and LSJR is considered low due to prior disturbance of the riparian corridors by natural and historic-era anthropogenic processes.

The potential for undocumented paleontological resources (Impact CUL-3) to be contained within the rock units in proximity to the reservoirs is low. Additionally, documented remains would be protected and managed under the existing cave management plans. Along the channel margins of the three eastside tributaries, any buried paleontological resources would be found at soil and rock depths too deep to be affected by changes in the rates of flow.

The incremental contribution of LSJR Alternatives 2, 3 and 4 with or without adaptive implementation to cultural resource impacts would not be significant when considered in combination with the impacts from the FERC relicensing projects and the BOs discussed above. Given the previous natural and anthropogenic disturbances and the fact that expected changes from the LSJR alternatives and these projects are within historical fluctuations, significant cumulative changes in cultural resources are unlikely. Moreover, cultural resources are protected and managed under the HPMPs for the Don Pedro and Merced Hydroelectric Projects and under the RMP for the New Melones Reservoir. Therefore, the LSJR alternatives would not result in significant cumulative impacts related to cultural resources.

Similar to the discussion in the plan area, there is a low potential for cultural resources to be disturbed in the extended plan area because either there is a low potential for them to exist due to previous anthropogenic disturbances or natural and continual hydrologic disturbances (e.g., floods), or the changes that occurred under baseline have previously affected cultural resources at reservoirs and, thus, conditions under the LSJR alternatives would be unlikely to result in impacts. Past, present, and reasonably foreseeable projects, described in Table 17-1, may have effects on cultural resources in the extended plan area if they disturb areas beyond that of existing reservoirs, result in elevation changes beyond the historical variation of drawdown levels at reservoirs, or result in changes beyond existing river channels. Projects, described in Table 17-1, that may result in these types of impacts include the following.

- FERC Relicensing of the Don Pedro Hydroelectric Project (FERC Project No. 2299)
- FERC Relicensing of Lyons Reservoir
- TUD Phoenix Lake Preservation and Restoration project

All of these projects would result in potential disturbances at existing reservoirs, and it is expected that all of the projects, with the exception of the Phoenix Lake Preservation and Restoration Project, would occur within the design capacity of the existing reservoir. This means the reservoirs would continue to operate within the bounds of the design capacity constraints and within historical elevation variation. The Phoenix Lake Preservation and Restoration Project would construct a sediment bay, increase capacity, and would involve dredging. These activities have the potential to uncover unknown cultural resources that may not have been exposed during normal operations of this particular reservoir. Depending if cultural resources are uncovered and what they might be, this could be a significant impact. However, if the impact were to occur, it would be localized to this particular reservoir and would not contribute to an overall significant cumulative impact to cultural resources in the extended plan area. The LSJR alternative's incremental contribution to cumulative impacts related to cultural resources in the extended plan area would not be cumulatively considerable when viewed in connection with the effects of other past, present, and probable future projects.

Service Providers

As stated in Chapter 13, *Service Providers*, under the LSJR alternatives, surface water diversions would be reduced in both the plan area and the extended plan area. Table 17-2 summarizes the service provider impact determinations for each alternative in the plan area and the extended plan area. LSJR Alternative 2 without adaptive implementation would have less-than-significant impacts for Impacts SP-1, SP-2a, SP-2b, and SP-3. LSJR Alternative 2, with adaptive implementation, and LSJR Alternatives 3 and 4, with or without adaptive implementation, would have less-than-significant impacts for Impacts SP-2a and SP-3. LSJR Alternative 2, with adaptive implementation, and LSJR Alternatives 3 and 4, with or without adaptive implementation, would have significant and unavoidable impacts for Impacts SP-1 and SP-2b. SDWQ Alternative 2 would have a significant and unavoidable impact for Impact SP-1 and a less than a significant impact for Impact SP-2a. SDWQ Alternative 3 would have a less-than-significant impact for both Impacts SP-1 and SP-2a. SDWQ

Alternatives 2 and 3 are not relevant to Impacts SP-2b and SP-3 and, thus, have no cumulative impact. Therefore, they are not discussed further in this section.

The impacts considered in Chapter 13 are as follows.

- Impact SP-1: Require or result in the construction of new water supply facilities or wastewater treatment facilities or expansion of existing facilities, the construction of which could cause significant environmental effects
- Impact SP-2a: Violate any water quality standards such that drinking water quality from public water systems would be affected
- Impact SP-2b: Violate any water quality standards such that drinking water quality from domestic wells would be affected
- Impact SP-3: Result in substantial changes to SJR inflows to the Delta such that insufficient water supplies would be available to service providers relying on CVP/SWP exports

Table 17-2. Summary of Chapter 13, *Service Providers*, Impact Determinations for LSJR and SDWQ Alternatives

		LSJR Alternative 2	LSJR Alternative 3	LSJR Alternative 4	SDWQ Alternative 2	SDWQ Alternative 3
SP-1	Without AI	L	S	S	S (N)	L (N)
	With AI	S	S	S	N	N
SP-2a	Without AI	L	L	L	L (N)	L (N)
	With AI	L	L	L	N	N
SP-2b	Without AI	L	S (L)	S (L)	N	N
	With AI	S (L)	S (L)	S (L)	N	N
SP-3	Without AI	L	L	L	N	N
	With AI	L	L	L	N	N

Notes:
The impact determinations for SP-2b under LSJR Alternatives 2, without adaptive implementation, and LSJR Alternatives 3 and 4 in the extended plan area are different from those in the plan area.
The parentheses () denote the determination for the extended plan area.
AI = adaptive implementation (as described in Chapter 3, *Alternatives Description*).
S = significant and unavoidable impact
L = less-than-significant impact
N = no impact or not applicable

The geographic scope of this cumulative analysis focuses on projects within the plan area, the Eastern San Joaquin, Modesto, Turlock, and Extended Merced[4] Subbasins, other areas outside the plan area where there are service providers that are affected by the project and the extended plan area because these are the areas where impacts could occur.

As discussed in Chapter 5, *Surface Hydrology and Water Quality*, changes in flow upstream of the rim dams would be minimal and would not change flows downstream of the rim dams or in the southern Delta. Therefore, under LSJR Alternative 2 without adaptive implementation and LSJR Alternatives 3 and 4, for Impacts SP-1, SP-2a, and SP-3, there would be similar impacts on service providers in the plan area and extended plan area. However, under LSJR Alternative 2 with adaptive implementation and LSJR Alternatives 3 and 4, impacts for Impact SP-2b in the extended plan area would be less than significant, which is different from the plan area (where the impact for Impact SP-2b is significant and unavoidable). As discussed in Chapter 13, there were 55 service providers identified in the extended plan area. These service providers are geographically removed from the southern Delta and, thus, will not be affected by the SDWQ alternatives. Therefore, SDWQ alternatives, as they relate to the extended plan area, are not discussed further in this section.

Past, present, and reasonably foreseeable projects, described in Table 17-1, may have effects on service providers through the following mechanisms.

- Reduction of surface water availability in the three eastside tributaries substantially, such that service providers would need to construct new or expanded existing water supply or wastewater treatment facilities to compensate for the reduction, the construction of which could result in significant environmental effects.
- Increase in groundwater pumping to compensate for reduced surface water availability such that groundwater resources are substantially depleted and groundwater levels are lowered.
- Degradation of water quality such that water quality from public water systems and domestic (i.e., private) wells violate drinking water standards.
- Reduction of SJR inflows to the Delta such that water supplies would be insufficient to service providers relying on CVP/SWP exports.

Projects, described in Table 17-1, that could change through any of the four mechanisms stated above, include the following.

- California High Speed Rail Project
- California WaterFix
- CV-SALTS and Central Valley-Wide SNMP
- Merced County’s AMP for Development of Castle Airport
- Proposed San Joaquin 2035 General Plan
- Proposed Stanislaus County General Plan Update
- UC Merced 2020 Project
- Update to the 2006 Bay-Delta Water Plan, Phase II

Development projects, such as the California High Speed Rail Project, development of Castle Airport and, the UC Merced 2020 Project, would increase water demand in the region where the development takes place. Service providers are planning for and have identified future water sources for municipal and agricultural uses. However, these projects could place pressure on the existing capacity of the service providers such that suppliers respond by constructing new water supply facilities or wastewater treatment facilities, or expanding existing facilities, the construction of which could cause environmental impacts. Furthermore, increased water demand may result in more groundwater being pumped, leading to depletion of groundwater resources. The draft EIRs for the proposed general plan updates for San Joaquin and Stanislaus Counties state that there will be significant impacts associated with the construction of new water supply or treatment facilities or expansion of existing facilities to meet water demands associated with buildout under these plans.

California WaterFix, CV-SALTS and SNMP, and the update to the 2006 Bay-Delta Plan, Phase II could alter the hydrodynamics in the southern Delta which could affect salinity. Although there may be occasions in which salinity would be increased, overall degradation of water quality is not expected in the southern Delta. In general, these projects are designed to maintain or improve water quality in the three eastside tributaries, the LSJR, and the southern Delta. For example, California WaterFix could lead to reductions in export salinity, and with additional export capacity, project water could be released to the SJR during low flow periods, which could improve water quality.

In general, under the LSJR alternatives with or without adaptive implementation, salinity in the southern Delta is not expected to differ much from baseline salinity and, overall, would decrease on average. Therefore, surface water quality is not expected to degrade such that drinking water standards would be violated in the southern Delta. Thus, the incremental contribution of the LSJR alternatives to cumulative impacts on drinking water quality (Impact SP-2a) in the SJR at Vernalis would not be cumulatively considerable since overall salinity would decrease under the LSJR alternatives with or without adaptive implementation, and cumulative impacts would be less than significant.

Sufficient surface water supplies are expected under LSJR Alternative 2 such that additional water supply or wastewater treatment facilities would not be required. Thus, the incremental contribution of the alternative to cumulative impacts (Impact SP-1) associated with the construction of new or expanded facilities would be less than significant. However, as discussed in Chapter 13, if adaptive implementation method 1 is implemented frequently and on a long-term basis, surface water diversions would be substantially reduced on the Tuolumne and Merced Rivers. Similarly, reductions in surface water supply diversions would occur under LSJR Alternatives 3 and 4 with or without adaptive implementation on these rivers as well as on the Stanislaus River. These reductions would affect service providers that rely primarily on surface water from these rivers and those providers that rely on some surface water from these rivers (Table 13-2 of Chapter 13). Some service providers are also planning to obtain additional surface water, which could be restricted under LSJR Alternative 2 with adaptive implementation and LSJR Alternatives 3 and 4 with or without adaptive implementation. As such, these LSJR alternatives would likely result in the construction of new water supply or wastewater facilities or expansion of such facilities in the plan area, the construction of which could cause environmental effects. Similarly, service providers in the extended plan area may need to construct new water supply or wastewater treatment facilities or expand such existing facilities. The incremental contribution of LSJR Alternative 2 with adaptive implementation, or LSJR Alternatives 3 or 4 with or without adaptive implementation would be significant when considered in connection with the new or expanded water supply or wastewater treatment facilities (Impact SP-1) as a result of the projects listed above. Therefore, there would be a significant cumulative impact in both the plan area and extended plan area.

If new or expanded facilities are required as a result of reduced surface water supply, the facilities would be carried out as part of individual projects associated with the service providers and could result in potentially significant environmental impacts. As discussed in Chapter 13, Section 13.4.3, *Impacts and Mitigation Measures*, the State Water Board would not be responsible for or have discretionary authority to approve the construction of any new or modified facilities and, therefore, it is not feasible for the State Water Board to impose possible mitigation measures (listed in Chapter 16, Table 16-38). Moreover, the State Water Board lacks authority to impose mitigation measures related to impacts such as air and noise. There is no feasible mitigation the State Water Board can implement to reduce environmental impacts resulting from the need for new or modified facilities (Impact SP-1). Therefore, under LSJR Alternative 2 with adaptive implementation and LSJR Alternatives 3 and 4 with or without adaptive implementation, the impacts would remain cumulatively considerable and significant.

Furthermore, given the potential reductions in surface water supply on the Stanislaus, Tuolumne, and Merced Rivers, pumping would be expected to increase in the Extended Merced, Modesto, and Turlock Subbasins, which would experience decreases in groundwater levels under LSJR Alternative 2 with adaptive implementation and LSJR Alternatives 3 and 4 with or without adaptive implementation. The Eastern San Joaquin Subbasin would also be affected under LSJR Alternative 4. These impacts on groundwater levels could result in reductions in groundwater supply and degradation of the quality of groundwater that the service providers and domestic well owners rely on as a source of drinking water. While water quality from public water system would not be impacted significantly, water quality from domestic wells could be impacted significantly, as discussed in Chapter 13, Section 13.4.3. The new or expanded water facilities that could be constructed as a result of projects like the California High Speed Rail Project, Castle Airport, and the UC Merced 2020 Project, could include new or expanded groundwater wells that would increase the groundwater pumping capacity. As discussed previously, increased pumping could reduce groundwater levels and potentially degrade groundwater as a source of drinking water. However, the incremental contribution of LSJR Alternative 2 with adaptive implementation or LSJR Alternatives 3 or 4 with or without adaptive implementation on drinking water quality from public water systems would not be significant when viewed in connection with these and other past and present projects; this is because public water system operators are required to comply with drinking water standards and would have to take corrective actions if their drinking water wells exceed the drinking water standards. As such, there would not be a cumulative significant impact (Impact SP-2a). In contrast, the incremental contribution of LSJR Alternative 2 with adaptive implementation or LSJR Alternatives 3 or 4 with or without adaptive implementation on drinking water quality from domestic wells would be significant when viewed in connection with the additional pumping and the potential groundwater degradation that may result from these projects. Additionally, there are no mechanisms to prevent domestic wells from using groundwater that exceeds drinking water standards as domestic wells are largely unregulated. Therefore, under LSJR Alternative 2 with adaptive implementation, or LSJR Alternatives 3 or 4 with or without adaptive implementation, cumulative impacts on drinking water (Impact SP-2b) in the plan area would remain cumulatively considerable and significant.

The State Water Board does not have authority to require implementation of mitigation that could reduce these cumulative impacts to a less-than-significant level, because it does not regulate domestic wells. As discussed in Chapter 13, the State Water Board can and does assist in identifying water quality threats through the Groundwater Ambient Monitoring and Assessment (GAMA) Program, the State Water Board's comprehensive groundwater quality monitoring program for California, and GeoTracker GAMA, a publically accessible online database of groundwater water quality data in California. Using the data collected in GAMA since year 2000, the State Water Board also provides the online, map-based tool "Is My Property Near a Nitrate-Impacted Water Well?" to assist domestic well owners in evaluating the risk of their wells to nitrate contamination.

Possible mitigation measures that owners and operators of domestic wells could undertake to avoid or reduce potential drinking water impacts at domestic wells include the following.

- Have a licensed contractor construct wells in accordance with well construction standards.
- Choose a location for a well to make sure it is free of potential sources of contamination.
- Test well water at certified drinking water laboratories to ensure its quality.

- If necessary, install a water treatment system tailored to the overall water chemistry and constituents that need to be removed (e.g., activated alumina filters, activated charcoal filters, air stripping, anion exchange, and ultraviolet radiation).
- If necessary, drill a new well that taps into a cleaner aquifer or find an alternative water source.
- Properly destroy unused and abandoned wells to prevent contamination.

In addition, local agencies can and should exercise their police powers and groundwater management authority under SGMA to address groundwater contamination so as to prevent and/or mitigate drinking water impacts on domestic wells. As discussed in the *Groundwater Resources* section of this chapter, SGMA requires local agencies to sustainably manage groundwater resources or, if local agencies are unable or unwilling, authorizes the state to intervene and develop an interim plan until locals can assume, or resume, management. Sustainable groundwater management is defined under SGMA as the management and use of groundwater in a manner that can be maintained during the 50-year planning and implementation horizon without causing undesirable results, including but not limited to: chronic lowering of groundwater levels; significant and unreasonable reductions in groundwater storage; significant and unreasonable degraded water quality; and significant and unreasonable subsidence that substantially interferes with surface land uses. (Wat. Code, § 10721.) Following the adoption of groundwater sustainability plans in either 2020 or 2022 (depending on if the basin is critically overdrafted), locals will have 20 years to achieve sustainable groundwater management. Plans must include milestones that, following initial submission of the plan, will be reviewed by the state every 5 years.

Thus, at this time, local agencies are vested with the mandatory duty to achieve sustainable groundwater management, which includes preventing significant and unreasonable degradation to water quality. These agencies can and should exercise their full authorities to address degradation of groundwater quality, both under SGMA and their police powers. Doing so would prevent and/or mitigate domestic well drinking water supply impacts. However, due to the inherent uncertainty in the degree to which this mitigation and those listed above may be implemented by local agencies and owners and operators of domestic wells, under LSJR Alternative 2, with adaptive implementation, and LSJR Alternatives 3 and 4, impacts related to drinking water impacts on domestic wells (SP-2b) would remain cumulatively considerable and significant in the plan area.

In the extended plan area, under LSJR Alternative 2 with adaptive implementation and LSJR Alternatives 3 and 4 with or without adaptive implementation, bypass flows could be required more frequently and be larger than under baseline conditions, which could result in significantly less surface water available to the 12 service providers (listed in Chapter 13, Table 13-6), who collectively divert a total of 7.61 TAF annually. Increased groundwater pumping may occur; however, the increased pumping is not likely to affect groundwater quality and, thus, drinking water from public or private wells. This is because in the extended plan area, the amount of water that may be pumped is small given the small amount of total municipal use that occurs in the extended plan area, and pumping primarily occurs in fractured rocks which produces relatively small and isolated groundwater areas such that pumping would have minimal influence on contaminant migration. The projects listed above would not affect the groundwater quality in the extended plan area. Therefore, LSJR Alternatives 2 with adaptive implementation and LSJR Alternatives 3 and 4 with or without adaptive implementation would not result in a cumulatively considerable incremental contribution to cumulative impacts or significant cumulative impacts related to drinking water (Impacts SP-2a and SP-2b), and cumulatively adverse impacts would be less than significant in the extended plan area.

With respect to Impact SP-3, in both the plan area and the extended plan area, there would be no reduction in annual average CVP/SWP exports. Hence, SJR inflows to the Delta would not be affected under LSJR Alternatives 2, 3 and 4. The incremental effect of the LSJR alternatives, when viewed in connection with the projects like the California High Speed Rail Project, Castle Airport, UC Merced 2020 Project, and water transfers, would not be cumulatively significant, and there would be no significant cumulative impact.

Under SDWQ Alternative 2, it is expected that some of the service providers (e.g., City of Tracy) would not be able to meet effluent limitations if the effluent limitations are set by the Central Valley Water Board to match the SDWQ Alternative 2 objective (i.e., 1.0 dS/m). Therefore, it can be expected that wastewater treatment requirements set by the Central Valley Water Board may be exceeded if a variance (i.e., under Central Valley Water Board Resolution No. R5-2014-0074, which authorizes variances that delays the deadline for compliance with salinity requirements) is not granted or its coverage expires. In order to comply, potential new facilities or modifications of existing facilities would be constructed as part of individual projects associated with the service providers could result in potentially significant environmental impacts. Projects like California WaterFix; CV-SALTS and SNMP; and the update to the 2006 Bay-Delta Plan, Phase II, could improve LSJR flow and water quality in the southern Delta, but it is unlikely that these projects could reduce the salinity of the effluent from the southern Delta wastewater treatment plant to such a degree that they would comply with a 1.0 dS/m effluent limitation. The incremental cumulative contribution of SDWQ Alternative 2 to the cumulative impact on service providers would be significant when viewed in connection with the new or expanded water supply or wastewater treatment facilities (Impact SP-1) that may be constructed as a result of projects, like the California High Speed Rail Project, Castle Airport, UC Merced 2020 Project, and the LSJR alternatives would result in a significant cumulative impact. As described above, there is no feasible mitigation the State Water Board could implement to reduce environmental impacts on service providers resulting from the need for new or modified facilities. Therefore, under SDWQ Alternative 2, this impact (Impact SP-1) would remain cumulatively considerable and significant.

Under SDWQ Alternative 3, potential new facilities or modifications to existing facilities are not expected, and all service providers would be expected to comply without new or modified facilities based on annual average EC data and previous EC violations. The incremental cumulative contribution of SDWQ Alternative 3 to cumulative impacts on service providers would not be considerable, and when viewed in connection with the related past, present, and reasonably foreseeable probable future projects listed above, this alternative would not result in a significant cumulative impact. Therefore, under SDWQ Alternative 3, this impact (Impact SP-1) would not be cumulatively significant. SDWQ Alternatives 2 and 3 are expected to maintain the historical range of salinity in the southern Delta because USBR would remain responsible for complying with the current salinity standards at Vernalis under its water right permits. Substantial degradation of water quality affecting service providers diverting drinking water from the southern Delta would not occur under SDWQ Alternatives 2 or 3. Therefore, the incremental contribution of SDWQ Alternatives 2 or 3 to cumulative impacts on drinking water quality from public water systems would not be considerable. And, when viewed in connection with relevant projects listed above, cumulative impacts (Impact SP-2a) would not be significant.

Energy and Greenhouse Gases

As stated in Chapter 14, *Energy and Greenhouse Gases*, LSJR Alternative 2 with or without adaptive implementation would have a less-than-significant impact on energy and GHGs in the plan area, while LJSR Alternatives 3 and 4 with or without adaptive implementation would have significant and unavoidable impacts on energy and GHGs in the plan area. LSJR Alternative 2 with adaptive implementation, and LJSR Alternatives 3 and 4 with or without adaptive implementation would have significant and unavoidable impacts on energy and GHGs in the extended plan area, while LSJR Alternative 2 without adaptive implementation would have a less-than-significant impact on these energy and GHGs in the extended plan area. Under the SDWQ alternatives, salinity would generally remain the same as baseline conditions. As such, SDWQ Alternatives 2 and 3 would have no impact on energy and GHGs (Impacts EG-1 through EG-4) and, therefore, are not considered further in this section.

The impacts considered in Chapter 14 are as follows.

- Impact EG-1: Adversely affect the reliability of California's electric grid
- Impact EG-2: Result in inefficient, wasteful, and unnecessary energy consumption
- Impact EG-3: Generate GHG emissions, either directly or indirectly, that may have a significant impact on the environment
- Impact EG-4: Conflict with an applicable plan, policy, or regulation adopted for the purposes of reducing GHG emissions
- Impact EG-5: Effect of climate change on the LSJR and SDWQ alternatives

The LSJR alternatives would not require energy consumption or generate GHG emissions directly. However, the LSJR alternatives may affect hydropower generation by requiring more water to be released instream during the February–June period, making less stored water available for release in the summer. This, in turn, could result in additional energy generation at other facilities to compensate for the loss of hydropower generation. In addition, the LSJR alternatives could result in increased energy consumption associated with increased groundwater pumping. These activities could result in increased GHG emissions.

While the LSJR alternatives may result in a loss of carbon-free hydropower generation, it is anticipated that electricity derived from existing carbon-free hydropower sources would be compensated for by ramping up other generation facilities. Additionally, while other sources to compensate for electricity would include renewable energy sources, not all renewable energy is carbon free. For example, biomass- and biofuel-derived energy does emit GHGs.

No single project is likely to generate enough GHG emissions to cause an appreciable impact on climate change by itself; rather, climate change is the result of the GHG contributions of countless past, present, and future sources. The relevant inquiry is whether a project's incremental impact is cumulatively considerable in light of the global problem. California has policies and procedures in place to reduce statewide GHG production. For example, the California Renewables Portfolio Standard (RPS) (discussed in Chapter 14, Section 14.3.2, *State [Regulatory Background]*) requires that all electricity producers increase procurement from eligible renewable energy resources to 33 percent of total procurement by 2020. Energy production and consumption in the SJR Basin and California is anticipated to result in the use of more renewable energy sources over the next few decades. This is already evident, as the SJR Basin and surrounding areas have seen an increase in renewable energy projects, which will help the state meet the RPS requirements.

Past, present, and reasonably foreseeable projects, described in Table 17-1, may have effects on energy and greenhouse gas resources through the following mechanisms.

- Adverse effects on the reliability of California's electric grid by decreasing energy production or resulting in inefficient, wasteful, and unnecessary energy consumption.
- Generation of GHG emissions, either directly or indirectly, that may have a significant impact on the environment, or conflict with an applicable plan, policy, or regulation adopted for the purposes of reducing GHG emissions.

The geographic scope of this cumulative analysis focuses on projects within the plan area and the extended plan area.

Projects, described in Table 17-1, that could adversely affect the reliability of California's electric grid or result in inefficient, wasteful, and unnecessary energy consumption include the following.

- FERC Relicensing of the Don Pedro Hydroelectric Project (FERC Project No. 2299)
- FERC Relicensing of Merced River Hydroelectric Project (FERC Project No. 2179) and Merced Falls Hydroelectric Project (FERC No. 2467)
- FERC Relicensing of Lyons Reservoir
- NMFS BO
- TUD Phoenix Lake Preservation and Restoration project
- Water transfers

These projects could result in re-operation of reservoirs that could lead to a change in the amount and timing of reservoir releases and water surface elevation fluctuations in the reservoirs. This has the potential to change the timing of and to reduce hydropower generation from the major dams on the Stanislaus, Tuolumne, and Merced Rivers. The overall operation of these reservoirs, however, is not expected to vary beyond the bounds analyzed for the LSJR alternatives. While hydropower generation may depend on the timing and amount of the transfer, surface water transfers typically must be within the same season, and so this would serve to limit potential changes. As discussed in Chapter 14, the transmission line loadings would not exceed the limits under contingency outage conditions under the LSJR alternatives because hydropower generation and reservoir elevation would not be substantially modified.

Additional energy generation at other facilities to compensate for a potential loss of hydropower under the LSJR alternatives would not be considered inefficient, wasteful, and unnecessary as it is energy that would be generated to maintain the energy supply level that is currently supplied by hydropower. Therefore, there would be no inefficient, wasteful, or unnecessary energy consumption under LSJR Alternatives 2, 3, and 4 with or without adaptive implementation.

The FERC projects listed above would include the flows associated with the LSJR alternatives and any other flow adopted by FERC. Additionally, the operation of New Melones Reservoir and Stanislaus River flows under the NMFS BO would include the flows associated with the LSJR alternatives. The effects of these other projects on grid stability and energy consumption would fall within the range of effects analyzed for the LSJR alternatives.

GHG emissions under LSJR Alternatives 2 would not exceed the 10,000 MT CO2e threshold with and without adaptive implementation. Therefore, GHG emissions would not have a significant impact on the environment under LSJR Alternative 2. GHG emissions under LSJR Alternatives 3 and 4 would exceed the 10,000 MT CO2e threshold with and without adaptive implementation. Thus, GHG emissions would have a significant impact on the environment under LSJR Alternatives 3 and 4 with or without adaptive implementation.

Projects, described in Table 17-1, that could generate GHG emissions, either directly or indirectly, that may have a significant impact on the environment, or conflict with an applicable plan, policy, or regulation adopted for the purposes of reducing GHG emissions, include the following.

- California High Speed Rail Project
- DSC Delta Plan
- Merced County's Castle AMP for Development of Castle Airport
- MRWTP Phase Two Expansion Project
- UC Merced 2020 Project

Physical improvements associated with these, and similar projects, could result in an increase in GHG emissions. GHG emissions are primarily generated during construction activities due to the considerable use of heavy equipment and construction vehicle trips, which are likely to have the greatest construction GHG emissions. Additionally, operation-phase impacts could occur directly (e.g., from maintenance activities) or indirectly (e.g., from increased electricity use).

RPS requirements would serve to reduce the carbon intensity of generated electricity, thereby helping to reduce the GHG emissions that would be associated with reduced hydropower generation and the increased use of electricity for groundwater pumping under LSJR Alternatives 3 and 4 with or without adaptive implementation. However, even if 33 percent of electricity in California were to be generated using renewable resources and the total GHG emissions resulting from LSJR Alternatives 3 and 4 were reduced by 33 percent, LSJR Alternatives 3 and 4 with or without adaptive implementation would still generate more than 10,000 MT CO2e per year (thereby exceeding the threshold) and would make a cumulatively considerable incremental contribution. Thus, impacts related to the energy and GHS resource under LSJR Alternatives 3 and 4 with or without adaptive implementation would be cumulatively considerable. There are no feasible mitigation measures beyond those proposed in Chapter 14, Section 14.4.3, *Impacts and Mitigation Measures,* to reduce this cumulative impact to less-than-significant levels.

As discussed in Chapter 14, Section 14.4.4, *Impacts and Mitigation Measures: Extended Plan Area*, the LSJR alternatives could affect energy (i.e., hydropower electrical production) resources in upstream reservoirs on the Stanislaus and Tuolumne Rivers. Hydropower production effects associated with the reservoir volume reduction under LSJR Alternatives 2 and 3 without adaptive implementation would be similar to baseline conditions. However, volume reductions would occur more frequently and be more severe during drought conditions, particularly under LSJR Alternatives 3 and 4 with or without adaptive implementation, but also under LSJR Alternative 2 with adaptive implementation. Consequently there could be significant hydropower production reductions at reservoirs under LSJR Alternatives 3 and 4 with or without adaptive implementation in the extended plan area, which could result in related adverse GHG emission if hydropower is replaced with non-renewable energy sources. Considering GHG emissions are cumulatively considerable since climate change is the result of the individual GHG contributions of countless sources, LSJR Alternatives 3 and 4 with or without adaptive implementation would result in cumulatively considerable GHG impacts in the extended plan area. There are no feasible mitigation measures beyond what is in Section 14.4.4 to reduce this cumulative impact to less-than-significant levels.

Finally, as discussed above, climate change results from multiple sources. Climate change, in combination with related projects, would not significantly affect the LSJR and SDWQ alternatives (Impact EG-5) because the proposed adaptive implementation would allow agencies to respond to changing circumstances with respect to flow and water quality that might arise due to climate change. Furthermore, the required periodic review and update of WQCPs continually accounts for changing conditions related to water quality such as climate change.

17.2.3 Additional Resource Areas Considered

Resource areas were initially evaluated using Appendix B, *State Water Board's Environmental Checklist*. Resource areas that were determined to need further analysis (i.e., impacts are listed as "Potentially Significant Impacts") are evaluated in the resource chapters (Chapters 5–14) and cumulative impacts are discussed in Section 17.2.2 of this chapter. However, some resource areas were determined to have "Less-than-Significant Impacts" and, thus, are only evaluated in Appendix B. These resource areas are discussed below to assess if their incremental impacts become cumulatively considerable when considered together with the potential impacts of the projects listed in Table 17-1. If an impact does not result in part from the LSJR and SDWQ alternatives, it is not discussed.

Air Quality

As discussed in Appendix B, Section III, the LSJR alternatives would result in changes in operations at the rim dams, which could result in decreased hydropower generation. This loss in hydropower generation may necessitate increased production from other power facilities to offset the loss. Implementation of the LSJR alternatives may also result in additional groundwater pumping to replace reduced surface water diversions. This groundwater pumping is anticipated to be within irrigation service areas and could require additional electrical use. It is assumed that electric pumps will be used to power increased groundwater pumping as electric pumps are cheaper and more efficient than diesel pumps on a long-term basis. Additionally, under the LSJR alternatives, reductions in surface diversion from the three eastside tributaries could result in removal of croplands from agricultural production (Threshold III[a]). As discussed in Threshold III(c), the net effect of this removal of croplands would not increase fugitive dust emissions. Furthermore, implementation of air quality plans would not be affected (Threshold III[b]). In general, potential impacts would increase as the percentage of unimpaired flows increases (i.e., LSJR Alternative 2 would have the fewest impacts and LSJR Alternative 4 would have the greatest impacts). However, as discussed in Appendix B, Section III, the LSJR alternatives would not result in a net change in pollutant emissions, and their implementation would be consistent with air quality management plans and regulations. The LSJR alternatives would not result in a cumulatively considerable incremental effect or contribute to a significant cumulative effect on air quality. The cumulative impact is less than significant.

Geology and Soils

Impacts on geology and soils are initially discussed in Appendix B, Section VI. An analysis of subsidence is included in Chapter 9, *Groundwater Resources*, and erosion is analyzed in Chapter 6, *Flooding, Sediment, and Erosion*. Erosion impacts related to reduced irrigation of irrigated lands are not cumulatively considerable and are less than significant. As discussed in Chapter 11, *Agricultural Resources*, while some agricultural land could be taken out of irrigated agricultural use as a result of the LSJR alternatives (particularly LSJR Alternatives 3 and 4), many of these lands could remain in agricultural use, even if they are not irrigated. Furthermore, the lands must remain in uses that are compatible with applicable local land use plans, policies or regulations. In addition, the implementation of agricultural practices to address dust control, weed abatement, and revegetation would result in an insubstantial amount of soil erosion or loss of topsoil. There would be no impacts on geology and soils specifically from implementation of the SDWQ alternatives. Any potential cumulative impacts related to subsidence and erosion caused by the LSJR alternatives are discussed in Section 17.2.2, *Cumulative Impact Analysis*, under the groundwater resources and flooding, sediment, and erosion sections, respectively. The other impact areas included in Appendix B, Section VI would not have impacts on geology and soils from implementation of the LSJR and SDWQ alternatives.

In general, potential impacts would increase as the percentage of unimpaired flows increases (i.e., LSJR Alternative 2 would have the fewest impacts and LSJR Alternative 4 would have the greatest impacts). However, other than those impacts discussed in Section 17.2.2 of this chapter, there are no cumulatively considerable impacts on geology and soils caused by the LSJR alternatives.

Recreation

Impacts on recreation resources are initially discussed in Appendix B, Section XV. Detailed analysis of recreation resources is included in Chapter 10, *Recreational Resources and Aesthetics*. As discussed in Appendix B, Section XV(b), any potential cumulative impacts related to recreation resources resulting from the LSJR alternatives are discussed in Section 17.2.2 under the *Recreation Resources and Aesthetics* section.7

However, other than those impacts discussed in Section 17.2.2 of this chapter, there are no cumulatively considerable impacts on recreation resources resulting from the LSJR alternatives.

17.2.4 Cumulative Impact Summary

In evaluating cumulative effects, the analysis in each of the resource chapters determines whether the incremental effects of the alternatives are significant when viewed in connection with the effects of past projects, the effects of other current projects, and the effects of probable future projects (Cal. Code Regs., tit. 14, §§ 15130, 15064, 15065, 15130.) The existence of significant cumulative impacts caused by other projects alone is not necessarily substantial evidence that the alternative's incremental effects are cumulatively considerable. (Cal. Code Regs., tit. 14, § 15064.) Therefore, the cumulative impact analysis examines whether the overall cumulative impact (considering past, present, and reasonably foreseeable probable future projects) is significant and whether the alternatives make a cumulatively considerable incremental contribution to an overall cumulative impact. (Cal. Code Regs., tit. 14, §§ 15064, 15065, 15130.)

The cumulative analysis uses the impact threshold topics and significance criteria (as discussed in the cumulative impact analysis section of the relevant resource chapter) to evaluate the significance of any cumulative effects. Where appropriate, the cumulative analysis is combined for various project alternatives. The cumulative effects analysis applies to all LSJR and SDWQ alternatives. Table 17-3 summarizes the cumulative impact determinations for each resource for the plan area. Table 17-4 summarizes the differences in the cumulative impact determinations for each resource between the plan area and the extended plan area. Analysis of the cumulative effects of LSJR Alternatives 2, 3, and 4 and SDWQ Alternatives 2 and 3, with respect to each resource can be found in Section 17.2.2, *Cumulative Impact Analysis*, of this chapter. Analysis of the cumulative effects of the No Project Alternative can be found in Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*.

Table 17-3. Summary of Cumulative Impacts in the Plan Area

Resource	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2	LSJR Alternative 3	LSJR Alternative 4	SDWQ Alternative 2	SDWQ Alternative 3
Surface Hydrology and Water Quality	X	—	—	—	—	—
Flooding, Sediment, and Erosion	—	—	—	—	—	—
Aquatic Biological Resources	X	—	—	—	—	—
Terrestrial Biological Resources	X	—	—	—	—	—
Groundwater Resources	X	X	X	X	—	—
Recreational Resources and Aesthetics	X	—	X	X	—	—
Agricultural Resources	X	X	X	X	—	—
Cultural Resources	X	—	—	—	—	—
Service Providers	X	X	X	X	X	—
Energy and Climate Change	X	—	X	X	—	—

Notes:

Cumulative impact determinations in this table incorporate impacts both with and without adaptive implementation and reflect the most significant impact determination.

X = cumulatively significant impact.

— = no cumulatively significant impact.

Table 17-4. Summary of CEQA Significance Determinations for Cumulative Impacts in the Extended Plan Area

Resource	LSJR Alternative 2	LSJR Alternative 3	LSJR Alternative 4
Surface Hydrology and Water Quality	—	—	—
Flooding, Sediment, and Erosion	—	—	—
Aquatic Biological Resources	X	X	X
Terrestrial Biological Resources	X	X	X
Groundwater Resources	—	—	—
Recreational Resources and Aesthetics	X	X	X
Agricultural Resources	—	—	—
Cultural Resources	—	—	—
Service Providers	X	X	X
Energy and Climate Change	X	X	X

Notes:

Cumulative impact determinations in this table incorporate impacts both with and without adaptive implementation and reflect the most significant impact determination.

The No Project Alternative (LSJR/SDWQ Alternative 1) and SDWQ Alternatives 2 and 3 would have no effect in the extended plan area and, therefore, are not included in this table.

Gray shading denotes a change in the significance determination for the cumulative impacts for a resource between the plan area and extended plan area.

X = cumulatively significant impact.

— = no cumulatively significant impact.

17.3 Growth-Inducing Effects

CEQA requires a discussion of "the ways in which the proposed project could foster economic or population growth, or the construction of additional housing, either directly or indirectly, in the surrounding environment." (Cal. Code Regs., tit. 14, § 15126.2, subd. (d).) Growth-inducing projects include projects that have the potential to remove obstacles that inhibit population growth, or encourage and facilitate other activities that can significantly affect the environment, either individually or cumulatively. This section discusses the potential growth-inducing effects of the LSJR and SDWQ alternatives, and the No Project Alternative (LSJR/SDWQ Alternative 1).

The evaluation of potential growth-inducing impacts is qualitative and discusses the possible ways the LSJR and SDWQ alternatives could have growth-inducing effects. It also addresses whether the project alternatives would directly or indirectly foster economic, population, or housing growth; remove obstacles to growth; or encourage and facilitate activities that could significantly affect the environment, either individually or cumulatively. (Cal. Code Regs., tit. 14, § 15126.2, subd. (d).) Growth-inducing impacts are not to be construed as necessarily beneficial, detrimental, or of little significance to the environment.

The LSJR alternatives would establish new flow objectives on the LSJR and its three eastside tributaries for the purpose of protecting fish and wildlife beneficial uses. The SDWQ alternatives would amend the southern Delta salinity objectives, as identified in the 2006 Bay-Delta Plan, for the purpose of continuing to protect agricultural beneficial use of agriculture in the southern Delta.

SDWQ Alternatives 2 and 3 generally would maintain the historical range of salinity in the southern Delta. Accordingly, implementation of the salinity objective is unlikely to result in expanded agricultural uses or the development of additional agriculture lands, and thus, the alternatives would not foster economic growth or attendant population or housing growth, or remove obstacles to growth. As discussed in Chapter 16, *Evaluation of Other Indirect and Additional Actions*, point-source dischargers (e.g., wastewater treatment plants) may take certain actions to comply with the salinity requirements imposed through water quality permits, such as developing new source water supplies; implementing salinity pretreatment programs that require commercial, institutional, or industrial facilities or residential salinity source controls; or implementing an effluent desalination process at the wastewater treatment plants before treated effluent is discharged to the southern Delta. Such activities would result from the need to achieve compliance with the salinity objective; it would be speculative to assume that such activities would provide infrastructure or increased capacity that could serve other unrelated projects, such as additional housing or industrial developments. These compliance actions would not create new sources of water or wastewater treatment facilities that would foster population, economic, or housing growth, or remove obstacles to growth. Thus, SDWQ Alternatives 2 and 3 do not have growth-inducing effects.

LSJR Alternatives 2, 3, and 4 do not have growth-inducing effects for the following reasons.

- Under the LSJR alternatives, changes in river flows would generally result in more water remaining in the three eastside tributaries rather than being used for consumptive purposes. Therefore, changes in river flows would not increase the reliable water supply and would not directly or indirectly induce economic, population, or housing growth.
- Under the LSJR alternatives, changes in river flows in the three eastside tributaries would generally result in an increase in Delta inflow. This is because additional flows would be required to remain in the tributaries, which ultimately discharge into the southern Delta from the LSJR. Within the legal Delta, water availability and quality are not limiting growth factors; numerous unrelated constraints (e.g., flooding risk and protections of agricultural lands) limit growth potential under existing conditions. Therefore, changes in river flows would not remove existing growth-limiting factors (i.e., obstacles to growth), and would not directly or indirectly induce growth.
- Under the LSJR alternatives, changes in river flows in the three eastside tributaries would generally result in slightly increased Delta outflow. To the extent that outflow is needed to meet water quality objectives (e.g., the Delta outflow objective), it is not available for appropriation. Therefore, an increase in outflow would not increase the reliable water supply and would not directly or indirectly induce growth. The potential for increases in exports is discussed below.
- The LSJR alternatives may potentially result in a reduction of surface water availability, thereby reducing the amount of surface water available for agricultural and other purposes. While this could result in land being removed from agricultural production, the location and area of such lands cannot be predicted with certainty. Therefore, the possibility that such lands would then be converted to housing or other economic uses is speculative.
- Modeling predicts a potential for minor increases in exports under the LSJR alternatives, on an average annual basis. Average annual increases in Delta exports under LSJR Alternatives 2, 3, and 4 were estimated to be 18 TAF, 76 TAF, and 194 TAF, respectively. These increases are minor because they represent only a small percentage (0.4 percent, 1 percent, and 4 percent under LSJR Alternatives 2, 3, and 4, respectively) of total Delta exports, which historically

averaged 5,185 TAF per year between 1995 and 2013. Such minor increases in exports under the LSJR alternatives are not considered to be growth-inducing for the following reasons.

- Delta exports make up less than half of the water supplies available to and used in California south of the Delta and in the CVP and SWP export service areas.
- Although modeling predicts minor increases in exports on an average annual basis, the annual variability of exports is high and actual exports are controlled by a variety of factors, including: weather patterns; annual agricultural practices; economic conditions; and availability of water from other sources (e.g., groundwater, local water sources, recycled water, Colorado River supplies) south of the Delta and in the CVP and SWP export service areas. Additionally, the timing and amount of permissible exports are controlled by many other laws, regulations, permits, and water rights, only some of which are related to water availability in the Delta for export, and these requirements vary from year to year. The minor modeled increases in exports are well within the range of normal variation experienced from year to year.

The No Project Alternative (LSJR/SDWQ Alternative 1) assumes full compliance with all flow and water quality objectives in the 2006 Bay-Delta Plan as implemented through D-1641 and the NMFS BO on the Stanislaus River (which is included in the baseline). The changes in river flow and salinity level under No Project Alternative would be small as compared to baseline. For the reasons identified above regarding the potential effects of the LSJR and SDWQ alternatives on growth, implementation of the No Project Alternative would not directly or indirectly foster economic, population, or housing growth; remove obstacles to growth; or facilitate or encourage other such activities.

17.4 Significant Irreversible Environmental Changes

Section 15126.2(c) of the State CEQA Guidelines directs a discussion of the significant irreversible environmental changes that would be caused by a proposed project. Section 15127(a) of the State CEQA Guidelines requires information about irreversible changes to be included in connection with the adoption, amendment, or enactment of a plan of a public agency, such as the amendment of the 2006 Bay-Delta Plan by the State Water Board. An significant irreversible change to resources is the permanent loss or damage of resources for future or alternative purposes. Irreversible changes to resources result in resources that cannot be recovered or recycled, or those that are consumed or reduced to unrecoverable forms. They can be caused, either directly or indirectly, by the use of natural resource so that it cannot be restored or returned to their original condition.

The LSJR and SDWQ alternatives and their implementation would not directly result in the significant irreversible commitment of resources because their primary effect is to protect water quality for fish and wildlife and agricultural beneficial uses. However, certain alternatives may indirectly result in the permanent loss or damage of resources for future or alternative purposes or may use natural resources such that they cannot be restored or returned to their original condition. These are described below.

LSJR Alternative 2 with adaptive implementation and LSJR Alternatives 3 and 4 with or without adaptive implementation may have potentially significant impacts associated with groundwater, agricultural, and energy resources, which are resources may not be recovered or recycled or may be used such they cannot be restored or returned to their original condition. Increased groundwater pumping could potentially deplete groundwater supplies and cause interference with groundwater recharge; both of which could increase the possibility of overdraft. As discussed in Chapter 9, *Groundwater Resources*, various actions, such as implementation of SGMA, groundwater recharge projects, conjunctive use, and other management projects, would benefit groundwater resources. Groundwater use could potentially be mitigated, through implementing management controls to reduce or manage pumping in groundwater subbasins; however management varies by subbasin. Additionally, given the variability of local agency response to implementing sustainable practices and the condition of the groundwater resources in the subbasins (including overdrafted and critically overdrafted groundwater basins), the LSJR alternatives could result in potentially significant irreversible environmental changes to groundwater resources. Reductions in surface water supply may result in reduced surface water availability for agricultural uses. In turn, this may result in some agricultural lands being removed from agricultural use and converted to other uses. Depending on the new use (e.g., housing or industrial uses), the change could be considered irreversible. While the location and extent of such conversion is speculative, the LSJR alternatives could result in potentially significant irreversible environmental changes to agricultural resources. The LSJR alternatives may affect hydropower generation by requiring more water to be released instream during the February–June period, making less stored water available for release in the summer. This, in turn, could result in additional energy generation at other facilities to compensate for the loss of hydropower generation, as well as hydropower generation. As discussed in Chapter 14, *Energy and Greenhouse Gases*, the other facilities could generate energy from hydropower. However, if they do not, they would likely result in the generation of energy that may not be able to be replaced and as such could result in a potentially significant irreversible environmental changes to energy resources.

To the extent that the LSJR Alternatives 2, 3, or 4 with or without adaptive implementation would result in the construction or maintenance of indirect actions or non-flow measures, this would likely result in the use of resources that may not be recovered or recycled or may be used such they cannot be restored or returned to their original condition. Depending on the scale and size of the indirect actions or non-flow measures described in Chapter 16, *Evaluation of Other Indirect and Additional Actions*, the following resources could be used such that they cannot be recovered or recycled: energy expended in the form of electricity, gasoline, diesel fuel, oil for construction equipment and transportation vehicles that would be needed; mined materials, such as sand, gravel, steel, lead, copper, or other metals as needed for the particular indirect action or non-flow measure, and other potentially petroleum based products, such as asphalt or plastic. The level of reduction or change to these types of resources would depend on the size and scale of the indirect action or non-flow measure. In addition, the indirect action of constructing new surface water supplies (i.e., surface water reservoir) would likely result in the use of forest land, or potentially other land uses, such that it could not be recovered or used for another purpose. This potential loss or change would depend on the size and location of a reservoir. Similar to the use of resources described above for construction and maintenance, it is expected that the operation of facilities under the following indirect actions could also result in energy expended in different forms (e.g., electricity): recycled water sources for water supply, in-delta diversions, and water supply desalination.

To the extent that SDWQ Alternatives 2 or 3 would result in the construction or maintenance of other facilities because of a method of compliance or the program of implementation, this would likely result in the use of resources that may not be recovered or recycled or may be used such that they cannot be restored or returned to their original condition. Depending on the scale and size of the facilities described in Chapter 16, the following resources could be used such that they cannot be recovered or recycled: energy expended in the form of electricity, gasoline, diesel fuel, oil for equipment and transportation vehicles that would be needed; mined materials, such as sand, gravel, steel, lead, copper, or other metals as needed for the particular facility; and other potentially petroleum based products such as asphalt or plastic. The level of reduction or change to these types of resources would depend on the size and scale of the facility being constructed and construction footprint. To the extent the SDWQ alternatives would result in the construction of facilities (e.g., desalination facilities), those facilities likely would be constructed on lands already committed to commercial, industrial, and institutional uses. However, if facilities are not constructed near or adjacent to existing facilities (e.g., canals associated with new source water supplies or agricultural return flow salinity control), then those types of facilities could result in a change to land such that it cannot be restored or returned to its original condition. Similar to the use of resources described above for construction and maintenance, it is expected that the operation of facilities under the following indirect actions could also result in energy expended in different forms (e.g., electricity): new source water supplies, salinity pretreatment programs, desalination, and low-lift pumping stations.

The No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) may have potentially significant impacts associated with agricultural resources associated with reduced surface water from the Stanislaus River. Similar to the effects described above for agricultural resources, this could result in agricultural lands being removed from agricultural use and converted to other uses. While the location and extent of such conversion is speculative, the LSJR alternatives could result in potentially significant irreversible environmental changes to agricultural resources. As described in Chapter 15, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)* if the southern Delta salinity objectives are not applied to existing municipal dischargers, then the No Project Alternative would not result in a change to the NPDES permit or other discharger requirements and the No Project Alternative would not result in the need to expand existing facilities or infrastructure. Thus significant irreversible changes would not occur and the use of resources would not occur such that they cannot be recovered or recycled. However, if the southern Delta salinity objectives are applied, then effects would be similar to those described above for SDWQ Alternatives 2 or 3. It would be expected that during construction, maintenance, and operation could result in significant irreversible changes to energy expended in the form of electricity, gasoline, diesel fuel, oil for equipment and transportation vehicles that would be needed; mined materials, such as sand, gravel, steel, lead, copper, or other metals as needed for the particular facility; and other potentially petroleum based products, such as asphalt or plastic. The level of reduction or change to these types of resources would depend on the size and scale of the facility being constructed and construction footprint under the No Project Alternative. Similarly, if facilities are not constructed near or adjacent to existing facilities (e.g., canals associated with new source water supplies or agricultural return flow salinity control) then they could result in a change to land such that it cannot be restored or returned to its original condition.

Chapter 18
Summary of Impacts and Comparison of Alternatives

18.1 Introduction

This chapter compares the alternatives that are described in Chapter 3, *Alternatives Description*, and evaluated in Chapters 5–15, and summarizes their environmental impacts. It also incorporates the evaluation and determinations identified in Chapter 16, *Evaluation of Other Indirect and Additional Actions*. The California Environmental Quality Act (CEQA) requires an analysis of a range of reasonable alternatives to a project, or its location, that will feasibly attain most of the project's objectives but that would avoid or substantially lessen any of the significant effects of the project. (Cal. Code Regs., tit. 14, § 15126.6(a); id., tit. 23, § 3777(b)(3).) Accordingly, this recirculated substitute environmental document (SED) analyzes four Lower San Joaquin River (LSJR) alternatives and three Southern Delta Water Quality (SDWQ) alternatives that feasibly meet the objectives of the 2006 *Water Quality Control Plan for the San Francisco Bay/Sacramento–San Joaquin Delta Estuary* (2006 Bay-Delta Plan) amendments, including LSJR Alternative 1 and SDWQ Alternative 1 (No Project Alternative). This analysis is intended to provide sufficient information about the environmental effects of each alternative to allow for informed decision-making. Section 15126.6 of the State CEQA Guidelines also requires an evaluation of the comparative merits of the alternatives and an identification of an environmentally superior alternative among the other alternatives if the environmentally superior alternative is the no project alternative.

As described in more detail in Chapter 3, *Alternatives Description*, the plan amendments[1] would include new February–June LSJR flow objectives for the protection of fish and wildlife beneficial uses and an associated program of implementation. The plan amendments would also modify the existing SDWQ objective for the protection of agricultural beneficial uses and the associated program of implementation for that objective. The LSJR flow objectives would be implemented through water right actions and water quality actions, including Federal Energy Regulatory Commission (FERC) hydropower licensing processes. The southern Delta salinity objective would be achieved through water right and water quality control actions. Both the LSJR flow objectives with adaptive implementation and the southern Delta salinity objective comprise the plan amendments, and the flow objectives may affect salinity as discussed in the various resource chapters (Chapters 5–14).

The LSJR alternatives, simply stated, are as follows.

- LSJR Alternative 1, which is the No Project Alternative, would be a continuation of, and full compliance with, the 2006 Bay-Delta Plan and the flow requirements as described by the plan and implemented through the State Water Board's Water Rights Decision 1641 (D-1641)[2].
- LSJR Alternative 2 would establish a range between 20 and 30 percent, with 20 percent as the starting percentage of unimpaired flow[3] in the program of implementation.

---

[1] These plan amendments are the *project* as defined in State CEQA Guidelines, Section 15378.

[2] In Water Right Decision 1641 (revised March 15, 2000), the State Water Board allocated responsibility for meeting the SJR flow objectives in the 1995 Bay-Delta Plan to the U.S. Bureau of Reclamation.

- LSJR Alternative 3 would establish a range between 30 and 50 percent, with 40 percent as the starting percentage of unimpaired flow in the program of implementation.
- LSJR Alternative 4 would establish a range between 50 and 60 percent, with 60 percent as the starting percentage of unimpaired flow in the program of implementation.

As described in more detail in Chapter 3, *Alternatives Description*, LSJR Alternatives 2, 3, and 4 would also include adaptive implementation intended to foster coordinated and adaptive management of flows based on best available scientific information in order to protect fish and wildlife beneficial uses. Adaptive implementation could also optimize flows to achieve the objective, while allowing for consideration of other beneficial uses, provided that these other beneficial uses do not reduce intended benefits to fish and wildlife.

There are four methods of adaptive implementation, detailed in Chapter 3, which allow for an adjustment of the volume of water required under LSJR Alternatives 2, 3, and 4. In general, the methods are as follows: method 1, increasing or decreasing the percent of unimpaired flow required by 10 percent depending on the LSJR alternative selected; method 2, adjusting the percent of unimpaired flow either within or between the months of February–June; method 3, adjusting the percent of unimpaired flow outside of February–June depending on the LSJR alternative selected; and method 4, maintaining a certain base flow in the San Joaquin River (SJR) at Vernalis at all times during the February–June period. The operational changes made using the adaptive implementation methods above may be approved if the best available scientific information indicates that the changes will be sufficient to support and maintain the natural production of viable native SJR Watershed fish populations migrating through the Delta and meet any biological goals. The changes may take place on either a short-term (e.g., monthly or annually) or a longer-term basis.

The Stanislaus, Tuolumne and Merced Working Group (STM Working Group) will assist with implementation, monitoring, and assessment activities for the unimpaired flow objectives and with developing biological goals to help evaluate the effectiveness of the unimpaired flow objectives and adaptive implementation actions.

The SDWQ alternatives, simply stated, are as follows.

- SDWQ Alternative 1, which is the No Project Alternative, would be a continuation of full compliance with the 2006 Bay-Delta Plan and the existing salinity objective in the plan (1.0 deciSiemens per meter [dS/m] September–March and 0.7 dS/m April–August in the southern Delta). It would also include continued conditioning of the U.S. Bureau of Reclamation (USBR) water rights at New Melones Dam to meet the water quality objective for salinity on the SJR at Vernalis (0.7 dS/m) and continued use of the temporary agricultural barriers in the southern Delta.
- SDWQ Alternative 2 would establish an annual 1.0 dS/m salinity objective for the southern Delta and include continued conditioning of USBR water rights to meet its current D-1641 salinity compliance requirement at Vernalis; allow for continued use of the temporary agricultural barriers; and establish various study, planning, and monitoring requirements.

---

[3] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.

- SDWQ Alternative 3 would establish an annual 1.4 dS/m salinity objective for the southern Delta and include continued conditioning of USBR water rights to meet its current D-1641 salinity compliance requirement at Vernalis; allow for continued use of the temporary agricultural barriers; and establish various study, planning, and monitoring requirements.

Details of these three SDWQ alternatives are provided in Chapter 3, *Alternatives Description,* and the language of the amended water quality control plan is included in Appendix K, *Revised Water Quality Control Plan*.

Other alternatives that were considered but eliminated during the alternatives screening process are summarized in Chapter 3.

18.2 LSJR Alternatives Comparison

Table 18-1 summarizes the results of the CEQA significance analysis for each resource area and the LSJR alternatives in the plan area, as discussed in Chapters 5–15. Table 18-2 summarizes the results of the CEQA significance analysis for each resource area and the LSJR alternatives in the extended plan area, as discussed in Chapters 5–15. Table 18-3 summarizes the results of the CEQA significance analysis for each resource area as discussed in Chapters 5–15 and the LSJR alternatives by geography. Table 18-4 (at the end of the chapter) summarizes the impacts, without adaptive implementation, by resource and threshold. Table 18-5 summarizes those significance determinations for each resource area that change with the inclusion of adaptive implementation. Additional information regarding these impact determinations can be found in Chapters 5–15. Although adaptive implementation is part of each LSJR alternative, impacts without adaptive implementation are also disclosed because it is unknown whether and to what extent adaptive implementation would be employed. The alternatives comparison includes the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1). This alternative is analyzed in detail in Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*, and technical information is presented in Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*.

As shown in Table 18-1, the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) would result in significant impacts on water quality, aquatic biological resources, terrestrial biological resources, agricultural resources, cultural resources, service providers, and energy and greenhouse gases.

LSJR Alternatives 2 would not result in significant and unavoidable impacts. LSJR Alternative 2, with adaptive implementation, would result in significant and unavoidable impacts on groundwater resources, agricultural resources, and service providers. In the extended plan area, LSJR Alternative 2, with adaptive implementation, could also result in significant and unavoidable impacts on aquatic biological resources, terrestrial biological resources, recreational resources and aesthetics, and energy and greenhouse gases.

Several significant and unavoidable impacts on various resources were identified for LSJR Alternative 3. LSJR Alternative 3 would result in significant and unavoidable impacts on groundwater resources, agricultural resources, service providers, and energy and greenhouse gases. LSJR Alternative 3, with adaptive implementation, would also result in significant and unavoidable impacts on recreational resources. In the extended plan area, LSJR Alternative 3, with or without adaptive implementation, could also result in significant and unavoidable impacts on aquatic biological resources, terrestrial biological resources, recreational resources and aesthetics, and energy and greenhouse gases.

Several significant and unavoidable impacts on various resources were identified for LSJR Alternative 4. LSJR Alternative 4, with or without adaptive implementation, would result in significant and unavoidable impacts on groundwater resources, recreational resources, agricultural resources, service providers, and energy and greenhouse gases. In the extended plan area, LSJR Alternative 4, with or without adaptive implementation, could also result in significant and unavoidable impacts on aquatic biological resources, terrestrial biological resources, recreational resources and aesthetics, and energy and greenhouse gases.

Table 18-1. Summary of CEQA Significance Determinations in Chapters 5–15

Notes:

Energy and greenhouse gases are not included in this table because while changes on each river were calculated, potential impacts associated with these resources (impacts on the California electric grid and global climate change) would affect a larger region.

Gray shading denotes a determination of a significant impact for a resource under a particular alternative.

AI = Adaptive implementation as described in Chapter 3, Alternatives Description. (%) reflects the maximum or minimum percent of unimpaired flow allowed under adaptive implementation method 1. If there is a change in significance determinations with and without adaptive implementation, it is because of this method.

S = significant impact

SU = significant and unavoidable impact

L = less-than-significant impact

N = no impact

[a] As described in Chapter 9, *Groundwater Resources*, northern portion of the Chowchilla Subbasin is combined with the Merced Subbasin because the small area between the Merced Subbasin and the Chowchilla River is part of the surface water delivery area for the Merced River.

[b] Impact would be less than significant at 30% unimpaired flow.

Table 18-5. Impact Determinations that Change with Adaptive Implementation (LSJR Alternatives 2 and 3) [a,b]

Impact	Without Adaptive Implementation	With Adaptive Implementation[c,d]
Chapter 9: Groundwater Resources—LSJR Alternative 2		
Impact GW-1: Substantially deplete groundwater supplies or interfere substantially with groundwater recharge	Less than significant— The average annual groundwater balance is expected to be reduced by less than the equivalent of 1 inch across each of the subbasins. This is not expected to produce a measurable decrease in groundwater elevations. Therefore, there would not be a substantial depletion of groundwater supplies or substantial interference with groundwater recharge.	Significant and unavoidable— If adaptive implementation method 1 were implemented on a long-term basis (an increase in the February–June percent of unimpaired flow from 20% up to 30%), it is expected that the average annual groundwater balance would be reduced by the equivalent of more than 1 inch across the Extended Merced Subbasin, thus producing an eventual measurable decrease in groundwater elevations. Therefore, it is expected that there would be a substantial depletion of groundwater supplies or substantial interference with groundwater recharge in this subbasin under LSJR Alternative 2.
Impact GW-2: Cause subsidence as a result of groundwater depletion	Less than significant—The average annual groundwater balance is expected to be reduced by less than the equivalent of 1 inch across each of the subbasins. This is not expected to produce a measurable decrease in groundwater elevations or associated subsidence.	Significant and unavoidable— If adaptive implementation method 1 were implemented on a long-term basis (an increase in the February–June percent of unimpaired flow from 20% up to 30%), the average annual groundwater balance could potentially be reduced by the equivalent of more than 1 inch across the Extended Merced Subbasin. If this occurred, it could worsen subsidence that is already occurring in this subbasin. Therefore, subsidence could potentially significantly increase under LSJR Alternative 2.
Chapter 11: Agricultural Resources—LSJR Alternative 2		
Impact AG-1: Convert Prime Farmland, Unique Farmland, or Farmland of Statewide Importance to nonagricultural use	Less than significant— Conversion of Prime Farmland, Unique Farmland, or Farmland of Statewide Importance to nonagricultural uses is not expected because potential reductions in surface water diversions would result in less than 4% average reduction in irrigated acreage for the irrigation districts in the LSJR area of potential effects.	Significant and unavoidable— If adaptive implementation method 1 were implemented on a long-term basis (an increase in the February–June percent of unimpaired flow from 20% up to 30%), environmental impacts would be potentially significant and unavoidable as it is estimated that OID could experience a 4.4% average reduction in irrigated crops, which equates to 2,356 acres receiving reduced irrigation, and MID could experience a 4.5% average reduction in irrigated crops, which equates to 2,589 acres receiving reduced irrigation. It is

Impact	Without Adaptive Implementation	With Adaptive Implementation^c,d^
		reasonable to assume that a portion of the reduced irrigated acreage is Prime Farmland, Unique Farmland, or Farmland of Statewide Importance, and that some portion of acreage with reduced irrigation could potentially be converted to nonagricultural uses even though there are many factors affecting whether land is converted. Conversely, land can be maintained in agricultural use through crop substitution, crop rotation, fallowing, and dry land farming.
Chapter 10: Recreational Resources and Aesthetics—LSJR Alternative 3		
Impact REC-1: Substantially physically deteriorate existing recreational facilities on the rivers or at the reservoirs	Less than significant—Modeled frequencies of flows greater than 2,500 cfs would change little on the Stanislaus and Merced Rivers, and therefore on-bank recreational facilities would not experience substantially more inundation relative to baseline conditions. However, flows greater than 2,500 cfs would increase in frequency on the Tuolumne River in May and June, but would remain close to baseline values July – September. Although the flows on the Tuolumne River could result in an increase in the frequency of inundation of on-bank recreation areas during May and June, recreational facilities are not anticipated to substantially physically deteriorate along the river. On-bank recreational facilities are built to withstand periodic inundation with higher river flows.	Significant and unavoidable— If adaptive implementation method 1 were implemented on a long-term basis (an increase in the February–June percent of unimpaired flow from 40% up to 50%), it is expected that the modeled seasonal average frequency of river flows above 2,500 cfs on the Tuolumne River would greatly increase, especially during May and June. The frequency of inundation of on-bank facilities on the Tuolumne River and, to a lesser extent, on the Stanislaus River is expected to increase compared to baseline and result in substantial deterioration of existing recreational facilities.
Chapter 13: Service Providers—LSJR Alternative 2		
Impact SP-1: Require or result in the construction of new water supply facilities or wastewater treatment facilities or expansion of existing facilities, the construction of which could cause significant environmental effects.	Less than significant—Average surface water diversions on the Stanislaus, Tuolumne, and Merced Rivers would be reduced by 2%, 2%, and 6%, respectively, compared to baseline conditions, and there would not be a substantial depletion of groundwater supplies. Therefore, it is not expected that service providers or public water suppliers would need to construct or operate new wastewater treatment facilities or water supply	Significant and unavoidable—If adaptive implementation method 1 were implemented on a long-term basis (an increase in the February–June percent of unimpaired flow from 20% up to 30%) it is expected that there would be a substantial reduction in the water supply on the Tuolumne and Merced Rivers of approximately 7%, and 10%, respectively, and a substantial depletion of groundwater supplies in the Extended Merced Subbasin. These reductions would potentially require service

Impact	Without Adaptive Implementation	With Adaptive Implementation[c,d]
	facilities or infrastructure.	providers to construct new or expanded water supply or wastewater treatment facilities, which could result in significant and unavoidable environmental impacts.
Impact SP-2b: Violate any water quality standards such that drinking water quality from domestic wells would be affected.[e]	Less than significant—Because service providers and irrigation districts relying primarily on surface water would not need to supplement their supply with groundwater under LSJR Alternative 2, there would likely be no degradation of groundwater quality.	Significant and unavoidable—If an increase in the February–June percent of unimpaired flow from 20% up to 30% were implemented on a long-term basis, increased groundwater pumping and reductions in groundwater levels in the Extended Merced Subbasin could affect groundwater quality. Domestic well users are largely unregulated and are not subject to any state requirements to monitor, test, and treat their water to meet the state and federal Safe Drinking Water Act. There is no required mechanism to prevent private domestic wells from using groundwater that may exceed Maximum Contaminant Levels.

[a] The No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) and SDWQ Alternatives 2 and 3 have no adaptive implementation and therefore are not included in this table.

[b] As discussed in Section 18.2.1, *Summary of Alternatives Impact Analysis*, there are no differences in the impact determinations between LSJR Alternative 4 with the inclusion of adaptive implementation, and as such, it is not included in this table.

[c] Four adaptive implementation methods could occur under the LSJR alternatives, as described in Chapter 3, *Alternatives Description*, and summarized in the Chapters 9, 11, and 13 *Methods and Approach* sections.

[d] Implementing adaptive implementation method 1 on a more frequent basis can result in a change in the impact determination for LSJR Alternative 2, as analyzed in Chapters 9, 11, and 13 and LSJR Alternative 3, as analyzed in Chapters 10.

[e] Salinity in the SJR at Vernalis and in the southern Delta is not relevant to groundwater and drinking water quality from domestic wells and, therefore, there would be no impact from the changes in salinity in these surface waters, and this is not discussed further in Impact SP-2b.

18.2.1 Summary of Alternatives Impact Analysis

Overall, LSJR alternatives (e.g., LSJR Alternative 2, without adaptive implementation) that require similar unimpaired flows when compared to baseline on the three eastside tributaries[4] have less-than-significant impacts on resources that require or are dependent on surface water diversion. These resources include agricultural resources, groundwater resources, service providers, and energy and greenhouse gases. Overall, LSJR alternatives (e.g., LSJR Alternative 4, with adaptive implementation) that could require higher percentages of unimpaired flows when compared to baseline conditions on all three eastside tributaries have less-than-significant impacts on resources requiring or relying on flow, such as surface hydrology, water quality; aquatic biological resources; and terrestrial biological resources.

Generally, the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) would result in lower flows on the Merced River and less surface water diversion on the Stanislaus River when compared to baseline (see Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1,* for impact analysis and Appendix D, *Evaluation of the No Project Alternative [LSJR Alternative 1 and SDWQ Alternative 1]* for technical assumptions and results). This would result in significant impacts on resources requiring or relying on flow in the river(s) or relying on surface water diversions. Specifically, there would be significant impacts on water quality; aquatic biological resources; terrestrial biological resources; agricultural resources; recreational resources, cultural resources, service providers; and energy and greenhouse gases. Thus, the alternative that results in a continuation of, and full compliance with, the existing 2006 Bay-Delta Plan would not avoid significant environmental impacts.

Generally, LSJR Alternative 2 would result in flows similar to, or slightly greater than, baseline conditions on the three eastside tributaries. This alternative would result in less-than-significant impacts on all resources. However, if adaptive implementation method 1 is implemented long-term and the percent of unimpaired flow is increased from 20 to 30, then significant and unavoidable impacts would occur to resources that require water for beneficial uses other than fish and wildlife, such as groundwater resources, agricultural resources and service providers.

LSJR Alternatives 3 or 4, with or without adaptive implementation, generally require higher flow on the Stanislaus, Tuolumne, and Merced Rivers when compared to baseline. Thus, these alternatives result in significant and unavoidable impacts on resources that require water for uses other than fish and wildlife, such as agricultural resources, service providers, and energy and greenhouse gases. These alternatives would also result in significant and unavoidable impacts on groundwater resources because of the average annual groundwater balance is expected to be reduced by less than the equivalent of 1 inch across each of the four primary subbasins, which could produce a measurable decrease in groundwater elevations and substantially deplete groundwater supplies. In addition, LSJR Alternative 3, with adaptive implementation, and LSJR Alternative 4, with or without adaptive implementation, would have significant and unavoidable impacts on recreational resources because of increased flows on the eastside tributaries that would result in more frequent inundation of on-bank recreational facilities.

---

[4] In this document, the term *three eastside tributaries* refers to the Stanislaus, Tuolumne, and Merced Rivers.

Construction and operation of different facilities could occur in the plan area or extended plan area as a result of either indirect actions that entities could take as a result of the LSJR alternatives or as a result of implementing non-flow measures in order to inform the body of scientific information potentially used to make adaptive implementation decisions under LSJR Alternatives 2, 3, and 4. The construction and operation of these facilities could involve impacts on different resources (summarized in Tables 18-6 and 18-7). While many of these activities would result in no impacts or less-than-significant impacts on different resources, it primarily depends on the location of the activity, the duration of the activity, and the ability of a lead agency to mitigate potential significant impacts as to whether activities would result in no impacts or significant and unavoidable impacts, as described below in Section 18.2.2, *Significant and Unavoidable Impacts.*

18.2.2 Significant and Unavoidable Impacts

Generally, the contribution of the LSJR alternatives to significant and unavoidable impacts depends on the percent of unimpaired flow required and the number of rivers, reservoirs, groundwater subbasins, or irrigation districts affected. It also depends on whether the percent of unimpaired flow would be adjusted through adaptive implementation on a more frequent basis or a longer duration to a higher or lower unimpaired flow (i.e., adaptive implementation method 1). As such, generally lower flows that may be adjusted more frequently and for longer periods of time may result in a smaller contribution to a significant and unavoidable impact when compared to higher flows that may be adjusted less frequently.

Surface Hydrology and Water Quality

The No Project Alternative (LSJR Alternative 1 and SDWQ Alternative) would result in significant impacts on water quality because the flows on the Merced River would be reduced when compared to baseline (especially during drier years and in April and May), thereby potentially increasing the pollutant concentrations.

Aquatic Biological Resources

LSJR Alternative 1 and SDWQ Alternative 1 (No Project Alternative) would result in significant impacts on aquatic biological resources on the Merced and Stanislaus Rivers and at New Melones Reservoir and Lake McClure. Flows on the Merced River would be reduced when compared to baseline (especially during drier years and in key months of April and May), thereby increasing temperatures for aquatic species, as well as increasing the risk of disease and exposure to pollutants and predation. Significant impacts would also occur on the Stanislaus River because higher summer and fall release temperatures associated with reduced storage in New Melones Reservoir would increase the frequency of stressful water temperatures, as well as increasing the risk of disease and exposure to pollutants and predation. Reservoir water levels at New Melones Reservoir and Lake McClure would substantially fluctuate April–September, such that spawning success and habitat availability for warmwater species would be significantly reduced. Furthermore, at New Melones, given the end-of-September changes in storage, coldwater species reservoir habitat would also be significantly affected.

In the extended plan area, LSJR Alternative 2, with adaptive implementation, and LSJR Alternatives 3 and 4, with or without adaptive implementation, could also result in significant and unavoidable impacts on aquatic biological resources. This is because of potential loss, or substantial decrease, in suitable habitat (including temperature) in existing reservoirs and rivers, particularly on the Stanislaus and Tuolumne Rivers.

Terrestrial Biological Resources

LSJR Alternative 1 and SDWQ Alternative 1 (No Project Alternative) would result in significant impacts on terrestrial biological resources, particularly riparian habitat and those terrestrial species relying on riparian habitat, because the flows on the Merced River would be reduced when compared to baseline (especially during drier years and potentially in the spring), thereby reducing riparian habitat that is currently limited under baseline.

In the extended plan area, LSJR Alternatives 2, with adaptive implementation, and LSJR Alternatives 3 and 4, with or without adaptive implementation, could also result in significant and unavoidable impacts on terrestrial biological resources. This is because of potential loss, or substantial decrease in, habitat at existing reservoirs and on rivers, particularly on the Stanislaus and Tuolumne Rivers.

Groundwater Resources

LSJR Alternative 2, with adaptive implementation, would have significant and unavoidable impacts on groundwater resources. The magnitude of the significance is related to the amount of expected groundwater pumping needed to replace the lost surface water diversions under each of the alternatives. There would be a higher magnitude of pumping expected in the Extended Merced Subbasin when compared to the three other subbasins evaluated. It is expected that the average annual groundwater balance would be reduced by the equivalent of more than 1 inch across the Extended Merced Subbasin, thus producing an eventual measurable decrease in groundwater elevations. Therefore, it is expected that there would be a substantial depletion of groundwater supplies or substantial interference with groundwater recharge in this subbasin.

LSJR Alternatives 3 and 4, with or without adaptive implementation, would have significant and unavoidable impacts on groundwater resources. Similar to LSJR Alternative 2, with adaptive implementation, the average annual groundwater balance would be reduced, producing eventual measureable decrease across multiple subbasins. These subbasins include: Eastern San Joaquin, Modesto, Turlock, and Extended Merced.

LSJR Alternative 2, with adaptive implementation, is expected to have the smallest contribution of the alternatives that have significant and unavoidable impacts on groundwater resources because less groundwater is expected to be pumped and because only the Extended Merced Subbasin is affected.

Recreational Resources and Aesthetics

The No Project Alternative (LSJR Alternative 1 and SDWQ Alternative) would result in significant impacts on recreation and aesthetics because the elevation levels of New Melones Reservoir would be substantially reduced more frequently and visual quality of the reservoir would be degraded, thereby affecting recreational facilities (e.g., boat ramps) and the visual character and quality of the reservoir.

There are significant and unavoidable impacts on recreational resources for LSJR Alternative 3, with adaptive implementation, and LSJR Alternative 4, with or without adaptive implementation. It is expected that the modeled seasonal average frequency of river flows above 2,500 cubic feet per second (cfs) on the Tuolumne River would greatly increase, especially during May and June, under LSJR Alternative 3, with adaptive implementation, and on the Stanislaus and Tuolumne Rivers, under LSJR Alternative 4, with adaptive implementation. Thus, the frequency of inundation of on-bank facilities would be substantially more, when compared to baseline, particularly in May and June, during the recreational season. As such, implementation of LSJR Alternative 3, with adaptive implementation and LSJR Alternative 4, with or without adaptive implementation, could substantially physically deteriorate existing recreational facilities.

In the extended plan area, LSJR Alternative 2, with adaptive implementation, and LSJR Alternatives 3 and 4, with or without adaptive implementation, could also result in significant and unavoidable impacts on recreational resources and aesthetics. This is because of potential significant reductions in reservoir elevation and river levels, particularly on the Stanislaus and Tuolumne Rivers, in areas frequently used by recreationists or that are designated as wild and scenic rivers or areas that are along designated state scenic highways.

Agricultural Resources

Significant impacts on agricultural resources would result from the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) because the flow would be increased on the Stanislaus River when compared to baseline to comply with the 2006 Bay-Delta Plan, and surface water diversions that are currently used to irrigate Prime, Unique, and Farmland of Statewide Importance lands would be reduced. As such, it is anticipated that a substantial reduction in crop acreage would occur in irrigation districts (i.e., Stockton East Water District/Central San Joaquin Water Conservation District, South San Joaquin Irrigation District [SSJID], and Oakdale Irrigation District [OID]) that rely on Stanislaus surface water, and these types of farmland could potentially be converted to nonagricultural uses.

LSJR Alternative 2, with adaptive implementation, would experience a reduction in surface water diversions that are currently used to irrigate Prime, Unique, and Farmland of Statewide Importance lands. As such, it is anticipated that substantial reduction in crop acreage would occur in the Modesto Irrigation District (MID) that relies on Tuolumne River surface water, and Oakdale Irrigation District (OID) that relies on Stanislaus River surface water. As such, these types of farmland could potentially be converted to nonagricultural uses.

LSJR Alternatives 3 and 4, with or without adaptive implementation, would also experience a reduction in surface water diversions on the Stanislaus, Tuolumne, and Merced Rivers that are currently used to irrigate Prime, Unique, and Farmland of Statewide Importance lands. As such, it is anticipated that a substantial reduction in crop acreage could occur in more irrigation districts that rely on surface water from the three eastside tributaries when compared to LSJR Alternative 2 (i.e. SSJID, OID, TID, MID, and Merced Irrigation District). As such, these types of farmland could be converted to nonagricultural uses.

The No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1), and LSJR Alternative 2, with adaptive implementation, would have the smallest contribution of the other alternatives that have significant and unavoidable impacts on agricultural resources because it is expected that any potential conversion of agricultural land to nonagricultural land would only occur within those areas served by Stanislaus River water (i.e., SEWD/CSJWCD, SSJID, and OID) or Tuolumne River surface water (i.e., MID) and Stanislaus River surface water (i.e., OID), whereas under LSJR Alternatives 3 or 4, with or without adaptive implementation, more irrigation districts could potentially experience a conversion of designated farmland to nonagricultural lands.

Cultural Resources

The No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) would result in significant impacts on cultural resources because the end-of-September storage at New Melones Reservoir is anticipated to be greatly reduced in over half the years when compared to baseline. This would most likely expose cultural resources and could result in a substantial adverse change to the significance of existing cultural resources if they were disturbed by people or disturbed by another physical method (e.g., light, exposure).

Service Providers

The No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) would result in significant impacts on service providers; LSJR Alternative 2, with adaptive implementation, and LSJR Alternatives 3 and 4, with or without adaptive implementation, would result in significant and unavoidable impacts on service providers. This is because it is expected the increase in unimpaired flows on the rivers under the alternatives would result in a corresponding decrease in surface water diversions for other beneficial uses. As a result, service providers that rely on surface water supplies from the tributary rivers (e.g., TID, MID, City of Modesto, CCSF, and Merced ID under LSJR Alternative 2 with adaptive implementation and TID, MID, City of Modesto, CCSF, Merced ID, SSJID, OID, City of Tracy, and SEWD under LSJR Alternatives 3 and 4 with or without adaptive implementation) may have to construct new or expanded water treatment facilities or water supply infrastructure, the construction of which could cause significant environmental effects on other resources (e.g., aesthetics, terrestrial or aquatic biological resources, cultural resources, etc.). In addition, service providers that rely on groundwater in the Extended Merced Subbasin under LSJR Alternative 2 with adaptive implementation, the Merced, Modesto, Turlock Subbasins, and Eastern San Joaquin Subbasin for LSJR Alternative 3 with or without adaptive implementation may also need to construct new or expanded facilities. The need to construct new facilities depends on a variety of factors, including the size of the population being served and the number of active municipal wells in their service area, the range of differences between well depths and depths to groundwater, the physical condition of wells, and other factors.

As a result of increased groundwater pumping, reductions in groundwater levels in the Extended Merced Subbasin under LSJR Alternative 2, with adaptive implementation, in the Modesto, Turlock, and Extended Merced Subbasins under LSJR Alternative 3, with or without adaptive implementation, and also in the Easter San Joaquin Subbasin under LSJR Alternative 4, with or without adaptive implementation, could affect groundwater quality such that drinking water from domestic wells could be significantly affected. Domestic well users are largely unregulated and are not subject to any state requirements to monitor, test, and treat their water to meet the state and federal Safe Drinking Water Act. There is no required mechanism to prevent private domestic wells from using groundwater that may exceed maximum contaminant levels (MCLs). Therefore, impacts would be significant and unavoidable.

In the extended plan area, LSJR Alternative 2, with adaptive implementation, and LSJR Alternatives 3 and 4, with or without adaptive implementation, could also result in significant and unavoidable impacts on service providers (Table 13-6). This is similar to the impacts in the plan area and relate to the potential reductions in surface water supply. The reduction could result in construction of new or expanded water treatment facilities or water supply infrastructure, the construction of which could cause significant environmental effects on other resources.

Energy and Greenhouse Gases

The No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) would have significant greenhouse gas impacts. LSJR Alternatives 3 and 4, with or without adaptive implementation, would have significant and unavoidable greenhouse gas impacts. The magnitude of the significance is related to the amount of hydropower reduced and potential groundwater that could be pumped to replace the lost surface water diversions under each of the alternatives. Compared to LSJR Alternatives 3 and 4, the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) is expected to have the smallest contribution on climate change because it is expected the groundwater pumping would take place as a result of the decrease in surface water diversions from the Stanislaus River alone, whereas LSJR Alternative 3 or 4, with or without adaptive implementation, would experience a decrease in surface water diversions from additional eastside tributaries (the Merced and Tuolumne Rivers).

In the extended plan area, LSJR Alternative 2, with adaptive implementation, and LSJR Alternatives 3 and 4, with or without adaptive implementation, could also result in significant and unavoidable impacts on energy and greenhouse gases. This is because of potential changes to surface water elevations of reservoirs on the Stanislaus and Tuolumne Rivers.

Indirect Actions and Non-Flow Measures

The evaluation contained in Chapter 16, *Evaluation of Other Indirect and Additional Actions,* provides a discussion of other indirect actions and additional actions associated with LSJR Alternatives 2, 3, and 4. The actions include those that the regulated community could take to reduce potential reservoir or water supply effects associated with implementing LSJR Alternatives 2, 3, and 4 or that would inform the body of scientific information potentially used to make adaptive implementation decisions under LSJR Alternatives 2, 3, and 4 (i.e., non-flow measures). This subsection presents a suite of reasonably foreseeable actions that affected entities may undertake to address possible surface water supply reductions anticipated under LSJR Alternatives 2, 3, and 4 and analyzes the indirect environmental impacts associated with those actions. The combination of the different types of additional actions and other indirect actions that entities could take in response to each of the alternatives is unknown. While entities could take one or more of these actions, the combination of actions taken under each alternative is speculative and cannot be predictably aligned with each alternative. As such, the summary tables below (Tables 18-6 and 18-7) focus on the actions (discussed primarily in Chapter 16) that agencies or entities could undertake as a result of each alternative, without specifically assigning the actions to a particular alternative.

In many cases, the evaluations of actions presented in Chapter 16 include both construction and operation impacts. In cases with both construction and operation, the summary tables reflect the highest level of impact, which is generally construction-related. The determinations are post-mitigation level of significance. Potential mitigation measures are proposed in Chapter 16 to reduce potentially significant impacts; however, the particular circumstances of the actions and appropriate mitigation measures would be project specific. In addition, as required by CEQA (State CEQA Guidelines § 15126.2) lead agencies would describe a reasonable range of alternatives based on project-specific conditions and project-specific objectives, and one of the project-specific alternatives may in and of itself reduce significant environmental impacts. A project-specific alternative could be selected as a proposed project. The effectiveness of mitigation is contingent upon several other factors, such as those listed below.

- The ability of lead agencies or other entities to implement the mitigation.

- The other responsible agencies involved in the project.
- The thresholds lead agencies use to evaluate the impact.
- Site-specific conditions.

Lead agencies or other entities with discretionary approval authority can and should impose the relevant mitigation measures identified in Tables 16-38 and 16-39. However, depending on project specifics, implementing mitigation measures may not be fully able to reduce significant impacts, and such impacts may remain significant and unavoidable after mitigation. Until such time that potential mitigation measures are implemented, the impacts would remain significant and unavoidable, consistent with State CEQA Guidelines Section 15091. The summary tables reflect this.

Table 18-6. CEQA Significance Summary of LSJR Alternatives—Other Indirect Actions

18.2.3 Environmentally Superior Alternative

CEQA requires a discussion of the environmentally superior alternative. If that alternative is the no project alternative, the environmental document shall also identify an environmentally superior alternative among the other alternatives. (Cal. Code Regs., tit. 14, § 15126.6(e).) In considering the selection of the environmentally superior alternative, this SED evaluates which alternatives result in fewer significant impacts relative to the other alternatives, and also considers whether those alternatives are feasible, taking into account economic, environmental, social, technological, and other factors. (Pub. Resources Code, §§ 21081(a)(3), 21061.1.) An agency may conclude that an alternative is infeasible, for example, if it is inconsistent with agency goals or policies or if it will not satisfy project objectives.

LSJR Alternatives

The No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) would result in significant changes when compared to baseline conditions in Merced River flows (reduced flows) and Stanislaus River flows (increased flows). Therefore, the No Project Alternative is expected to result in significant impacts on Merced River resources such as aquatic biological resources, terrestrial biological resources, and recreational resources that rely on existing baseline flows because the flows would be reduced under No Project Alternative conditions. In addition, the No Project Alternative is expected to result in impacts on agricultural resources, service providers, and other resources that rely on surface water diversions from the Stanislaus River because surface water diversions would be reduced on the Stanislaus River to allow for the increase in flow. No Project Alternative conditions would be the same on the Tuolumne River and, therefore, would result in impacts that are less than significant. In sum, the No Project Alternative is not the environmentally superior alternative because it would not avoid impacts relative to the other alternatives (and, in fact, would result in more significant effects than the other alternatives). As discussed below, it also would not satisfy the purposes and goals of the plan amendments.

LSJR Alternative 2, without adaptive implementation, has no significant and unavoidable impacts when compared to the other LSJR alternatives, as baseline flows on the rivers are similar to the unimpaired flow (20 percent) that would be required by this alternative. As such, LSJR Alternative 2, without adaptive implementation, is the environmentally superior alternative because it has no significant and unavoidable environmental impacts. As discussed below, however, the alternative does not meet the purposes and goals of the proposed plan amendments. In addition, adaptive implementation is part of, and one of the goals of, the plan amendments.

Typically the type, magnitude, and severity of impacts from the LSJR alternatives would increase as the percent of unimpaired flow increases. LSJR Alternative 2, with adaptive implementation, has significant and unavoidable environmental impacts on three resources: groundwater resources, agricultural resources, and service providers. Impacts on these resources would primarily occur as a result of long-term implementation of adaptive implementation method 1 (increase to 30 percent unimpaired flow) and the reduction of surface water supply that could result in impacts on groundwater resources in one out of four subbasins (Extended Merced Subbasin); agricultural resources in two out of eight irrigation districts (MID and OID); and five service providers that rely on surface water diversions (TID, MID, City of Modesto, CCSF, and Merced ID). LSJR Alternatives 3 or 4, with or without adaptive implementation, generally result in impacts that are less than significant on those resources requiring or relying on flow (e.g., aquatic biological resources, terrestrial biological resources) but significant and unavoidable impacts on those resources that rely on surface water diversions (e.g., groundwater resources; recreation, agricultural resources; service providers; and energy and greenhouse gases). None of the LSJR alternatives would result in growth-inducing effects.

Generally, the LSJR alternatives, with adaptive implementation, all have significant and unavoidable impacts on the following resources in the extended plan area: aquatic biological resources, terrestrial biological resources, recreational resources and aesthetics, service providers, and energy and greenhouse gases. As such, there is very little difference between the LSJR alternatives. However, it is expected that the potential magnitude and severity of impacts on these resources would increase from LSJR Alternative 2 with adaptive implementation (i.e., 30 percent unimpaired flow) to LSJR Alternative 4 without adaptive implementation (i.e., 60 percent unimpaired flow). Under all LSJR alternatives, the program of implementation and the proposed mitigation measure (of considering carryover storage and other requirements to implement the flow water quality objectives in a water right proceeding to ensure that reservoir levels upstream of the rim dams[5] do not cause significant resource impacts, unless doing so would be inconsistent with applicable laws), could potentially reduce impacts on these resources. However, impacts are considered significant because mitigation may not fully mitigate impacts in all situations. Significant and unavoidable agricultural resource impacts in the plan area may be reduced if the extended plan area were affected because potentially more water could be used below the rim dams to irrigate agricultural resources; however, the extent of the offset and potential reduction of impacts is unknown until a water right proceeding occurs and the responsibility of meeting the approved unimpaired flow objectives is assigned.

Under all of the LSJR alternatives, indirect actions and non-flow measure could occur (as disclosed in Chapter 16, Section 18.2.2, and Tables 18-6 and 18-7). While implementation of indirect actions and non-flow measures may be less likely under certain LSJR alternatives (e.g., LSJR Alternative 2, with or without adaptive implementation, given this alternative is more similar to baseline conditions when compared to other LSJR alternatives), it cannot be predicted as to the number or type of actions that could occur under each LSJR alternative. The indirect actions and non-flow measures have been identified as having significant and unavoidable impacts. Since the potential combination of indirect actions and non-flow measures under the LSJR alternatives is unknown, so is the scope, magnitude, and location of the significant and unavoidable impacts. As such, it cannot be concluded that specific significant and unavoidable impacts would occur under one LSJR alternative when compared to another with respect to the indirect and non-flow actions.

In evaluating whether an alternative is feasible or infeasible, a lead agency may take into account a broad range of factors, including whether an alternative is inconsistent with agency goals or policies, meets the project objectives, and other considerations. The purpose and goals of the plan amendments (flow objectives and associated program of implementation), as described in Chapter 3, *Alternatives Description*, are as follows.

1. Maintain inflow conditions from the SJR Watershed sufficient to support and maintain the natural production of viable native fish populations migrating through the Delta.

---

[5] In this document, the term *rim dams* is used when referencing the three major dams and reservoirs on each of the eastside tributaries: New Melones Dam and Reservoir on the Stanislaus River; New Don Pedro Dam and Reservoir on the Tuolumne River; and New Exchequer Dam and Lake McClure on the Merced River.

2. Provide flows that more closely mimic the natural hydrographic conditions (including frequency, timing, magnitude, and duration of natural flows) in the LSJR and three eastside, salmon-bearing tributaries—the Stanislaus, Tuolumne, and Merced Rivers—to which these migratory native fish species are adapted.
3. Provide flows in a quantity necessary to achieve functions essential to native fishes such as increased floodplain inundation, improved temperature conditions, improved migratory conditions, and promote other conditions that favor native fishes over nonnative fishes.
4. Allow adaptive implementation of flows that will afford maximum flexibility in establishing beneficial habitat conditions for native fishes, addressing scientific uncertainty and changing conditions, developing scientific information that will inform future management of flows, and meeting biological goals, while still reasonably protecting the fish and wildlife beneficial uses.
5. Promote transparency in decision-making and provide certainty to the regulated community by expressing flow requirements for the protection of fish and wildlife as a share of the total quantity of water available for all beneficial uses.
6. In establishing flow water quality objectives to reasonably protect fish and wildlife, take into consideration all of the demands being made and to be made on waters in the LSJR and the three eastside, salmon-bearing tributaries and the factors to be considered for establishing water quality objectives in Water Code Section 13241, including, but not limited to, past, present and probable future beneficial uses and economic considerations.
7. Provide for the development and implementation of an appropriate monitoring and evaluation program to inform adaptive implementation of LSJR flows and future changes to the Bay-Delta Plan.
8. Provide for, and encourage, collaboration, coordination, and integration of regulatory, scientific, and management processes related to LSJR flows.

These goals are used in conjunction with the significance determinations to inform the feasibility of the environmentally superior alternatives relative to the other alternatives. The No Project Alternative does not meet most of the purpose and goals, in part, because it does not allow for flows that more closely mimic the natural hydrographic conditions, it does not provide flows in the geographic area under consideration (it does not allow for flows on the three salmon-bearing tributaries) and it does not allow for adaptive implementation. LSJR Alternatives 2, with adaptive implementation, does not meet purpose and goal 1 and 2 as fully as LSJR Alternatives 3, and 4, with adaptive implementation, since increased flows better advance purpose and goal 1 and 2 related to maintaining inflow conditions from the SJR Watershed sufficient to support and maintain the natural production of viable native fish populations and to providing flows that more closely mimic the natural hydrographic conditions between February through June. LSJR Alternatives 2, 3, and 4 tend to meet purpose and goal 4, 5, 7, and 8 by providing for adaptive implementation, promoting transparency, establishing the STM Working Group and implementing an appropriate monitoring and evaluation program to inform adaptive implementation of LSJR flows and future changes to the Bay-Delta Plan.

There is, however, a difficult tradeoff between providing sufficient inflow to support and maintain the natural production of viable native fish populations migrating through the Delta or flows in a quantity necessary to achieve functions essential to native fishes, as is reflected in goals 1 and 3, and taking into consideration all of the demands being made of the water, as is reflected in goal 6. The degree to which goals 1 and 3 are achieved reduces the amount of water available for other beneficial uses, and vice versa. LSJR Alternative 3, with adaptive implementation, strikes a balance between goals 3 and 6 more fully than the other LSJR alternatives. LSJR Alternative 3 provides flows in a quantity necessary to achieve functions essential to native fishes, such as increased floodplain inundation, improved temperature conditions, improved migratory conditions, and other conditions that favor native fishes over nonnative fishes (Chapter 19, *Analyses of Benefits to Native Fish Populations from Increased Flow Between February 1 and June 30,* Tables 19-3 through 19-14 [temperature] and Tables 19-19 through 19-24 [floodplain]). LSJR Alternative 3 also satisfies goal 6 because it takes into consideration the potential costs and economic effects of the flow objective (Chapter 20, *Economic Analyses*). Thus, LSJR Alternative 3, with adaptive implementation, meets more of the purposes and goals of the plan amendments more fully than the other LSJR alternatives.

18.3 SDWQ Alternatives Comparison

18.3.1 Summary of Alternatives Impact Analysis

As stated above in Section 18.2.1, *Summary of Alternatives Impact Analysis*, generally, the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) would result in significant impacts on resources requiring or relying on flow in the river(s) or relying on surface water diversions. Specifically, there would be significant impacts on water quality; aquatic biological resources; terrestrial biological resources; agricultural resources; recreational resources, cultural resources, service providers; and energy and greenhouse gases. Thus, the alternative that results in a continuation of, and full compliance with, the existing 2006 Bay-Delta Plan would not avoid environmental impacts.

As discussed in Chapter 5, *Surface Hydrology and Water Quality*, the water quality of the southern Delta under SDWQ Alternatives 2 or 3 would not result in a change to the general range of historical salinity in the southern Delta (0.2 dS/m–1.2 dS/m). This is because the program of implementation included in these alternatives does not call for a change to the USBR compliance requirements at Vernalis (0.7 dS/m from April–August and 1.0 dS/m from September–March as a 30-day average), and the relationship between the salinity at SJR at Vernalis and the southern Delta is not expected to change; thus, a change in baseline is not expected. Therefore, because there is no change to baseline conditions, there are very few impact mechanisms that could result in impacts on resources. As such, Table 18-4 presents a summary of impact determinations related to potential impacts primarily associated with water quality, identified in Chapters 5–15.

SDWQ Alternative 2 would reduce the number of water quality exceedances experienced at the three interior southern Delta compliance stations when compared to baseline. There would be no water quality exceedances at the three interior southern Delta compliance stations under SDWQ Alternative 3 because salinity at these stations has never exceeded 1.4 dS/m. Under SDWQ Alternative 2 or SDWQ Alternative 3, impacts on agricultural resources would be less than significant.

SDWQ Alternative 2 would result in significant impacts on service providers. This is because SDWQ Alternative 2 could result in a change to existing wastewater treatment requirements established by the Central Valley Regional Water Quality Control Board (Central Valley Water Board) in National Pollution Discharge Elimination System (NPDES) permits. The Central Valley Water Board would have to impose effluent limitations consistent with the water quality objective adopted for the southern Delta by the State Water Board in point-source discharge permits for wastewater treatment plants (WWTPs). Therefore, service providers (i.e., City of Tracy and Mountain House Community Services District [CSD]) may not meet the new NPDES effluent limitations that are based on this objective. As such, they may need to modify or construct water treatment facilities or infrastructure, the construction or operation of which could have significant environmental impacts. SDWQ Alternative 3 would not result in significant and unavoidable impacts on service providers because there would be no change from baseline conditions with respect to water quality in the southern Delta. Furthermore, service providers in the southern Delta without existing NPDES permit limitations could likely meet the new effluent limitations if the Central Valley Water Board implements the water quality objective specified in SDWQ Alternative 3.

To comply with either specific salinity water quality objectives or the program of implementation under SDWQ Alternatives 2 or 3, construction and operation of different facilities in the southern Delta could occur, which could involve impacts on different resources (summarized in Table 18-8). While many of these activities would result in no impacts or less-than-significant impacts on different resources, it primarily depends on the location of the activity, the duration of the activity, and the ability of a lead agency to mitigate potentially significant impacts, as to whether activities would result in no impacts or significant and unavoidable impacts, as discussed below, in Section 18.3.2, *Significant and Unavoidable Impacts*.

18.3.2 Significant and Unavoidable Impacts

SDWQ Alternative 2 would result in significant impacts on service providers because SDWQ Alternative 2 could result in a change to existing wastewater treatment requirements established by the Central Valley Water Board in NPDES permits. Therefore, significant and unavoidable impacts could result because service providers may not meet NPDES effluent limitations and may need to construct or operate new WWTP facilities or infrastructure that could cause significant environmental effects on other resources (e.g., aesthetics, terrestrial or aquatic biological resources, cultural resources, etc.).

SDWQ Methods of Compliance

The evaluation contained in Chapter 16, *Evaluation of Other Indirect and Additional Actions,* provides a discussion of the potential methods of compliance associated with SDWQ Alternatives 2 and 3. This chapter does not prescribe different activities under the SDWQ alternatives. Under SDWQ Alternative 2, service providers in the southern Delta (i.e., Cities of Tracy and Stockton and Mountain House CSD) may need to modify current wastewater treatment practices or obtain different source water supplies given their potential to exceed 1.0 dS/m salinity objective (Tables 13-8, 13-9 and 13-19). This could occur through new source water supplies, salinity pretreatment programs or desalination (at wastewater treatment plants). In addition, under the program of implementation for SDWQ Alternative 2, agricultural return flow salinity control in the southern Delta or low lift pumping stations could occur. For SDWQ Alternative 3, modifications to wastewater treatment plants or different source water supply would likely not occur, given the potential ability of the service providers to meet 1.4 dS/m salinity objective (Table 13-20); however, agricultural return flow salinity control or low lift pumping stations could occur under the program of implementation for SDWQ Alternative 3. As such, the combination of different types of methods of compliance that could be taken in response to each of the SDWQ alternatives are unknown; therefore, specific combinations of actions cannot be predictably matched with each alternative.

While agencies could take one or more of these actions, the combination of actions that entities would take under each alternative is speculative and cannot be predictably aligned with each alternative. As such, the summary table below (18-8) focus on the methods of compliance (discussed primarily in Chapter 16) that agencies or entities could undertake under each alternative, without specifically assigning the actions to a particular alternative.

In many cases, the evaluations presented in Chapter 16 include both construction and operation impacts. In cases with both construction and operation, Table 18-8 reflects the highest level of impact, which is frequently related to construction. The determinations are post-mitigation level of significance. Potential mitigation measures are proposed in Chapter 16 to reduce potentially significant impacts (Table 16-38); however, the particular circumstances of the actions and appropriate mitigation measures would be project specific. In addition, as required by CEQA (State CEQA Guidelines § 15126.2) lead agencies would describe a reasonable range of alternatives based on project-specific conditions and project-specific objectives, and one of the alternatives may in and of itself reduce significant environmental impacts. This alternative could be selected as a proposed project. The effectiveness of mitigation is contingent upon several other factors, such as those listed below.

- The ability of lead agencies or other entities to implement the mitigation.
- The other responsible agencies involved in the project.
- The thresholds lead agencies use to evaluate the impact.
- Site-specific conditions.

Lead agencies or other entities with discretionary approval authority can and should impose the relevant mitigation measures identified in Tables 16-38. However, depending on project specifics, implementing mitigation measures may not be fully able to reduce significant impacts, and such impacts may remain significant and unavoidable after mitigation. Until such time that potential mitigation measures are implemented, the impacts would remain significant and unavoidable, consistent with State CEQA Guidelines Section 15091. Table 18-8 reflects this.

Table 18-8. CEQA Significance Summary SDWQ Alternatives—Methods of Compliance

Notes:

Bold text indicates primarily construction-driven impacts. Operation-driven impacts are not bold.

* Indicates that the impact after mitigation may be less than significant; however, given the various factors influencing the potential implementation of mitigation, and until such time that mitigation measures are implemented, the impacts would remain significant and unavoidable, consistent with State CEQA Guidelines Section 15091.

SU = significant and unavoidable impact

L = less-than-significant impact

N = no impact

18.3.3 Environmentally Superior Alternative

CEQA requires a discussion of the environmentally superior alternative. If that alternative is the no project alternative, the environmental document shall also identify an environmentally superior alternative among the other alternatives. (Cal. Code Regs., tit. 14, § 15126.6(e).) In considering the selection of the environmentally superior alternative, this SED evaluates which alternatives result in fewer significant impacts relative to the other alternatives, and also considers whether those alternatives are feasible, taking into account economic, environmental, social, technological, and other factors. (Pub. Resources Code, §§ 21081(a)(3), 21061.1.) An agency may conclude that an alternative is infeasible, for example, if it is inconsistent with agency goals or policies or if it will not satisfy project objectives

As discussed above, the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) would result in significant impacts resulting from changes in flows on the tributaries. Although these changes are not directly related to the implementation of the salinity objective, they are still effects resulting from the No Project Alternative and it is not the environmentally superior alternative.

Under SDWQ Alternative 2, there would be significant and unavoidable impacts on service providers because some service providers (i.e., Cities of Tracy and Stockton and Mountain House CSD) may exceed effluent limitations set at the salinity objective proposed under SDWQ Alternative 2, thus potentially necessitating construction or operation of new, upgraded, or expanded WWTP facilities or infrastructure. Under SDWQ Alternative 3, impacts on service providers would be less than significant because it is expected all service providers may be able to meet effluent limitations if the limitations are set at the salinity objective proposed under SDWQ Alternative 3, with the exception of Deuel Vocational Institution (Deuel). However, currently Deuel is not meeting the effluent limitations, and SDWQ Alternative 3 would not increase the number of existing violations or increase the salinity of the discharge at Deuel. As the Deuel facility comes into compliance with its existing NPDES permit limits, salinity conditions in the southern Delta would correspondingly improve. When considering the environmental impacts of SDWQ Alternatives 2 and 3, SDWQ Alternative 3 would be considered the environmentally superior alternative because it has fewer significant and unavoidable impacts.

Under SDWQ Alternatives 2 and 3, the reasonably foreseeable methods of compliance could result in significant and unavoidable impacts (as disclosed in Chapter 16, *Evaluation of Other Indirect and Additional Actions*, and Section 18.3.2, *Significant and Unavoidable Impacts*). Fewer methods of compliance (i.e., agricultural return flow and low lift pump stations) may occur under SDWQ Alternative 3, given service providers may not need to modify existing wastewater treatment plants or change source water supplies, when compared to SDWQ Alternative 2. However, significant and unavoidable impacts could still occur under SDWQ Alternative 3 because of the program of implementation and the potential for agricultural return flow salinity control or low lift pumping stations. Since the potential combination of methods of compliance under the SDWQ alternatives is unknown, so is the scope, magnitude and location of the significant and unavoidable impacts. As such, it cannot be concluded that specific significant and unavoidable impacts from the methods of compliance would occur under one SDWQ alternative when compared to another.

The purpose and goals of the salinity objectives and associated program of implementation, as described in Chapter 3, *Alternatives Description,* are as follows.

1. Provide salinity conditions that reasonably protect agricultural beneficial uses of surface waters in the southern Delta.
2. In establishing salinity water quality objectives to reasonably protect agricultural beneficial uses, take into consideration all of the demands being made and to be made on waters in the southern Delta, the LSJR and the three eastside, salmon-bearing tributaries, and the factors to be considered for establishing water quality objectives in Water Code Section 13241, including, but not limited to, past, present and probable future beneficial uses and economic considerations.
3. Establish salinity objectives, supported by existing scientific information, that are not lower than necessary to reasonably protect the most salt sensitive crops currently grown or suitable to be grown on saline- and drainage-impaired soils in the southern Delta.
4. Maintain or improve salinity conditions in the southern Delta to comply with state and federal antidegradation policies.
5. Provide for development and implementation of monitoring and modeling studies needed to better understand the characteristics of salinity conditions in the southern Delta and the dynamics of factors controlling or contributing to those conditions.

These goals are used in conjunction with the significance determinations to inform the feasibility of the environmentally superior alternatives. SDWQ Alternative 3 does not meet purpose and goal 1 and 4 because it requires salinity in the southern Delta at a level that is less protective of agricultural beneficial uses than either SDWQ Alternative 2 or the No Project Alternative. It also does not meet goal 2 because it does not take into consideration the water quality conditions that could reasonably be achieved through the coordinated control of all factors that affect water quality, as required under Water Code Section 13241, because water quality better than the proposed salinity objective could be achieved. The No Project Alternative does not meet goal 3 because the existing salinity objective is lower than necessary to protect the most sensitive crops in the southern Delta. SDWQ Alternative 2 fully meets goals 1 through 5.

Table 18-4. Impact Determinations Identified in Chapters 5–15

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
Chapter 5: Surface Hydrology and Water Quality						
WQ-1: Violate water quality standards by increasing the number of months with EC above the water quality objectives for salinity at Vernalis or southern Delta compliance stations	Less than significant— The No Project Alternative is the continuation of the existing 2006 Bay-Delta Plan, which includes implementation measures to achieve water quality objectives (e.g., the Vernalis and southern Delta EC objectives).Evaluation of monthly flows shows that although a few of the median No Project flows are less than baseline, Vernalis flows are generally higher under the No Project Alternative, especially during years with low flow (which would be more likely to have EC violations). Because higher flows generally reduce EC, the No Project Alternative would not be expected to cause an increase in the amount of time the water quality objectives for salinity are exceeded at Vernalis or southern Delta compliance stations.	Less than significant—There would be an overall reduction in monthly exceedances of EC values for the interior southern Delta compliance stations.	Less than significant—There would be an overall reduction in monthly exceedances of EC values for the interior southern Delta compliance stations.	Less than significant—There would be an overall reduction in monthly exceedances of EC values for the interior southern Delta compliance stations.	Less than significant—There would be an overall reduction of EC values above the new constant 1. 0 dS/m EC objective when compared to existing EC objectives.	Less than significant—There would be a reduction of EC values above the new constant 1.4 dS/m EC objective when compared to existing EC objectives such that there would no longer be any violations.
WQ-2: Substantially degrade water quality by increasing Vernalis or southern Delta salinity (EC) such that agricultural beneficial uses are impaired	Less than significant— See WQ-1.	Less than significant—The range of average EC values during the irrigation season of April–September in the SJR at Vernalis and in the southern Delta channels is expected to be reduced. Accordingly, it is not anticipated that agricultural beneficial uses would be impaired.	Less than significant—The range of average EC values during the irrigation season of April–September in the SJR at Vernalis and in the southern Delta channels is expected to be reduced. Accordingly, it is not anticipated that agricultural beneficial uses would be impaired.	Less than significant—The range of average EC values during the irrigation season of April–September in the SJR at Vernalis and in the southern Delta channels is expected to be reduced. Accordingly, it is not anticipated that agricultural beneficial uses would be impaired.	No impact—This alternative does not have the ability to result in an increase in EC because the baseline 0.7 dS/m Vernalis EC objective would continue to be maintained as part of the program of implementation. Therefore, this alternative would not cause a change in flow or water quality. Accordingly, it is not anticipated that agricultural beneficial uses would be impaired.	No impact—This alternative does not have the ability to result in an increase in EC because the baseline 0.7 dS/m Vernalis EC objective would continue to be maintained as part of the program of implementation. Therefore, this alternative would not cause a change in flow or water quality. Accordingly, it is not anticipated that agricultural beneficial uses would be impaired.
WQ-3: Substantially degrade water quality by increasing pollutant concentrations caused by reduced river flows	Significant—Under the No Project Alternative flows would not be substantially reduced on the Stanislaus, Tuolumne, or LSJR such that contaminant concentrations would increase. However, on the Merced River, flows under the No Project Alternative would be substantially reduced during April and May compared to baseline, which could result in a significant	Less than significant—Flows would generally increase, and no months with low to median flows (10th and 50th percentiles) would experience flow reductions greater than 33% of the baseline flows on the Stanislaus, Tuolumne or Merced Rivers or the LSJR. Therefore, it is expected that the change in concentrations	Less than significant—Flows would generally increase, and no months with low to median flows (10th and 50th percentiles) would experience flow reductions greater than 33% of the baseline flows on the Stanislaus, Tuolumne, or Merced Rivers or the LSJR. Therefore, it is expected that the change in concentrations	Less than significant—Flows would generally increase, and no months with low to median flows (10th and 50th percentiles) would experience flow reductions greater than 33% of the baseline flows on the Stanislaus, Tuolumne or Merced Rivers or the LSJR. Therefore, it is expected that the change in concentrations	No impact – This alternative does not have the ability to result in an increase in pollutant concentrations because the baseline 0.7 dS/m Vernalis EC objective would continue to be maintained as part of the program of implementation. Therefore, this alternative would not cause a change in flow or water quality.	No impact – This alternative does not have the ability to result in an increase in pollutant concentrations because the baseline 0.7 dS/m Vernalis EC objective would continue to be maintained as part of the program of implementation. Therefore, this alternative would not cause in flow or water quality.

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
	increase in contaminant concentrations above baseline conditions.	would not substantially degrade water quality.	would not substantially degrade water quality.	would not substantially degrade water quality.		
Chapter 6: Flooding, Sediment, and Erosion						
FLO-1: Substantially alter the existing drainage pattern of the site or area, including through the alteration of the course of a stream or river in a manner that would result in substantial erosion or siltation on- or off-site	Less than Significant— Under the No Project Alternative, flows would be lower than channel capacities on the Stanislaus, Tuolumne, and Merced Rivers as described under LSJR Alternative 4, in Chapter 6, Flooding, Sediment, and Erosion. Sediment transport, bank erosion or meander-bend migration issues and contribution to levee instability would not increase. It is expected that very occasional gravel transport and bank erosion would occur in the upper gravel-bedded reaches of the Stanislaus, Tuolumne, and Merced Rivers. The amount of bank erosion would be limited by flood action levels and existing bank armoring. Impacts would be less than significant.	Less than significant—Substantial erosion is caused by high flow events resulting from flood control releases of peak flows. These flows would not increase under this alternative. On average, the occurrence of monthly flows greater than 1,500 cfs on the Stanislaus River would be similar to baseline and would not influence stream bank erosion. Therefore, substantial alterations of the existing drainage patterns would not occur and would not result in substantial erosion or siltation.	Less than significant—Very occasional gravel transport and bank erosion would occur in the upper gravel-bedded reaches of the three eastside tributaries. The amount of bank erosion is limited by flood stage action levels, which is the river stage at which actions are presumed to occur to reduce flood risk, and existing bank armoring. Flows greater than 1,500 cfs on the Stanislaus River would occur with somewhat greater frequency than baseline, particularly during April to June; however, these flows are not sufficiently high to increase stream bank erosion. Therefore, substantial alterations of the existing drainage patterns would not occur and would not result in substantial erosion or siltation.	Less than significant—Similar to LSJR Alternative 3, there would be occasional gravel transport and bank erosion in the upper gravel-bedded reaches of the three eastside tributaries. The amount of bank erosion is limited by the action stage, which is the river stage at which actions are presumed to occur to reduce flood risk, and existing bank armoring. Flows greater than 1,500 cfs on Stanislaus River would occur with greater frequency than baseline, particularly during April to June; however, these flows are not sufficiently high to increase stream bank erosion. Therefore, substantial alterations of the existing drainage patterns would not occur and would not result in substantial erosion or siltation.	No impact—Any change in salinity in the southern Delta as a result of southern Delta water quality is expected to be similar to that of the historic range of salinity because Vernalis water quality would be maintained under the SDWQ alternatives through the program of implementation. Furthermore, change in water quality does not affect flooding, sedimentation, or erosion.	No impact—Any change in salinity in the southern Delta as a result of southern Delta water quality (SDWQ) Alternatives 2 or 3 is expected to be similar to that of the historic range of salinity because Vernalis water quality would be maintained under the SDWQ alternatives through the program of implementation. Furthermore, change in water quality does not affect flooding, sedimentation, or erosion.
FLO-2: Substantially alter the existing drainage pattern of the site or area, including through the alteration of the course of a stream or river, or substantially increase the rate or amount of surface runoff in manner that would result in flooding on- or off-site	Less than significant— Flows would be much lower than channel capacities on the Stanislaus, Tuolumne, and Merced Rivers, as described under LSJR Alternative 4, in Chapter 6, Flooding, Sediment, and Erosion. Therefore, significant flooding impacts would not occur outside of floodways. The No Project Alternative would not change reservoir flood storage capacity and would not violate USACE flood reservation, so there would be no changes in flood control releases during major flood events.	Less than significant—Controlled reservoir releases would be much lower than channel capacities and no significant flooding would occur outside of floodway. LSJR Alternative 2 would not change reservoir flood storage capacity and would not violate USACE flood reservation so there would be no changes in flood control operation procedures during major flood events. Therefore, substantial alterations of the existing drainage patterns would not occur and would not result in flooding. Consequently, people or structures would not be exposed to a significant risk of loss, injury or death involving flooding.	Less than significant – Similar to LSJR Alternative 2 with respect to flood control operations. Therefore, substantial alterations of the existing drainage patterns would not occur and would not result in flooding. Consequently, people or structures would not be exposed to a significant risk of loss, injury or death involving flooding.	Less than significant—Similar to LSJR Alternative 2, with respect to flood control operations. Substantial alterations of the existing drainage patterns would not occur and would not result in flooding. Consequently, people or structures would not be exposed to a significant risk of loss, injury or death involving flooding.	No impact—See FLO-1.	No impact—See FLO-1.

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
Chapter 7: Aquatic Biological Resources						
AQUA-1: Changes in spawning success and habitat availability of warmwater species resulting from changes in reservoir water levels	Significant—Under the No Project Alternative, month-to-month fluctuations in reservoir elevations at New Don Pedro Reservoir would remain similar to the baseline elevations during April-September (the primary spawning, incubation, and early rearing –). Therefore, the availability of warmwater reservoir species habitat and their spawning success would not change at the New Don Pedro Reservoir. However, month-to-month fluctuations at New Melones Reservoir and Lake McClure would be increased under the No Project Alternative during April–September, as compared to baseline. Monthly fluctuations of greater than or equal to 15 feet (ft) would increase by more than 10% during April–August at New Melones Reservoir and during April at Lake McClure. Therefore, warmwater reservoir species habitat would be significantly altered under the No Project Alternative, which would affect the spawning success of these species.	Less than significant—The frequency of 15-foot fluctuations in reservoir levels would not change or would be reduced relative to baseline conditions. Therefore, no significant reductions in spawning success and habitat availability for warmwater species would occur.	Less than significant—The frequency of 15-foot fluctuations in reservoir levels would not change or would be reduced relative to baseline conditions. Therefore, no significant reductions in spawning success and habitat availability for warmwater species would occur	Less than significant—The frequency of 15-foot fluctuations in reservoir levels would not change or would be reduced relative to baseline conditions. Therefore, no significant reductions in spawning success and habitat availability for warmwater species would occur.	No impact – This alternative does not have the ability to result in changes to reservoir salinity because it is not applied at the reservoirs.	No impact – This alternative does not have the ability to result in changes to reservoir salinity because it is not applied at the reservoirs.
AQUA-2: Changes in availability of coldwater species reservoir habitat resulting from changes in reservoir storage	Significant—Under the No Project Alternative, end-of-September storage at New Don Pedro and Lake McClure are expected to remain similar to, or be greater than, the storage under baseline elevations. End-of-September storage is not expected to be significantly reduced when compared to baseline. Therefore, the availability of coldwater reservoir species habitat and their spawning success are not expected to change at these reservoirs. However, on average, end-of-September storage at New Melones Reservoir would be reduced by 27%. Therefore, coldwater reservoir species habitat would be significantly altered under the No Project Alternative, which would affect the spawning success of these species.	Less than significant—Changes in average reservoir storage levels at the end-of-September would range from little or no change to substantial increases relative to baseline levels. Therefore, no significant reductions in coldwater habitat availability would occur.	Less than significant—Changes in average reservoir storage levels at the end-of-September would range from little or no change to substantial increases relative to baseline levels. Therefore, no significant reductions in coldwater habitat availability would occur.	Less than significant—Changes in average reservoir storage levels at the end-of-September would range from little or no change to substantial increases relative to baseline levels. Therefore, no significant reductions in coldwater habitat availability would occur.	No impact – See AQUA-1.	No impact – See AQUA.1.

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
AQUA-3: Changes in quantity/ quality of physical habitat for spawning and rearing resulting from changes in flow	Less than significant—Under the No Project Alternative, flows on the Stanislaus River would increase, while flows on the Tuolumne River would be similar to baseline flows and thus would not reduce the quantity and quality of spawning and rearing habitat. Under the No Project Alternative, the Merced River would experience a relatively large percentage reduction in flows in April and May compared to baseline. However, predicted changes in flow within this range correspond to only minor increases or decreases in WUA and no changes in floodplain inundation area. Therefore, they are not likely to substantially affect the amount of physical habitat for Chinook salmon juvenile rearing and steelhead fry rearing.	Less than significant—Suitable spawning habitat on the three eastside tributaries would remain unchanged or increase. Therefore, no significant adverse impacts on the amount of spawning habitat for Chinook salmon and steelhead in the Stanislaus, Tuolumne, and Merced Rivers would occur. No reductions in Chinook salmon fry and juvenile rearing habitat are expected on the Stanislaus River or LSJR compared to baseline. In the Tuolumne and Merced Rivers, weighted usable area (WUA) for Chinook salmon fry and juvenile rearing would decrease, but floodplain habitat would increase in response to higher spring flows. No substantial differences would occur in WUA for steelhead fry and juvenile rearing compared to baseline conditions. No long-term reductions in habitat availability for other native fish species would occur. Therefore, no significant adverse impacts on the amount of habitat for Chinook salmon, steelhead, and other native fishes in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would occur.	Less than significant—Reductions in WUA for Chinook salmon spawning would occur in the three eastside tributaries, but higher flows and lower temperatures are expected to improve attraction and migration and the longitudinal extent of suitable spawning habitat. This alternative would substantially improve rearing habitat conditions for Chinook salmon and steelhead in the three eastside streams and LSJR. Considering the overall beneficial effects of higher flows on rearing habitat availability, no significant adverse impacts on Chinook salmon and steelhead populations would occur. Higher spring flows under this alternative would also benefit other native fish species.	Less than significant—Predicted changes in WUA values for Chinook salmon and steelhead spawning in the Stanislaus, Tuolumne, and Merced Rivers would be similar in magnitude to those predicted under LSJR Alternative 3. This alternative would further improve rearing habitat conditions for Chinook salmon and steelhead in the three eastside tributaries and LSJR. Higher spring flows under this alternative would also further improve habitat conditions for other native fish species. Therefore, no significant adverse impacts would occur.	No impact—this alternative does not have the ability to result in changes to flow because it is a water quality objective for salinity; furthermore, the volume of water needed to meet the Vernalis EC objective is included in the modeling results and, thus, in the impact determinations, for the LSJR alternatives.	No impact – this alternative does not have the ability to result in changes to flow because it is a water quality objective for salinity; furthermore the volume of water needed to meet the Vernalis EC objective is included in the modeling results and, thus, in the impact determinations, for the LSJR alternatives.
AQUA-4: Changes in exposure of fish to suboptimal water temperatures resulting from changes in reservoir storage and releases	Significant—Under the No Project Alternative, temperatures would not increase on the Tuolumne because flows and end-of-September storage would be similar to baseline. However, reductions in April and May flows on the Merced River would very likely increase temperatures in the river in more than half the years (mostly below normal and dry years), in which would increase the frequency of stressful temperatures for Chinook salmon and steelhead rearing and smolt life stages. On the Stanislaus River, higher summer and fall	Less than significant—No substantial changes would occur in exposure of Chinook salmon and steelhead adult migration, spawning and incubation, juvenile rearing, and smolt life stages to suboptimal water temperatures in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR. Therefore, no significant adverse impacts on Chinook salmon and steelhead populations would occur.	Less than Significant—Decreases in exposure of Chinook salmon and steelhead life stages to suboptimal water temperatures would occur for spawning/incubation in the Tuolumne River (March); spring rearing in the Tuolumne, Merced, and LSJR (April–May); and summer rearing (steelhead only) in the Stanislaus, Tuolumne, and Merced Rivers (July). Therefore, no significant adverse impacts would occur. This alternative would have beneficial temperature effects	Less than significant—Decreases in exposure of Chinook salmon and steelhead life stages to suboptimal water temperatures would occur for spawning/incubation in the Stanislaus, Tuolumne, and Merced Rivers (February–March); spring rearing in the Stanislaus, Tuolumne, Merced, and LSJR (March–May); spring outmigration in the Stanislaus, Tuolumne, and Merced Rivers (April–June); and summer rearing (steelhead only) in the Tuolumne River (July).	No impact— See AQUA-3.	No impact—See AQUA-3.

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
	release temperatures associated with reduced storage in New Melones Reservoir are also expected to increase the frequency of stressful water temperatures for Chinook salmon and steelhead adult migration, Chinook salmon spawning and incubation, and steelhead rearing life stages, especially in dry years. Flows and water temperatures in the LSJR would remain largely unchanged relative to baseline conditions, which would result in little or no change in exposure of migrating adults and juveniles to stressful water temperatures.		on Chinook salmon and steelhead in the Stanislaus, Tuolumne, and Merced Rivers (including Chinook salmon reared at Merced River Hatchery), and the LSJR.	Therefore, no significant adverse impacts would occur. Overall, this alternative would have beneficial temperature effects on Chinook salmon and steelhead in the Stanislaus, Tuolumne, and Merced Rivers (including Chinook salmon reared at Merced River Hatchery), and the LSJR.		
AQUA-5 : Changes in exposure to pollutants resulting from changes in flow	Significant—Under the No Project Alternative, the exposure to pollutants resulting from changes in flow would not increase on the Stanislaus or Tuolumne Rivers because flows in these rivers would generally be similar to, or greater than, baseline flows. However, on the Merced River, reduction in April and May flows under the No Project Alternative, especially during dry periods, would likely increase pollutant exposure to fish on this river compared to the baseline.	Less than significant—Changes in the frequency and magnitude of flows would not be sufficient to result in long-term changes in dilution effects and exposure of fish to potentially harmful contaminants.	Less than significant—Similar or higher 10th and 50th (median) percentile flows in most months would result in similar or reduced long-term exposure of fish to potentially harmful pollutants. Decreases in exposure of Chinook salmon and steelhead life stages to suboptimal water temperatures would contribute to reductions in the potential for adverse effects associated with contaminant exposure.	Less than significant—Dilution would potentially increase as a result of the increase in flows, and temperatures would either be maintained or reduced; thus, an increase in exposure to pollutants would not occur.	No impact– See AQUA-3.	No impact – See AQUA-3.
AQUA-6: Changes in exposure to suspended sediment and turbidity resulting from changes in flow	Less than significant—Changes in the frequency, duration, and magnitude of increased suspended sediment and turbidity levels would be minor and within the range of historical levels experienced by native fishes and other aquatic species on the three eastside tributaries and the LSJR. Because the No Project Alternative flows during wet years are expected to be less than those described in LSJR Alternative 4 on the Stanislaus River, impacts would be less than those described above. Similar but fewer impacts as those described above would occur on the Tuolumne and Merced Rivers because flows under the No Project Alternative would be similar to or less than baseline flows on these rivers.	Less than significant—Changes in the frequency, duration, and magnitude of increased suspended sediment and turbidity levels are expected to be minor and within the range of historical levels experienced by native fishes and other aquatic species on the three eastside tributaries and the LSJR.	Less than significant—Changes in the frequency, duration, and magnitude of increased suspended sediment and turbidity levels are expected to be minor and within the range of historical levels experienced by native fishes and other aquatic species on the three eastside tributaries and the LSJR.	Less than significant—Changes in the frequency, duration, and magnitude of increased suspended sediment and turbidity levels are expected to be minor and within the range of historical levels experienced by native fishes and other aquatic species on the three eastside tributaries and the LSJR.	No impact—See AQUA-3.	No impact—See AQUA-3

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
	Therefore, the change in flows would not mobilize more suspended sediment.					
AQUA-7: Changes in redd dewatering resulting from flow fluctuations	Less than significant—Changes in the frequency and magnitude of flow reductions under the No Project Alternative are not expected in the Stanislaus, Tuolumne, and Merced Rivers when compared to baseline conditions. Therefore, redd dewatering impacts on Chinook salmon and steelhead populations in the Stanislaus, Tuolumne, and Merced Rivers would be less than significant.	Less than significant— There would be no substantial changes on the major SJR tributaries or the LSJR in the frequency and magnitude of flow reductions associated with potential impacts on Chinook salmon and steelhead redd dewatering.	Less than significant—There would be no substantial changes on the major SJR tributaries or the LSJR in the frequency and magnitude of flow reductions associated with potential impacts on Chinook salmon and steelhead redd dewatering.	Less than significant—There would be no substantial changes on the major SJR tributaries or the LSJR in the frequency and magnitude of flow reductions associated with potential impacts on Chinook salmon and steelhead redd dewatering.	No impact—See AQUA-3.	No impact—See AQUA-3.
AQUA-8: Changes in spawning habitat quality resulting from changes in peak flows	Less than significant—Under the No Project Alternative, substantial changes in the frequency and magnitude of peak flows would not occur relative to LSJR Alternatives 2, 3, and 4 (because the February – June flows at the zero to 10% exceedance level are between those for LSJR Alternatives 2 and 4, Figure 15-2a). Therefore, changes in peak flows would not deleteriously affect the frequency and magnitude of gravel mobilization events in the Stanislaus, Tuolumne, and Merced Rivers, and long-term changes in geomorphic conditions significantly affecting spawning and rearing habitat quality would not occur.	Less than significant—Modeled results indicate that changes in peak flows are not expected to affect the frequency and magnitude of gravel mobilization events in the Stanislaus, Tuolumne, and Merced Rivers. Therefore, no long-term changes in geomorphic conditions significantly affecting spawning and rearing habitat quality are expected to occur.	Less than significant—Modeled results indicate that changes in peak flows are not expected to affect the frequency and magnitude of gravel mobilization events in the Stanislaus, Tuolumne, and Merced Rivers. Therefore, no long-term changes in geomorphic conditions significantly affecting spawning and rearing habitat quality are expected to occur.	Less than significant—Modeled results indicate that changes in peak flows are not expected to affect the frequency and magnitude of gravel mobilization events in the Stanislaus, Tuolumne, and Merced Rivers. Therefore, no long-term changes in geomorphic conditions significantly affecting spawning and rearing habitat quality are expected to occur.	No impact—See AQUA-3.	No impact—See AQUA-3.
AQUA-9: Changes in food availability resulting from changes in flow and floodplain inundation	Less than significant— Under the No Project Alternative, no substantial in frequency and magnitude of floodplain inundation and associated food web conditions would occur on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR (because there would be no substantial decreases in the highest flows). Therefore, no significant impacts on food availability are expected to occur.	Less than significant—No substantial changes are likely to occur in frequency and magnitude of floodplain inundation and associated food web conditions in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR. Therefore, no significant impacts on food availability are expected to occur.	Less than significant—Higher spring flows and associated increases in riparian and floodplain inundation in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would potentially increase food abundance and growth opportunities for fish on floodplains as well as contribute to downstream food web support. This represents a beneficial effect on aquatic biological resources in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR.	Less than significant—Higher spring flows and associated increases in riparian and floodplain inundation in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would potentially increase food abundance and growth opportunities for fish on floodplains as well as contribute to downstream food web support. This represents a beneficial effect on aquatic biological resources in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR.	No impact—See AQUA-3.	No impact—See AQUA-3.

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
AQUA-10: Changes in predation risk resulting from changes in flow and water temperature	Significant— Under the No Project Alternative, predation risk would be unlikely to change on the Tuolumne River because flow, storage, and water temperature would be similar to baseline. However, reductions in flow and associated higher temperatures on the Merced River in April and May would very likely increase predation risk for Chinook salmon and steelhead rearing and smolt life stages. On the Stanislaus River, higher summer and fall release temperatures associated with reduced storage in New Melones Reservoir would also increase predation risk for juvenile steelhead, especially in dry years. Flows and water temperatures on the LSJR are expected to remain largely unchanged relative to baseline, which would result in little or no change in predation risk.	Less than significant—No substantial changes are predicted to occur in habitat availability and water temperatures potentially affecting Chinook salmon and steelhead populations or conditions supporting predator populations.	Less than significant—Higher flows and cooler water temperatures in the three eastside tributaries would reduce predation impacts by improving growth opportunities and reducing temperature-related stress in juvenile Chinook salmon and steelhead and limiting the distribution and abundance of largemouth bass and other nonnative species that prey on juvenile salmonids.	Less than significant—Higher flows and cooler water temperatures in the three eastside tributaries would reduce predation impacts by improving growth opportunities and reducing temperature-related stress in juvenile Chinook salmon and steelhead and limiting the distribution and abundance of largemouth bass and other nonnative species that prey on juvenile salmonids.	No impact—See AQUA-3.	No impact—See AQUA-3.
AQUA-11: Changes in disease risk resulting from changes in water temperature	Significant—Under the No Project Alternative, higher summer and fall release temperatures on the Stanislaus River associated with reduced storage in New Melones Reservoir would increase disease risk for Chinook salmon and steelhead adult migration, Chinook salmon spawning and incubation, and steelhead-rearing life stages, especially in dry years. On the Tuolumne River, disease risk would be unlikely to change because flow, storage, and water temperature would be very similar to baseline. However, reductions in flow and associated higher temperatures on the Merced River in April and May would very likely increase disease risk for Chinook salmon and steelhead-rearing and smolt life stages. Flows and water temperatures on the LSJR would remain largely unchanged relative to baseline, which would result in little or no change in disease risk	Less than significant—The frequency of spring water temperatures associated with potential increases in disease risk would stay the same or decrease.	Less than significant—The frequency of spring water temperatures associated with potential increases in disease risk would stay the same or decrease.	Less than significant—The frequency of spring water temperatures associated with potential increases in disease risk would stay the same or decrease.	No impact—See AQUA-3	No impact—See AQUA-3

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
AQUA-12: Changes in southern Delta and estuarine habitat resulting from changes in SJR inflows and export effects	Less than significant—Under the No Project Alternative, Delta operations would continue to be governed by current restrictions on export pumping rates, inflow/export ratios, and Old Middle River (OMR) flows to protect listed fish species from direct and indirect impacts of southern Delta operations. Furthermore, during the primary months of concern for fish using the Delta (December–June), changes in exports would be relatively small and less than the changes under LSJR Alternatives 3 and 4, while average monthly Delta outflow would either be similar to or slightly greater than baseline outflow. Therefore, no significant changes in southern Delta and estuarine habitat are expected to occur under the No Project Alternative.	Less than significant—No substantial changes in southern Delta and estuarine habitat are expected to occur. The combination of monthly changes in pumping rates, SJR flow, and Delta outflow would not have substantial long-term effects on flow patterns in the southern Delta. Furthermore, there would be little effect on Delta outflows and the position of X2; Delta operations would continue to be governed by current restrictions on export pumping rates, inflow/export ratios, and Old Middle River flows to protect listed fish species from direct and indirect impacts of southern Delta operations.	Less than significant—No substantial changes in southern Delta and estuarine habitat are expected to occur. The combination of monthly changes in pumping rates, SJR flow, and Delta outflow would not have substantial long-term effects on flow patterns in the southern Delta. Furthermore, there would be little effect on Delta outflows and the position of X2; Delta operations would continue to be governed by current restrictions on export pumping rates, inflow/export ratios, and Old Middle River flows to protect listed fish species from direct and indirect impacts of southern Delta operations.	Less than significant —No substantial changes in southern Delta and estuarine habitat are expected to occur. Furthermore, there would be little effect on Delta outflows and the position of X2; Delta operations would continue to be governed by current restrictions on export pumping rates, inflow/export ratios, and Old Middle River flows to protect listed fish species from direct and indirect impacts of southern Delta operations.	No impact—See AQUA-3.	No impact—See AQUA-3.
Chapter 8: Terrestrial Biological Resources						
BIO-1 : Have a substantial adverse effect on any riparian habitat or other sensitive natural terrestrial communities identified in local or regional plans, policies, regulations or by CDFW and USFWS	Significant—Fluctuations in reservoir elevations would not be substantially different than those that currently occur. Therefore, the No Project Alternative would not have adverse effects on riparian or other sensitive natural terrestrial communities around the reservoirs. Under the No Project Alternative, flow on the Stanislaus and Tuolumne Rivers and LSJR would not substantially alter riparian habitat or other sensitive natural terrestrial communities because flows on these rivers would be similar to, or greater than, baseline. However, the reduced flow on the Merced River under the No Project Alternative when compared to the baseline would very likely result in a substantial alteration of riparian habitat or other sensitive natural terrestrial communities on this river, especially during moderate to dry years in the spring growing season (April and May).	Less than significant—The change in median monthly flows or overall cumulative distribution of flows on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would not substantially effect riparian habitat or other sensitive terrestrial communities because the plants located within the area of potential effects can survive inundation, are resistant to the effects of scouring and deposition, and are limited by water availability. Fluctuations in reservoir elevations would not be substantially different than those that currently occur. Therefore, the LSJR alternatives would not have significant adverse effects on riparian or wetland habitats or other sensitive terrestrial communities around the reservoirs.	Less than significant—The change in median monthly flows or overall cumulative distribution of flows on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would not substantially effect riparian habitat or other sensitive terrestrial communities because the plants located within the area of potential effects can survive inundation, are resistant to the effects of scouring and deposition, and are limited by water availability. Fluctuations in reservoir elevations would not be substantially different than those that currently occur. Therefore, the LSJR alternatives would not have significant adverse effects on riparian or wetland habitats or other sensitive terrestrial communities around the reservoirs.	Less than significant—The change in median monthly flows or overall cumulative distribution of flows on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would not substantially effect riparian habitat or other sensitive terrestrial communities because the plants located within the area of potential effects can survive inundation, are resistant to the effects of scouring and deposition, and are limited by water availability. Fluctuations in reservoir elevations would not be substantially different than those that currently occur. Therefore, the LSJR alternatives would not have significant adverse effects on riparian or wetland habitats or other sensitive terrestrial communities around the reservoirs.	No impact—No ability to result in changes to flow because it is a water quality objective for salinity; furthermore, the volume of water needed to meet the Vernalis EC objective is included in the modeling results and, thus, in the impact determinations for the LSJR alternatives. Finally, salinity in the southern Delta would remain within the historical range, and the terrestrial plant and animal species can adapt to the variable salinity levels that the southern Delta currently experiences.	No impact—No ability to result in changes to flow because it is a water quality objective for salinity; furthermore, the volume of water needed to meet the Vernalis EC objective is included in the modeling results and, thus, in the impact determinations for the LSJR alternatives. Finally, salinity in the southern Delta would remain within the historical range, and the terrestrial plant and animal species can adapt to the variable salinity levels that the southern Delta currently experiences.

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
BIO-2: Have a substantial adverse effect on federally protected wetlands as defined by Section 404 of the Clean Water Act (including, but not limited to, marsh, vernal pool, coastal, etc.) through direct removal, filling, hydrologic interruption, or other means	Significant— See BIO-1.	Less than significant—Monthly median flows or the cumulative distribution of flows on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would generally increase. Increased flow would not adversely affect wetland communities because wetland plants can survive inundation, are resistant to the effects of scouring and deposition, and are growth-limited by water availability. Little change is expected in the frequency and range in water level fluctuation in the reservoirs as a result of this alternative, therefore adverse effects are not expected to occur on wetland communities surrounding the reservoirs. Therefore, substantial adverse effects on wetland communities would not occur.	Less than significant—Monthly median flows or the cumulative distribution of flows on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would generally increase. Increased flow would not adversely affect wetland communities because wetland plants can survive inundation, are resistant to the effects of scouring and deposition, and are growth-limited by water availability. Little change is expected in the frequency and range in water level fluctuation in the reservoirs as a result of this alternative, therefore adverse effects are not expected to occur on wetland communities surrounding the reservoirs. Therefore, substantial adverse effects on wetland communities would not occur.	Less than significant—Monthly median flows or the cumulative distribution of flows on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would generally increase. Increased flow would not adversely affect wetland communities because wetland plants can survive inundation, are resistant to the effects of scouring and deposition, and are growth-limited by water availability. Little change is expected in the frequency and range in water level fluctuation in the reservoirs as a result of this alternative, therefore adverse effects are not expected to occur on wetland communities surrounding the reservoirs. Therefore, substantial adverse effects on wetland communities would not occur.	No impact—See BIO-1.	No impact – See BIO-1.
BIO-3: Facilitate an increase in distribution and abundance of invasive plants or nonnative wildlife that would have a substantial adverse effect on native terrestrial species	Less than significant— Invasive plants and animals already exist throughout the watersheds of the Stanislaus, Tuolumne, and Merced Rivers and the LSJR. Although the No Project Alternative could alter vegetation patterns at specific locations, there is no information available to suggest that increased flows on the Stanislaus River or decreased flows on the Merced River would substantially increase the distribution or abundance of invasive plant or nonnative wildlife in a manner that would substantially native terrestrial species.	Less than significant—Changes in flows in the LSJR and the three eastside tributaries and fluctuations in reservoir elevations may result in alteration of vegetation patterns in specific locations, but there is no basis to suggest increased flows would substantially increase the distribution and abundance of invasive plant species. Little change is expected in the frequency and range in water level fluctuation in the reservoirs as a result of this alternative. In addition, the potential for invasive plants and nonnative wildlife species to increase due to a reduction in irrigation water supply availability or potential fallowing would not be expected to exceed existing levels because some agricultural lands would be farmed less intensively,	Less than significant—Changes in flows in the LSJR and the three eastside tributaries and fluctuations in reservoir elevations may result in alteration of vegetation patterns in specific locations, but there is no basis to suggest increased flows would substantially increase the distribution and abundance of invasive plant species. Little change is expected in the frequency and range in water level fluctuation in the reservoirs as a result of this alternative. No impact—See BIO-1.

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
		fallowed lands can retain growth, and existing invasive species programs would continue to be implemented. Therefore, an increase in the distribution and abundance of invasive plants or nonnative wildlife is not expected to result from implementation of this alternative.	fallowed lands can retain growth, and existing invasive species programs would continue to be implemented. Therefore, an increase in the distribution and abundance of invasive plants or nonnative wildlife is not expected to result from implementation of this alternative.	fallowed lands can retain growth, and existing invasive species programs would continue to be implemented. Therefore, an increase in the distribution and abundance of invasive plants or nonnative wildlife is not expected to result from implementation of this alternative.		
BIO-4: Have a substantial adverse effect, either directly or through habitat modifications, on any terrestrial animal species identified as a candidate, sensitive, or special-status species in local or regional plans, policies, or regulations or by CDFW and USFWS	Significant—Under the No Project Alternative, flows on Stanislaus and Tuolumne Rivers and the LSJR would be similar to, or greater than, baseline. Therefore, the special-status animal species on these rivers would not be substantially affected. However, the reduced flow on the Merced River under the No Project Alternative compared to the baseline would very likely result in substantial effects on special-status species reliant on riparian habitat on this river. Therefore, the special-status animal species on the Merced River would be adversely affected.	Less than significant—Most of the special-status animal species present in the area of potential effects are dependent on riparian habitat. As described above for BIO-1, there would not be a substantial change to available riparian habitat. Similarly, the frequency and range in reservoir elevation fluctuation are not expected to change substantially compared to the baseline conditions consequently, adverse effects are not expected to occur to special-status species or their habitat at the reservoirs. A potential reduction in irrigation water supply in the area of potential indirect effects would not have a substantial adverse effect on special status species due to indirect habitat modification because agricultural land cover would not necessarily be fallowed in perpetuity, as lands could be dryland farmed, deficit irrigated, or rotated. This could result in less agricultural intensive practices on some lands. The resulting halt of mechanized agriculture, pesticide and rodenticide application, and anthropogenic disturbance as a result of less agricultural intensive practices is unlikely to result in a substantial adverse effect on sensitive or special-status	Less than significant—Most of the special-status animal species present in the area of potential effects are dependent on riparian habitat. As described above for BIO-1, there would not be a substantial change to available riparian habitat. Similarly, the frequency and range in reservoir elevation fluctuation are not expected to change substantially compared to the baseline conditions consequently, adverse effects are not expected to occur to special-status species or their habitat at the reservoirs. The potential reduction of monocultural irrigated crops is likely to support the species and ecosystem recovery strategy outlined in the USFWS recovery strategy. Therefore, it is not expected that special-status animal species would be adversely affected.		
BIO-5: Conflict with the provisions of an adopted habitat conservation plan, natural community conservation plan, or other approved local, regional, or state habitat conservation plan or conflict with any local policies or ordinances protecting biological resources	Significant—Under the No Project Alternative, flow on Stanislaus and Tuolumne Rivers and the LSJR would not substantially affect riparian habitat or special-status species. Therefore, the No Project Alternative would not conflict with habitat conservation plans or natural community conservation plans for these rivers. However, the reduced flow on the Merced River under the No Project Alternative when compared to baseline conditions could reduce habitat value, which could result in conflicts with habitat conservation plans or natural community plans.	Less than significant—The change in median monthly flows or overall cumulative distribution of flows on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR and changes to the range and/or frequency in reservoir fluctuation would not substantially affect riparian habitat or other sensitive terrestrial communities or the special-status animal species dependent on them (Impact BIO-1and Impact BIO-4). In addition, it is expected that wildlife refuges would continue to receive surface water, as needed, and continue to implement existing water management plans. Therefore, impacts on habitat value would not occur and there would not be a potential to conflict with plans protecting biological resources.	Less than significant—The change in median monthly flows or overall cumulative distribution of flows on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR and changes to the range and/or frequency in reservoir fluctuation would not substantially affect riparian habitat or other sensitive terrestrial communities or the special-status animal species dependent on them (BIO-1and BIO-4). In addition, it is expected that wildlife refuges would continue to receive surface water, as needed, and continue to implement existing water management plans. Therefore, impacts on habitat value would not occur and there would not be a potential to conflict with plans protecting biological resources.	Less than significant—The change in median monthly flows or the overall cumulative distribution of flows on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR and changes to the range and/or frequency in reservoir fluctuation would not substantially affect riparian habitat or other sensitive terrestrial communities or the special-status animal species dependent on them (BIO-1 and BIO-4). In addition, it is expected that wildlife refuges would continue to receive surface water, as needed, and continue to implement existing water management plans. Therefore, impacts on habitat value would not occur and there would not be a potential to conflict with plans protecting biological resources. .	No impact—See BIO-1.	No impact—See BIO-1.
Chapter 9: Groundwater Resources						
Impact GW-1: Substantially deplete groundwater supplies or interfere substantially with groundwater recharge	Less than significant— Surface water diversions on the Tuolumne and Merced Rivers would be similar under the No Project Alternative and baseline. Because there would be no change in surface water availability, the groundwater subbasins (Modesto, Turlock, and Extended Merced) served by these rivers would not be affected by the No Project Alternative. However, surface water diversions on the Stanislaus River would be reduced by approximately 9% under the No Project Alternative; diversions	Less than significant—The average annual groundwater balance is expected to be reduced by less than the equivalent of 1 inch across each of the subbasins. This is not expected to produce a measurable decrease in groundwater elevations. Therefore, there would not be a substantial depletion of groundwater supplies or substantial interference with groundwater recharge.	Significant and unavoidable—The average annual groundwater balance could potentially be reduced by more than the equivalent of 1 inch in three subbasins (Modesto, Turlock, and Extended Merced). If this occurred, it would eventually produce a measurable decrease in groundwater elevations. The effect would be more severe during dry years and in areas farther from the SJR, the valley low point toward which	Significant and unavoidable—The average annual groundwater balance could potentially be reduced by more than the equivalent of 1 inch in all four subbasins (Eastern San Joaquin, Modesto, Turlock, and Extended Merced). If this occurred, it would eventually produce a measurable decrease in groundwater elevations. The effect would be more severe during dry years and in areas farther from the SJR, the valley low point toward which	No impact— This alternative would not result in a change in groundwater pumping or groundwater recharge from surface water that currently takes place in the plan area.	No impact— This alternative would not result in a change in groundwater pumping or groundwater recharge from surface water that currently takes place in the plan area.

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
	would also be reduced under LSJR Alternatives 2 and 3 (average reduction of 2% and 12%, respectively). As such, the Eastern San Joaquin Subbasin, with is served by the Stanislaus River, would be affected by the reduced surface water diversions. However, the groundwater impacts associated with LSJR Alternative 3 would be less than significant. Because surface water diversions reductions under No Project Alternative (9%) would be less than surface water diversion reductions under LSJR Alternative 3 (12%, the groundwater affects associated with the No Project Alternative would also be less than significant.		groundwater slowly moves. Therefore, there could potentially be a significant and unavoidable depletion of groundwater supplies or substantial interference with groundwater recharge, and resulting potential migration of groundwater contamination under this alternative.	groundwater slowly moves. Therefore, there could be a potentially significant and unavoidable depletion of groundwater supplies or substantial interference with groundwater recharge, and resulting potential migration of groundwater contamination under this alternative.		
Impact GW-2: Cause subsidence as a result of groundwater depletion	Less than significant— As described above for impact GW-1, the effect of the No Project Alternative on groundwater supplies is expected to be less than significant. As a result, subsidence resulting from the No Project Alternative is also expected to be less than significant.	Less than significant— The average annual groundwater balance is expected to be reduced by less than the equivalent of 1 inch across each of the subbasins. This is not expected to produce a measurable decrease in groundwater elevations or associated subsidence.	Significant and unavoidable — The average annual groundwater balance could potentially be reduced by more than the equivalent of 1 inch across three subbasins (Modesto, Turlock, and Extended Merced) under LSJR Alternative 3 and across all four subbasins under LSJR Alternative 4. If this occurred, it could worsen subsidence that is already occurring in the Extended Merced Subbasin. Therefore, there could be a potentially significant and unavoidable increase in subsidence.	Significant and unavoidable — The average annual groundwater balance could potentially be reduced by more than the equivalent of 1 inch across three subbasins (Modesto, Turlock, and Extended Merced) under LSJR Alternative 3 and across all four subbasins under LSJR Alternative 4. If this occurred, it could worsen subsidence that is already occurring in the Extended Merced Subbasin. Therefore, there could be a potentially significant and unavoidable increase in subsidence.	No impact—See GW-1.	No impact—See GW-1.
Chapter 10: Recreational Resources and Aesthetics						
REC-1: Substantially physically deteriorate existing recreation facilities on the rivers or at reservoirs	Significant— During the primary recreation months of May–September, the No Project Alternative could slightly shift recreational activities on the Stanislaus River between May and August to those months that are more suited to higher flows and slightly shift recreational activities on the Merced River during May to those more suited for lower flows. These shifts are unlikely to cause significant recreational impacts.	Less than significant—Modeled flows are not expected to cause substantial physical deterioration of on-bank recreational facilities because the seasonal average frequency of river flows (cubic feet per second [cfs]) would not change substantially from baseline. Modeled flows would also not affect in-water recreational activities because they would not change significantly from	Less than significant— Modeled frequencies of flows greater than 2,500 cfs would change little on the Merced and Stanislaus Rivers, and therefore on-bank recreational facilities would not experience substantially more inundation relative to baseline conditions. However, flows greater than 2,500 cfs would increase in frequency on the Tuolumne River in May and June, but	Significant and unavoidable— There would be a substantial increase in flows above 2,500 cfs on the Tuolumne and Stanislaus Rivers under this alternative. Although on-bank recreational facilities are built to withstand periodic inundation, facilities may substantially physically deteriorate from the expected significant increase in inundation frequency relative	No impact—Changes in salinity would not result in changes to water-dependent or water-enhanced recreation opportunities in the southern Delta. Salinity levels are imperceptible to recreationists who use the southern Delta for water-dependent activities, such as boating or kayaking and water-enhanced activities, such as wildlife viewing.	No impact—Changes in salinity would not result in changes to water-dependent or water-enhanced recreation opportunities in the southern Delta. Salinity levels are imperceptible to recreationists who use the southern Delta for water-dependent activities, such as boating or kayaking, and water-enhanced activities, such as wildlife viewing.

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
	Under the No Project Alternative, reservoir elevations at New Don Pedro and Lake McClure are expected to remain similar to baseline conditions. Therefore, substantial physical deterioration at existing recreational facilities at these reservoirs is not expected to occur. However, end-of-September reservoir elevations at New Melones would be greatly reduced when compared to baseline, especially during the years with lowest storage. At New Melones Reservoir, boat launches are inoperable when the reservoir elevation is below 850 ft; under the No Project Alternative, the surface of New Melones Reservoir would be below 850 ft approximately 30% of the time in September, which is when recreationists use the reservoir. Therefore, it is anticipated that the No Project Alternative would interfere with the operation of boat ramps and this could result in a substantial physically deterioration of facilities at New Melones Reservoir, and thus reduce the use of existing recreation facilities.	baseline. Under this alternative, there would be relatively small changes in reservoir elevations. These changes would not substantially deteriorate existing recreational facilities at the reservoirs because all boat ramps and other facilities would remain available to recreationists.	would remain close to baseline values July – September. Although the flows on the Tuolumne River could likely result in an increase in the frequency of inundation of on-bank recreation areas during May and June, recreational facilities are not anticipated to substantially physically deteriorate along the river. On-bank recreational facilities are built to withstand periodic inundation with higher river flows. The modeled seasonal average frequency of low flows (less than 500 cfs) on the Merced and Tuolumne Rivers would decrease more than 10% relative to baseline conditions. However, during July-September, the most popular recreational months for the three eastside tributaries, the frequency of low flows would change by less than 10% relative to baseline for the three eastside tributaries. Therefore, this alternative is not anticipated to affect in-water activities. The change in reservoir elevations under this alternative would not significantly affect recreation at New Melones or Lake McClure. It is expected that there would be a substantial decrease in elevation at New Don Pedro Reservoir. However, because all boat ramps would remain operable at the 30% cumulative distribution elevation (e.g., dry years), and some boat ramps in New Don Pedro Reservoir are still operable at minimum reservoir elevations, there would be no physical deterioration nor reduction in the use of existing recreation	to baseline. The modeled seasonal average frequency of low flows on the Merced and Tuolumne Rivers, without adaptive implementation, would decrease more than 10%. The decrease is mostly due to low flow reduction in May and June. However, because there would be little change in low flows on the Stanislaus, Merced, and Tuolumne Rivers relative to baseline during the warmest months in the San Joaquin Valley when swimming and wading are most popular (July–August), the reduced opportunity for swimming and wading on the three eastside tributaries in May, and particularly in June (i.e., early in the summer recreational season), is not expected to substantially reduce recreational use for the season. Seasonal average elevations at Lake McClure and New Melones Reservoir are expected to increase. The seasonal average elevation at New Don Pedro Reservoir is expected to decrease at the 30% cumulative distribution elevation. Decreased reservoir levels at New Don Pedro Reservoir would not substantially physically deteriorate existing recreation facilities at the reservoirs (marinas and boat ramps), and all boat ramps would remain operable. There would be no reduction in use of the facilities at New Don Pedro Reservoir. Therefore, given the significant increase in the modeled frequency of high seasonal average flows (greater than 2,500 cfs) on the Tuolumne and Stanislaus Rivers associated with LSJR Alternative 4,		

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
			facilities at this location.	substantial physical deterioration of existing recreational facilities is expected.		
REC-2: Substantially degrade the existing visual character or quality of the reservoirs	Significant— Under the No Project Alternative, reservoir elevations at New Don Pedro and Lake McClure would remain relatively constant and would not be substantially reduced compared to baseline. Therefore, substantial degradation of the visual character and quality of area surrounding these reservoirs would not occur. However, summer elevations at New Melones Reservoir would be reduced when compared to baseline, especially during years with lowest storage. At the 30% cumulative distribution level, the May–September seasonal average No Project Alternative elevation would be reduced by more than 50 ft, well above the 10-foot level identified as the criteria for significance. This reduction would substantially degrade the existing visual character or quality of the New Melones Reservoir.	Less than significant—Under certain conditions, reservoir elevations at Lake McClure and New Melones Reservoir could increase and could result in an improvement to the existing views. The decrease in reservoir elevation that could occur at New Don Pedro Reservoir would not result in a substantial degradation of existing visual character or quality.	Less than significant—Under certain conditions, reservoir elevations would increase at Lake McClure and New Melones Reservoir and could improve the existing views. At New Don Pedro Reservoir, decreases in water surface elevation during some dry years could cause a substantial degradation of existing visual character or quality; however, views at this location are Class III, and changes to the character of the landscape can be moderate without compromising visual quality.	Less than significant—Under certain conditions, reservoir elevations would increase at Lake McClure and New Melones Reservoir and could improve the existing views. At New Don Pedro Reservoir, decreases in water surface elevation during some dry years could cause a substantial degradation of existing visual character or quality; however, views at this location are Class III, and changes to the character of the landscape can be moderate without compromising visual quality.	No impact— This alternative would not apply directly to the reservoirs, and the USBR Vernalis salinity requirement in the program of implementation for this alternatives is the same as under baseline conditions.	No impact—This alternative would not apply directly to the reservoirs, and the USBR Vernalis salinity requirement in the program of implementation for this alternatives is the same as under baseline conditions
Chapter 11: Agricultural Resources						
AG-1: Potentially convert Prime Farmland, Unique Farmland, or Farmland of Statewide Importance to nonagricultural uses	Significant— Under the No Project Alternative, in areas that receive surface water from the Tuolumne and Merced Rivers, a conversion of Prime Farmland, Unique Farmland, or Farmland of Statewide Importance to non-agricultural uses would not be expected because surface water diversions on the Tuolumne and Merced Rivers would not be significantly reduced. Therefore, it is anticipated that a substantial reduction in crop acreage would not occur in these watersheds and a conversation of these types of farmland to nonagricultural uses would not occur. The No Project Alternative would result in conversion of Prime Farmland, Unique Farmland, or Farmland of Statewide Importance	Less than significant—Potential reductions in surface water diversions could result in a less than 4% average reduction in irrigated acreage for the irrigation districts in the LSJR area of potential effects.	Significant and unavoidable—Approximately 22,879 acres, on average, of Prime or Unique farmland or Farmland of Statewide Importance requiring irrigation, could have reduced surface water diversions, and it is reasonable to assume that a portion could potentially be converted to nonagricultural uses even though land can be maintained in agricultural use through crop substitution, crop rotation, and dry land farming. Specifically, reductions in surface water diversions could result in reduced acres of irrigated land for Alfalfa for SSJID, MID, and TID; Grain in MID; Field Crops in SSJID, MID and TID; Pasture in SSJID, OID, MID, and TID; Rice in SSJID and	Significant and unavoidable—Approximately 70,640 acres on average of Prime or Unique Farmland or Farmland of Statewide Importance requiring irrigation could have reduced surface water diversions, and it is reasonable to assume that a portion could potentially be converted to nonagricultural uses even though land could be maintained in agricultural use through the crop substitution, crop rotation, and dry land farming. Specifically, reductions in surface water diversions could result in reduced acres of irrigated land for Alfalfa, Pasture, Corn, Grain, and Field in SSJID, OID, MID, and Merced ID; Rice and Safflower in SSJID, OID, and MID; Dry Bean and	Less than significant—No reduction or conversion of agricultural acreage is likely because water quality within the southern Delta is expected to remain unchanged as USBR would be responsible for complying with the same salinity requirements that currently exist at Vernalis.	Less than significant—No reduction or conversion of agricultural acreage is likely because water quality within the southern Delta is expected to remain unchanged as USBR would be responsible for complying with the same salinity requirements that currently exist at Vernalis.

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
	to nonagricultural uses as a result of the reductions in surface water diversions on the Stanislaus River. The average reduction in surface water diversions of 9% would be slightly greater than the reduction under LSJR Alternative 2 with adaptive implementation (average reduction of % with implementation of adaptive implementation method 1[30% unimpaired flow]) and slightly less than the reduction described for LSJR Alternative 3 (average reduction of 12% at 40% unimpaired flow requirement). LSJR Alternative 3 would result in significant impacts on agricultural resources of the irrigation districts that receive water from the Stanislaus River. Although reductions in surface water supply under the No Project Alternative would be slightly less than those expected for LSJR Alternative 3, significant impacts would occur.		MID; and Dry Beans and Processing Tomatoes in SSJID. Those potential average reductions in irrigated acreage range from 0.8% for Merced ID to 9.9% for MID.	Cucurbits in SSJID, OID, MID, and Merced ID; Processing and Fresh Tomato and Truck in SSJID, and Truck in SSJID, MID, and TID. Those potential average reductions in irrigated acreage range from 2.6% for Merced ID to 27.5% for MID.		
AG-2: Involve other changes in the existing environment which, due to their location or nature, could result in a conversion of farmland to nonagricultural use	Less than significant—Flows on the Stanislaus River would be increased, which may result in seepage; however, given the small amount of acreage for crops that could be affected, impacts would be less than significant. Similar to conditions under the LSJR alternatives, given the cost of feed input compared to other dairy inputs and the availability of the feed input, the value of dairy production in the LSJR area of potential effects, and the potential use of equitable distributions from local water suppliers, it is unlikely that dairies, as an agricultural use, would be converted to nonagricultural uses. Impacts would be less than significant.	Less than significant—Impacts on irrigated agriculture from a high water table resulting from increased river flows on the Stanislaus River are expected on less than 0.01% of irrigated acreage; therefore, crop production would not be substantially reduced.	Less than significant—Impacts on irrigated agriculture from a high water table resulting from increased river flows on the Stanislaus River are expected on less than 0.1% of irrigated acreage; therefore, crop production would not be substantially reduced. Given cost of feed input compared to other dairy inputs and the availability of the feed input, the value of dairy production in the LSJR area of potential effects, and the potential use of equitable distribution of local water suppliers, it is unlikely dairies, as an agricultural use, would be converted to nonagricultural uses.	Less than significant—Impacts on irrigated agriculture from a high water table resulting from increased river flows on the Stanislaus River are expected on less than 0.1% of irrigated acreage; therefore, crop production would not be substantially reduced. Given cost of feed input compared to other dairy inputs and the availability of the feed input, the value of dairy production in the LSJR area of potential effects, and the potential use of equitable distribution of local water suppliers, it is unlikely dairies, as an agricultural use, would be converted to nonagricultural uses.	Less than significant – Conversion of farmland to nonagricultural use is not expected because water quality within the southern Delta is expected to remain unchanged as USBR would be responsible for complying with the same salinity requirements that currently exist at Vernalis.	Less than significant – Conversion of farmland to nonagricultural use is not expected because water quality within the southern Delta is expected to remain unchanged as USBR would be responsible for complying with the same salinity requirements that currently exist at Vernalis.
AG-3: Conflict with existing zoning for agricultural use or a Williamson Act contract	Less than significant—The No Project Alternative would not conflict with existing zoning for agricultural use or Williamson Act contracts because the No Project Alternative would not change zoning. Lands that are under	Less than significant—This alternative would not conflict with existing zoning for agricultural use or Williamson Act contracts because it would not change zoning, and lands that are under Williamson Act	Less than significant—This alternative would not conflict with existing zoning for agricultural use or Williamson Act contracts because it would not change zoning, and lands that are under Williamson Act	Less than significant—This alternative would not conflict with existing zoning for agricultural use or Williamson Act contracts because it would not change zoning, and lands that are under Williamson Act	Less than significant—This alternative would not conflict with existing zoning for agricultural use or Williamson Act contracts because it would not change zoning, and agricultural lands would	Less than significant—This alternative would not conflict with existing zoning for agricultural use or Williamson Act contracts because it would not change zoning, and agricultural lands would

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
	Williamson Act contracts must be maintained in the compatible uses specified in those contracts until non-renewed, canceled, or otherwise withdrawn from contract. Lands that experience a reduction in surface water supply could be dry farmed, rotated, or fallowed, all of which would be agricultural activities that are consistent with agricultural zoning and Williamson Act contracts.	contracts must be maintained in the compatible uses specified on those contracts until non-renewed, canceled, or otherwise withdrawn from contract. AG-4: Conflict with any applicable land use plan, policy, or regulation related to agriculture of an agency with jurisdiction over a project (including, but not limited to the general plan, specific plan, local coastal program, or zoning ordinance) adopted for the purpose of avoiding or mitigating an environmental effect	Less than significant— The No Project Alternative would not conflict with applicable land use plans, policies, or regulations because while some agricultural land could be taken out of irrigated agricultural use as a result of the No Project Alternative, many of these lands could actually remain in agricultural use, even if they are not irrigated. Furthermore, local agencies have accommodated the conversion and preservation or protection of agricultural lands through various means including: agricultural mitigation programs, agricultural preservation easements, or general plan policies that protect and preserve agricultural land.	Less than significant— This alternative would not conflict with applicable land use plans, policies, or regulations because it is not proposing amendments to existing land use plans, policies, or regulations. While some agricultural land could be taken out of irrigated agricultural use as a result of this alternative, many of these lands could remain in agricultural use, even if they are not irrigated and must remain in uses that are compatible with applicable local land use plans, policies or regulations.	Less than significant— This alternative would not conflict with applicable land use plans, policies, or regulations because it is not proposing amendments to existing land use plans, policies, or regulations. While some agricultural land could be taken out of irrigated agricultural use as a result of this alternative, many of these lands could remain in agricultural use, even if they are not irrigated and must remain in uses that are compatible with applicable local land use plans, policies or regulations.	Less than significant— This alternative would not conflict with applicable land use plans, policies, or regulations because it is not proposing amendments to existing land use plans, policies, or regulations. While some agricultural land could be taken out of irrigated agricultural use as a result of this alternative, many of these lands could remain in agricultural use, even if they are not irrigated and must remain in uses that are compatible with applicable local land use plans, policies or regulations.	No impact— This alternative would not conflict with applicable land use plans, policies, or regulations because it would not change zoning, and agricultural lands would continue to divert water from existing waterways and rely on suitable water quality to irrigate crops.	No impact— This alternative would not conflict with applicable land use plans, policies, or regulations because it would not change zoning, and agricultural lands would continue to divert water from existing waterways and rely on suitable water quality to irrigate crops.
Chapter 12: Cultural Resources						
CUL-1: Cause a substantial adverse change in the significance of a historical or archaeological resource	Significant—Changes in river flows are not expected to alter the low potential for significant cultural resources to exist along rivers due to previous natural and anthropogenic disturbances. Given the low potential, impacts would be less than significant on the three eastside tributaries and the LSJR. Reservoir elevations at New Don Pedro and Lake McClure are expected to remain relatively constant when compared to baseline. Therefore, substantial adverse changes in the significance of historical or archeological resources are not expected at these	Less than significant—The expected changes in reservoir elevations are within historical fluctuations, and known or unknown significant cultural resources are expected to continue to be inundated or exposed as usual under current operations. Additionally, historic property management plans at the reservoirs would continue to be implemented. Changes in river flows are not expected to alter the low potential for significant cultural resources to exist along rivers due to previous natural and	Less than significant—The expected changes in reservoir elevations are within historical fluctuations, and known or unknown significant cultural resources are expected to continue to be inundated or exposed as usual under current operations. Additionally, historic property management plans at the reservoirs would continue to be implemented. Changes in river flows are not expected to alter the low potential for significant cultural resources to exist along rivers due to previous natural and	No impact – The historic range of salinity because Vernalis water quality would be maintained through the program of implementation. Since the chemical properties of the baseline water quality conditions would not change, there would be no potential to substantially adversely impact significant cultural resources.	No impact—The historic range of salinity because Vernalis water quality would be maintained through the program of implementation. Since the chemical properties of the baseline water quality conditions would not change, there would be no potential to substantially adversely impact significant cultural resources.

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
	reservoirs. However, the end-of-September storage at New Melones Reservoir is anticipated to be greatly reduced in over half the years when compared to baseline, and this would most likely expose cultural resources, and could result in a substantial adverse change to the significance of existing cultural resources if they were disturbed by people or disturbed by another physical method (e.g., light, exposure).	anthropogenic disturbances.	anthropogenic disturbances.	anthropogenic disturbances.		
CUL-2: Disturb any human remains, including those interred outside formal cemeteries	Less than significant—The potential for human remains to exist within the fluctuation zone of the reservoirs is low. As a result, the changes in New Melones Reservoir elevations under the No Project Alternative are unlikely to result in disturbance of human remains. In addition, considering the prior disturbance by agriculture, irrigation practices, mining activities, and development within the riverine floodplains, the change in flows under the No Project Alternative would have an extremely low potential to disturb documented or currently undocumented human remains, including those interred outside formal cemeteries.	Less than significant—The expected changes in reservoir elevations are within historical fluctuations and are not expected to affect human remains due to low potential for human remains to exist within the fluctuation zone of the reservoirs Additionally, existing management plans at the reservoirs would continue to be implemented. Additionally, any human remains would be treated in accordance with existing state and federal regulations. Changes in river flows are not expected to alter the low potential for undocumented human remains to exist along rivers due to previous natural and anthropogenic disturbances.	Less than significant—The expected changes in reservoir elevations are within historical fluctuations and are not expected to affect human remains due to low potential for human remains to exist within the fluctuation zone of the reservoirs Additionally, existing management plans at the reservoirs would continue to be implemented. Additionally, any human remains would be treated in accordance with existing state and federal regulations. Changes in river flows are not expected to alter the low potential for undocumented human remains to exist along rivers due to previous natural and anthropogenic disturbances.	Less than significant—The expected changes in reservoir elevations are within historical fluctuations and are not expected to affect human remains due to low potential for human remains to exist within the fluctuation zone of the reservoirs Additionally, existing management plans at the reservoirs would continue to be implemented. Additionally, any human remains would be treated in accordance with existing state and federal regulations. Changes in river flows are not expected to alter the low potential for undocumented human remains to exist along rivers due to previous natural and anthropogenic disturbances.	No impact – See CUL-1.	No impact – See CUL-1.
CUL-3: Directly or indirectly destroy a unique paleontological resource or site or unique geologic feature	Significant—The potential for paleontological resources within and adjacent to the LSJR and the Stanislaus, Tuolumne, and Merced Rivers is considered low due to the depth of occurrence of rock units with high paleontological potential below reworked surficial sediments and Holocene-age floodplain and channel deposits. Buried paleontological resources would be found at soil and rock depth too deep for the rivers to modify or change. Reservoir elevations at New Don Pedro and Lake McClure are expected to remain relatively	Less than significant—The expected changes in reservoir elevations are within historical fluctuations, and unique paleontological or geologic resources, specifically caves, are expected to continue to be inundated and exposed as they currently are under operations. Additionally, the documented caves are managed and protected under a cave management plan. Changes in river flows are not expected to alter the low potential for paleontological resources to	Less than significant—The expected changes in reservoir elevations are within historical fluctuations, and unique paleontological or geologic resources, specifically caves, are expected to continue to be inundated and exposed as they currently are under operations. Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
	constant or generally greater, not significantly reduced, when compared to baseline. Therefore, disturbance of unique paleontological resources is not expected at these reservoirs. However, the-end-of September storage at New Melones is anticipated to be greatly reduced in over half the years when compared to baseline, and this could lead to the disturbance of paleontological resources, such as caves.	exist along rivers due to depth of occurrence of rock units with high paleontological potential.	resources to exist along rivers due to depth of occurrence of rock units with high paleontological potential.	resources to exist along rivers due to depth of occurrence of rock units with high paleontological potential.		
Chapter 13: Service Providers						
SP-1: Require or result in the construction of new water supply facilities or wastewater treatment facilities or expansion of existing facilities, the construction of which could cause significant environmental effects	Significant— Under existing conditions, existing wastewater treatment plant dischargers (i.e., Cities of Tracy, Stockton, and Manteca, and Mountain House CSD) are required to comply with National Pollution Discharge Elimination System (NPDES) permit requirements and waste discharge requirements. However, the southern Delta salinity water quality objectives do not currently apply to the City of Tracy and other municipal dischargers. If the southern Delta salinity objectives are not applied to the municipal dischargers, then the No Project Alternative would not result in a change to the NPDES permit or other discharger requirements; the No Project Alternative would not result in the need to expand existing facilities or infrastructure and would not result in significant environmental effects. However, it is reasonable to expect that the litigation in City of Tracy v. California State Water Resources Control Board will be resolved in the foreseeable future in a manner that will allow for the application of the Delta salinity objectives to municipal wastewater dischargers. The increase in flow expected under the No Project Alternative would reduce the salinity in the southern Delta at the interior compliance stations and achieve compliance at	Less than significant—Average surface water diversions on the Stanislaus, Tuolumne, and Merced Rivers would be reduced by 2%, 2%, and 6%, respectively, compared to baseline conditions. Further, there would not be a substantial depletion of groundwater supplies; therefore, it is not expected that service providers or public water suppliers would need to construct or operate new water supply or wastewater treatment facilities or expand existing facilities.	Significant and unavoidable—Surface water diversion reductions on the Stanislaus, Tuolumne, and Merced Rivers are expected to be approximately 12%, 14% and 16%, respectively. Further, as a result of the substantial reduction of surface water supply on the rivers, it is expected that there would be a substantial depletion of groundwater supplies in the Modesto, Turlock, and Extended Merced Subbasins. These reductions would potentially require service providers to construct new or expanded water supply or wastewater treatment facilities, the construction of which could result in significant environmental effects.	Significant and unavoidable—Surface water diversion reductions on the Stanislaus, Tuolumne, and Merced Rivers are expected to be approximately 32%, 35%, and 32%, respectively. Further, as a result of the substantial reduction of surface water supply on the rivers, it is expected that there would be a substantial depletion of groundwater supplies in the Eastern San Joaquin, Modesto, Turlock, and Extended Merced Subbasins. These reductions would potentially require service providers to construct new or expanded water supply or wastewater treatment facilities, the construction of which could result in significant environmental effects.	Significant and unavoidable—The Cities of Tracy, Stockton and Mountain House CSD may need to construct new wastewater treatment facilities or expand existing facilities to comply with potential changes to NPDES effluent limitation implementing a 1.0 dS/m salinity objective, the construction of which could result in significant environmental effects.	Less than significant—The construction of new wastewater treatment facilities is not expected in order to comply with changes to NPDES effluent limitations implementing a 1.4 dS/m objective for salinity. As such, construction would not occur and would not result in significant environmental effects.

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
	these stations. However, based on current effluent discharge concentrations and past violations, it is unlikely that existing service providers would be able to meet the current 2006 Bay-Delta Plan salinity objective of 0.7 dS/m from April to August. Additionally, it is unlikely that the Cities of Tracy and Stockton meet the current 2006 Bay-Delta Plan salinity objective of 1.0 dS/m from September–March. Therefore, it is expected that these service providers would exceed wastewater treatment requirements during some parts of the year and that the construction of new wastewater treatment facilities, or the expansion of existing facilities or infrastructure, could result; construction or operation of the facilities could cause significant environmental effects.					
SP-2a: Violate any water quality standards such that drinking water quality from public water systems would be affected	Less than significant— The No Project Alternative is unlikely to reduce surface drinking water quality because flows at Vernalis would be higher than baseline. In addition, a higher flow at Vernalis is generally associated with better water quality. A reduction in the quality of groundwater drinking supply is not expected because the effect of the No Project Alternative on groundwater supplies is expected to be less than significant (as shown in Impact GW-1 has under the No Project Alternative).	Less than significant—Because service providers and irrigation districts relying primarily on surface water would not need to supplement their supply with groundwater under LSJR Alternative 2, there would likely be no degradation of groundwater quality. During some months, salinity in the SJR at Vernalis and in the southern Delta channels may increase slightly, but on average, salinity is expected to be reduced; therefore, a substantial degradation of water quality affecting service providers diverting drinking water from the southern Delta would not occur, and impacts would be less than significant	Less than significant—As a result of increased groundwater pumping, reductions in groundwater levels in the Modesto, Turlock, and Extended Merced Subbasins under LSJR Alternative 3 could affect groundwater quality. However, a substantial increase in groundwater pumping would not necessarily result in an increase in violation of water quality standards for drinking water because recent data do not indicate increased water quality standard violations in public water systems despite greatly increased groundwater pumping, and if a drinking water quality problem is detected, action would be taken (as covered under SP-1) to improve water quality. Salinity in the SJR at Vernalis and in the southern Delta channels is expected to be reduced; therefore, a substantial degradation of	Less than significant—As a result of increased groundwater pumping, reductions in groundwater levels in the Modesto, Turlock, Merced and Easter San Joaquin Subbasins. However, a substantial increase in groundwater pumping would not necessarily result in an increase in violation of water quality standards for drinking water because recent data do not indicate increased water quality standard violations in public water systems despite greatly increased groundwater pumping, and if a drinking water quality problem is detected, action would be taken (as covered under SP-1) to improve water quality. Salinity in the SJR at Vernalis and in the southern Delta channels is expected to be reduced; therefore, a substantial degradation of water quality affecting service providers diverting drinking	Less than significant—The USBR water rights permits will continue to include requirements to meet the current 0.7 EC April–August Vernalis salinity standard, as contained in the program of implementation. This would maintain the historical range of salinity in the southern Delta. Therefore, a substantial degradation of water quality affecting service providers diverting drinking water from the southern Delta would not occur.	Less than significant—The USBR water rights permits will continue to include requirements to meet the current 0.7 EC April–August Vernalis salinity standard, as contained in the program of implementation. This would maintain the historical range of salinity in the southern Delta. Therefore, a substantial degradation of water quality affecting service providers diverting drinking water from the southern Delta would not occur.

Impact	No Project Alternative (LSJR/SDWQ Alternative 1)	LSJR Alternative 2a	LSJR Alternative 3 a	LSJR Alternative 4 a	SDWQ Alternative 2	SDWQ Alternative 3
			water quality affecting service providers diverting drinking water from the southern Delta would not occur. Therefore, impacts would be less than significant.	water from the southern Delta would not occur. Therefore, impacts would be less than significant.		
SP-2b: Violate any water quality standards such that drinking water quality from domestic wells would be affected.c	Less than significant- See SP-2a.	Less than significant—Because service providers and irrigation districts relying primarily on surface water would not need to supplement their supply with groundwater under LSJR Alternative 2, there would likely be no degradation of groundwater quality.	Significant and unavoidable—As a result of increased groundwater pumping, reductions in groundwater levels in the Modesto, Turlock, and Extended Merced Subbasins could affect groundwater quality. Domestic well users are largely unregulated and are under no state requirements to monitor, test, and treat their water to meet the state and federal Safe Drinking Water Act. There is no required mechanism to prevent private domestic wells from using groundwater that may exceed MCLs. Therefore, impacts would be significant.	Significant and unavoidable—As a result of increased groundwater pumping, reductions in groundwater levels in the Modesto, Turlock, Merced and Easter San Joaquin Subbasins could affect groundwater quality. Domestic well users are largely unregulated and are under no state requirements to monitor, test, and treat their water to meet the state and federal Safe Drinking Water Act. There is no required mechanism to prevent private domestic wells from using groundwater that may exceed MCLs. Therefore, impacts would be significant.	No impact—Salinity in the SJR at Vernalis and in the southern Delta is not relevant to groundwater and drinking water quality from domestic wells and, therefore, there would be no impact from the changes in salinity in these surface waters.	No impact—Salinity in the SJR at Vernalis and in the southern Delta is not relevant to groundwater and drinking water quality from domestic wells and, therefore, there would be no impact from the changes in salinity in these surface waters.
SP-3: Result in substantial changes to SJR inflows to the Delta such that insufficient water supplies would be available to service providers relying on CVP/SWP exports	Less than significant—Under the No Project Alternative, average annual inflows to the Delta at Vernalis would increase slightly relative to baseline as a result of the No Project Alternative, and average annual exports could increase slightly, by 26 TAF/y. Consequently, service providers relying on CVP/SWP exports would not be adversely affected.	Less than significant—Inflows would generally remain similar to baseline and, as such, a reduction in average annual exports to the CVP and SWP export service areas is not expected. Therefore, insufficient water supplies to service providers relying on exports would not occur and would not require or result in the construction of new water supply facilities or wastewater treatment facilities or the expansion of existing facilities.	Less than significant—Inflows would generally increase relative to baseline, which would result in an estimated average increase in exports of 76 TAF/y to the CVP and SWP export service areas. Therefore, insufficient water supplies to service providers relying on exports would not occur and would not require or result in the construction of new water supply facilities or wastewater treatment facilities or the expansion of existing facilities.	Less than significant—Inflows would generally increase relative to baseline, which would result in an estimated average increase in exports of 194 TAF/y to the CVP and SWP export service areas. Therefore, insufficient water supplies to service providers relying on exports would not occur and would not require or result in the construction of new water supply facilities or wastewater treatment facilities or the expansion of existing facilities.	No impact – The flows to satisfy the USBR Vernalis EC requirement contained in the program of implementation are already included in the modeling results for the LSJR alternatives.	No impact – The flows to satisfy the USBR Vernalis EC requirement contained in the program of implementation are already included in the modeling results for the LSJR alternatives.
Chapter 14: Energy and Greenhouse Gases						
EG-1: Adversely affect the reliability of California's electric grid	Less than significant—Under the No Project Alternative, a moderate reduction in the capacity of New Melones hydroelectric plant in July and August during dry years could result in minor reliability violations. However, the New Melones hydroelectric plant is located in a SMUD region. The report of SMUD's	Less than significant—Transmission line loadings would not exceed the limits under contingency outage conditions because hydropower generation and reservoir elevation would not be substantially modified. Therefore, adverse effects on	Less than significant—Transmission line loadings would not exceed the limits under contingency outage conditions because hydropower generation and reservoir elevation would not be substantially modified. Therefore, adverse effects on	Less than significant—Transmission line loadings would not exceed the limits under contingency outage conditions after re-dispatch of generator facilities to correct a minor violation between Borden and Gregg substations and Gregg and Storey	No impact—The general historical range of salinity in the southern Delta would remain unchanged under and, thus, would not adversely affect the reliability of California's electric grid.	No impact— The general historical range of salinity in the southern Delta would remain unchanged and, thus, would not adversely affect the reliability of California's electric grid.

	2013 Ten-year Transmission Assessment Plan indicates that there are adequate generating resources in the SMUD region to meet its load demand and planning reserve margin obligations until 2018. So it is likely that the minor violations could be alleviated by re-dispatching electrical power from other generating resources available either in a local region or neighboring regions. Therefore, the No Project Alternative would not adversely affect the reliability of California's electric grid and the impact of the reduction in the New Melones capacity would be less than significant.	the reliability of California's electric grid would not occur.	the reliability of California's electric grid would not occur.	substations. Re-dispatches are regular occurrences in the California energy grid, and they provide a solution to redistribute power. Therefore, adverse effects on the reliability of California's electric grid would not occur.		
EG-2: Result in inefficient, wasteful, and unnecessary energy consumption	Less than significant— The No Project Alternative could result in additional energy consumption as a result of groundwater pumping. However, because groundwater pumping may be necessary to maintain the water supply irrigation demand, the No Project Alternative would not result in inefficient, wasteful, and unnecessary consumption of energy. Furthermore, it is anticipated that if new groundwater wells were to be installed, they would be efficient. The No Project Alternative could result in additional energy generation at other facilities to compensate for a potential loss of hydropower. However, this increased electricity generation is not considered inefficient, wasteful, and unnecessary as it is energy that would be generated to maintain the energy supply level that is currently supplied by hydropower.	Less than significant—Additional groundwater pumping would not result in inefficient, wasteful, and unnecessary consumption of energy to the extent groundwater pumping is used to meet water supply irrigation demand in accordance with state law. Additional energy generation at other facilities to compensate for a potential loss of hydropower would not be considered inefficient, wasteful, and unnecessary as it is energy that would be generated to maintain the energy supply level that is currently supplied by hydropower. Therefore, there would be no inefficient, wasteful or unnecessary energy consumption.	Less than significant—Additional groundwater pumping would not result in inefficient, wasteful, and unnecessary consumption of energy to the extent groundwater pumping is used to meet water supply irrigation demand in accordance with state law. Additional energy generation at other facilities to compensate for a potential loss of hydropower would not be considered inefficient, wasteful, and unnecessary as it is energy that would be generated to maintain the energy supply level that is currently supplied by hydropower. No impact—The general historical range of salinity in the southern Delta would remain unchanged under and, thus, would not result in inefficient, wasteful, and unnecessary energy consumption.
EG-3: Generate GHG emissions, either directly or indirectly, that have a significant impact on the environment	Significant—The No Project Alternative could result in an increase in groundwater pumping and a potential shift from hydropower to non-hydropower energy production as a result of the expected reduction in surface water diversions and change to flow on the Stanislaus River. Both of these	Less than significant—Emissions would not exceed the 10,000 MTCO2e threshold. Therefore, GHG emissions would not have a significant impact on the environment.	Significant and unavoidable—Emissions exceed the 10,000 MT CO2e threshold. Therefore, GHG emissions would have a significant impact on the environment. 	would be expected to generate GHG emissions greater than the threshold of 10,000 MT of GHGs, as described for both LSJR Alternative 3 and 4.				(Table 18-8) that could exceed GHG thresholds depending on the nature of the activity.	facilities in the southern Delta (Table 18-8) that could exceed GHG thresholds depending on the nature of the activity.
EG-4: Conflict with an applicable plan, policy, or regulation adopted for the purposes of reducing the GHG emissions	Significant—Since the No Project Alternative would exceed the 10,000 MT GHG threshold, it would conflict with existing applicable plans, policies, or regulations adopted for the purposes of reducing GHG emissions, such as AB32, the California Global Warming Solutions Act.	Less than significant—Since GHG emissions would not exceed the 10,000 MT CO2e threshold, there would be no conflict with applicable plans, policies or regulations adopted for the purpose of reducing GHGs.	Significant and unavoidable— – Since GHG emissions would exceed the 10,000 MT CO2e threshold, there would be a conflict with applicable plans, policies or regulations adopted for the purpose of reducing GHGs.	Significant and unavoidable—Since GHG emissions would exceed the 10,000 MT CO2e threshold, there would be a conflict with applicable plans, policies or regulations adopted for the purpose of reducing GHGs.	No impact – The general historical range of salinity in the southern Delta would remain unchanged and, thus, would not result in GHG emissions or conflict with an applicable plan, policy or regulation adopted for the purpose of reducing GHG emissions.	No impact – The general historical range of salinity in the southern Delta would remain unchanged and, thus, would not result in GHG emissions or conflict with an applicable plan, policy or regulation adopted for the purpose of reducing GHG emissions.
EG-5: Effect of global climate change on the LSJR and SDWQ alternatives	Less than significant—The State Water Board is required to prepare WQCPs. The WCQPs are regularly reviewed to update water quality standards. As a result, the planning process continually accounts for changing conditions related to water quality and water planning, such as climate change. Therefore, the effect of global climate change on the No Project Alternative would be less than significant.	Less than significant—Climate change would not significantly affect LSJR Alternative 2 because adaptive implementation would allow agencies to respond to changing circumstances with respect to flow and water quality that might arise due to climate change. Furthermore, the required review and update of WQCPs, accounted for in the program of implementation, continually accounts for changing conditions related to water quality and water planning such as climate change.	Less than significant—Climate change would not significantly affect LSJR Alternative 3 because adaptive implementation would allow agencies to respond to changing circumstances with respect to flow and water quality that might arise due to climate change. Furthermore, the required review and update of WQCPs, accounted for in the program of implementation, continually accounts for changing conditions related to water quality and water planning such as climate change.	Less than significant—Climate change would not significantly affect LSJR Alternative 4 because adaptive implementation would allow agencies to respond to changing circumstances with respect to flow and water quality that might arise due to climate change. Furthermore, the required review and update of WQCPs, accounted for in the program of implementation, continually accounts for changing conditions related to water quality and water planning such as climate change.	Less than significant—Climate change would not significantly affect SDWQ Alternative 2 because the required review and update of WQCPs, accounted for in the program of implementation, continually accounts for changing conditions related to water quality and water planning, such as climate change.	Less than significant – Climate change would not significantly affect SDWQ Alternative 3 because the required review and update of WQCPs, accounted for in the program of implementation, continually accounts for changing conditions related to water quality and water planning, such as climate change.

Chapter 19
Analyses of Benefits to Native Fish Populations from Increased Flow between February 1 and June 30

19.1 General Introduction

The State Water Resources Control Board (State Water Board) is in the process of reviewing the San Joaquin River (SJR) flow objectives for the protection of fish and wildlife beneficial uses, water quality objectives for the protection of southern delta agricultural beneficial uses, and the program of implementation for those objectives contained in the 2006 Water Quality Control Plan for the San Francisco Bay/Sacramento-San Joaquin Delta Estuary (2006 Bay-Delta Plan). The project area, which includes the Stanislaus, Tuolumne, and Merced Rivers and the Lower SJR (LSJR) between the confluence of the Merced River and Vernalis, is the focus of the following benefits analysis.

This chapter presents biologically important and measurable benefits of providing higher and more variable flow during the February 1 through June 30 time period. Specifically, the benefits of improved temperature and floodplain habitat relative to Central Valley fall-run Chinook salmon (*Oncorhynchus tshawytscha*) and Central Valley steelhead (*Oncorhynchus mykiss*) during February through June are quantified and compared between Baseline flows, and 20%, 30%, 40%, 50%, and 60% unimpaired flows[1] on the lower Stanislaus, Tuolumne, Merced, and LSJ Rivers. However, modifying flows in this time period may have unanticipated temperature benefits or impacts during other time periods. For example, modifying flow requirements in the spring season could alter reservoir levels in the fall and result in changes to river temperatures. Therefore, potential temperature effects were analyzed during all months of the year on these rivers. By evaluating the full range of unimpaired flows (20-60%), and evaluating effects during all months of the year, this chapter includes the range of unimpaired flows that could occur under the LSJR alternatives described in Chapter 3, *Alternatives Description*, because adaptive implementation could be applied to each of the alternatives.

In addition to evaluating temperature and floodplain benefits of the project, a life-history population simulation model for fall-run Chinook salmon originating from the SJR and its upper three east-side salmon bearing tributaries (Stanislaus, Tuolumne, and Merced Rivers) was used to provide insight into population level changes that could be expected under a variety of unimpaired flow scenarios. The model used is called SalSim and was developed by the California Department of Fish and Wildlife (CDFW), AD Consultants, and a variety of other modeling and fisheries experts (CDFW 2013a; CDFW 2014). The State Water Board used the model to compare effects of unimpaired and baseline flow scenarios on salmon by evaluating potential changes in annual salmon production.

---

[1] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.

The results of the temperature, floodplain, and SalSim analysis presented in this chapter indicate that as the percentage of unimpaired flow is increased during the February through June time period, the flow related benefits to salmon and steelhead also increase. Improving flows that mimic the natural hydrographic conditions including related temperature and floodplain regimes to which native fish species are adapted, are expected to provide many juvenile salmonids with additional space, time, and food resources which are necessary for required growth, development, and survival. Extending spatial, temporal, and nutritional opportunities available to juvenile fall-run Chinook salmon and steelhead in the Stanislaus, Tuolumne, and Merced Rivers is expected to improve abundance, productivity, diversity, and spatial structure of the SJR Basin and Central Valley populations, and should also provide substantial benefits to other native fish in the SJR Watershed. Improving and maintaining these important population attributes should help buffer SJR Basin and Central Valley fall-run Chinook salmon populations from catastrophic events and conditions in the future.

Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*, documents the scientific basis and technical resources that were used in the recirculated substitute environmental document (SED) to analyze project effects in accordance with CEQA requirements. The purpose of this chapter is to supplement the information contained in Appendix C by quantitatively evaluating the benefits of this project in terms of potentially available cold water and floodplain habitats, and associated population implications to native salmonids.

The information contained in this chapter is intended to assist the State Water Board in its water quality control planning process and decision making as part of that process. The water quality control planning process has requirements separate and apart from CEQA and the information contained in this chapter is not a requirement of CEQA. One of the purposes of CEQA is to inform governmental decision makers and the public about the potential, significant environmental effects of proposed activities (State CEQA Guidelines, § 15002(a)(1)). Significant effects on the environment are defined as a substantial adverse change in physical conditions which exist in the area affected by the proposed project (i.e., significant impacts) (State CEQA Guidelines, § 15002(g)). To satisfy CEQA requirements, impacts on various resources are evaluated and significance determinations are made in Chapters 5 through 16 and Appendix B, *State Water Board's Environmental Checklist*, of this SED.

19.1.1 Problem Statement

Scientific evidence indicates that reductions in flows and alterations to the flow regime in the SJR Basin, resulting from water development over the past several decades, have negatively impacted fish and wildlife beneficial uses. As outlined in Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*, water development in the SJR Basin has resulted in: reduced annual flows, fewer peak flows, reduced and shifted spring and early summer flows, reduced frequency of peak flows from winter rainfall events, shifted fall and winter flows, and a general decline in hydrologic variability over multiple spatial and temporal scales. Currently, there is relatively little unregulated runoff from the SJR Basin with dams regulating at least 90% of the inflow (Cain et al. 2010). Dams and diversions in the SJR Basin have caused a substantial overall reduction of flows, compared to unimpaired hydrographic conditions, with a median reduction in annual flows at Vernalis of 54% and median reduction of spring flows of 74%, 83%, and 81% during April, May, and June, respectively.

The SJR Basin once supported large spring-run and fall-run (and possibly late fall-run) Chinook salmon populations; however, the basin now only supports fall-run Chinook salmon populations, and these populations are facing a high risk of extinction (see Mesick 2009, 2010a, 2010b). The Stanislaus, Tuolumne, and Merced Rivers (individually or combined) have had larger reductions in the natural production of adult fall-run Chinook salmon than any of the other tributaries (or combination of three tributaries) to the Sacramento or San Joaquin Rivers when comparing the 1967-1991 and 1992-2011 time periods (Figure 19-1).

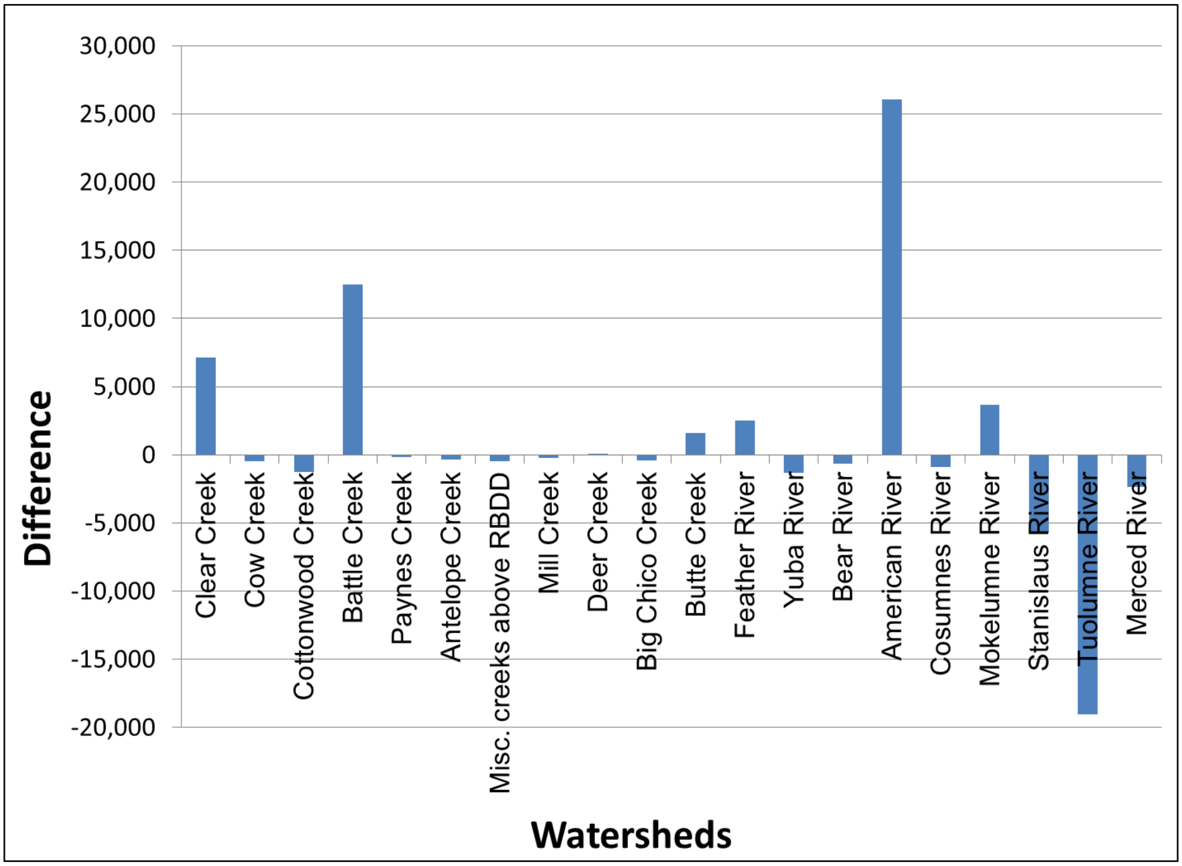

Figure 19-1. Difference in natural production of adult fall-run Chinook salmon when comparing the 1967-1991 average and the 1992-2011 average in tributaries to the Sacramento or San Joaquin Rivers, showing that salmon declines in the tributaries to the San Joaquin River are greater compared to other watersheds in recent decades. Difference = (1992-2011 time period average of estimated yearly natural production as reported in USFWS 2013a) minus (1967-1991 time period average of estimated yearly natural production as reported in USFWS 2013a) (repeated for each watershed).

Flows in the SJR Basin affect various life stages of fall-run Chinook salmon, including adult migration, adult spawning, egg incubation, juvenile rearing, and outmigration to the Pacific Ocean. Analyses of historical abundance indicate that late winter and spring flows (February through June) in the tributaries and mainstem SJR have had a strong influence on survival and abundance of SJR Basin salmon since records began in the 1940s or 1950s (Figure 19-2; and CDFG 2005a; Mesick and Marston 2007; Mesick et al. 2007; Mesick 2009; Sturrock et al. 2015).

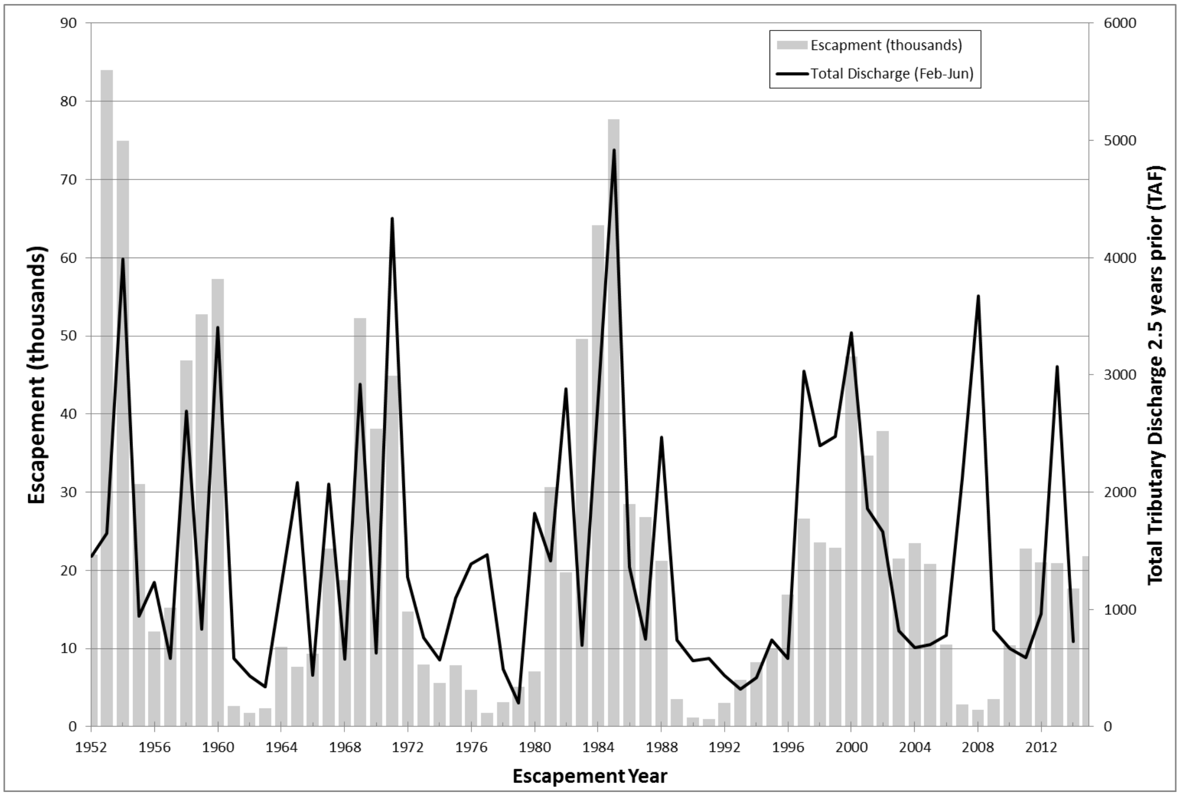

Figure 19-2. Relationship between adult salmon returns to the San Joaquin basin and the river flows they experienced as juveniles. Fall-run Chinook salmon returns (escapement) to the Stanislaus, Tuolumne, and Merced rivers combined from 1952-2014 relative to the total discharge (Thousand Acre-Feet) during the February through June outmigration period they experienced 2.5 years prior as juveniles. Salmon data from CDFW GrandTab 2014.04.22 and GrandTab 2016.04.11. Flow data for the Stanislaus, Tuolumne, and Merced Rivers combined from USGS gages 11303000, 11290000, and 11270900 respectively. Note that adult abundance estimates have not been corrected for age distributions (we assumed that all adults returned at age 3), or for out-of-basin straying. The large deviation in 2007 reflects poor returns that were attributed to poor ocean conditions (Lindley 2009) and resulted in the closure of the fishery. Adapted from Sturrock et al. 2015.

Therefore, while SJR Basin flows at other times are also important, the focus of the State Water Board's current review is on flows within the salmon-bearing tributaries and the mainstem SJR at Vernalis (inflows to the Delta) during the critical salmon rearing and outmigration period of February through June. Scientific evidence indicates that in order to protect fish and wildlife beneficial uses in the SJR Basin, including increasing the populations of SJR Basin fall-run Chinook salmon and Central Valley steelhead to sustainable levels, changes to the current flow regime of the SJR Basin are needed. Specifically, a more natural flow regime from the salmon bearing tributaries (Stanislaus, Tuolumne, and Merced Rivers) is needed during the February through June time frame (see Appendix C *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*,).

19.1.2 Importance of a Natural Flow Regime

There are many important benefits to maintaining a natural flow regime, some of which are described in the following summary by Kiernan et al. (2012, page 1472):

> The flow regime of a stream is often regarded as the ''master variable'' that determines composition of biotic assemblages (Poff and Ward 1989, Power et al. 1995, Matthews 1998). Many environmental factors that affect assemblage structure, including temperature, water chemistry, and physical habitat complexity, are determined by flow to a certain extent (Bunn and Arthington 2002). For streams in Mediterranean climates, such as northern California, USA, annual patterns of precipitation produce a hydrograph characterized by episodic high-discharge events during winter and by protracted periods of low flow throughout summer and early fall. Although the magnitude and frequency of hydrologic disturbance events such as extreme floods and extended low flows are highly variable from year to year, the timing (seasonality) of these events is largely predictable (Gasith and Resh 1999, Power et al. 2008). Thus, many native freshwater and riparian species have evolved traits and life-history strategies to withstand natural hydrologic variability and to rapidly recover from disturbance (Bonada et al. 2007, Power et al. 2008, Yarnell et al. 2010). Conversely, alien (nonnative) species often lack biological and behavioral mechanisms to cope with region-specific flow regimes and are often disproportionately vulnerable (e.g., via physical displacement, recruitment failure, or direct mortality) to high and low stream flow conditions.

As described in Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*, natural flow regimes have been dramatically altered in the Bay-Delta plan area. The Stanislaus, Tuolumne, and Merced Rivers have significantly lower and flatter winter and spring hydrographs, and significantly higher summer and fall hydrographs. See Figure 19-3 as an example of an altered hydrograph during a wet year, and see Figure 19-4 as an example of an altered hydrograph during a critically dry year.

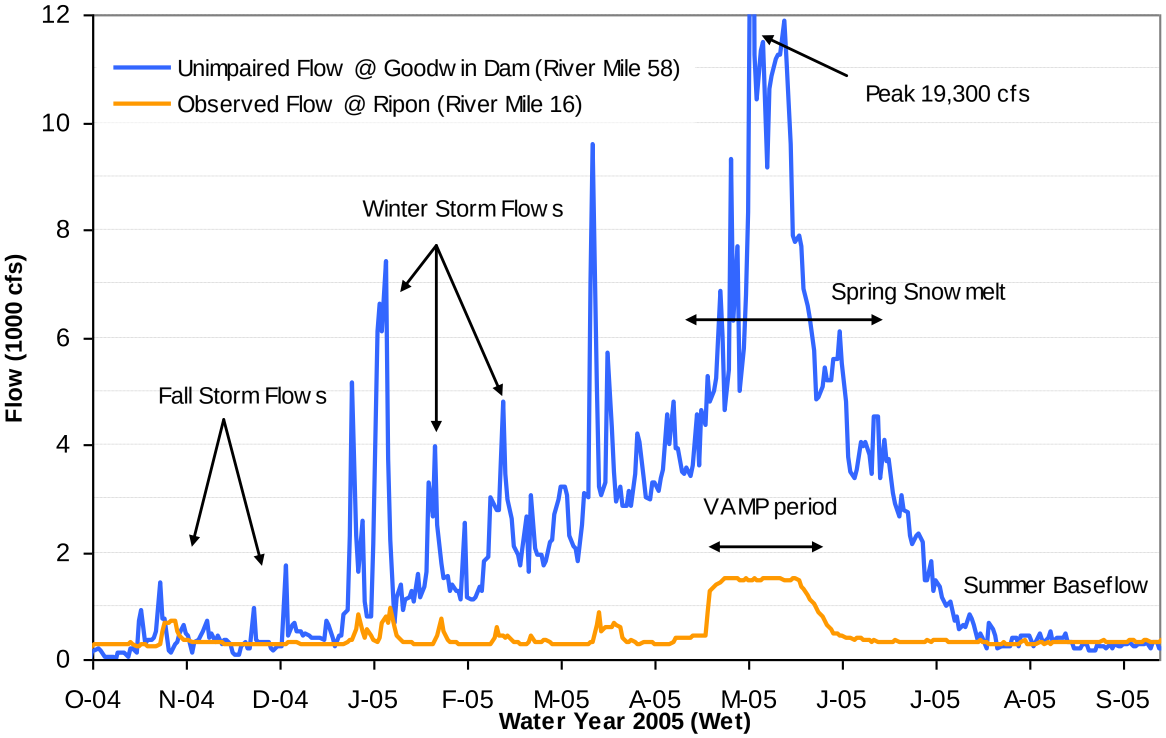

Figure 19-3. Typical Stanislaus River annual hydrograph of daily average unimpaired and observed flows during a wet water year (2005) illustrating important hydrograph components.

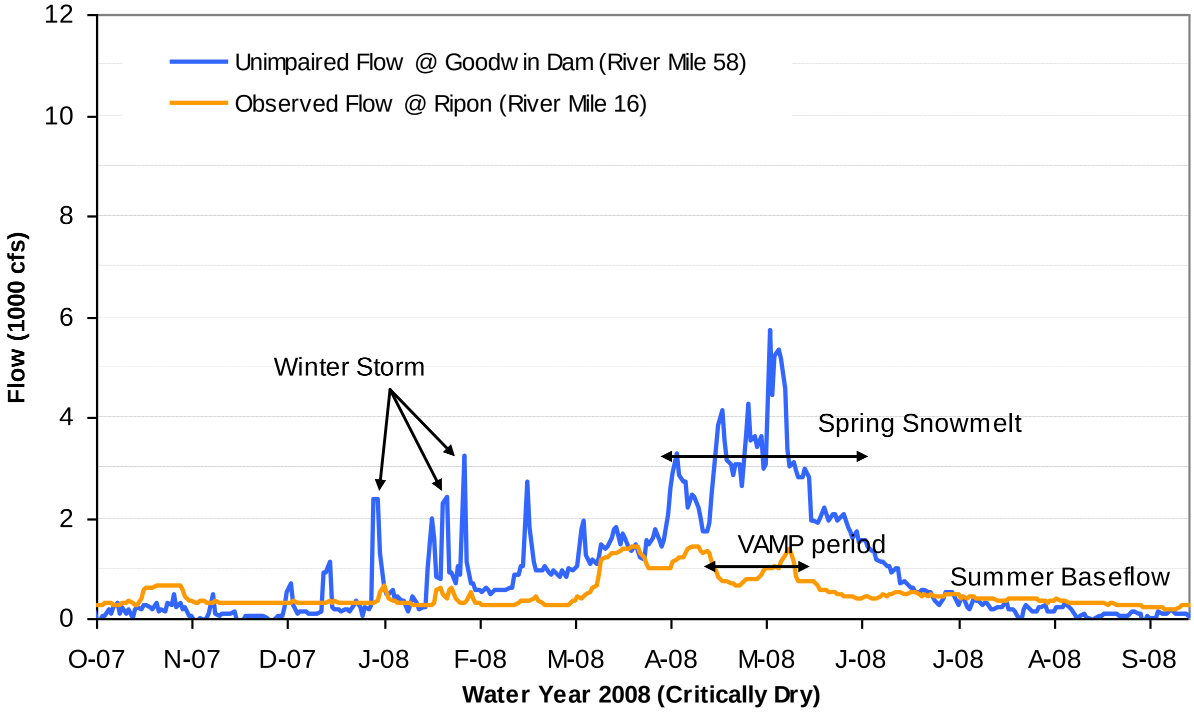

Figure 19-4. Typical Stanislaus River annual hydrograph of daily average unimpaired and observed flows during a critically dry water year (2008) illustrating important hydrograph components.

CalFED (2008) suggested that altering the hydrographs of Central Valley rivers has had significant ecological consequences—including changes in the establishment, distribution, composition, and survival of naturally recruited riparian vegetation; and changes in the timing and distribution of migration, spawning, and rearing of green sturgeon, Chinook salmon, and steelhead.

Seasonally-correct variable flow conditions provide the environment needed to support biological and ecosystem processes which are imperative to the protection of native fish and wildlife beneficial uses. Although changes to ecosystem attributes, in addition to flows, are needed to fully restore biological and ecosystem processes in the Bay-Delta plan area, flow remains a critical element of that restoration.

Using a river's unaltered hydrographic conditions as a foundation for determining ecosystem flow requirements is well supported by scientific literature (Poff et al. 1997; Tennant 1976; Orth and Maughan 1981; Marchetti and Moyle 2001; Mazvimavi et al. 2007; Moyle et al. 2011). In addition, major regulatory programs in Texas, Florida, Australia and South Africa have developed flow prescriptions based on unimpaired hydrographic conditions in order to enhance or protect aquatic ecosystems (Arthington et al. 1992; Arthington et al. 2004; NRDC 2005; Florida Administrative Code 2010), and the World Bank now uses a framework for ecosystem flows based on the unaltered quality, quantity, and timing of water flows (Hirji and Davis 2009). Many researchers involved in developing ecologically protective flow prescriptions concur that mimicking the unimpaired hydrographic conditions of a river is essential to protecting populations of native aquatic species and promoting natural ecological functions (Sparks 1995; Walker et al. 1995; Richter et al. 1996; Poff et al. 1997; Tharme and King 1998; Bunn and Arthington 2002; Richter et al. 2003; Tharme

2003; Poff et al. 2006; Poff et al. 2007; Brown and Bauer 2009). Poff et al. (1997) describe that the flow regime limits the distribution and abundance of riverine species (Resh et al. 1988; Power et al. 1995) and regulates the ecological integrity of rivers. The structure and function of riverine ecosystems, and the adaptations of their constituent freshwater and riparian species, are determined by patterns of intra- and inter-annual variation in river flows (Poff et al. 1997; Naiman et al. 2008, Mount et al. 2012). A key foundation of the natural flow paradigm is that the long-term physical characteristics of flow variability have strong ecological consequences at local to regional scales, and at time intervals ranging from days (ecological effects) to millennia (evolutionary effects) (Lytle and Poff 2004). Nearly every other habitat factor that affects community structure, from temperature, to water chemistry to physical habitat complexity, is determined by flow to a certain extent (Bunn and Arthington 2002).

In a recent analysis of methods used for establishing environmental flows for the Bay-Delta, Fleenor et al. (2010) reported on two methods for determining flows needed to protect the ecosystem: 1) flows based on the unimpaired flow, and 2) flows based on the historical flow. These methods attempt to prescribe flows for the protection of the ecosystem as a whole, and use the biological concept that more variable inflows to the Sacramento-San Joaquin Delta (Delta), which mimic unaltered hydrographic conditions to which native aquatic species have adapted, will benefit native aquatic species. In a separate review of instream flow science by Petts (2009), he reports the importance of two fundamental principles that should guide the derivation of flow needs: 1) flow regime shapes the evolution of the aquatic biota and ecological process; and 2) every river has a characteristic flow regime and associated biotic community. Petts (2009) also finds that flow management should sustain flows that mimic the yearly, seasonal, and perhaps daily variability to which aquatic biota have adapted.

The current updates to the Bay-Delta Plan include improving flow conditions during the February through June time period so that they more closely mimic the natural hydrographic conditions to which native fish species are adapted, including the relative magnitude, duration, timing, and spatial extent of flows as they would naturally occur. This document describes the benefits of the project to native salmon and steelhead in terms of improvements to temperature and floodplain habitat in response to the proposed changes in flow conditions which will more closely mimic the natural hydrographic conditions during February through June.

19.2 Temperature

Dams and reservoirs, and their associated operations, alter the temperature regime of rivers, often to the detriment of native species such as salmonids and other animals, and plants, that are adapted to the natural flow regime of their native rivers (Richter and Thomas 2007; CDFG 2010b). Typically, water stored in reservoirs is warmer at the surface and cooler below the thermocline in deeper waters. The temperature of water within these layers is generally different than the temperature of water entering the reservoir at any given time depending on the season, and is also dissimilar to downstream water temperatures that would occur under a natural flow regime (USACE 1987; Bartholow 2001). In addition to altering downstream temperature regimes, dams also physically block access to cooler high elevation habitats historically available to native migratory fish species.

Currently, temperature management on the major SJR tributaries can only be achieved directly through flow management (NMFS 2009c). While temperature control devices can control the temperature of water released from dams for the protection of downstream fisheries by varying operations of release gates for example, there are currently no temperature control devices to aid in water temperature management on the major SJR tributary dams.

Often, water released from reservoirs is colder in the summer and warmer in the winter compared to water temperatures that would have occurred in the absence of a dam and reservoir (see Figures 19-7, 19-8, and 19-9; Williams 2006). As a result, native aquatic species can experience additional temperature stress due to the river's altered flow and temperature regimes. However, where temperatures are cooler than they would be under a more natural flow regime (because of reservoir discharges of cold water through the summer), populations of *O. mykiss* (both anadromous and resident forms) are often able to persist at lower elevations than they would have historically. These areas are typically in the reaches immediately below dams.

In addition to the changes in water temperature due to reservoir storage, reservoirs and diversions also modify the temperature regime of downstream river reaches by diminishing the volume and thermal mass of water. A smaller quantity of water has less thermal mass and, therefore, a decreased ability to absorb temperatures from the surrounding environment (air and solar radiation) without being impacted (USACE 1987). The greatest impact typically occurs with less flow (less thermal mass) and warmer climate (increased solar radiation), usually in the late spring, summer, and early fall periods (DWR 2013). In highly altered systems such as the SJR Basin, channelization, levees, and loss of riparian habitat contribute to thermal loading which impacts water temperature and native fish species (Williams 2006; Moyle 2008).

On the Stanislaus, Tuolumne, and Merced Rivers water temperature is largely controlled by flow released from the reservoirs. For example, Figure 19-5 illustrates the relationship between average daily water temperature and average daily flow on the Tuolumne River during May at river mile 28.1 from 1980 to 2010 (modeled historic information from the SJR HEC-5Q model).

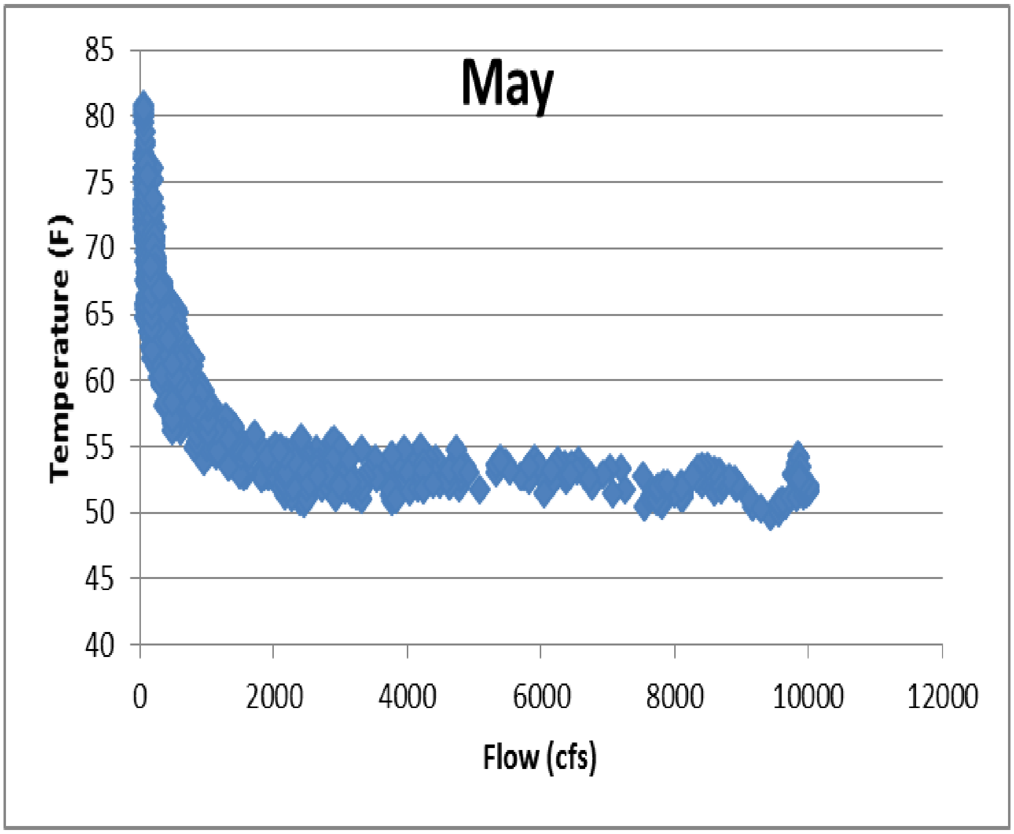

Figure 19-5. Average daily water temperature versus average daily flow relationship on the Tuolumne River during May at river mile 28.1 from 1980 to 2010 (modeled historic information from the SJR HEC-5Q model).

The remainder of this section describes the expected temperature benefits from increased flows during the February through June time period, and provides information as to why improved temperature conditions are important to native fish.

19.2.1 Importance of a Natural Temperature Regime in Aquatic Environments

Effects of Temperature on Aquatic Organisms

Water temperature is crucial to aquatic organisms because it directly influences their metabolism, respiration, feeding, growth, and reproduction. Most aquatic species have an optimal temperature range for growth and reproduction, and they are also bound by upper and lower limits in which they can no longer survive or successfully reproduce. Thus, their natural spatial and temporal distributions are largely determined by regional differences in temperatures driven by climate and elevation along with more local effects from riparian shading, groundwater influence, and other physical influences including flow alteration. Furthermore, water temperature can influence water chemistry, such as the solubility of oxygen in water (Carlisle et al. 2013).

Thermal stress to aquatic organisms can occur when a temperature or a change in temperature produces a significant change to biological functions leading to decreased likelihood of survival and reproduction. Thermal stress can lead to lethal effects either immediately, in a period of days, or even weeks or months from the onset of the elevated temperature. Thermal stress can also result in sublethal or indirect effects resulting in reduced fitness that impairs processes such as growth, spawning, or swimming speed. Metabolic processes are directly related to temperature, and the metabolic rate increases as a function of temperature (Marine and Cech 2004). Thus, aquatic organisms are most likely to thrive within their preferred range of temperatures (USEPA 2001a).

Effects of Temperature on Salmonids

Like other aquatic organisms, water temperatures significantly affect the distribution, health, and survival of native salmonids. Because salmonids are ectothermic (cold-blooded), their survival is dependent on external water temperatures and they will experience adverse effects when exposed to temperatures outside their optimal range. Salmonids have evolved and thrived under the water temperature patterns that historically existed (i.e., prior to significant anthropogenic impacts that altered temperature patterns) in streams and rivers. Although evidence suggests that historical water temperatures exceeded optimal conditions for Pacific salmonids at times, during the summer months on some rivers at some locations, the temperature diversity in these unaltered rivers provided sufficient access to cold water to allow salmonid populations as a whole to thrive (USEPA 2003). Across North America, human-caused elevated water temperatures significantly increase the magnitude, duration, and extent of thermal conditions unsuitable for salmonids (USEPA 2003).

The freshwater life histories of salmonids are closely tied to water temperatures. Cooling rivers in the autumn serve as a signal for upstream migrations. Fall spawning is initiated when water temperatures decrease to suitable temperatures. Eggs generally incubate over the winter or early spring when temperatures are coolest. Rising springtime water temperatures can serve as a cue for downstream migration (USEPA 2003).

Because of the overall importance of water temperature for salmonids in the Pacific Northwest, human-caused changes to natural temperature patterns have the potential to significantly reduce the size of salmonid populations. Of particular concern are human activities that have led to the excess warming of rivers, loss of temperature diversity (USEPA 2003), and the loss of access to coldwater habitats blocked by dams.

In the Central Valley, Myrick and Cech (2001 page iii) suggest that "water temperature is perhaps the physical factor with the greatest influence on Central Valley salmonids, short of a complete absence of water", and that "the changes made to Central Valley rivers have had, and will continue to have far-reaching effects on Chinook salmon and steelhead populations." The National Marine Fisheries Service (2009a) indicated that improving water temperatures in the Merced and Tuolumne Rivers (and many other Central Valley rivers) are key restoration actions for steelhead recovery in these watersheds. Additionally, NMFS (2009b) indicated that the primary limiting factor to the Central Valley steelhead distinct population segment (DPS) is the inaccessibility of more than 95% of its historic spawning and rearing habitat due to impassable dams, which among other factors, block access to cold water habitat found at higher elevations. The California Department of Fish and Game (2010a) indicated that rivers in the San Joaquin Basin do not meet (cool) temperature water quality criteria to protect anadromous fish beneficial uses, and that one critical factor limiting anadromous salmon and steelhead population abundance is high water temperatures which exist during critical life-stages in the tributaries and main-stem.

The following sections further discuss some of the specific mechanisms in which water temperature influences salmonids:

Influence of Temperature on Salmonid Behavior

Water temperature has the ability to influence the behavior of salmonids in several ways, including: causing movement to habitat with temperature refugia (e.g., stratified pools, shaded habitat, and subsurface flow), causing movement into areas with less cover but additional food resources (Nielsen et al. 1994; Torgersen et al. 1999; Myrick and Cech 2001; Torgersen et al. 2012), increasing competition between different fish species, changing metabolic rates, hindering the ability to avoid and evade predators, diminishing aquatic biodiversity, and increasing susceptibility of both juveniles and adults to certain parasites and diseases (Myrick and Cech 2001; Reese and Harvey 2002). As temperatures rise above optimal conditions, these modifications to behavior can be costly in terms of expending additional energy and increasing predation risk.

Influence of Temperature on Disease Risk in Salmonids

Chinook salmon are susceptible to a variety of different diseases, many of which have specific water temperature requirements (Boles et al. 1988). The effects of disease on salmonids is directly linked to water temperature, as water temperature greatly influences the immune system of fishes, and the quantity and virulence of water borne pathogens (Nichols and Foot 2002; Ferguson 1981). Although certain diseases become more prevalent in cold water environments, the more prevalent diseases that afflict Chinook salmon occur in warmer water temperatures (>56°F; Boles et al. 1988). Consequently, changes in water temperatures caused by dams and other water infrastructure can alter the susceptibility of salmonids to infection by various pathogens (Spence et al. 1996).

Disease adversely impacts fish populations by directly increasing mortality, and by indirectly contributing to increased susceptibility to predation and decreasing the ability of fish to perform essential functions, such as feeding, swimming, and defending territories (McCullough 1999; Nichols and Foott 2002). The susceptibility of salmonids to disease can also be affected by other stressors including insufficient dissolved oxygen, and chemical pollution. Temperature may interact synergistically with these factors, causing disease to appear in organisms that might be resistant in the absence of other forms of stress (Spence et al. 1996).

Diseased fish are present and have been caught in the Stanislaus, Tuolumne, Merced and San Joaquin Rivers. Naturally produced Chinook salmon juveniles caught in these rivers were infected with the causative agents of bacterial kidney disease (BKD) and proliferative kidney disease (PDK). These diseases and others can rapidly increase in the population as water temperature rises above the optimal temperature range of salmonids (Nichols and Foott 2002).

Flows have dilution effects on the presence of pathogens, flush diseases out of the ecosystem, and can lower water temperatures thus reducing disease outbreaks. Additionally, a greater amount of instream habitat affords individuals with a greater area in which to disperse and, consequently, there can be a lower probability of coming into close contact with diseased individuals (Spence et al. 1996).

Influence of Temperature on Predation Risk to Salmonids

In addition to disease, Chinook salmon juveniles are also increasingly vulnerable to predation as water temperatures increase. Predation on juvenile Chinook salmon is both directly and indirectly affected by water temperatures (Myrick and Cech 2001; McBain and Trush 2002). These direct and/or indirect impacts related to the influence of temperature on predation can add unnecessary stress to an already struggling salmonid population. First, direct effects can occur when water temperatures rise or fall to levels that alter the behavior of, or physically harm, the juvenile salmonid. An example of a direct effect is increasing water temperature that leads to premature utilization of the yolk sac by developing alevins, which may result in early emergence from the redd in an underdeveloped and vulnerable state. Second, the ability for a juvenile salmonid to maintain normal swimming abilities and adequately avoid predators is an important factor contributing to survival. Specifically, larval and early life-stage salmonids have relatively weak swimming abilities, making them particularly vulnerable to predation (McBain and Trush 2002). Increased temperatures may compound this effect. Third, increased water temperatures may decrease food availability, increase fish metabolic demand, and subsequently decrease growth rates and survival of salmonids (Boles et al. 1988). Increased water temperatures have the potential to drive salmon juveniles away from the more favorable and protective shallow water habitat (due to a limited food supply) into the main drift or deeper waters of the stream to forage for food. As Chinook salmon juveniles venture to more open instream habitats in search of food, they become an easier target for predatory fish who, in addition to salmon juveniles, need to sustain an increased metabolic demand for food as a result of warm water temperatures (Boles et al. 1988). Lastly, warm water temperatures can also increase vulnerability to predation by affecting the performance of juvenile Chinook salmon or by creating favorable conditions for predatory fish (Boles et al. 1988). As optimal water temperatures for salmonids are exceeded, many predatory fish are just beginning to enter their optimal water temperature range (CDFG 2010a). When water temperatures increase above preferred ranges, juvenile salmonids become stressed and potentially disoriented and erratic, which consequently causes them to become more vulnerable to increased predation rates (CDFG 2010a). Marine and Cech (2004) found that juvenile salmon that were reared in 21-24°C (69.8°F-75.2°F) were significantly more vulnerable to predation by striped bass than juvenile salmon reared at lower temperatures.

It is expected that restoring more natural temperature and flow regimes will help to better support the various life history adaptations of native fish and other native aquatic organisms, and may reduce predation from non-natives. The effectiveness of restoring the natural flow regime was demonstrated by Kiernan et al. (2012) in lower Putah Creek where a new flow regime was implemented that mimics the seasonal timing of natural increases and decreases in streamflow. Monitoring of several sites pre- and post- implementation of the new flow regime showed a change in the distribution of the native fish community. At the onset of the study, native fishes were constrained to habitat immediately (<1 km) below the diversion dam, and non-native species were numerically dominant at all downstream sample sites. Following implementation of the new flow regime, native fish populations expanded and regained dominance across more than 20 km of lower Putah Creek. The authors (Kiernan et al. 20012) proposed that that the expansion of native fishes was facilitated by creation of favorable spawning and rearing conditions (e.g., elevated springtime flows), cooler water temperatures, maintenance of lotic (flowing) conditions over the length of the creek, and displacement of alien species by naturally occurring high-discharge events.

Influence of Temperature on Adult Salmonid Migration

Adult salmonids migrate great distances in river systems throughout the Pacific Northwest, including the Central Valley. The success of these migrations can depend substantially on water temperatures. Most stocks of anadromous salmonids have evolved with the temperature regime of the streams they use for spawning and migration, and alteration of the normal temperature pattern can result in reduced fitness (USEPA 2001a).

If adult salmonid migration occurs at high temperatures just prior to spawning, gametes held internally in adults can be severely affected, resulting in a loss of viability that appears as poor fertilization or poor embryo survival (USEPA 2001a). Additionally, delayed migration caused by sub-optimal water temperatures may also affect the temperature conditions that the juvenile offspring will experience by pushing their in-river development further into the late spring or summer seasons during periods with higher temperatures. Furthermore, upstream migrating adult salmon that are delayed in the mainstem SJR and Delta can be subject to sport harvest, whereas adults that migrate into the tributaries are somewhat protected by sport fishing regulations that generally prohibit angling in the primary spawning reaches and times (Mesick 2001).

Thermal blockage to adult fall-run Chinook salmon migration was reported at a temperature of 21°C in the Sacramento-SJR Delta, but even temperatures as low as 19°C caused a partial blockage (Hallock et al. 1970).

Influence of Temperature on Salmonid Reproduction

Like with many other organisms, embryonic development of salmonids is a particularly important and sensitive life stage. Temperatures can influence salmonid egg development and success in a variety of ways. For example, sub-optimal temperatures can alter the formation of vertebrae in Central Valley Chinook salmon, and can cause direct mortality at high or low temperatures (Seymour 1959). Seymour (1956 as cited in DWR 1988) found that inadequate temperatures may not always lead to direct egg mortality, but can also cause mortality exceeding 50% of sac-fry (alevin) even when egg mortality was low. Additionally, even before eggs are deposited in gravels, exposure of adult females holding ripe eggs to warm water temperatures can cause egg mortality and can negatively alter egg and alevin development (Rice 1960 and Leitritz and Lewis 1976 as cited in McCullough 1999).

Chinook salmon have a narrow range of temperatures which lead to successful egg development. Myrick and Cech (2001) illustrated the effects of incubation temperature on direct mortality of Chinook salmon eggs from a variety of studies, as seen below in Figure 19-6.

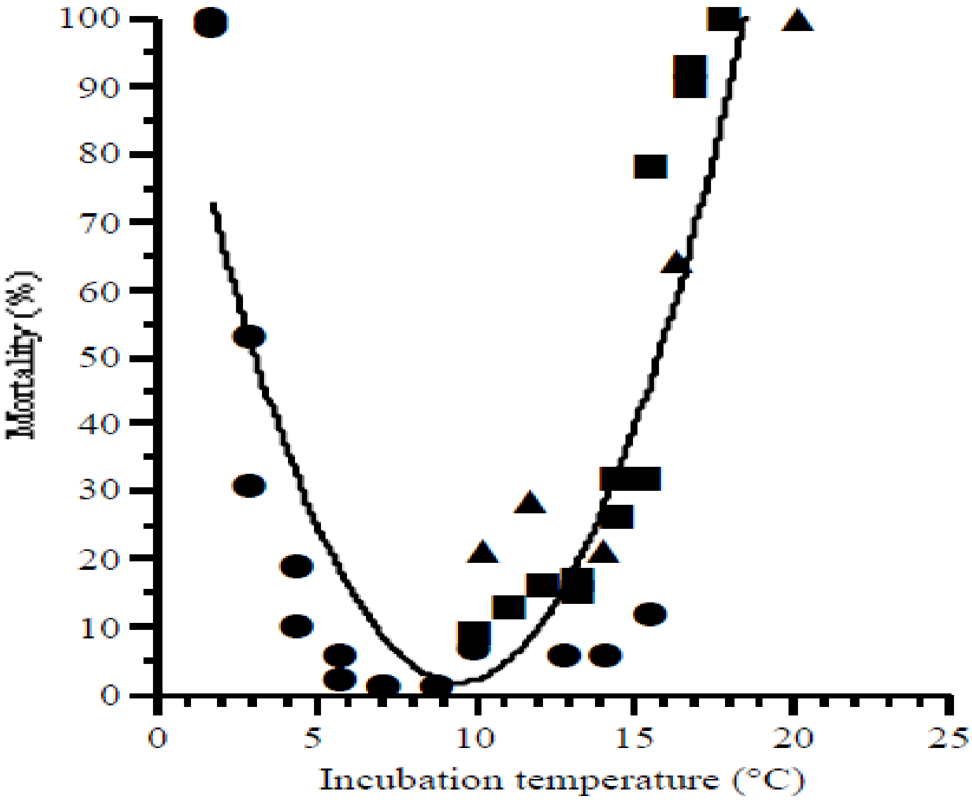

Figure 19-6. Myrick and Cech (2001) illustrate effects of incubation temperature on mortality of Chinook salmon eggs. Data are from Combs and Burrows (1957; solid circles), USFWS (1999; solid squares), and Jenson and Groot (1991; solid triangles).

With optimal conditions, Chinook salmon embryos hatch after 40-60 days and remain in the gravel as alevins for another 4-6 weeks, usually until the yolk sac is fully absorbed (Moyle et al 2008). Alevin are the life stage between eggs and fry, and these newly hatched salmon have not yet fully absorbed their yolk sac (NMFS 2009b). During this life stage alevin are still relatively sensitive to temperatures, with thermal requirements similar to those of eggs (USEPA 2001a, Myrick and Cech 2001).

Under existing conditions, elevated water temperatures appear to be impairing reproductive life-stages of salmonids in the SJR Basin, including its tributaries (CDFG 2010a). The magnitude in which poor temperatures effect the survival of incubating eggs, and ultimately population abundance, is currently unknown.

Influence of Temperature on Juvenile Salmonid Growth, Smoltification, and Emigration

Growth is perhaps the most powerful and complete integrator of environmental, behavioral, and physiological influences on a fish's fitness. Growth is the storage of excess energy and positive growth indicates an energy surplus, which is necessary to advance to and complete later life stages and ultimately complete successful reproduction (Myrick and Cech 2001).

Temperature affects growth directly through its effect on metabolic processes, and indirectly, through its effects on food availability and physical activity. Both Central Valley Chinook salmon and steelhead have high growth rates at temperatures approaching 19°C when they are fed to satiation in laboratory experiments. However, under partial food rations and reduced water quality, maximum growth rates occur at lower temperatures (Myrick and Cech 2001). Additionally, lower temperatures are required to complete the physiological and morphological adaptations that juvenile salmon undergo to transition from living in freshwater to living in saltwater, which is the process known as smoltification (Myrick and Cech 2001).

Freshwater fish are hypertonic to their environment and must actively excrete water and acquire ions (primarily Na+ and Cl-) (Moyle and Cech 2000 as cited in Myrick and Cech 2001). Marine fish are hypotonic (less salty than environment) and must drink copious quantities of sea water (Moyle and Cech 2000 as cited in Myrick and Cech 2001) and actively excrete salt (Myrick and Cech 2001). The smoltification process transforms salmonids from freshwater to saltwater physiology, which has high energetic costs associated with it (Cooperman et al. 2010; Gross et al. 1988, Sheridan et al. 1983). This costly transition suggests that the optimal habitats for growth, survival, and reproduction are necessary and separated spatially and/or seasonally (Northcote 1984). Survival of smolts upon reaching the marine environment depends heavily upon the degree of smoltification, and two of the most important factors regulating seawater adaptability of salmonids are freshwater rearing temperature and time of transfer to seawater (McCullough 1999). Additionally, it appears that the development of seawater tolerance in Chinook salmon and steelhead is partially a function of size (Clarke and Shelbourn 1985; Johnson and Clarke 1988), making it important that salmonids reach an appropriate size before they reach saltwater (Myrick and Cech 2001). Therefore, juvenile salmonids must grow large enough and have access to suitable temperature conditions to undergo the stress of completing the smoltification process and entering the ocean (Morinville and Rasmunsen 2003).

By controlling biochemical and physiological reaction rates, water temperature affects the physiological development of smolts, as well as the timing and duration of smoltification. Of particular significance is the inhibition of the gill ATPase osmoregulatory enzyme at high water temperatures, which leads to a loss of migratory behavior in salmonids (USEPA 2001b). Furthermore, warm water temperatures can decrease, arrest, or reverse the physiological function of smoltification, and subsequently delay the outmigration of juveniles into a more unfavorable timeframe (e.g., June; Boles et al. 1988; CDFG 2010a).

In addition to physiological impairment of smolts caused by elevated temperatures during migration, Baker et al. (1995) found that direct effects of high temperature explain a large part of the smolt mortality observed in the Delta. Additionally, using data from 1986–2010, Mesick (2012) evaluated the hypothesis that recruitment of naturally produced fall-run Chinook salmon in the major SJR tributaries was primarily a function of the suitability of water temperatures for smoltification. He found that the environmental variables that best explained variation in natural recruitment over the period of record were either mean flow in the mainstem SJR during the March 1 to April 30 parr migratory period or the number of days that water temperatures were less than a 15°C threshold for smoltification between March 1 and June 15 in the major SJR tributaries. Others (Baker et al 1995; CDFG 2010a; Kjelson et al 1982; Mesick 2010a) have also reached similar conclusions that temperature is one of the key limiting factors of smolt survival in the Central Valley.

Summary

The importance of suitable temperature habitats to aquatic organisms in the Central Valley has been well documented. Like other aquatic organisms, water temperature significantly affects the distribution, health, survival, and reproduction of native salmonids, and because salmonids are ectothermic (cold-blooded), their success is dependent on water temperature and they will experience adverse effects when exposed to temperatures outside their optimal range. In the Central Valley, water and land development has dramatically altered natural water temperature regimes available to many of California's native fish and wildlife. The following analysis will evaluate how increasing river discharge during February through June will improve temperature habitat relative to native salmonids in the Stanislaus, Tuolumne, Merced, and Lower San Joaquin Rivers.

19.2.2 Methods of Temperature Evaluation

This temperature analysis is based on predicted effects to key evaluation, or "indicator species." For this analysis, the indicator species used are Central Valley fall-run Chinook salmon (*Oncorhynchus tshawytscha*) and California Central Valley steelhead (*Oncorhynchus mykiss*). These indicator species were selected based on their sensitivity to potential changes in environmental conditions in the project area and their utility in evaluating broader ecosystem and community-level effects of these changes on native aquatic resources. The temperature requirements of Central Valley fall-run Chinook salmon and Central Valley steelhead are generally representative of the temperature requirements of other native fishes in the project area (see Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*).

Computer Modeling Used in Temperature Evaluation

To model effects on temperature in the LSJR and three eastside tributaries[2] for the SED, the State Water Board used the San Joaquin River Basin-Wide Water Temperature and EC Model (shorthand used here is SJR HEC-5Q model or temperature model) developed by a group of consultants between 2003 and 2008 through a series of CALFED contracts that included peer review and refinement (CALFED 2009). The temperature model was most recently updated by the CDFW and released in June of 2013 (CDFW 2013b).

The temperature model uses the Hydrologic Water Quality Modeling System (HWMS-HEC5Q), a graphical user interface that employs HEC-5Q, the USACE Hydrologic Engineering Center (HEC) flow and water quality simulation model, to model reservoir and river temperatures subject to historical climate conditions and user defined operations. The temperature model was designed to provide a SJR basin-wide evaluation of temperature response at 6-hour intervals for alternative conditions, such as operational changes, physical changes, and combinations of the two. The extent of the model includes the Merced, Tuolumne, and Stanislaus River systems from their LSJR confluences to the upstream end of their major reservoirs (i.e., McClure, Don Pedro, and New Melones, respectively). The upstream extent of the model on the LSJR is the Merced River confluence. The downstream extent of the model is the LSJR at Mossdale. The model simulates the reservoir stratification, release temperatures, and downstream river temperatures as a function of the inflow temperatures, reservoir geometry and outlets, flow, meteorology, and river geometry. Calibration data was used to accurately simulate temperatures for a range of reservoir operations, river flows, and meteorology.

---

[2] In this document, the term *three eastside tributaries* refers to the Stanislaus, Tuolumne, and Merced Rivers.

The temperature model interfaces with CALSIM (see Appendix F.1, *Hydrologic and Water Quality Modeling*) or monthly data formatted similarly to CALSIM output. A pre-processing routine converts the monthly output to a format compatible with the SJR HEC-5Q model. This routine serves two purposes: 1) to allow the temperature model to perform a long-term simulation compatible with the period used in CALSIM II, and 2) to convert monthly output to daily values used in the temperature model.

Using the monthly output from the Water Supply Effects (WSE) model (see Appendix F.1), the "CALSIM to HEC-5Q" temperature model pre-processor was used by the State Water Board, and the temperature model was run to determine the river temperature effects of different flow scenarios within the Stanislaus, Tuolumne, Merced, and Lower San Joaquin Rivers. The temperature model was run for the period 1970 through 2003, a period with sufficient length and climatic variation to determine the effects of the LSJR alternatives on river temperatures.

Temperature Criteria Used in Evaluation

The temperature thresholds used in this evaluation are based on the U.S. Environmental Protection Agency (USEPA) recommended temperature criteria for protection of salmonids using the 7-day average of the daily maximum (7DADM) unit of measurement (USEPA 2003). The 7DADM metric is recommended by USEPA because it describes the maximum temperatures in a stream, but is not overly influenced by the maximum temperature of a single day. Thus, it reflects an average of maximum temperatures that fish are exposed to over a week-long period. Because this metric is oriented to daily maximum temperatures, it can be used to protect against acute effects such as lethality and migration blockage conditions and also to protect against sub-lethal or chronic effects (e.g., temperature effects on growth, disease, smoltification, and competition) (USEPA 2003).

For this temperature evaluation of the Bay-Delta Plan update, USEPA's recommended criteria were used as a benchmark to measure changes in protective temperature conditions for Central Valley fall-run Chinook salmon and Central Valley steelhead under a variety of unimpaired flows. These protective temperature criteria represent the upper limits of the optimal temperature range for each evaluated life stage. The percentage of days during each month over the modeled 34-year period (1970-2003; n= number of days per specific month multiplied by 34 years) that USEPA criteria are expected to be met at each river location identified in Table 19-1 and Table 19-2 were used to quantify changes between baseline conditions and the conditions resulting from the modeled unimpaired flows. A 10% change in the amount of time that USEPA criteria is met, in combination with professional judgment, is used to determine a significant benefit or impact. Ten percent was selected because it accounts for a reasonable range of potential error associated with the assumptions used in the various analytical and modeling techniques. In addition, lacking quantitative relationships between a given change in environmental conditions and relevant population metrics (e.g., survival or abundance), a 10% change was considered sufficient to potentially result in beneficial or adverse effects to sensitive species at the population level.

Additionally, the average daily 7DADM values for each month (n= number of days per specific month multiplied by 34 years), and the 90th percentile daily 7DADM values for each month (n= number of days per specific month multiplied by 34 years) were evaluated for both baseline and unimpaired flows during the 34-year temperature model period. The 90th percentile temperature represents the 7DADM value in which temperatures are lower 90% of the time and temperatures are higher 10% of the time. These two temperature metrics provide additional insight into expected effects on native salmonids from different unimpaired flows.

Life Stage Timing Used in Temperature Evaluation

This evaluation focuses on the most sensitive and relatively abundant salmonid species and life stages during each given time period. The life stage timings which were used are based on the general distribution and abundance of each life stage in the rivers. For example, water temperatures at locations approximately three-quarters of the distance from the mouth of each tributary to the first impassable dam were used to characterize water temperatures in the primary Chinook salmon and steelhead spawning reaches. This location was selected because it generally represents conditions in the spawning reaches, and therefore reflects water temperatures available for spawning and incubation. Table 19-1 provides a summary of the primary points of reference used for this comparative temperature analysis (between baseline and different unimpaired flows) in the Stanislaus, Tuolumne, and Merced Rivers.

On the LSJR, similar life stage timing was used as in the tributaries, except that spawning, egg incubation, and fry emergence were not used because salmonid reproduction typically does not take place in the LSJR, currently. Instead, the adult migration life stage was used during September through December, and the core juvenile rearing life stage was used during January through March. Table 19-2 provides a summary of the points of reference used for this comparative temperature analysis (between baseline and different unimpaired flow cases) in the LSJR.

Table 19-1. Primary Stanislaus, Tuolumne, and Merced River fall-run Chinook salmon and steelhead (composite) temperature evaluation considerations. For the primary evaluation locations, the anadromous portion of the river was split into quarters, with ¼ River being closer to the confluence and ¾ River being closer to the dam that limits anadromous migrations.

Evaluation Time Period	Primary Life Stage (fall-run Chinook and steelhead composite)	Temperature Evaluation Thresholds (°C)	Temperature Evaluation Thresholds (°F)	Primary Evaluation Locations
September 1 to October 31	Adult Migration	18 (7DADM)	64.4 (7DADM)	Confluence ¼ River ½ River
October 1 to March 31	Spawning, Egg Incubation, and Fry Emergence	13 (7DADM)	55.4 (7DADM)	½ River ¾ River Dam
March 1 to May 31	Core Juvenile Rearing	16 (7DADM)	60.8 (7DADM)	Confluence ¼ River ½ River ¾ River Dam
April 1 to June 30	Smoltification	14 (7DADM)	57.2 (7DADM)	Confluence ¼ River ½ River
June 1 to August 31	Summer Rearing	18 (7DADM)	64.4 (7DADM)	½ River ¾ River Dam

Table 19-2. Primary Lower San Joaquin River fall-run Chinook salmon and steelhead (composite) temperature evaluation considerations.

Evaluation Time Period	Primary Life Stage (fall-run Chinook and steelhead composite)	Temperature Evaluation Thresholds (°C)	Temperature Evaluation Thresholds (°F)	Primary Evaluation Locations
September 1 to December 31	Adult Migration	18 (7DADM)	64.4 (7DADM)	Vernalis
January 1 to March 31	Core Juvenile Rearing	16 (7DADM)	60.8 (7DADM)	Vernalis
April 1 to June 30	Smoltification	14 (7DADM)	57.2 (7DADM)	Vernalis

19.2.3 Results of Temperature Evaluation

Based on this evaluation and the conclusions and discussions of others (Baker et al. 1995; Brandes and McLain 2001; CDFG 2005b, 2010a; Kjelson et al 1982; Kjelson and Brandes 1989; Marine and Cech 2004; Mesick 2010a; Myrick and Cech 2001; NMFS 2009a; Zeug et al. 2014), existing baseline temperature conditions in the Bay-Delta Plan area including the Stanislaus, Tuolumne, and Merced Rivers are likely to be detrimental to salmonids, and other native fishes, that use these waterways. Temperature conditions in September, October, and November are often poor at many locations used by adult migrating and spawning salmon. Furthermore, fry emergence, rearing, smoltification, and emigration life stages are also exposed to suboptimal and even harmful temperature conditions from roughly March through June during many years. Finally, salmonids that stay in the rivers to over summer between June and September have little chance of thriving unless they find the little cold water refugia that potentially exists (depending on the year and river) directly below the dams.

The results of this analysis indicate that significant temperature benefits to Central Valley fall-run Chinook salmon and Central Valley steelhead will occur on the Stanislaus, Tuolumne, Merced, and LSJ Rivers under some of the unimpaired flow alternatives which were evaluated. Significant temperature improvements in the Stanislaus River primarily occur under 50%-60% unimpaired flows, and in the Merced River primarily occur under 30%-60% unimpaired flows. Significant temperature improvements in the Tuolumne River occur under all alternative unimpaired flows with the least benefit occurring under 20% unimpaired flow and the most benefit occurring under 60% unimpaired flow. However, modeling results indicate that significant temperature benefits to the smoltification life stage will occur only with 50% and 60% unimpaired flows on the Stanislaus and Merced Rivers during April and May (Tables 19-3 and 19-9). In the LSJR, significant temperature improvements to the availability of optimal conditions occur during March under the 60% unimpaired flow, with other months and other unimpaired flows not expected to produce significant benefits or impacts on optimal salmonid temperature habitat. Although there are limited benefits to optimal salmonid temperature habitat in the LSJR, there are substantial reductions in average temperatures and 90th percentile temperatures primarily during the March through June time period with higher unimpaired flows providing greater reductions to these measures of temperature.

It is important to note that interpretations of the results do not place too much emphasis on temperature criteria compliance at the dam release locations, because releasing small amounts of cold water can indicate that adequate temperature habitat exists, but may not actually provide favorable conditions for native fish in these rivers due to rapid warming as the water flows downstream under low flow conditions. A better location to evaluate temperature during many months in each river is near the ¾ river location, or further downstream. However, there is information that can be gathered from the temperatures at the dam releases. For example, the temperature of water at the dam release can indicate whether or not there is cold water available for release.

The remainder of this section provides an interpretation of the results presented in Tables 19-3 through 19-14, and is organized in sections specific to each evaluation time period, life stage, and location.

Table 19-3. The percentage of time on the Stanislaus River that USEPA salmon and steelhead temperature criteria (7DADM unit of measurement) are met each month under modeled baseline (base) conditions during 1970 to 2003, and the magnitude of expected percent change under modeled unimpaired flows of 20%, 30%, 40%, 50% and 60% at different river mile (RM) locations. Positive numbers under the unimpaired flows represent the magnitude of increases compared to baseline in the percentage of time that criteria are expected to be met, and negative numbers under the unimpaired flows represent the magnitude of reductions compared to baseline in the percentage of time that criteria are expected to be met. Expected changes in the amount of time that USEPA temperature criteria are met which are greater than positive 10% or less than negative 10% are highlighted green or red respectively (if applicable), and represent significant changes to salmon and steelhead temperature habitat if indicated at locations which are utilized by that life stage.

AM = Adult Migration
R = Reproduction (Spawning, Egg Incubation, and Fry Emergence)
CR = Core Rearing
S = Smoltification
SR = Summer Rearing

Table 19-4. The average daily 7DADM temperature values for each month on the Stanislaus River under modeled baseline (base) condition from 1970 to 2003, and the modeled difference in °F for each of the unimpaired flow percentages between 20% to 60%. Negative numbers represent the expected magnitude of reductions in 7DADM values and positive numbers represent the expected magnitude of increases in 7DADM values. Expected changes in the magnitude of 7DADM values greater than positive 1°F or less than negative 1°F are highlighted either red or green respectively (if applicable). The green and/or reds cells were highlighted to aid the visual review of this table and do not necessarily represent significant changes to salmon and steelhead temperature habitat.

Stanislaus Average 7DADM	Confluence (RM0)						1/4 River (RM13.3)						1/2 River (RM28.2)						3/4 River (RM43.7)						Below Goodwin (RM58.5)

Table 19-5. The 90th percentile daily 7DADM temperature values for the 1970 to 2003 model period for each month at different Stanislaus River locations, and the expected difference in °F for each of the unimpaired flow percentages between 20% and 60%. Each of the 90th percentile values which are displayed for baseline (base) indicate that daily 7DADM values were less than that temperature 90% of the time, or were greater than that temperature 10% of the time during each month and river location. Expected changes in the magnitude of 90th percentile 7DADM values greater than positive 1°F or less than negative 1°F are highlighted either red or green respectively (if applicable). The green and/or reds cells were highlighted to aid the visual review of this table and do not necessarily represent significant changes to salmon and steelhead temperature habitat.

Table 19-6. The percentage of time on the Tuolumne River that USEPA salmon and steelhead temperature criteria (7DADM unit of measurement) are met each month under modeled baseline (base) conditions during 1970 to 2003, and the magnitude of expected percent change under modeled unimpaired flows of 20%, 30%, 40%, 50% and 60% at different river mile (RM) locations. Positive numbers under the unimpaired flows represent the magnitude of increases compared to baseline in the percentage of time that criteria are expected to be met, and negative numbers under the unimpaired flows represent the magnitude of reductions compared to baseline in the percentage of time that criteria are expected to be met. Expected changes in the amount of time that USEPA temperature criteria are met which are greater than positive 10% or less than negative 10% are highlighted green or red respectively (if applicable), and represent significant changes to salmon and steelhead temperature habitat if indicated at locations which are utilized by that life stage.

Table 19-7. The average daily 7DADM temperature values for each month on the Tuolumne River under modeled baseline (base) condition from 1970 to 2003, and the modeled difference in °F for each of the unimpaired flow percentages between 20% to 60%. Negative numbers represent the expected magnitude of reductions in 7DADM values and positive numbers represent the expected magnitude of increases in 7DADM values. Expected changes in the magnitude of 7DADM values greater than positive 1°F or less than negative 1°F are highlighted either red or green respectively (if applicable). The green and/or reds cells were highlighted to aid the visual review of this table and do not necessarily represent significant changes to salmon and steelhead temperature habitat.

Tuolumne Average 7DADM	Confluence (RM0)						1/4 River (RM13.2)						1/2 River (RM28.1)						3/4 River (RM38.3)						Below La Grange (RM53.5)

Table 19-8. The 90th percentile daily 7DADM temperature values for the 1970 to 2003 model period for each month at different Tuolumne River locations, and the expected difference in °F for each of the unimpaired flow percentages between 20% and 60%. Each of the 90th percentile values which are displayed for baseline (base) indicate that daily 7DADM values were less than that temperature 90% of the time, or were greater than that temperature 10% of the time during each month and river location. Expected changes in the magnitude of 90th percentile 7DADM values greater than positive 1°F or less than negative 1°F are highlighted either red or green respectively (if applicable). The green and/or reds cells were highlighted to aid the visual review of this table and do not necessarily represent significant changes to salmon and steelhead temperature habitat.

Table 19-9. The percentage of time on the Merced River that USEPA salmon and steelhead temperature criteria (7DADM unit of measurement) are met each month under modeled baseline (base) conditions during 1970 to 2003, and the magnitude of expected percent change under modeled unimpaired flows of 20%, 30%, 40%, 50% and 60% at different river mile (RM) locations. Positive numbers under the unimpaired flows represent the magnitude of increases compared to baseline in the percentage of time that criteria are expected to be met, and negative numbers under the unimpaired flows represent the magnitude of reductions compared to baseline in the percentage of time that criteria are expected to be met. Expected changes in the amount of time that USEPA temperature criteria are met which are greater than positive 10% or less than negative 10% are highlighted green or red respectively (if applicable), and represent significant changes to salmon and steelhead temperature habitat if indicated at locations which are utilized by that life stage.

SR = Summer Rearing

Table 19-10. The average daily 7DADM temperature values for each month on the Merced River under modeled baseline (base) condition from 1970 to 2003, and the modeled difference in °F for each of the unimpaired flow percentages between 20% to 60%. Negative numbers represent the expected magnitude of reductions in 7DADM values and positive numbers represent the expected magnitude of increases in 7DADM values. Expected changes in the magnitude of 7DADM values greater than positive 1°F or less than negative 1°F are highlighted either red or green respectively (if applicable). The green and/or reds cells were highlighted to aid the visual review of this table and do not necessarily represent significant changes to salmon and steelhead temperature habitat.

Table 19-11. The 90th percentile daily 7DADM temperature values for the 1970 to 2003 model period for each month at different Merced River locations, and the expected difference in °F for each of the unimpaired flow percentages between 20% and 60%. Each of the 90th percentile values which are displayed for baseline (base) indicate that daily 7DADM values were less than that temperature 90% of the time, or were greater than that temperature 10% of the time during each month and river location. Expected changes in the magnitude of 90th percentile 7DADM values greater than positive 1°F or less than negative 1°F are highlighted either red or green respectively (if applicable). The green and/or reds cells were highlighted to aid the visual review of this table and do not necessarily represent significant changes to salmon and steelhead temperature habitat.

Table 19-12. The percentage of time on the San Joaquin River that USEPA salmon and steelhead temperature criteria (7DADM unit of measurement) are met each month under modeled baseline (base) conditions during 1970 to 2003, and the magnitude of expected percent change under modeled unimpaired flows of 20%, 30%, 40%, 50% and 60% at different river mile (RM) locations. Positive numbers under the unimpaired flows represent the magnitude of increases compared to baseline in the percentage of time that criteria are expected to be met, and negative numbers under the unimpaired flows represent the magnitude of reductions compared to baseline in the percentage of time that criteria are expected to be met. Expected changes in the amount of time that USEPA temperature criteria are met which are greater than positive 10% or less than negative 10% are highlighted green or red respectively (if applicable), and represent significant changes to salmon and steelhead temperature habitat if indicated at locations which are utilized by that life stage.

Table 19-14. The 90th percentile daily 7DADM temperature values for the 1970 to 2003 model period for each month at different San Joaquin River (SJR) locations, and the expected difference in °F for each of the unimpaired flow percentages between 20% and 60%. Each of the 90th percentile values which are displayed for baseline (base) indicate that daily 7DADM values were less than that temperature 90% of the time, or were greater than that temperature 10% of the time during each month and river location. Expected changes in the magnitude of 90th percentile 7DADM values greater than positive 1°F or less than negative 1°F are highlighted either red or green respectively (if applicable). The green and/or reds cells were highlighted to aid the visual review of this table and do not necessarily represent significant changes to salmon and steelhead temperature habitat.

SJR 90th Percentile 7DADM	Vernalis (RM 69.31)						Above Stanislaus Confluence (RM 72.501)						Above Tuolumne Confluence (RM 81.401)						Above Merced Confluence (RM 116.001)

Adult Migration Evaluation Time Period, September 1 to October 31:

USEPA temperature criteria for adult salmon and steelhead migration were evaluated during the September 1 through October 31 time period. During September, adult salmon are beginning to enter the Stanislaus, Tuolumne, and Merced Rivers as they return from the ocean to spawn. During the first part of September there are few salmon found in these rivers. By the end of September, more salmon are beginning to migrate up each river, although most of the upstream migration occurs after September with peak migration typically occurring in late October and early November (CFS 2007a; CDFG 2001, 2002). The USEPA criteria used in this evaluation, and which corresponds with the adult migration life stage is less than or equal to 64.4°F using the 7-day average of the daily maximum (7DADM) unit of measurement.

Stanislaus River Adult Migration September 1 to October 31 (results in Tables 19-3, 19-4, and 19-5)

Baseline: Under modeled baseline conditions in the Stanislaus River, USEPA temperature criteria are met 10% of the time on average during September and 71% of the time on average during October at the confluence with the LSJR. Adult salmon experience temperature improvements as they swim upstream until they reach their spawning grounds (near ¾ river) where USEPA adult migration temperature criteria are met 67% of the time during September and 87% of the time during October.

20-60% Unimpaired Flows: During September, the model results indicate that compliance with USEPA adult temperature criteria (64.4°F) will increase by 12% under each unimpaired flow at the Goodwin Reservoir release location, thus achieving 100% compliance with the recommended USEPA temperature criteria for each unimpaired flow at the dam release in September. At the ½ river evaluation location, the 40%, 50%, and 60% unimpaired flows provide 14%, 13% and 11% improvements in USEPA temperature criteria compliance respectively during September. The confluence temperatures are not expected to change significantly under any of the alternative flows in September.

During October, the model results indicate that compliance with USEPA temperature criteria for adult migration (64.4°F) will increase by approximately 11%-12% under each of the unimpaired flows between the ¾ river and Goodwin evaluation locations. Additionally, model results indicate the 40%, 50%, and 60% unimpaired flows will result in increased compliance with adult migration criteria by approximately 10%-12% between the confluence and ½ river locations. However, the amount of time that reproductive criteria (55.4°F) are met in October did not increase at these locations.

Tuolumne River Adult Migration September 1 to October 31 (results in Tables 19-6, 19-7, and 19-8)

Baseline: Under modeled baseline conditions in the Tuolumne River, USEPA temperature criteria for adult migration (64.4°F) are met 2% of the time on average during September and 25% of the time on average during October at the confluence with the LSJR. Moving upstream during September, criteria are met 3%, 11%, 33%, and 100% of the time at the ¼, ½, ¾, and dam release evaluation locations respectively on average. Moving upstream during October, criteria are met 37%, 63%, 81%, and 100% of the time at the ¼, ½, ¾, and dam release evaluation locations respectively on average. Although the water released from the dam meets USEPA temperature criteria 100% of the time in September, the water temperature quickly warms, and by the time it reaches the ¾ river location USEPA compliance has already dropped to 33%. During October this warming between the dam (100% compliance) and the ¾ river (81% compliance) locations is not as dramatic.

20-60% Unimpaired Flows: Modeling indicates that the compliance with USEPA adult salmon migration criteria (64.4°F) will increase by approximately 17% under the 40% to 60% unimpaired flows at the ½ river location. No significant changes from baseline were predicted by model results on the Tuolumne River during October under any of the evaluated unimpaired flows to the amount of time that adult migration criteria (64.4°F) are met.

Merced River Adult Migration September 1 to October 31 (results in Tables 19-9, 19-10, and 19-11)

Baseline: Under modeled baseline conditions in the Merced River, USEPA adult migration temperature criteria (64.4°F) are met 3% of the time on average during September and 38% of the time on average during October at the confluence with the LSJR. Moving upstream during September, adult migration temperature criteria are met 4%, 9%, 14%, and 82% of the time at the ¼, ½, ¾, and dam evaluation locations respectively on average. Moving upstream during October, adult migration temperature criteria are met 39%, 51%, 55%, and 82% of the time at the ¼, ½, ¾, and dam evaluation locations respectively on average.

20-60% Unimpaired Flows: Modeling indicates that the 20% unimpaired flows may increase the amount of time that adult migration criteria (64.4°F) are met below Crocker Huffman Dam by approximately 10%. No other significant changes are expected in the amount of time that adult migration criteria (64.4°F) are met during September. During October, modeling results indicate that the dam release will meet adult migration criteria approximately 14% to 18% more often under the 20% to 50% unimpaired flows. The 60% unimpaired flow modeling indicates near significant improvements (8%) in the amount of time adult migration temperature criteria are met at the dam release.

Reproduction Evaluation Time Period, October 1 to March 31:

USEPA temperature criteria for salmon and steelhead reproductive life stages, which include pre-spawning, spawning, egg incubation, and fry emergence, were evaluated during the October 1 to March 31 time period. Most SJR fall-run Chinook salmon spawn between late October and early January when temperatures in the rivers are less than 55°F. Spawning generally occurs in areas where suitable habitat exists. In the Stanislaus, Tuolumne, and Merced Rivers, suitable habitat generally exists in the upper half of the anadromous portion of each river, with the majority of spawning activity typically occurring upstream of this point. Egg incubation typically occurs between November and March, lasting 40–60 days, but can vary depending on water temperatures and timing of spawning. Optimal water temperatures for egg incubation range from 41°F to 55°F (Moyle 2002; USEPA 2003). Eggs that incubate at temperatures higher than 60°F and lower than 38°F often suffer high mortality rates (Boles et al. 1988; Myrick and Cech 2001).

Newly hatched salmon (alevin) remain in the gravel for about 4–6 weeks (temperature dependent) until their yolk sacs have been absorbed (Moyle 2008). Generally, alevins suffer low mortality when consistently incubated at water temperatures between 50°F and 55°F. However, if incubated at constant temperatures between 55°F and 57.5°F, mortality has been shown to increase in excess of

50% (Boles et al. 1988). Once alevins emerge with their yolk-sac absorbed, they become fry, which tend to aggregate along stream edges, seeking cover in bushes, swirling water, and dark backgrounds (Moyle et al. 2008).

The USEPA criteria used in this evaluation, and which corresponds with the spawning, egg incubation, and fry emergence life stages is less than or equal to 55.4°F using the 7-day average of the daily maximum (7DADM) unit of measurement. For this evaluation on the Stanislaus, Tuolumne, and Merced Rivers; ½ river, ¾ river, and dam locations were used as primary indicator locations for the spawning and egg incubation life stages and all river evaluation locations were used to evaluate temperatures related to the fry life stage during this time period.

Stanislaus River Reproduction October 1 to March 31 (results in Tables 19-3, 19-4, and 19-5)

Baseline: At the ½ river, ¾ river, and dam release locations, which are representative of the spawning reach, USEPA spawning and incubation temperature criteria are met 5%, 17%, and 55% of the time respectively during October, and 36%, 45%, and 64% of the time respectively during November under baseline conditions. These sub-optimal temperature conditions during many years in in the heart of the spawning period and location may limit reproductive success on the Stanislaus River.

During December through the end of February, USEPA reproductive criteria are met greater than 90% of the time at all primary spawning locations on the Lower Stanislaus River under baseline conditions. During December, the river is warmer on average at the dam release (52.3 average 7DADM) than at the confluence (50.9 °F average 7DADM).

During March, USEPA reproductive temperature criteria (55.4°F) are met 100% of the time at the dam release under baseline conditions, but temperatures gradually warm heading downstream until USEPA criteria compliance drops to 53% of the time at ½ river.

20-60% Unimpaired Flows: The modeled flows indicate significant temperature improvements compared to baseline in the amount of time USEPA reproductive criteria are met on the Stanislaus River during the October through March time period. These temperature improvements occur in March under the 40% to 60% unimpaired flows from the confluence up to the ¾ river location. At the dam release, USEPA reproductive criteria are already met 100% of the time under baseline condition during March.

Tuolumne River Reproduction October 1 to March 31 (results in Tables 19-6, 19-7, and 19-8)

Baseline: At the ¾ river evaluation location, which is representative of much of the spawning reach, USEPA spawning and incubation temperature criteria are met less than 1% of the time during October and less than 27% of the time during November under baseline conditions. These sub-optimal temperature conditions in the heart of the spawning period and location may limit reproductive success on the Tuolumne River under baseline conditions.

During December through the end of January, USEPA reproductive temperature criteria are met greater than 93% of the time at all river locations on the Lower Tuolumne River under baseline conditions. During December, the river is warmer at the dam release (52.9 °F average 7DADM) than at the confluence (50.2 °F average 7DADM).

During February through the end of March, USEPA temperature criteria are met 100% of the time at the dam release. Temperatures gradually warm moving downstream until USEPA temperature criteria compliance drops to 72% and 54% of the time in February and March respectively at the ½ river evaluation location.

20-60% Unimpaired Flows: During this time period, significant improvements to USEPA reproductive temperature criteria compliance occur in February and March under the 30%, 40%, 50%, and 60% unimpaired flows. No significant temperature changes, relative to the reproductive criteria, are expected during October through January under any of the modeled unimpaired flows.

During February, the 60% unimpaired flow resulted in significant temperature improvements to reproductive criteria at most river evaluation locations. The 50% unimpaired flow results in significant improvements at the ½ river and ¾ river locations during February. Under the 40% unimpaired flow, temperature conditions had near significant improvements at ½ river and ¾ river during February where criteria compliance improved by 9.8% and 9.99% of the time, respectively.

During March, improvements to reproductive criteria compliance at the ¾ river evaluation location improve significantly under each of the unimpaired flows between 30-60%. At ½ river, 40-60% unimpaired flows result in significant improvements to reproductive criteria.

Merced River Reproduction October 1 to March 31 (results in Tables 19-9, 19-10, and 19-11)

Baseline: In the spawning reach (between ½ river and Crocker Huffman Dam), USEPA spawning and incubation criteria are met 0% of the time during October and between 9% and 31% of the time (depending on location) during November under baseline conditions. In November, 7DADM temperatures greater than 64°F occur 10% of the time at ¾ river. During October the frequency of warm temperatures is worse in the spawning reach with temperatures greater than 70.5°F occurring 10% of the time at ¾ river. These sub-optimal temperature conditions in the heart of the spawning period and location, likely limit reproductive success on the Merced River.

Between December and the end of February, river temperatures meet USEPA reproductive temperature criteria greater than 74% of the time at the primary spawning locations under baseline conditions.

During March, USEPA criteria are met less than 28% of the time between ¾ river and ½ river under baseline conditions.

20-60% Unimpaired Flows: The only significant temperature improvements during this time period to the USEPA reproductive temperature criteria occur during March under 60% unimpaired flow at the ½ river and ¾ river locations where compliance increases by approximately 13% of the time.

Core Juvenile Rearing Evaluation Time Period, March 1 to May 31

The USEPA salmon and steelhead core juvenile rearing temperature criterion (less than or equal to 60.8°F using the 7DADM metric) was evaluated from March 1 to May 31. During March and April fry, parr, and smolt life stages can all be found in the Stanislaus, Tuolumne, and Merced Rivers. This time period is one of relatively fast growth rates for these juvenile life stages, and is a transitional time period where fry are becoming less frequent and smolts are becoming more frequent (see CFS 2007b). By May most of the juvenile fish are classified as smolts and the fast growth rates observed in March and April have slowed as the smolts prepare for ocean entry. Juvenile salmonids can be found throughout much of the Stanislaus, Tuolumne, and Merced Rivers in March, April, and May.

Stanislaus River Core Juvenile Rearing March 1 to May 31 (results in Tables 19-3, 19-4, and 19-5)

Baseline: During March in the Stanislaus River, USEPA core juvenile rearing temperature criteria (60.8°F using the 7DADM metric) are met greater than 91% of the time at all river evaluation locations. During April this rearing criterion is met 78%, 81%, 90%, 99%, and 100% of the time at the confluence, ¼, ½, ¾, and dam release locations respectively. During May this rearing criterion is met 51%, 61%, 73%, 94%, and 100% of the time at the confluence, ¼, ½, ¾, and dam release locations respectively.

20-60% Unimpaired Flows: During March the core rearing temperature criteria was met greater than 91% of the time at all river locations under baseline conditions, therefore significant increases (>10%) in the amount of time that this criteria is met is not applicable. However, the higher unimpaired flows (40%-60%) increased USEPA core juvenile rearing temperature compliance to 100%, or close to 100%, at most river locations.

During April, modeling indicates that the 60% unimpaired flow increases core juvenile rearing temperature criteria compliance by 13% at both the confluence and ¼ river. The 50% unimpaired flow also produces significant increases in temperature compliance (11%) at the ¼ river location and near significant improvements (9.9%) at the confluence.

During May, the 50% and 60% unimpaired flows produced significant increases ranging from 11% to 22% in the amount of time that USEPA core juvenile rearing temperature criteria were met between the confluence and ½ river. Modeling also indicates that the 40% unimpaired flow increased the amount of time that USEPA juvenile rearing temperature criteria are met at the ½ river location by 9.7%.

Tuolumne River Core Juvenile Rearing March 1 to May 31 (results in Tables 19-6, 19-7, and 19-8)

Baseline: During March, the core juvenile rearing criteria are met approximately 65%, 72%, 84%, 91%, and 100% of the time at the time at the confluence, ¼, ½, ¾, and dam release locations respectively on the Tuolumne River.

During April, the core juvenile rearing criteria are met approximately 50%, 57%, 74%, 92%, and 100% of the time at the confluence, ¼, ½, ¾, and dam release locations respectively on the Tuolumne River.

During May, the core juvenile rearing criteria are met approximately 19%, 34%, 59%, 74%, and 100% of the time at the confluence, ¼, ½, ¾, and dam release locations respectively on the Tuolumne River.

20-60% Unimpaired Flows: During March through May, 30-60% unimpaired flows indicate significant temperature benefits at the confluence and ¼ river evaluation location, and 20-60% unimpaired flows indicate significant temperature benefits at the ½ and ¾ river evaluation locations. At each of the evaluation locations the higher unimpaired flows indicate greater temperature benefits when compared to the lower unimpaired flows or baseline. Modeling indicates that the largest increase in the amount of time that USEPA core juvenile rearing temperature criteria is met could occur under the 60% unimpaired alternative at the ¼ river location where criteria compliance increases by 58% during May.

Merced River Core Juvenile Rearing March 1 to May 31 (results in Tables 19-9, 19-10, and 19-11)

Baseline: During March, the core juvenile rearing criteria (60.8°F) are met approximately 70%, 72%, 85%, 87%, and 100% of the time at the confluence, ¼, ½, ¾, and dam release locations respectively on the Merced River.

During April, the core juvenile rearing criteria are met approximately 22%, 25%, 39%, 43%, and 100% of the time at the confluence, ¼, ½, ¾, and dam release locations respectively on the Merced River.

During May, the core juvenile rearing criteria are met approximately 8%, 12%, 18%, 24%, and 99% of the time at the confluence, ¼, ½, ¾, and dam release locations respectively on the Merced River.

20-60% Unimpaired Flows: Temperature modeling in March indicates that 50-60% unimpaired flows will result in significant increases in the amount of time that USEPA core juvenile rearing temperature criteria are met at the confluence and ¼ river evaluation locations. Additionally, 60% unimpaired flows will increase core juvenile rearing temperature criteria compliance at the ½ evaluation location.

During April and May, each of the 30-60% unimpaired flows result in significant increases in the amount of time that USEPA core juvenile rearing temperatures criteria are met at the ½, and ¾ river evaluation locations. At the confluence evaluation location only the 40% to 60% unimpaired flows produce significant increases in temperature criteria compliance. At each evaluation location, the higher unimpaired flows result in greater temperature benefits when compared to the lower unimpaired flows or baseline. Modeling indicates that the largest increases in the amount of time that USEPA core juvenile rearing temperature criteria are met could occur under the 60% unimpaired alternative at the ¼, ½, and ¾ river locations where criteria compliance increases by between 37% and 45% during April and May.

Smoltification Evaluation Time Period, April 1 to June 30

The primary evaluation life stages considered during the April 1 to June 30 time period are smoltification and emigration. During this time many ocean bound juvenile salmonids (steelhead and salmon) are finishing the in river growing stage and are exiting the tributaries on their way to the ocean (CFS 2006, CFS 2007b, Fish BIO 2007, Ford and Kirihara 2010). This transition from the freshwater to ocean environment (smoltification) requires significant physiological and morphological changes (Cooperman et al. 2010, Gross et al. 1988, Sheridan et al. 1983), and smolts are particularly sensitive to high temperatures during this transition (Mesick 2010a, Mesick and Marston 2007; Myrick and Cech 2001; USEPA 2003).

The USEPA temperature criteria used in this evaluation, and which corresponds with the smoltification and emigration life stages is 57.2°F or lower using the 7-day average of the daily maximum (7DADM) unit of measurement. For this evaluation on the Stanislaus, Tuolumne, and

Merced Rivers during April, May, and June; the confluence, ¼ river, and ½ river locations were used as primary indicator locations for smoltification and emigration.

Stanislaus River Smoltification April 1 to June 30 (results in Tables 19-3, 19-4, and 19-5)

Baseline: During April, May, and June Goodwin Reservoir release temperatures meet USEPA smoltification temperature criteria (57.2°F) greater than 96% of the time under baseline conditions. The river water temperature warms going downstream until the water reaches the confluence with the LSJR where USEPA criteria is met 39% of the time during April, 5% during May, and 0% during June. During May near the confluence, the 90th percentile 7DADM temperature is 66.4°F. During June near the confluence, the 90th percentile 7DADM temperature is 73.3°F under baseline conditions, which means that 10% of the time temperatures are greater than 73.3°F at the confluence in June.

20-60% Unimpaired Flows: The 50% and 60% unimpaired flows produced significant improvements in the amount of time USEPA smoltification criteria is met on the Stanislaus River during the April 1 to June 30 time period. The other alternative unimpaired flows did not produce significant improvements or reductions in temperature criteria compliance during this period.

During April on the Stanislaus River, significant improvements to smoltification temperature compliance occur under the 50% and 60% unimpaired flows at the ¾ river location by approximately 11%. Under the 60% unimpaired flow, improved temperature compliance is expected at the ¼ river evaluation location by approximately 11%.

Under 60% unimpaired flows on the Stanislaus River during May, compliance with USEPA smoltification temperature criteria increased by 17%, 22%, 22%, and 13% at the confluence, ¼ river, ½ river, and ¾ river respectively. Under 50% unimpaired flow in May, significant improvements occur at the ¼ river, ½ river, and ¾ river locations (11%, 16%, and 10% respectively). During June under the 60% unimpaired flow significant improvements (13-17%) are expected in the amount of time that smoltification criteria are met at ½ river and ¾ river locations, and under the 50% unimpaired flow significant improvements (11%) are expected at ¾ river.

Tuolumne River Smoltification April 1 to June 30 (results in Tables 19-6, 19-7, and 19-8)

Baseline: During April, May, and June La Grange Reservoir release temperatures are meeting USEPA criteria 100% of the time. Water temperature warms heading downstream until the water reaches the confluence with the LSJR where USEPA criteria is met 22% during April, 3% during May, and 0% during June under baseline conditions. The rate of warming as water flows downstream is affected by the amount of water being discharged from the reservoir.

20-60% Unimpaired Flow: Each of the evaluated unimpaired flows produced significant temperature improvements during April and May on the Tuolumne River. However during June only the 30-60% unimpaired flows indicate that significant improvements to smoltification criteria compliance will occur. Generally, the lower unimpaired flows (20% and 30%) do not result in significant improvements to smoltification temperatures in the lower reaches of the river (confluence and ¼ river locations).

On the Tuolumne River during this time period the expected temperature benefits from increased flow are greater than in any of the other time periods and/or rivers. These results indicate that the smoltification life stage within the Tuolumne River will experience far better temperature conditions under the higher unimpaired flows compared to baseline.

Modeling results indicate that the 90th percentile 7DADM temperature is reduced by up to 15.4°F (from 77.0°F to 61.6°F) under 60% unimpaired flow during June at the ¾ river location in the Tuolumne River. These reductions in high temperatures are substantial and would provide significant benefits to salmon and steelhead during June.

Merced River Smoltification April 1 to June 30 (results in Tables 19-9, 19-10, and 19-11)

Baseline: During April, May, and June at the confluence, USEPA temperature criteria are met 7%, 2%, and 0% of the time respectively under baseline conditions. At the ¾ river location USEPA temperature criteria are met 16% during April, 10% during May, and 11% during June under baseline conditions. At the dam release, USEPA temperature criteria are met 95%, 88%, and 69% during April, May, and June respectively. The dramatic decrease in USEPA temperature criteria compliance between the dam release and the ¾ river location (approximately 14.4 miles downstream) is partially a result of low releases of water. Between these same two locations, there is an approximately eleven degree difference (65.0°F at the ¾ river location versus 53.8°F at the dam release) in average daily 7DADM temperatures during May. During June a similar condition occurs where average daily 7DADM temperatures at the dam release (55.4°F) are substantially cooler than those observed at the ¾ river evaluation location (69.9°F).

20-60% Unimpaired Flow: During April in the Merced River, only the 50% and 60% unimpaired flows result in significant increases to the amount of time USEPA smoltification temperature criteria are met. Under the 60% unimpaired flow during April, significant temperature improvements occur at the confluence, ¼, ½, and ¾ river locations. Under the 50% unimpaired flow, only the ½ river and ¾ river evaluation locations improve significantly compared to baseline temperatures.

During May, the 60% unimpaired flow produced significant increases in the time of compliance with USEPA temperature criteria by 15% and 24% at the ½ river and ¾ river locations respectively. The 50% unimpaired flow produced significant benefits to smoltification temperature compliance (16%) at the ¾ river location.

During June there are not any expected temperature benefits to compliance with USEPA smoltification criteria at any Merced River locations or alternatives. However, there are substantial reductions in average daily and 90th percentile 7DADM temperatures during April, May, and June at multiple river locations.

Summer Rearing Evaluation Time Period, June 1 to August 31:

The focus of the summer rearing evaluation is on juvenile salmon and steelhead that over summer in the tributaries during the hottest time of the year and then may migrate to the ocean at a later date when water temperatures are cooler. Suitable over summering temperature habitats in the project area are usually limited to areas immediately below the impassable dams, however, during certain years there may be little or no suitable over summering temperature habitats in these tributaries. The USEPA recommended temperature criteria for the salmon and steelhead summer rearing life stage is 18°C (64.4°F) using the 7DADM metric.

Stanislaus River Summer Rearing June 1 to August 31 (results in Tables 19-3, 19-4, and 19-5)

Baseline: Modeled baseline temperatures meet USEPA summer rearing criteria 38%, 5%, and 5% of the time at the confluence during June, July, and August respectively. At ¾ river, USEPA criteria are met 81%, 43%, and 47% of the time respectively, and at the dam release USEPA criteria are met 100%, 100%, and 96% respectively during June, July, and August.

August is the month with the highest average 7DADM temperatures on the Stanislaus River. At the confluence during the modeled period, the average 7DADM temperature is 73.0 °F, and the 90th percentile temperature is 76.9°F.

20-60% Unimpaired Flow: During June, the 50% and 60% unimpaired flows produce significant improvements in the amount of time that USEPA summer rearing temperature criteria are met at the confluence, ¼ river, and ½ river evaluation locations. These unimpaired flows improve USEPA temperature compliance between 11% and 19% of the time at these locations during this time period. The other alternative unimpaired flows do not produce significant temperature benefits or impacts during June.

None of the evaluated unimpaired flows produce significant changes to the amount of time USEPA summer rearing temperature criteria are met on the Stanislaus River during July or August.

Tuolumne River Summer Rearing June 1 to August 31 (results in Tables 19-6, 19-7, and 19-8)

Baseline: Under modeled baseline conditions, June confluence temperatures meet USEPA summer rearing criteria 30% of the time, and the ¾ river evaluation location meets USEPA criteria 46% of the time. During July, modeled baseline conditions meet USEPA criteria 6% and 26% at the confluence and ¾ river evaluation locations respectively. During August, USEPA criteria are met 0% and 9% of the time at the confluence and ¾ river evaluation locations, respectively.

During June through August, the La Grange Reservoir release meets USEPA criteria 100% of the time, although the amount of water being released influences how far downstream the suitable temperatures are maintained.

During June through August, the 90th percentile 7DADM temperatures are above 81.2°F for each month at the confluence. Even at the ¾ river location the 90th percentile 7DADM temperatures are above 77.0°F during June through August.

20-60% Unimpaired Flow: During this time period modeling indicates that significant temperature benefits to summer rearing will occur during June and July, but not August. During June, each of the unimpaired flows produced significant temperature benefits at the ½ river and ¾ river evaluation locations. At the ¾ river evaluation location during June, USEPA temperature criteria compliance increases by 29%-47% under the 20% through 60% unimpaired flows. At the confluence only the 30% to 60% unimpaired flows produce significant temperature benefits which range from 11% to 36% improvement in USEPA temperature criteria compliance.

Maximum temperatures during June are dramatically reduced under most of the unimpaired flows evaluated at all river locations except at the dam release. For example, at the ½ river location during June the 90th percentile temperature is reduced 14.7°F from 79.0°F under baseline to 64.3°F under the 60% unimpaired flow.

Merced River Summer Rearing June 1 to August 31 (results in Tables 19-9, 19-10, and 19-11)

Baseline: During June through August, USEPA summer rearing temperature criteria are met at the confluence evaluation location 16%, 5%, and 0% of the time respectively. At the ¾ river evaluation location, USEPA temperature criteria are met 28%, 23%, and 19% during June, July, and August respectively. At the Crocker Huffman Reservoir release, USEPA temperature criteria are met greater than 87% of the time during this period, however, the distance in which suitable temperatures travel downstream is dependent on the amount of flow in the river.

20-60% Unimpaired Flow: Modeling during the June through August time period indicates that there are both significant increases and reductions in the amount of time that USEPA summer rearing temperature criteria are met under some of the alternative unimpaired flows.

During June, improvements to USEPA summer rearing temperature compliance occur under the 30% to 60% unimpaired flows at the ¾ river evaluation location, occur under the 40% to 60% unimpaired flows at the ½ river evaluation location, occur under the 50% and 60% unimpaired flows at the ¼ river evaluation locations, and occur under the 60% unimpaired flow at the confluence.

The reduction in USEPA summer rearing temperature criteria compliance occurs in August under the 60% unimpaired flow at the ¾ river evaluation location. Although the compliance was reduced significantly under this unimpaired flow, average daily temperatures and 90th percentile temperatures did not change substantially.

Lower San Joaquin River Temperature Analysis All Time Periods (results in Tables 19-12, 19-13, and 19-14)

On the LSJR, modeling indicates that significant temperature benefits occur during March under the 60% unimpaired flow, while other months and other unimpaired flows are not expected to produce significant benefits or impacts on optimal salmonid temperature habitat. Although there are limited benefits to optimal salmonid temperature habitat in the LSJR, there are substantial reductions in average temperatures and 90th percentile temperatures primarily during the March through June time period with higher flows providing greater reductions to these measures of temperature. These expected temperature reductions may benefit salmonids by reducing suboptimal and lethal temperature exposure. Additionally, increased flows may provide reduced travel times in the LSJR, which can reduce the time of exposure to harmful temperatures experienced by juvenile salmonids migrating in the LSJR.

Summarized Temperature Results

When considering temperature results at different river locations and different times of the year, it becomes difficult to provide an overall picture of potential temperature benefits. One way to summarize the temperature benefits of different unimpaired flows is to consider a data output we refer to as “mile-days”. This result is a measure of temperature criteria compliance in both space and time.

To calculate mile-days of temperature compliance on the Stanislaus, Tuolumne, and Merced Rivers, first 19 points are selected along each river based on output of the HEC-5Q temperature model. The rivers are then divided into 19 sections around the selected locations. The length of each section around a particular location is equal to half the distance from the preceding location plus half the distance to the following location. For example, if A, B, and C are three consecutive locations, the section around location B would have a length equal to half the distance from B to A plus half the distance from B to C. If location A is at the confluence then its corresponding section is only equal to half the distance from A to B. Similarly, if location C is at one of the dams, then the length of its corresponding section is only equal to half the distance from B to C.

7DADM temperature results are then extracted from the temperature model for each of the 19 locations. To summarize compliance with USEPA temperature criteria listed in Table 19-1, the length of each section, in miles, is multiplied by the amount of time that the corresponding location is below the temperature criterion. For example, the length of section around location B is multiplied by the number of days each month that the 7DADM temperature at location B did not exceed the specified criteria for that month. Another way to describe it is that this measurement represents the total number of river miles in compliance with the temperature criteria across all days in a given month. This is similar to the acre-days measurement that is frequently used for evaluating floodplain inundation (see USFWS 2014). Mile-days and acre-days are useful because they summarizes spatial and temporal changes while considering both frequency and magnitude. However, some of the details of exactly when and where certain changes may occur are absent in this type of statistic. Table 19-15 provides a summary of the expected temperature benefits from the proposed project for the Stanislaus, Tuolumne, and Merced Rivers combined.

Table 19-15. Summary of Mean Annual Temperature Benefits Combined for the Stanislaus, Tuolumne, and Merced Rivers from Different February through June Unimpaired Flow (UF) Percentages for all Modeled Water Years.

The number of mile-days generally increases under increasing unimpaired flows, relative to baseline. Temperatures targets are already achieved much of the time under baseline during the cold weather and high flow months of December and January. The biggest improvements occur for the core rearing life stage in April and May. Under baseline, 69 and 54 percent of maximum attainment is achieved in April and May, respectively, for this critical core rearing life stage. Attainment increases to 83 and 73 percent, respectively for April and May, with 40 percent unimpaired flow. This summary statistic of temperature improvement for all year types, however, masks the benefits in critically dry years when baseline flows are lowest and benefits to temperature habitat are highest from increased flows.

Table 19-16 shows the average number of mile-days that these temperature targets are achieved in all three tributaries, combined, under baseline, and also for unimpaired flows of 20, 30, 40, 50, and 60 percent, for only critically dry years. The improvements from baseline are much bigger than the average over all years. This is important because low flow conditions in dry years currently have a negative effect on salmon survival. Under baseline in the three tributaries, 38 and 22 percent of maximum compliance is achieved in April and May, respectively for core rearing in critically dry years. Attainment of the temperature criteria increases to 64 and 46 percent, respectively for April and May, with 40 percent unimpaired flow. The temporal and spatial attainment of the temperature targets more than doubles in May. Table 19-17 also shows a similar pattern of potential improvements for dry years, and additional tables in Attachment 1 provide tributary specific summary tables.

As indicated by these summary tables and the previously discussed temperature results tables, there is tremendous potential to increase suitable temperature habitat in these rivers under the proposed project. Temperature targets that are protective of salmonids are attained more frequently under 30, 40, and 50 percent unimpaired flow than under baseline for all life stages from February through June. These improvements are low estimates of the temperature improvements that can be achieved with increased flow, because flow patterns were not optimized to achieve temperature benefits. Adaptive implementation of the blocks of water represented by the various percentages of unimpaired flow can result in even larger benefits.

19.2.4 Summary and Conclusions of Temperature Evaluation

Of all of the habitat attributes for native fishes, water temperature is likely the most important one (besides having water itself), because without adequate water temperature all of the other habitat attributes (including floodplain inundation) become unusable. This temperature evaluation indicates that increasing flows during the February through June time period can provide significant temperature benefits to juvenile Fall-run Chinook salmon and steelhead. Significant temperature improvements in the Stanislaus River primarily occur under 50%-60% unimpaired flows, and in the Merced River primarily occur under 30%-60% unimpaired flows. Significant temperature improvements in the Tuolumne River occur under all alternative unimpaired flows with the least benefit occurring under 20% unimpaired flow and the most benefit occurring under 60%

unimpaired flow. Modeling results on the Tuolumne River also indicate that the 90th percentile temperature can be reduced by 15.4°F (from 77.0°F to 61.6°F) during June at the ¾ river location under 60% unimpaired flow, and that the other unimpaired flows evaluated also provide substantial reductions of the hottest temperatures at multiple locations when compared to baseline. Reductions of the hottest temperatures are possible in each month from February through June on the Tuolumne River, and would provide significant benefits to salmon and steelhead during this time period. On the Stanislaus and Merced Rivers, modeling results indicate that significant improvements in the amount of time USEPA smoltification criteria is met will only occur under the 50% or 60% unimpaired flows during April, May, and June. This is an important result because temperature impacts on the smolt life stage have been repeatedly reported as one of the limiting factors to salmonid populations in the Central Valley and SJR Basin (Kjelson et al 1982; Newman and Rice 1997; Mesick 2010a). However, there are substantial reductions to both average and 90th percentile 7DADM temperatures under all of the evaluated unimpaired flows on the Merced River during this time period that will likely benefit salmonids. Temperature improvements in the LSJR to optimal salmonid temperature habitat are expected only in March under the 60% unimpaired flow. However there are expected reductions to both average and 90th percentile 7DADM temperatures on the LSJR primarily during March through June that may be beneficial to migrating salmonids. These temperature reductions occur under all modeled unimpaired flows with the higher flows providing greater temperature improvements.

As explained by the CDFW (CDFG 2010a page 3):

> Elevated water temperatures appear to be a factor in the continued decline in adult salmon escapement abundance in the San Joaquin River Basin Watershed, either by: (1) inducing adult mortality as adults migrate into the San Joaquin River, and tributaries, to spawn (i.e., pre-spawn mortality); (2) reducing egg viability for eggs deposited in stream gravels (redds), (3) increasing stress levels and therefore reducing survival of juveniles within the tributary nursery habitats, and (4) reducing salmon smolt out-migration survival as smolts leave the nursery habitats within tributaries to migrate down the San Joaquin River to Vernalis and through the south Delta.

The results of this analysis support these conclusions by CDFW (formerly the California Department of Fish and Game [CDFG]), and the conclusions and discussions of others (Baker et al. 1995; Brandes and McLain 2001; CDFG 2005b, 2010a; Kjelson et al 1982; Kjelson and Brandes 1989; Marine and Cech 2004; Mesick 2010a; Myrick and Cech 2001; NMFS 2009a; Zeug et al. 2014) who have suggested that temperature is a limiting factor to fall-run Chinook salmon in the Bay-Delta plan area. Temperature conditions in September, October, and November are generally poor at most locations used by adult migrating and spawning salmon. Furthermore, fry emergence, rearing, smoltification, and emigration life stages are also exposed to suboptimal and even harmful temperature conditions from roughly March through June during many years. Finally, salmonids that stay in the rivers to over summer between June and September have little chance of thriving unless they find the little cold water refugia that potentially exists (depending on the year and river) directly below the dams.

Extending optimal temperature conditions both spatially (further downstream) and temporally (further into each year) will provide many juvenile salmonids with additional space and time to complete their freshwater rearing and outmigration life stages under suitable conditions. The addition of suitable temperature habitats in both space and time will reduce negative temperature effects to native fish, and will provide additional life history flexibility which can help to avoid risks that are associated with populations which lack spatial and temporal habitat diversity. Additionally, improving February through June temperature conditions will allow many anadromous salmonids to better prepare for the physiological and morphological transition they must make before entering the saltwater environment. Improving temperature conditions during this crucial and energetically expensive life stage (smoltification) (Cooperman et al. 2010, Gross et al. 1988, Sheridan et al. 1983) should increase the odds of survival of many fish, and should therefore minimize one of the key limiting factors (unsuitable water temperature) of fall-run Chinook salmon and steelhead populations in the Stanislaus, Tuolumne, and Merced Rivers (Baker et al. 1995; Brandes and McLain 2001; CDFG 2005b; Kjelson et al. 1981; Kjelson et al 1982; Marine and Cech 2004; Mesick 2010a; Myrick and Cech 2001; NMFS 2009a; Zueg et al. 2014).

Although not the focus of this project, fall spawning temperatures are less than ideal on the Stanislaus, Tuolumne, and Merced Rivers under existing baseline conditions. For example, the amount of time that USEPA spawning temperature criteria are met under modeled baseline conditions at the ¾ river locations in October and November are as follows: Stanislaus River equals 17% and 45% respectively, Tuolumne River equals 1% and 27% respectively, and Merced River equals 0% and 9% respectively. These sub-optimal temperature conditions during the core spawning period and locations are likely to dramatically limit salmon egg survival in these rivers. Reservoirs in California are often touted as being able to store cold water, and while this can be true, they also often have the unfortunate consequence of storing warm water and/or heating the stored cold water. Releases of stored warm water in the fall or early winter can delay the availability of cold water habitat needed by salmon to spawn, and this is likely impacting fall-run Chinook salmon reproductive success in the LSJR tributaries. To illustrate the delay in suitable fall-spawning temperatures, the 1960 to 2010 average daily reservoir inflow temperatures from the SJR HEC-5Q Temperature Model (CDFW 2013b) have been plotted against downstream river temperatures for each of the LSRJ tributaries (Figures 19-7, 19-8, and 19-9). The inflow temperature provides insight into temperature conditions that salmon and steelhead would have historically had access to without the current dam configurations and operations. The reservoir release temperatures and ¾ river temperatures represent the current temperature conditions that salmon and steelhead now have access to. The reservoir release temperature is a "best case" scenario, and represents temperature habitat that few fish actually experience because temperatures can warm rapidly moving downstream under many flow conditions. The approximately 1-month delay (see Figures 19-7 and 19-8) in access to optimal spawning temperatures (55.4 °F) that occurs on the Merced and Stanislaus Rivers during the fall season, creates a disconnect between migratory cues that salmon and steelhead experience in the ocean, and the currently available spawning habitat in these rivers. This delay in access to optimal spawning temperature likely affects egg viability, and potentially shortens the overall window of opportunity available to juvenile salmon and steelhead for successful development and migration prior to ocean entry.

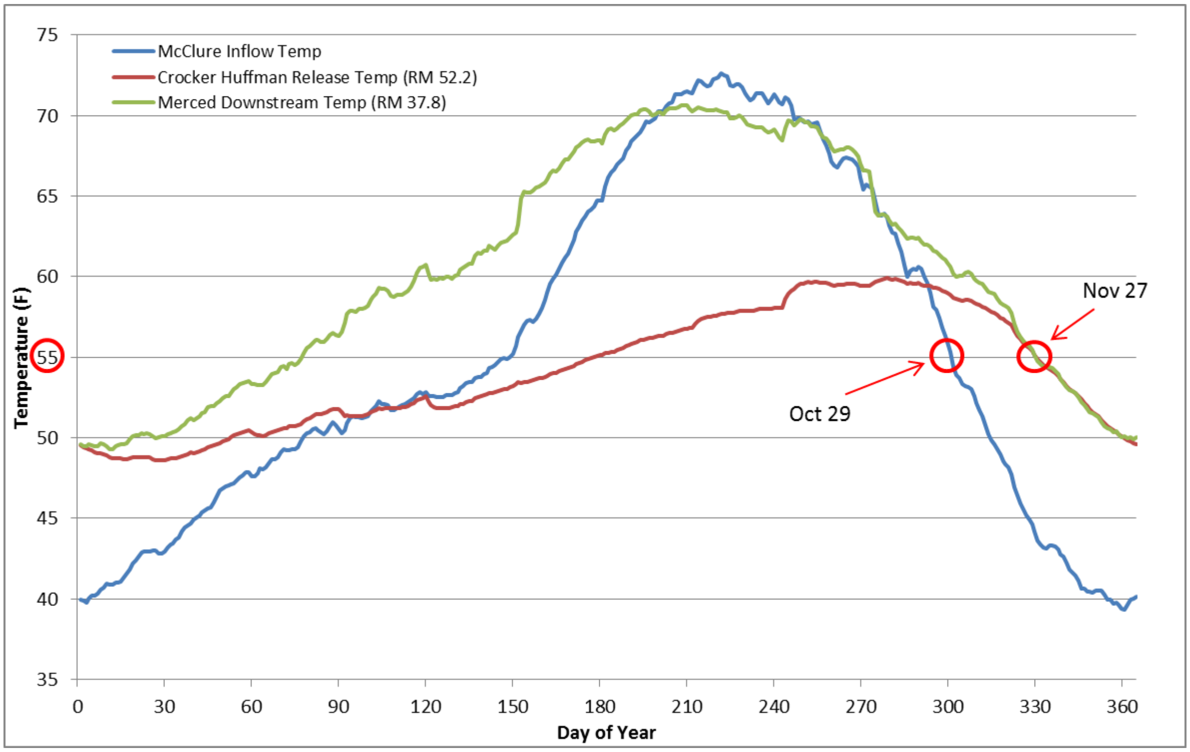

Figure 19-7. Merced River average daily temperature under baseline conditions from 1960 to 2010 at three different locations, which illustrates that both fall and spring temperature windows have been negatively altered compared to more natural conditions. There is an approximately 1-month delay from when fall-run Chinook salmon should be able to access optimal spawning temperatures (less than 55.4 °F) to when they can under current conditions.

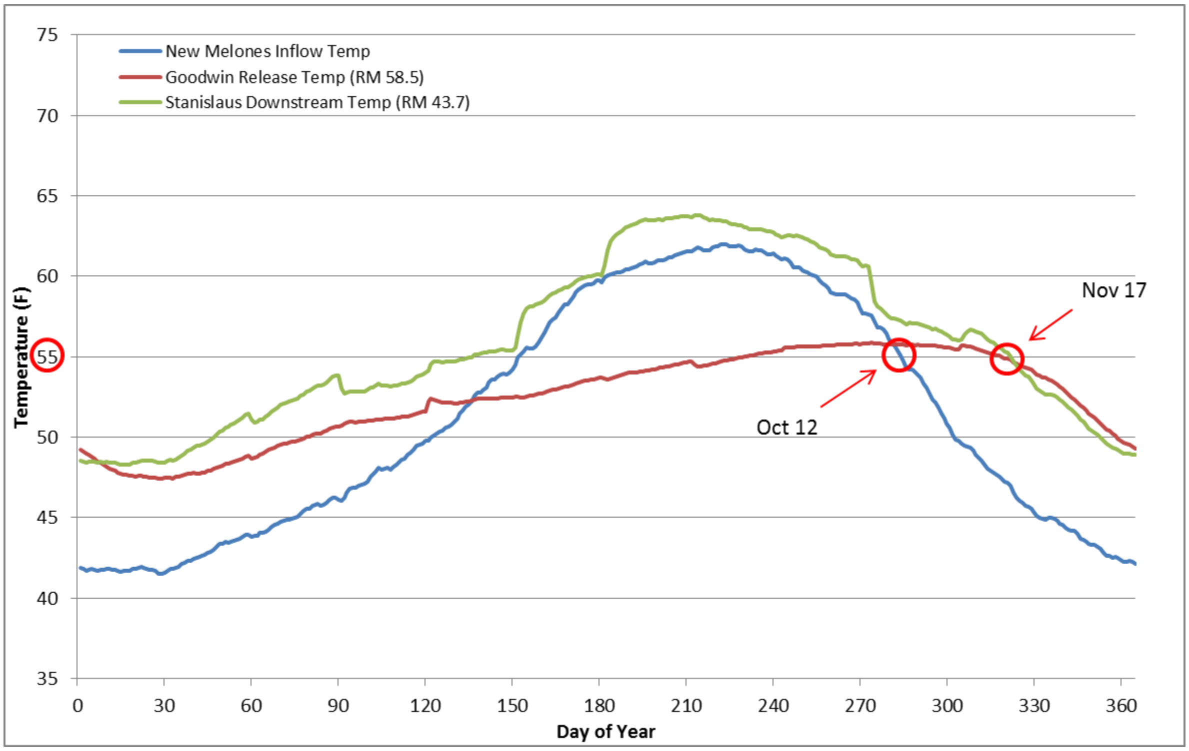

Figure 19-8. Stanislaus River average daily temperature under baseline conditions from 1960 to 2010 at three different locations. There is an approximately 1-month delay from when fall-run Chinook salmon should be able to access optimal spawning temperatures (less than 55.4 °F) to when they can under current conditions.

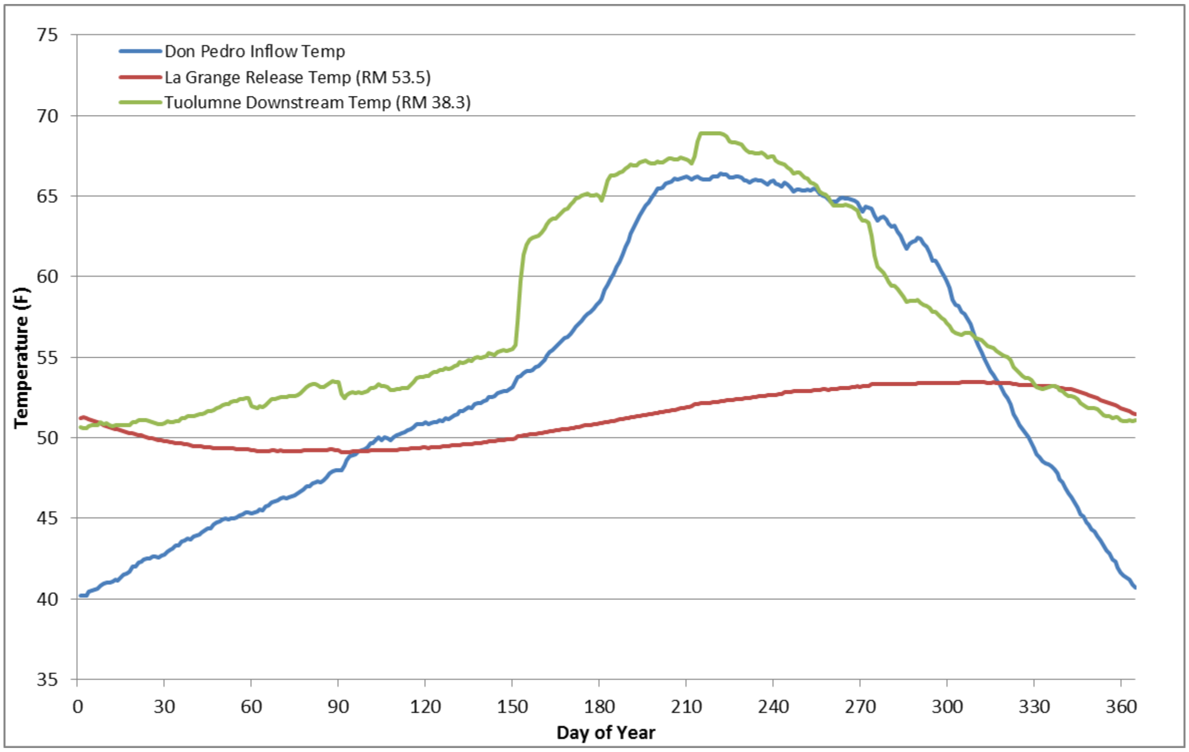

Figure 19-9. Tuolumne River average daily temperature under baseline conditions from 1960 to 2010 at three different locations, which illustrates that there is an altered temperature regime.

19.3 Floodplain Inundation

On the Stanislaus, Tuolumne, and Merced Rivers floodplain inundation is largely controlled by flows released from the reservoirs. This section describes the expected floodplain inundation benefits to juvenile salmonids and other native fishes from increased flows during the February through June time period, and provides information as to why improved floodplain inundation is important to native fish.

19.3.1 Importance of a Natural Floodplain Inundation Regime

General Introduction to Floodplain Habitat

Wetlands are celebrated world-wide for the many services they provide. They help regulate climate, store surface water, control pollution and flooding, replenish aquifers, promote nutrient cycling, protect shorelines, maintain natural communities of plants and animals, serve as critical nursery areas, and provide opportunities for education and recreation (CNRA 2010).

Within the SJR Basin and related to this Bay Delta Plan update, perhaps the most important type of wetland habitats are floodplain habitats which are adjacent to the Stanislaus, Tuolumne, Merced, and LSJ Rivers. Opperman (2012, pages 1-3) describes that:

> Floodplains are among the most biologically productive and diverse ecosystems on Earth… However, floodplains are also among the most converted and threatened ecosystems. Floodplain habitats in the

> Sacramento-San Joaquin Delta, and throughout California's Central Valley, have been greatly reduced from their historic extent and key processes that create and maintain floodplains, such as flood flows and meander migration, have been greatly altered. These widespread alterations to habitats and processes have led to declines in many species' populations in California's Central Valley and Delta.
>
> …Before the expansion of the European population in California, the Central Valley contained approximately one million hectares of floodplain habitats, including riparian forests and savannas, oxbow lakes and other water bodies, and vast expanses of tule marsh (Katibah 1984; TBI 1998). These habitats supported large, culturally important populations of fish, waterfowl, and ungulates. Diverse economic activities lead to conversion of these habitat types and it is estimated that currently less than 10% of original floodplain habitats remain (Katibah 1984; Barbour and Billings 1988)… Hydrological connectivity between rivers and floodplains has declined further because of flow regulation from large upstream multipurpose dams…

In the last 2 decades, numerous studies have demonstrated that both aquatic and riparian ecosystems benefit from dynamic connectivity between rivers and their floodplains (see Jeffres et al. 2008). Riparian species benefit from nutrients mobilized by inundation of floodplain areas (Junk et al. 1989), while riverine species benefit by having access to the floodplain for foraging, spawning, and as a refuge from high velocities found in the river during high flow events (Moyle et al. 2007). Additionally, fish yields in watersheds generally increase when water surface area in floodplains is increased (Bayley 1991 as cited in Jeffres et al. 2008; USFWS 2014).

Use of Floodplains by Salmonids

Floodplain habitats in the Central Valley have been found to have a positive effect on growth of juvenile Central Valley salmonids (Sommer et al. 2001; Sommer et al. 2005; Jeffres et al. 2008), and larger and faster growth has been associated with increased survivorship in river and to adulthood (Bond et al. 2008; Healey 1982; Fritts and Pearsons 2006; Mesick and Marston 2007a; Parker 1971; Unwin 1997; Ward et al. 1989; Zabel and Williams 2002). On the Stanislaus River, USFWS (2014) found a significant relationship between juvenile survival and floodplain acre-days, with floodplain acre-days explaining 77% of the year to year variation in juvenile survival.

The higher growth rates of juvenile Chinook salmon using Central Valley floodplains, relative to other river habitat types, have largely been attributed to the greater availability of prey within floodplain habitats (Sommer et al. 2001; Jeffres et al. 2008). For example, prey items can be orders of magnitude greater in floodplains than in adjacent rivers (Sommer et al. 2001; Grosholz and Gallo 2006). Additionally, increased growth rates may also be related to improved velocity conditions that ephemeral floodplain habitat and other side-channels can provide for juvenile salmon compared to river channels during high flow events when, in the absence of such habitat, juvenile salmon may expend excessive energy or are displaced downstream (Jeffres et al. 2008) before they are ready for downstream migration.

The timing of floodplain inundation for the protection of Central Valley Chinook salmon should generally occur from winter to mid-spring to coincide with the peak juvenile Chinook salmon outmigration period (which itself generally coincides with historic peak flows) (see State Water Board 2010). The benefits of floodplain inundation generally increase with increasing duration, with even relatively short periods of 2 weeks providing potential benefits to salmon (Jeffres et al. 2008). Benefits to salmon may also increase with increasing inter-annual frequency of flooding. Repeated pulse flows and associated increased residence times may be associated with increased productivity which would benefit salmon growth rates and potentially reduce stranding (see State Water Board 2010).

The USFWS's 2005 *Recommended Streamflow Schedules to Meet the AFRP Doubling Goal in the San Joaquin River Basin* (AFRP 2005), concludes that the declines in salmon in the SJR Basin primarily resulted from reductions in the frequency and magnitude of spring flooding in the basin from 1992-2004 compared to the baseline period of 1967-1991. In addition to floodplain being important to salmon, it may also be important to steelhead, sturgeon, splittail (as discussed below), bank swallow, western pond turtle, Fremont cottonwood and many other species important to the riverine ecosystems (CalFED 2008).

Population trend analyses for the SJR Basin suggest that salmon recruitment, which is the number of salmon that survive to the adult stage, is highly correlated with the magnitude and duration of spring flows when the fish were sub-yearling juveniles rearing in the tributaries (Mesick and Marston 2007a; Sturrock et al. 2015; USFWS 2014). The number of smolt-sized outmigrants from the Stanislaus and Tuolumne Rivers is also highly correlated with flow magnitude between February and mid-June (Mesick et al. 2007). These results suggest that fry survival in the tributaries is highest during prolonged periods of flooding and that adult recruitment is highly dependent on fry survival in the tributaries. It is likely that prolonged flooding affects fry survival by providing additional food resources, providing refuge from predators, reducing water temperatures particularly during downstream migrations in May and June, slowing the rate of disease infestation, diluting contaminants, and reducing entrainment (Mesick et al. 2007). Some of these benefits such as increased food resources and refuge from predators could be provided either by higher flows inundating existing floodplains or by constructing lower-elevation floodplains that become inundated on an annual basis with existing flows. However, other benefits such as reduced water temperatures and contaminant dilution would probably only occur during high flows (USFWS 2008).

Use of Floodplains by Splittail

The primary focus of this document is to quantify some of the benefits to salmon and steelhead from a more natural flow regime during February through June. As discussed before, native salmonids were chosen as indicator species, and providing them with more natural habitat conditions is expected to provide many other native species with more natural habitat conditions. However, when considering floodplain habitat a very important species to mention is the Sacramento splittail (*Pogonichthys macrolepidotus*), because the splittail may be one of the few native California fish that can be considered an obligate floodplain spawner (Opperman 2012), with population dynamics closely associated with annual patterns of flow and floodplain inundation (Moyle et al. 2004). Adults can spawn from late January through early July (Wang 1986), but most frequently spawning occurs during March and April (Moyle et al. 2004).

Floodplain inundation appears to be a primary factor required for strong year-classes of splittail (Sommer et al. 1997). Long-duration floodplain inundation is necessary for successful spawning, incubation, and initial rearing of larval splittail, because splittail eggs require 3 to 5 days to hatch and larval and juvenile splittail will remain on the floodplain while conditions are appropriate (Moyle et al. 2004). Long-duration flooding also allows adults time to feed on earthworms on floodplains before they spawn, and may improve spawning success by improving their condition and egg production (Moyle et al. 2004).

The splittail was historically one of the most abundant estuarine species in the Sacramento-San Joaquin estuary and supported a small hook-and-line fishery (Caywood 1974 as cited in Young and Cech 1996). It was once widely distributed in lakes and rivers throughout California's Central Valley

(Moyle et al. 2004) but disappeared from much of its native range because of loss or alteration of lowland habitats following dam construction, water diversion, and agricultural development (Young and Cech 1996). The species is now largely restricted to the Sacramento-San Joaquin estuary except during upstream spawning migrations (Moyle et al. 2004).

Food Production of Floodplains

Inundated floodplains produce phytoplankton and other algae (Ahearn et al. 2006), which are sources of biologically available carbon that are particularly important to downstream food-limited ecosystems such as the Sacramento–San Joaquin Delta (Sobczak et al. 2002; Opperman 2012). The flow of energy from algae to zooplankton and other invertebrates influences floodplain resources for native fish. In the Yolo Bypass drift macroinvertebrates, including chironomids and terrestrial invertebrates, were the primary food resource for juvenile Chinook salmon (Sommer et al. 2001), and were positively correlated with flow (Opperman 2012). In the Yolo Bypass, these organisms attain high densities soon after inundation, providing a food source to fish that is available before food web productivity develops, which requires longer inundation events (Sommer et al. 2004).

Quality of Floodplain Habitat

While it is important to have a natural flow regime which inundates floodplains with proper timing, frequency, magnitude, and duration, it is also important to note that the quality of floodplain habitat is important. A floodplain with sufficient heterogeneity and habitat complexity will facilitate desired ecosystem responses (i.e. diversity of the food web) that may be utilized by salmonids (Bellmore et al. 2013). However, as an example, flooding a parking lot with sufficient timing, frequency, magnitude, and duration necessary for fish will not produce the kinds of ecosystem responses that are desired. In addition, areas with engineered and managed water control structures can have comparatively higher rates of stranding fish (Sommer et al. 2005). Further, floodplains that are too shallow or that lack vegetative cover may also make salmon more susceptible to avian predation (Gawlik 2002). Therefore, it is important that restored floodplains, or multi-benefit projects (i.e. agriculture/floodplain projects) are managed and designed in a manner that provides cost effective results and do not have unintended ecological consequences.

Summary

The importance of floodplain habitats to native fish and wildlife in the Central Valley has been well documented, but floodplains and the frequency which the remaining ones are inundated, have been greatly reduced from their historic extent. Properly managed floodplains can have widespread benefits at multiple levels ranging from individual organisms to ecosystems (Junk et al. 1989; Moyle et al. 2007). The following analysis will evaluate how increasing river flow during February through June will improve floodplain inundation in the Stanislaus, Tuolumne, Merced, and LSJ Rivers.

19.3.2 Methods of Floodplain Inundation Evaluation

Modeled flow outputs were used to predict the frequency and magnitude of monthly flow and floodplain events during the February through June time period in the Stanislaus, Tuolumne, Merced, and LSJ Rivers under baseline and several unimpaired flow percentages. Average monthly flow for each month (February through June) during 1922 to 2003 (n=82 years for each month) was used to estimate the expected frequency and magnitude of floodplain inundation. The February through June time period represents the time period that this project could potentially benefit rearing juvenile salmonids by increasing floodplain habitat. The following methods sections provide additional details regarding the flow modeling, evaluation criteria, and floodplain versus flow relationships used for each water body evaluated.

Methods: Computer Modeling Used in Floodplain Evaluation

The State Water Resource Control Board (State Water Board) developed the WSE model to simulate the baseline and LSJR alternatives for water years 1922-2003 and to determine the effects on reservoir operations, water supply diversions, and river flow for each of the eastside tributaries (Stanislaus, Tuolumne, and Merced Rivers) and flow and salinity at Vernalis on the SJR. The WSE model was used for this floodplain inundation analysis by estimating monthly average flows for the 82-year period under different unimpaired flow scenarios. The scientific basis for the WSE model is described in Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*, and the detailed methods and results for the LSJR alternatives are presented in Appendix F.1, *Hydrologic and Water Quality Modeling*.

Methods: Floodplain Evaluation Criteria

The frequency during the 82-year modeling period (1922 to 2003) that different monthly average flows, and the related floodplain acreages, are achieved was compared between baseline and unimpaired flows of 20%, 30%, 40%, 50%, and 60%. A 10% change in the frequency of floodplain flows, in combination with professional judgment, is used to determine a significant benefit or impact. Ten percent was selected because it accounts for a reasonable range of potential error associated with the assumptions used in the various analytical and modeling techniques. In addition, lacking quantitative relationships between a given change in environmental conditions and relevant population metrics (e.g., survival or abundance), a 10% change was considered sufficient to potentially result in beneficial or adverse effects to sensitive species at the population level.

Methods: Floodplain Versus Flow Relationships

Stanislaus River

This section presents a summary of the methods used by USFWS to develop floodplain versus flow relationships on the Stanislaus River. The USFWS (2011, 2012, and 2013) documentation should be reviewed for a complete description of the methods used.

The USFWS (2011, 2012, and 2013) developed two-dimensional hydraulic models to quantify the relationship between floodplain area and flow for the following four reaches of the Stanislaus River: 1) mouth of Stanislaus River to Ripon, 2) Ripon to Jacob Meyers, 3) Jacob Meyers to Orange Blossom, and 4) Orange Blossom to Knight's Ferry (Figure 19-10). Light Detection and Ranging (LIDAR) and Sound Navigation and Ranging (SONAR) data collected for the Stanislaus River instream flow study was used as the topographic data source for the hydraulic model.

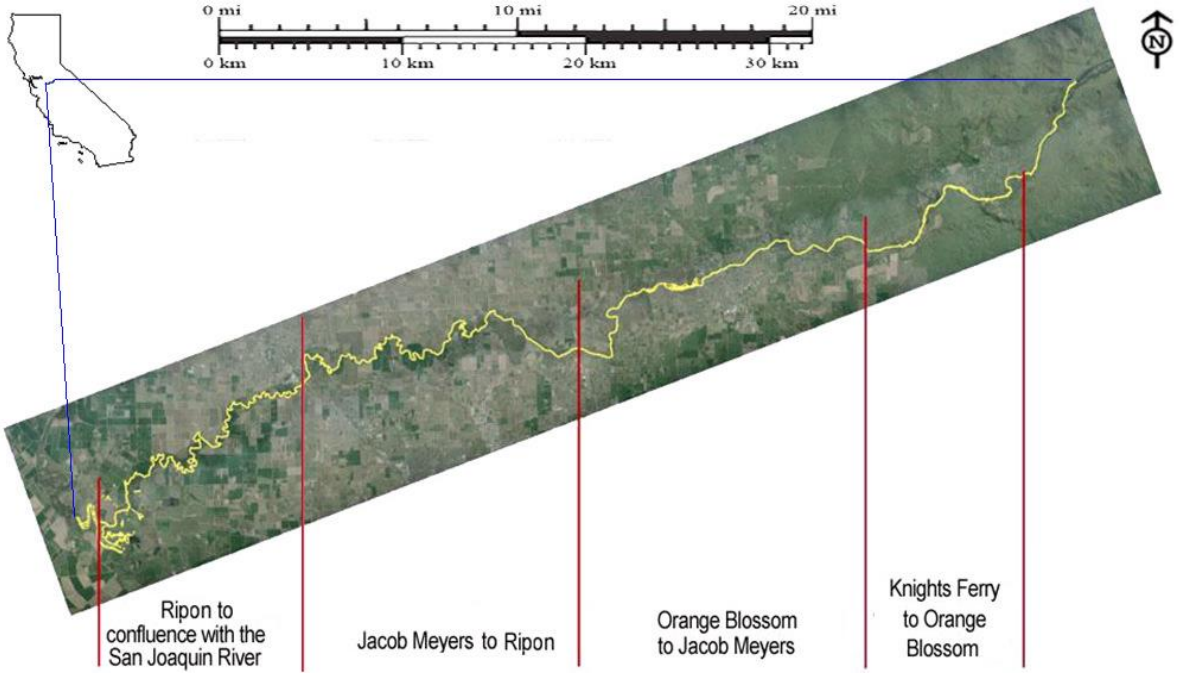

Figure 19-10. Reaches for Stanislaus River floodplain area versus flow modeling. This figure was developed by the USFWS (2013).

The calibrated model was then used for hydraulic simulations at flows ranging from 250 to 5,000 cfs. The model output was then processed in SMS to compute the total wetted area at each flow. The resulting total wetted area versus flow graph was then examined to determine the flow at which floodplain inundation begins, as shown by an inflection point in the graph. The total wetted area at higher flows was then subtracted from the total wetted area at which floodplain inundation begins to determine the inundated floodplain area at each flow and for each reach.

USFWS (2011, 2012, 2013) found that in the Stanislaus River confluence (with the LSJR) to Ripon reach floodplain inundation starts at 1,500 cfs, in the Ripon to Jacob Meyers reach floodplain inundation starts at 1,250 cfs, in the Jacob Meyers to Orange Blossom reach floodplain inundation starts at 1,000 cfs, and in the Orange Blossom to Knight's Ferry reaches floodplain inundation starts at 1,250 cfs. They were not able to develop hydraulic models for the Goodwin Dam to Knight's Ferry Bridge reach, because SONAR data is not available for that reach.

The current State Water Board floodplain analysis uses USFWS' Stanislaus River floodplain area versus flow relationship (Table 19-18) to analyze the potential effects that a range of unpaired flows (20%, 30%, 40%, 50%, and 60%) could have on available floodplain habitat used by fall-run Chinook salmon and steelhead.

Tuolumne River

This section presents a summary of the methods used by USFWS (2008) to develop floodplain versus flow relationships on the Tuolumne River. The USFWS documentation should be reviewed for a complete description of the methods used.

The USFWS (2008) used direct observation, aerial photography, and GIS techniques to map the wetted surface area for a range of flows between 100 cfs and about 8,500 cfs in order identify potential floodplain habitat on the Tuolumne River. The lower Tuolumne River was chosen for this study, as appropriate GIS data were available for the reach between La Grange Dam at RM 52 and just upstream of Santa Fe Bridge at RM 21.5 near the town of Empire. The data used for this analysis were originally developed as part of the FERC relicensing proceedings for the Don Pedro Project (Project No. 2299). From the information available, USFWS developed a wetted surface area versus flow relationship for the study site (Figure 19-11).

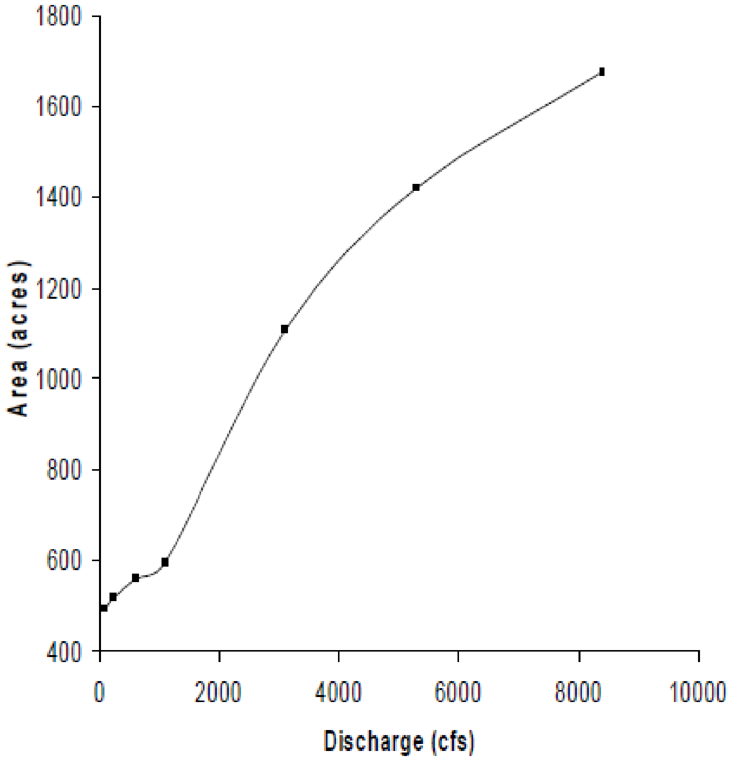

Figure 19-11. Lower Tuolumne River wetted surface area as a function of discharge from RM 52 to RM 21.5. This figure and relationship were developed by USFWS (2008).

The wetted surface area versus discharge relationship indicates a primary inflection around 1,100 cfs which suggests that this is the minimum point where flows may begin to inundate "overbank" areas, or extend out of the channel and into the floodplain. Using the wetted surface area versus discharge relationship and the overbank flow of 1,100 cfs, USFWS developed an overbank (floodplain) area versus discharge relationship by subtracting the in-channel area from the total wetted area for each flow value above initial inundation (Figure 19-12).

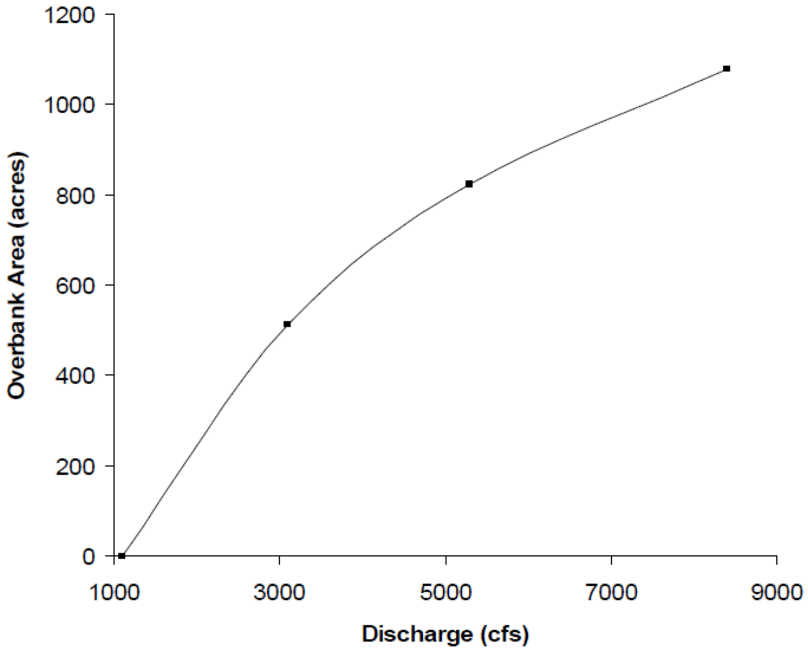

Figure 19-12. Lower Tuolumne River overbank (floodplain) inundated area as a function of discharge from RM 52 to RM 21.5. This relationship was developed by USFWS (2008).

We used this Tuolumne River floodplain area versus flow relationship (Figure 19-12 and Table 19-19) to analyze the potential effects that a range of unpaired flows (20%, 30%, 40%, 50%, and 60%) could have on available floodplain habitat used by fall-run Chinook salmon and steelhead.

Table 19-19. Lower Tuolumne River overbank (floodplain) inundated area as a function of discharge from RM 52 to RM 21.5. These table values were developed by USFWS (2008).

Flow (cfs)	FP Acres
1100	0
3100	513
5300	823
8400	1079

To provide further information for this State Water Board evaluation, additional floodplain values were estimated by fitting a line to the data in Table 19-19. The resulting equation is: $y=530.68\ln(x) - 3728.5$ ($R^2 = 0.9986$), where y equals floodplain acreage and x equals flow in cubic feet per second (cfs).

Merced River

On the Merced River, floodplain versus flow relationships have not been developed to the level of detail of those developed on the Stanislaus, Tuolumne, and LSJR. Therefore, water surface widths (cross sections) from the HEC-5Q temperature model were used at roughly 1-mile increments along the Merced River for a range of flow values. These cross sections were used between Crocker Huffman Dam (RM 52.2) and Santa Fe Road (RM 27) to develop a reach wide water surface area versus flow relationship to estimate floodplain acreage. The relationship for this portion of the river indicated that floodplain inundation begins between 500 and 1000 cfs. We determined that a floodplain inundation threshold of 1000 cfs on the Merced River above RM 27 was appropriate for this evaluation based on the above information, and on the inundation thresholds determined by USFWS on the Stanislaus (1000 cfs) and Tuolumne (1100 cfs) Rivers. Once the inundation threshold was determined, the in-channel water surface area was subtracted from the total water surface area to determine the out-of-channel surface area (floodplain area). The resulting floodplain versus flow relationship used is: $y = 342.69\ln(x) - 2380.9$ ($R^2 = 0.9952$) (Table 19-20), where y equals floodplain acreage and x equals flow in cfs.

Table 19-20. Merced River floodplain area versus flow from Crocker Huffman Dam (RM 52.2) to Santa Fe Road (RM 27).

Lower San Joaquin River

cbec, inc. (2010) utilized a 1D hydraulic model for the SJR, between the Merced River confluence and the Mossdale Bridge, to characterize the relationship between floodplain inundation and flow (Table 19-21 (data from cbec's Table 5)). Inundation mapping was performed by running a range of flows through the model in increments of 1,000 cfs from 1,000 cfs up to 25,000 cfs. The inundation mapping data was delineated into four reaches: Reach 1 is from Newman (Hills Ferry Road just downstream from the Merced River) to E Las Palmas Avenue (19 miles), Reach 2 is from E Las Palmas Avenue to the Tuolumne River (14 miles), Reach 3 is from the Tuolumne River to the Stanislaus River (10 miles), and reach 4 is from the Stanislaus River to Mossdale (Interstate 5) Bridge (17 miles). Flow versus floodplain inundation relationships developed by cbec, were used in this State Water Board analysis to evaluate effect of different unimpaired flows on floodplain in the LSJR.

Table 19-21. Inundated floodplain acreage in San Joaquin River between Mossdale (Interstate-5 Bridge (RM 56.2) and the confluence with the Stanislaus River (RM 72.5). This information is from Table 5 in cbec 2010, but acres are rounded to the nearest whole number.

19.3.3 Results of Floodplain Inundation Evaluation

The results of the current floodplain analysis indicate that improvements (compared to baseline) to the frequency of floodplain inundation can be achieved by implementing the 20%, 30%, 40%, 50%, or 60% unimpaired flows. The improvements to the frequency of floodplain inundation events primarily occur during April, May, and June, although the higher unimpaired flows (40-60%) provide some benefit in February and March. During April through June, most of the unimpaired flows evaluated provide some benefit compared to baseline, with the lower unimpaired flow providing less benefit and the higher unimpaired flows providing greater benefit (Tables 19-22 through 19-27).

Table 19-22. Percentage of years under baseline (base) conditions with average monthly Stanislaus River flows at Goodwin Dam greater than the specified flow, and the expected percent change under each of the unimpaired flows between 20% and 60%. Corresponding floodplain acreages are from Knights Ferry (RM 54.5) to the confluence with the SJR (RM 0). The gray shading indicates flows which are below the floodplain inundation threshold. Changes to frequency of occurrence which are greater than positive 10% are highlighted green, and changes to frequency of occurrence which are less than negative 10% are highlighted red (if applicable).

Table 19-23. Percentage of years under baseline (base) conditions with average monthly Tuolumne River flows at La Grange Dam greater than the specified flow, and the expected percent change under each of the unimpaired flows between 20% and 60%. Corresponding floodplain acreages are from La Grange Dam (RM 52) to just upstream of Santa Fe Bridge (RM 21.5). The gray shading indicates flows which are below the floodplain inundation threshold. Changes to frequency of occurrence which are greater than positive 10% are highlighted green, and changes to frequency of occurrence which are less than negative 10% are highlighted red (if applicable).

Stanislaus River Floodplain Evaluation Results

Baseline: Under existing conditions on the Stanislaus River, April and May experience floodplain inundation flows most often, with average monthly flows greater than 1,000 cfs (floodplain inundation threshold) occurring approximately 60% and 59% of the years, respectively. Each of the other months between February and June have a lower frequency of floodplain inundation, with February having the lowest frequency (10%) of monthly average flows over 1,000 cfs. Interestingly though, February also has the highest frequency (4%) of monthly average flow greater than 3,000 cfs (326 acres) (Table 19-22).

20-60% Unimpaired Flow: During March, only the 60% unimpaired flow provides an increase of 10% or more (12%) in the amount of years with monthly average flows which are greater than 1000 cfs. However, even the 60% unimpaired flow in March does not provide a significant increase in the amount of time that monthly average flows are greater than 1,250 cfs (19 acres). During the other months from February through June, the higher unimpaired flows provide greater increases compared to the lower unimpaired flows in the amount of time that monthly average flows are greater than the floodplain inundation threshold. May is the month with the largest increase in floodplain flows, with monthly average flows greater than 2,000 cfs (161 acres) occurring approximately 51% more often than baseline under the 60% unimpaired flow (Table 19-22).

Tuolumne River Floodplain Evaluation Results

Baseline: Under existing conditions on the Tuolumne River, March and April experience floodplain inundation flows most often, with average monthly flows greater than 1,100 cfs (floodplain inundation threshold) occurring approximately 55% and 44% of the years respectively. Each of the other months between February and June have a lower frequency of floodplain inundation, with May and June having the lowest frequency (35% and 24% respectively) of monthly average flows greater than 1,100 cfs (Table 19-23).

20-60% Unimpaired Flow: During February and March, modeling does not indicate that the alternative unimpaired flows evaluated would produce significant floodplain benefits. During April through June, the higher unimpaired flows provide greater increases compared to the lower unimpaired flows in the amount of time that monthly average flows are greater than the floodplain inundation threshold. May is the month with the largest increase in floodplain flows, with monthly average flows greater than 1,500 cfs (152 acres) occurring approximately 78% more often than baseline under the 60% unimpaired flow (Table 19-23).

Merced River Floodplain Evaluation Results

Baseline: Under existing conditions on the Merced River, the frequency of monthly average flows greater than 1,000 cfs (floodplain inundation threshold) occurs similarly during February through June ranging between 5% (April) and 29% (February) (Table 19-24).

20-60% Unimpaired Flows: The 20-60% unimpaired flows result in significant increases in the frequency of flows greater than 1,000 cfs during the months of April, May, and June, but do not increase the occurrence of these events during February or March. During April through June, the higher unimpaired flows provide greater increases compared to the lower unimpaired flows in the amount of time that monthly average flows are greater than the floodplain inundation threshold.

May is the month on the Merced River with the largest increase in floodplain flows, with monthly average flows greater than 1,000 cfs occurring 70% more often under the 60% unimpaired flow (Table 19-24).

San Joaquin River Floodplain Evaluation Results

Baseline: Reaches 1 and 2 make up the section of the SJR between the Merced and Tuolumne Rivers. Under baseline flow conditions, floodplain inundation occurs most frequently during February and least frequently during June. Under existing channel configuration floodplain inundation occurs as low as 1,000 cfs (67 acres). Between 1,000 and 4,000 cfs there is a slow rate of increase in floodplain acreage with additional flow. Above 4,000 cfs (287 acres) the rate floodplain acreage increases rapidly (see Table 19-21). Under baseline conditions, monthly average flows greater than 4,000 cfs occur 18%, 16%, 12%, 16%, and 11% of the years during the 82-year period for February, March, April, May, and June respectively (Table 19-25).

The LSJR Reach 3 is located between the Tuolumne and the Stanislaus Rivers. Under existing channel configuration there is small amount of floodplain inundated at flows as low at 1000 cfs (8 acres). From 1,000 cfs to 7,000 cfs there are minimal gains to floodplain inundation with increasing flow. Above 7,000 cfs (286 acres) there is an increased rate of floodplain inundation as flows increase (see Table 19-21). Floodplain inundation under baseline conditions is similar from February to May, and then drops off in June. Monthly average flows greater than 1000 cfs occur 99%, 91%, 83%, 84%, 40% of the of the years during the 82-year period for February, March, April, May, and June respectively. Monthly average flows greater than 7,000 cfs occur 22%, 20%, 15%, 15%, and 15% of the years during the 82-year period for February, March, April, May, and June respectively (Table 19-26).

Reach 4 is located in the LSJR from the Stanislaus River confluence to Mossdale. In Reach 4, monthly average Vernalis flow greater than 7,000 cfs (125 acres) occur 28%, 34%, 26%, 21%, and 20% of the years during February, March, April, May, and June respectively. In general, each month from February through June has a similar pattern of monthly average flows that inundate floodplain, except that June has a lower frequency of lower flows. For example, a monthly average flow of 2,000 cfs (75 acres) occurs approximately 80% of the time during February through May, but only occurs 57% of years during June (Table 19-27).

20-60% Unimpaired Flow: Above the Tuolumne River in Reaches 1 and 2 significant floodplain improvements occur primarily under the 40%-60% unimpaired flows. These improvements in the frequency of floodplain inundation occur at flows between 1,000 cfs (67 acres) and 3,000 cfs (129 acres), and the largest floodplain improvements occur in May under the 40%-60% unimpaired flows. Monthly average flow events above 4,000 cfs (287 acres) do not increase substantially under any of the alternatives (Table 19-25).

Between the Stanislaus and Tuolumne Rivers (Reach 3), floodplain improvements from increased unimpaired flows primarily occur during April through June. The higher unimpaired flows produce larger increases in floodplain inundation compared to the lower unimpaired flows. During May, the 50% and 60% unimpaired flows increase floodplain inundation events greater than 7,000 cfs (286 acres) by 15% and 35% respectively (Table 19-26).

In Reach 4, significant improvements to the frequency of monthly average flows above 7,000 cfs (125 acres) occur under the 50% and 60% unimpaired flows in April, occur under the 30%-60% unimpaired flows in May, and occur under the 50% and 60% unimpaired flows in June. May is the month on the LSJR with the largest increase in floodplain flows, with monthly average flows greater than 7,000 cfs occurring 54% more often under the 60% alternative (Table 19-27).

Summarized Floodplain Results

When considering floodplain results on different rivers and different times of the year, it becomes difficult to provide an overall picture of potential floodplain benefits. One way to summarize the floodplain benefits of the evaluated unimpaired flows is to consider a data output commonly referred to as acre-days (see USFWS 2014). This measurement is the number of acres inundated each day, and then summed over an identified time period. Table 19-28 provides a summary of the acre-days of floodplain inundation in the three tributaries that occur under baseline, and under different unimpaired flows during February through June. The table also shows the percentage increase achieved under each percent of unimpaired flow, relative to baseline. There is an overall 35 percent increase in floodplain inundation, from 39,292 acre-days to 53,208 acre-days at 40 percent of unimpaired flow. The percent increase in floodplain inundation is 16 percent and 74 percent, respectively, for 30 and 50 percent of unimpaired flow.

Table 19-28. Annual average floodplain inundation in acre*days and percent increase during February through June for baseline and different unimpaired flow percentages.

Percent of Unimpaired Flow	Unit	Stanislaus	Tuolumne	Merced	Total
Baseline	Acre*Days	4,881	27,668	6,742	39,292
20% UF	Acre*Days	4,475	27,899	7,016	39,390
	Percent Increase	-8%	1%	4%	0%
30% UF	Acre*Days	5,618	31,882	7,895	45,395
	Percent Increase	15%	15%	17%	16%
40% UF	Acre*Days	7,509	36,644	9,055	53,208
	Percent Increase	54%	32%	34%	35%
50% UF	Acre*Days	11,805	44,426	12,055	68,287
	Percent Increase	142%	61%	79%	74%
60% UF	Acre*Days	16,818	53,936	15,879	86,634
	Percent Increase	245%	95%	136%	120%
UF = unimpaired flow					

A critically important time period for floodplain inundation, and also the time period that achieves the greatest benefit from the flow proposal, is the April through June period. Floodplain inundation does not change much during February and March because flows are relatively high during those months already under baseline. Table 19-29 provides a summary of acre-days of floodplain inundation that occur under baseline, and also for 20 to 60 percent of unimpaired flow, for the April through June period. The table also shows the percent increase achieved under each percent of unimpaired flow, relative to baseline. There is an overall 82 percent increase in floodplain inundation, from 21,034 acre-days to 38,352 acre-days at 40 percent of unimpaired flow in the three tributaries. The percent increase in floodplain inundation is 37 percent and 152 percent, respectively, for 30 and 50 percent of unimpaired flow.

Table 19-29. Annual average floodplain inundation in acre*days and percent increase during April through June for baseline and different unimpaired flow percentages.

Percent of Unimpaired Flow	Unit	Stanislaus	Tuolumne	Merced	Total
Baseline	Acre*Days	3,217	13,809	4,008	21,034
20% UF	Acre*Days	2,627	14,676	4,153	21,456
	Percent Increase	-18%	6%	4%	2%
30% UF	Acre*Days	3,844	19,873	5,113	28,831
	Percent Increase	19%	44%	28%	37%
40% UF	Acre*Days	5,716	26,046	6,589	38,352
	Percent Increase	78%	89%	64%	82%
50% UF	Acre*Days	9,543	33,939	9,507	52,988
	Percent Increase	197%	146%	137%	152%
60% UF	Acre*Days	13,909	41,689	13,016	68,615
	Percent Increase	332%	202%	225%	226%

UF = unimpaired flow

As is the case for potential temperature improvements, the benefits of floodplain inundation are greatest during dry and critically dry years. Table 19-30 shows floodplain inundation in the Tuolumne River for baseline and for each 10 percent increment of unimpaired flow from 20 to 60 percent for each water year type. Under baseline, there was no floodplain inundation in critically dry years, whereas under 40 percent unimpaired flow there are 4,172 acre-days of floodplain inundation from April through June. In dry years, floodplain inundation increases by a factor of 14 (1,390 percent), from 602 days to 8,964 acre-days of floodplain inundation. Improvements are similarly large for the Merced River, where there is no floodplain inundation under baseline conditions in below normal, dry, or critically dry years. Improvements are smaller in the Stanislaus River because flows are already relatively high in dry and critically dry years under baseline.

Table 19-30. Average annual floodplain inundation in acre*days and percent increase during April through June for baseline and different unimpaired flow percentages for the Tuolumne River.

Percent of Unimpaired Flow	Unit	All Year Types	Wet	Above Normal	Below Normal	Dry	Critical
Baseline	Acre*Days	13,809	41,553	7,501	555	602	0
20% UF	Acre*Days	14,676	43,300	9,318	964	202	0
	Percent Increase	6%	4%	24%	74%	-66%	NA
30% UF	Acre*Days	19,873	48,199	19,423	8,465	2,758	1,011
	Percent Increase	44%	16%	159%	1424%	358%	NA
40% UF	Acre*Days	26,046	50,334	30,383	19,862	8,974	4,172
	Percent Increase	89%	21%	305%	3477%	1390%	NA
50% UF	Acre*Days	33,939	56,322	41,223	31,160	16,617	9,411
	Percent Increase	146%	36%	450%	5511%	2658%	NA
60% UF	Acre*Days	41,689	63,025	50,896	40,833	24,441	15,187
	Percent Increase	202%	52%	579%	7253%	3957%	NA

UF = unimpaired flow

Note: The percent increase could not be calculated for some river and year type combinations because there was 0 Acre*Days of floodplain under baseline. These value are replaced with NA.

As indicated by these summary tables and the previously discussed floodplain results tables, there is tremendous potential to increase floodplain habitat in these rivers under the proposed project.

19.3.4 Summary and Conclusions of Floodplain Inundation Evaluation

The results of this floodplain analysis indicate that providing more flow with a more natural regime during the February through June time period will significantly increase the amount of floodplain habitat which is available to native fish, and that higher unimpaired flows will produce greater benefit, in terms of floodplain frequency and magnitude (and presumably duration), compared to lower unimpaired flows or baseline conditions. In general, floodplain inundation will increase the most (compared to baseline) during the months of April, May, and June under the evaluated unimpaired flows.

In the last 2 decades, numerous studies have demonstrated that both aquatic and riparian ecosystems benefit from dynamic connectivity between rivers and their floodplains (see Jeffres et al. 2008). For example, riparian species benefit from nutrients mobilized by inundation of floodplain areas (Junk et al. 1989), while riverine species benefit by having access to the floodplain for foraging, spawning, and as a refuge from high velocities in the river during high flow events (Moyle et al. 2007).

Floodplain habitats in the Central Valley have been found to have a positive effect on growth of juvenile Central Valley salmonids (Sommer et al. 2001; Sommer et al. 2005; Jeffres et al. 2008), and larger and faster growth has been associated with increased survivorship in river and to adulthood (Bond et al 2008; Healey 1982; Fritts and Pearsons 2006; Mesick and Marston 2007a; Parker 1971; Unwin 1997; Ward et al 1989; Zabel and Williams 2002). Additionally, fish yields in watersheds generally increase when water surface area in floodplains is increased (USFWS 2014; Bayley 1991 as cited in Jeffres et al. 2008).

Implementation of the proposed project will produce substantial increases in floodplain habitat which is available to native fish and wildlife populations, and it is expected that there will be significant positive population responses by native salmonids, and other native fishes.

19.4 SalSim

19.4.1 Introduction of SalSim

To provide insight into potential management decisions being evaluated for this Bay-Delta Plan update, the State Water Board staff used a life-history population simulation model for fall-run Chinook salmon originating from the SJR and its upper three east-side salmon bearing tributaries (Stanislaus, Tuolumne, and Merced Rivers). This model is called SalSim and was developed by the CDFW, AD Consultants, and a variety of other modeling and fisheries experts (CDFW 2013a; CDFW 2014). The State Water Board used SalSim to explore and compare a variety of flow scenarios in order to assess the response of fall-run Chinook salmon production from the Stanislaus, Tuolumne, and Merced Rivers that may have occurred if these different flow scenarios were implemented in the past. It is important to understand that this model does not predict what is expected to occur in the future. Instead, the model backcasts how salmon populations may have been different in the past (1994-2010) if water management was different in the three east-side tributaries.

Use of SalSim and Advisory for this Bay-Delta Plan Update

During the exploration and use of this model State Water Board staff discovered that the treatment of two of the most important salmon habitat attributes related to flow in the project area, water temperature and floodplain inundation, are not represented by the model in a manner that is consistent with current scientific information. Consequently, SalSim appears to underrepresent the benefit of habitat improvements related to floodplain and water temperature conditions during the spring time period that result from different flow scenarios which were evaluated for this project. Specifically, in SalSim, the downstream movement of juvenile salmon is slowed down when they pass inundated floodplains, which results in a later date and larger size of entry into the SJR and Delta, where a larger size improves survival. However, SalSim does not increase the growth rate of these fish when they are “on a floodplain”. Recent literature (see Jeffres et al. 2008) indicates that growth rates of juvenile salmon on a floodplain can be significantly greater than juvenile salmon rearing in the adjacent river channel. However, exactly how much faster salmon grow on a floodplain depends on many variables that are not completely understood in California, which may explain why SalSim does not contain a relationship between growth rates and floodplain use. By not having increased growth rates during floodplain use, SalSim likely underestimates the direct benefit of floodplain inundation to juvenile salmon survival. Additionally, negative temperature effects from warm water on juvenile salmon survival are under-sensitive during the spring time period in SalSim. For example, the density-independent mortality function (CDFW 2014) for juvenile salmon in SalSim calculates daily survival probabilities near 100% at daily maximum temperatures in excess of 40°C at flows of 550 cfs for salmon 65 mm in length. Temperatures above 30°C and certainly above 40°C are lethal to salmonids during exposure times of seconds or minutes (EPA 2003). Temperature modeling results presented in this chapter indicate that harmful and lethal temperatures can be dramatically reduced during the February through June time period for the proposed project. However, the SalSim model does not appear to apply the appropriate survival response to the reduction of harmful temperatures during the spring time period under some flow and temperature combinations and is likely underrepresenting the benefits of some of the scenarios evaluated. These observations suggest that SalSim functions should be updated to better respond to temperature and floodplain conditions.

These SalSim limitations were not unexpected. The developers of SalSim described in their documentation of SalSim (CDFW 2014) that their "ability to estimate average rates as a function of environmental variation, the key factors being local flow and temperature variables of the river system, is limited by the availability and accuracy of relevant existing empirical data".

Although SalSim's response to potential temperature and floodplain improvements appears to be conservative in nature, model runs by State Water Board staff were informative. Along with our separate temperature analyses, this model helped to evaluate the tradeoffs that are present in water management decisions. Specifically, the model enumerated tradeoffs between the needs of different life stages in the fall time period versus the spring time period. The use of this model informs some of the concepts behind the flow shifting paradigms that may occur through adaptive implementation.

Executive Summary of SalSim

The following executive summary was provided in CDFW's (2014) SalSim documentation:

> "SalSim is a life-history population simulation model for fall-run Chinook salmon originating from the San Joaquin River (SJR) and its upper three east-side salmon bearing tributaries (Stanislaus, Tuolumne, and Merced Rivers). Additionally, SalSim includes functionality for simulating the SJR below Friant Dam. This functionality is currently inactive relative to salmon production due to salmon paucity, but can be activated when that part of the river system begins producing salmon. SalSim does model this portion of the river system's temperatures as a function of flow, storage and meteorological conditions.
>
> The primary objectives of SalSim are to provide a modeling tool that will:
>
> - Serve as a decision support tool for CDFW, regulators and water managers as they seek to restore fall-run Chinook salmon in the SJR Basin;
> - Be used to identify, establish, and evaluate instream flow levels (both in-tributary and mainstem) necessary to enhance habitat conditions for fall-run Chinook salmon;
> - Have broad scientific community acceptance;
> - Have broad management utility and confidence;
> - Be useable by a variety of interested users; and
> - Be fully transparent.
>
> SalSim is essentially three models functioning together as one overall model. The three sub-models include:
>
> - A water operations model that accounts for water movement into and out of the lower rim dam reservoirs on the mainstem SJR (Friant) and the principal east-side tributaries including the Stanislaus River (New Melones), the Tuolumne River (New Don Pedro), and the Merced River (New Exchequer).
> - A water temperature response model that predicts reservoir release temperatures as a function of reservoir storage, ambient air temperature and release patterns. The model predicts water

temperature responses for the lower reaches of each tributary and the entire mainstem of the SJR from Friant downstream to Mossdale.

- A salmon production model, which predicts salmon abundance beginning with the egg stage and extending through the entire salmon life cycle to adults returning inland to spawn 2 to 4 years later.

SalSim is intended as a user-friendly web-based application. Users can interactively perform simulation runs for different water management scenarios, view results on the screen (GUI output) and then download results for further analysis using third party software, such as, HEC-DSS (USACE Data System Storage) and Excel (via CSV output files).

SalSim can also use external data generated by other basin-wide operational and/or water temperature models such as CALSIM II and the San Joaquin River Basin-wide Water Temperature Model (a.k.a. HEC-5Q)".

Model Use Advisory Issued by the Developers

The following model use advisory was provided in CDFW's (2014) SalSim documentation:

> "The SalSim model development team includes this advisory in order to provide clear direction in the use of SalSim. There are two overarching concerns we address below to moderate model user's expectations. The first precaution in SalSim's use is that SalSim, as with all models that have some mechanistic components, is an idealization of the processes occurring at a particular spatial and temporal scale: in SalSim's case that scale pertains to estimating daily growth, mortality, and movement rates. Further, our ability to estimate average rates as a function of environmental variation, the key factors being local flow and temperature variables of the river system, is limited by the availability and accuracy of relevant existing empirical data. In our opinion, given the limitations of these data, SalSim represents best modeling practices and, hence, the best available science for modeling the impacts of localized temperature and flow effects on the outmigrating SJR fall-run Chinook salmon. If the model user wants to modify the system to see a resulting average change in salmon production, currently there is no better tool available to perform this task.
>
> The second precaution in SalSim's use is that the parameters in SalSim are fitted using a "backcasting" approach and hence SalSim should not been seen as a model that is optimized for providing the most accurate possible forecasts. Rather, SalSim has been constructed as a tool to explore and compare scenario's and provide insights to answering "what if …?" questions. That is, SalSim allows the model user to change historical conditions, as represented in the model, in order to assess the response in the system that is most likely to occur. Put another way, SalSim should not be considered an accurate predictor of future salmon populations because, i) there are too many variables that cannot be reliably forecasted (i.e. future year ocean conditions and/or water year types, etc.) and ii) the underlying empirical data used to build SalSim has a considerable unexplained variability due to the absence of information on the availability of relevant factors (e.g. local availability of food for local populations), the use of laboratory rather than field data to estimate certain effects such as temperature effects on mortality and inherent variability itself in the measured environmental data (e.g. local flow is an average and cannot account for side-eddies and highly localized pools). That a full life cycle model has a high level of unexplained variability for an animal inhabiting such a diverse geographic life history spanning three ecosystems (i.e. inland, delta, and ocean) is to be expected.
>
> SalSim model developers fully understand that it is important to bound model predictions to frame uncertainty in a formal way. This has not yet been developed for SalSim predictions due to time and funding limitations. This, along with formal model parameter sensitivity assessment to refine the variance-bias trade-off in identifying the appropriate number of variables to include in a simulation model, is planned for future model versions pending funding availability. Despite this shortcoming, the model developers firmly believe that SalSim is nonetheless the best available tool to inform SJR fall-run Chinook salmon management decision making with the understanding that the results are couched in terms of what would be expected on average even though extremes (i.e. higher than or

lower than) might occur given the unexplained variability present in existing empirical data used to build SalSim. This type of situation where management decisions are made despite considerable uncertainties in the data is common in public health issues, such as analyses involving infectious diseases and vaccines, etc. Thus data uncertainty should not be used as an excuse not to use SalSim or to make management decisions.

It is worth noting that SalSim was not created in a vacuum. Rather, available empirical data combined with expert opinion and use of industry accepted (i.e. well established and proved) mathematical and statistical procedures and formulations coupled with formal peer review were used to build a state-of-the-art simulation model. SalSim predicts salmon population response given a suite of physical (abiotic) and biological (biotic) factors to visualize what would occur on average in the future if, and only if, the past were perfectly replicated in the future absent those changes the model user chooses to make.

Despite these model use precautions, SalSim developers are confident that the results arising from model runs represent on average what is most likely to happen if the defined environmental conditions that the model user chose had actually occurred. However, individual year nuances that are unforeseen cannot be accounted for in SalSim. Thus, it is important for model users to understand that SalSim results represent “on-average” conditions given the underlying likelihood survival probabilities occur that were developed per the empirical data available at the time of SalSim development.

A question arises in how to interpret various scenarios where the user conducts several runs making incremental changes in the system. It is not our intention that model runs be compared in terms of the specific number of salmon produced. Rather, various scenarios should be compared more broadly by looking at the percentage change in annual salmon production (foremost would be the percent change in adults and secondary would be the percent change in juveniles produced by each tributary, then total juveniles reaching the Delta, then entering the ocean). This analysis would be more of a qualitative evaluation versus a strictly quantitative comparison.

In summary, SalSim represents the best scientific tool available, gives both a qualitative and quantitative understanding of salmon life history and the underlying physical and biological systems influencing salmon production, and use of SalSim is substantially more reliable than making uninformed (i.e. uneducated) guesses about what would be expected to happen on average if the physical environment were changed from that which existed historically. This type of “backcasting” modeling is consistent with the philosophy employed by other widely used simulation models, such as CALSIM II, HEC-5Q, DSM2, to name a few. The idea is that by learning from the past we could better plan for the future.

Thus the State Board, and/or other management making decision bodies, are urged to use SalSim both to better inform present decision making and to inform decisions on how best to collect data in the future to get the most “bang for the buck” from the new information that is collected.”

19.4.2 Methods of State Water Board SalSim Evaluation

The State Water Board used SalSim to explore and compare a variety of flow scenarios in order to assess the response of fall-run Chinook salmon production from the Stanislaus, Tuolumne, and Merced Rivers that may have occurred if these different flow scenarios were implemented in the past. For this evaluation, total adult salmon production (defined below) was used as the primary comparative metric between each of the flow scenarios. To inform the iterative process of testing different scenarios other metrics such as egg production, egg survival, juveniles leaving each tributary, and juvenile survival were used to inform subsequent scenarios.

The following method subsections provide additional details regarding the inputs and outputs used for the State Water Board SalSim modeling runs and evaluation.

Methods: Flow and Temperature Inputs to SalSim

Flow and temperature inputs used in the State Water Board's SalSim runs can be organized in two basic categories: 1) inputs to SalSim that came from modeling used in the SED evaluation, and 2) inputs generated specifically for SalSim flow shifting scenarios. The following subsections describe the differences in temperature and flow inputs used for these SalSim runs.

(1) Inputs from flow and temperature modeling as used in the SED

SED Flow Modeling

The State Water Board developed the WSE model to simulate the baseline and LSJR alternatives for water years 1922-2003 and to determine the effects on reservoir operations, water supply diversions, and river flow for each of the eastside tributaries (Stanislaus, Tuolumne, and Merced Rivers) and flow and salinity at Vernalis on the SJR. The scientific basis for the WSE model is described in Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*, and the detailed methods and results for the LSJR alternatives are presented in Appendix F.1, *Hydrologic and Water Quality Modeling*. The WSE model was used to inform the SED to analyze project effects in accordance with CEQA requirements.

The WSE modeling runs which were used in the SED and in SalSim are referred to as unimpaired flow runs in the following SalSim sections, and are labeled SB20%UF for example for the 20% unimpaired flow run. This is to distinguish those scenarios from other scenarios where further consideration was given to temperature, flow, and storage to optimize adult salmon production. These additional modeling runs are referred to as flow shifting runs, and are described below in more detail.

SED Temperature Modeling

To model effects on temperature in the LSJR and three eastside tributaries for the SED, the State Water Board used the San Joaquin River Basin-Wide Water Temperature and EC Model (shorthand used here is SJR HEC-5Q model or temperature model) developed by a group of consultants between 2003 and 2008 through a series of CALFED contracts that included peer review and refinement (CALFED 2009). The temperature model was most recently updated by the CDFW and released in June of 2013 (CDFW 2013b).

The temperature model uses the Hydrologic Water Quality Modeling System (HWMS-HEC5Q), a graphical user interface that employs HEC-5Q, the USACE HEC flow and water quality simulation model, to model reservoir and river temperatures subject to historical climate conditions and user defined operations. The temperature model was designed to provide a SJR Basin-wide evaluation of temperature response at 6-hour intervals for alternative conditions, such as operational changes, physical changes, and combinations of the two. The extent of the model includes the Merced, Tuolumne, and Stanislaus River systems from their LSJR confluences to the upstream end of their major reservoirs (i.e., McClure, Don Pedro, and New Melones, respectively). The upstream extent of the model on the LSJR is the Merced River confluence. The downstream extent of the model is the LSJR at Mossdale. The model simulates the reservoir stratification, release temperatures, and downstream river temperatures as a function of the inflow temperatures, reservoir geometry and outlets, flow, meteorology, and river geometry. Calibration data was used to accurately simulate temperatures for a range of reservoir operations, river flows, and meteorology.

The temperature model interfaces with CALSIM (see Appendix F.1, *Hydrologic and Water Quality Modeling*) or monthly data formatted similarly to CALSIM output. A pre-processing routine converts the monthly output to a format compatible with the SJR HEC-5Q model. This routine serves two purposes: 1) to allow the temperature model to perform a long-term simulation compatible with the period used in CALSIM II, and 2) to convert monthly output to daily values used in the temperature model.

Using the monthly output from the WSE model (see Appendix F.1), the "CALSIM to HEC-5Q" temperature model pre-processor was used by the State Water Board, and the temperature model was run to determine the river temperature effects of different flow scenarios within the Stanislaus, Tuolumne, Merced, and Lower San Joaquin Rivers. The temperature model was run for the period 1970 through 2003, a period with sufficient length and climatic variation to determine the effects of the LSJR alternatives on river temperatures.

The HEC-5Q modeling outputs that were used for the State Water Board's SED evaluation were used as SalSim inputs for the unimpaired flow runs.

(2) Flow Modeling Modifications for the Purposes of SalSim

There are three additional flow and temperature modeling steps that were performed for the purpose of evaluating SalSim scenarios. First the WSE model was extended to run through 2010. Second, a scenario was evaluated where 25% of the February through June flow requirement water was shifted to other times of the year. Third, the temperature operations function in the temperature model (see CDFW 2013b: Appendix B, *System Operation for Temperature Control*) was used to set temperature and flow targets during all times of the year, and water from the February through June flow requirement could be used to try to meet these targets. For each of these modifications, all other constraints such as existing regulatory requirements, diversions, and end of year storage remained in effect as described in the WSE model. These three modeling steps are described below.

Extending the WSE Model

As described above, the State Water Board's WSE model operates from 1922 to 2003. SalSim is designed to operate from 1994 to 2010. To make full use of SalSim, the WSE model period was extended through 2010. This was accomplished by using the historical reservoir inflows, and estimated monthly data for downstream local inflows, return flows, and water supply diversions, using CALSIM inputs from years with similar hydrology (Table 19-31; also see Chapter 21, *Drought Evaluation*). Output parameters, such as diversions and flows, were then calculated within the WSE model as described in Appendix F.1, *Hydrologic and Water Quality Modeling*.

Table 19-31. Surrogate years that were used to extend the WSE model for the 2004 to 2010 time period

Water Year	Surrogate Year
2004	1972
2005	1980
2006	1998
2007	1994
2008	1930
2009	1971
2010	1973

Shifting 25% of the February through June Flow Requirement

As described in the SED, the proposed project allows for adaptive implementation actions that could shift a portion of the required February through June unimpaired flows to other times of the year to prevent adverse effects to fisheries, including temperature. To test the effect of shifting part of the annual water requirement for LSJR Alternative 3 (40% unimpaired flow) to other times of the year, a SalSim run (called SB40%MaxFS) was completed for this report which shifted 25% of required unimpaired flow to the months of September through December. Of the water that was shifted, 15% was shifted to September, 20% was shifted to October, 25% was shifted to November, and 40% was shifted to December (to total 100% of the shifted water). All rivers and water year types were treated the same. Within each month the shifted flow was distributed evenly for each day. Surface water supply allocations were calculated in the WSE model based on start of October storage that did not include the shifted water. This flow shifting modeling scenario was only done for the 40% unimpaired flow alternative.

Shifting Based on Defined Temperature and Flow Targets

As discussed above, the temperature model has a temperature operations function (see CDFW 2013b: Appendix B, *System Operation for Temperature Control*) which has the capability of operating the reservoirs to try to meet downstream temperature and flow targets. A SalSim modeling run (called SB40%OPP) was made using inputs from a temperature operations run made in the temperature model. This temperature operations run was used to determine if further refined temperature and flow management scenarios, compared to the unimpaired flow SED runs, resulted in improved salmon production in SalSim. The 40% unimpaired flow SED run (LSJR Alternative 3), and the 40% temperature operation run, both used the same volumes of water annually for fish benefit purposes, which is equal to the percent of unimpaired flow objective (40%) during the February through June time period. The SED run primarily allocates the "fish benefits water" during the February through June time period as described in Appendix F.1, *Hydrologic and Water Quality Modeling*. On the other hand, the temperature operations run treats the "fish benefits water" as a bank account and allocates it to meet temperature targets and flow constraints throughout the entire year. Diversions and end of year storage remained the same between the 40% temperature operations run and the 40% unimpaired flow SED run. However, other assumptions like State Water Project and Central Valley Project exports, and flow entering the Stockton Deep Water Ship Channel, were recalculated according to the standard WSE model and SalSim procedures.

The temperature targets and the flow constraints used in the temperature operations run are shown in Attachment 2.

Methods: SalSim Evaluation Criteria

For this evaluation, changes in annual SJR Basin (Stanislaus, Tuolumne, and Merced Rivers) total adult salmon production was used as the primary comparative metric. This metric includes annual SRJ Basin produced commercial and recreational harvest, annual SJR Basin produced salmon that stray out of basin as adults, and annual total SJR Basin produced escapement (hatchery and in-river). This metric does not include adult strays that come into the basin from other watersheds, because it is a set number in SalSim for each year that does not change based on the scenario. To inform the iterative process of testing different scenarios other metrics such as egg production, egg survival, juveniles leaving each tributary, and juvenile survival were used to inform subsequent scenarios.

19.4.3 Results of the SalSim Evaluation

The SalSim results for the unimpaired flow cases (as used in the SED analysis) and the two 40% flow shifting cases indicate that as percent of unimpaired flow is increased, annual average total adult salmon production would have also increased during the 1994 to 2010 time period (Figure 19-13, Figure 19-14, and Table 19-32).

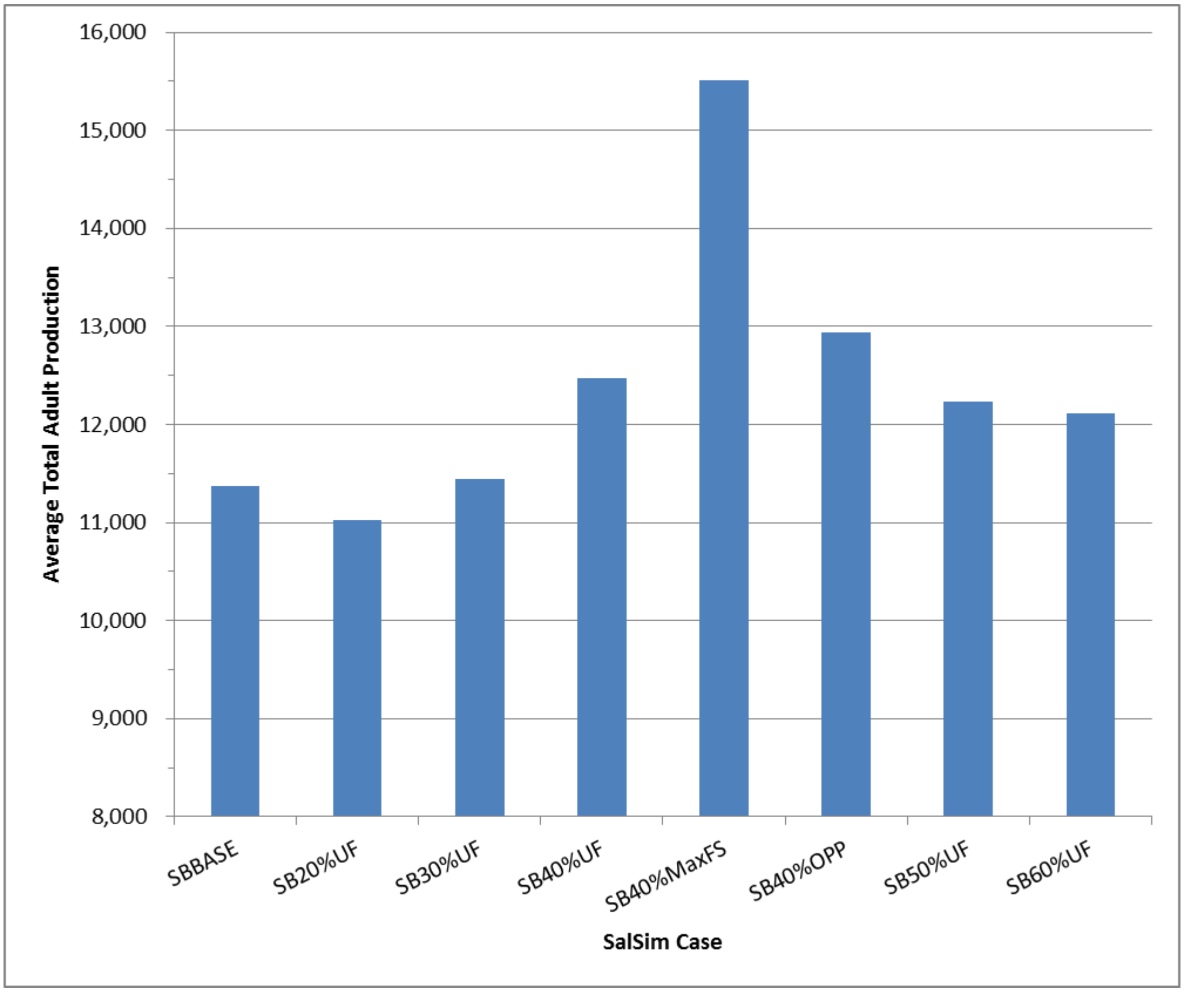

Figure 19-13. SalSim average total adult fall-run Chinook salmon production per year from 1994 to 2010 resulting from different flow cases. These results are the combined results for the Stanislaus, Tuolumne, and Merced Rivers.

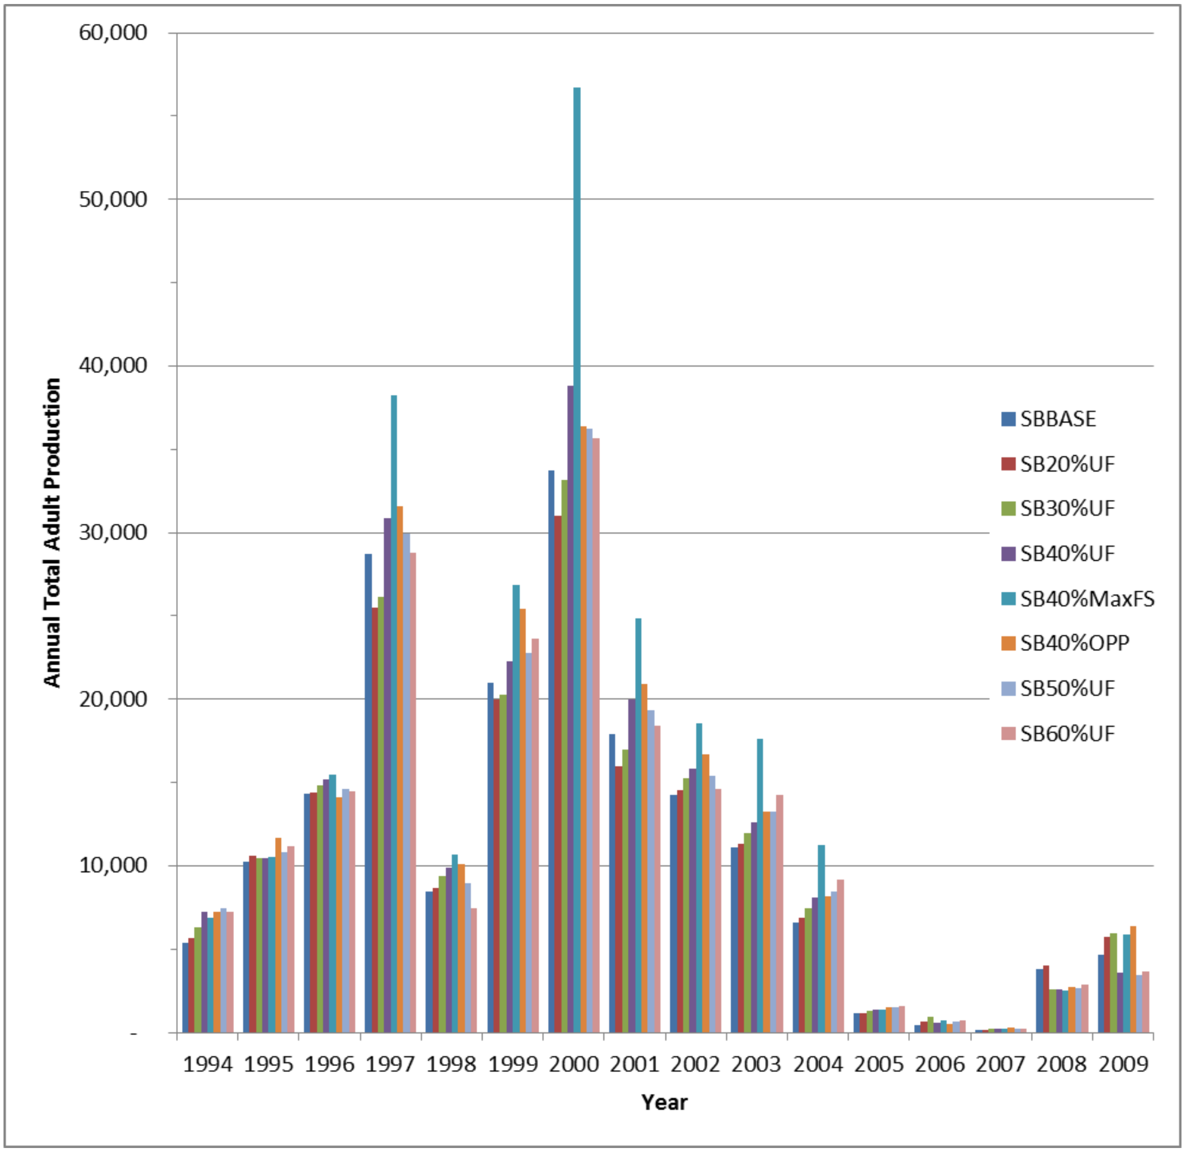

Figure 19-14. SalSim annual total adult fall-run Chinook salmon production from 1994 to 2010 resulting from different flow cases. These results are the combined results for the Stanislaus, Tuolumne, and Merced Rivers.

Table 19-32. SalSim Annual Total Adult Fall-Run Chinook Salmon Production for Different Flow Cases. These results are the combined results for the Stanislaus, Tuolumne, and Merced Rivers, and are also illustrated in Figure 19-14.

SalSim Case	Total Adult Production by Year																Average
	1994	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004	2005	2006	2007	2008	2009	
SBBASE	5,365	10,250	14,328	28,745	8,433	21,001	33,753	17,892	14,289	11,075	6,613	1,129	461	161	3,812	4,665	**11,373**

SB40%MaxFS	6,843	10,540	15,474	38,226	10,704	26,833	56,691	24,875	18,557	17,604	11,252	1,332	693	194	2,499	5,870	**15,512**
SB40%OPP	7,212	11,664	14,106	31,598	10,122	25,432	36,359	20,923	16,689	13,248	8,198	1,479	489	323	2,696	6,399	**12,934**
SB50%UF	7,462	10,791	14,632	29,908	8,959	22,803	36,206	19,362	15,411	13,252	8,486	1,517	671	219	2,681	3,460	**12,239**
SB60%UF	7,229	11,162	14,441	28,770	7,473	23,601	35,632	18,404	14,633	14,258	9,158	1,575	723	204	2,834	3,677	**12,111**

The results of this SalSim evaluation indicate that improving flow conditions during the spring time period with consideration for the fall time period can produce increases in average annual total adult production from the three eastside SJR tributaries during the 1994 to 2010 modeling period. It is important to read the summary section below with respect to what the results mean during this time period. The increases in total adult production can be further improved with refined flow, reservoir storage, and temperature management as shown with the two flow shifting scenarios that were evaluated. It is expected that further refinement of flow, reservoir storage, and temperature management for the 50% and 60% cases would produce increases in total adult production that exceed those that resulted from the 40% flow cases.

19.4.4 Summary and Conclusions of the SalSim Evaluation

The use of SalSim has provided insight into what may have happened in the past if water was managed differently. It is important to understand the SalSim tool when considering what the results mean. Particularly, it is important to understand the limitations of SalSim, and it is important to understand the limitations of making optimized temperature and flow modeling runs and then inputting those flow and temperature results into SalSim.

Limitations of SalSim

All models have limitations and uncertainty. Physically based models like temperature and flow models provide a much greater lever of certainty when compared to biological models like SalSim. Modeling living organisms which have complex behaviors, and experience multi-layered ecological interactions, is a difficult task. As complicated as biological modeling is, the SalSim model appears to generally represent expected patterns. However, SalSim is inherently limited in that it does not have perfect equations (as discussed above) to explain how each environmental variable affects growth, movement, survival, and reproduction of fall-run Chinook salmon. Additionally, it is important to understand that the first 4 years of adult production are priming years, meaning that the juvenile fish from brood year 1994 do not start returning as adults until 1996, 1997, and 1998 as 2-, 3-, and 4-year-old fish, respectively. Therefore, the 1994, 1995, 1996, and 1997 adult returns do not represent a complete comparative result between baseline and the flow cases that were evaluated. Furthermore, ocean crash years which are represented in SalSim affect total adult production from 2005 to 2009 (see CDFW's Table 24 and discussion in CDFW 2014), and appear to force adult production down to approximately the same very low number regardless of the flow case. Whether this forced crash is realistic or not is unclear, because it is possible that changes to the timing, health, and abundance of smolts entering the ocean during those years could have affected how many salmon made it through that bottleneck of poor conditions. It is also possible that improved Delta outflow may have altered bay and nearshore ocean conditions in a way that improved salmon survival. Consequently, looking at a 7-year time period (1998 through 2004) to evaluate improvements to adult salmon production may be a better output instead of looking at the full 16-year SalSim time period. When this 7-year time period is evaluated, average total adult production improvements are greater (compared to the full 16-year time period) for all of the flow cases evaluated except for the SB20%UF case which makes even less fish compared to baseline. For example, the total adult production increases by 4,139 adult fish per year on average when comparing the SB40%MaxFS case to the SBBASE case for the entire 16-year period, but increases by 7,637 adult fish per year on average when comparing these cases for the 7-year period. Because this 7-year time period is so short, it becomes difficult to make inferences about what the results mean in terms of what to expect from improved flow conditions in the long term. It is likely that the increases in adult fish production during this - year modeled time period represent an increasing trend in adult production and do not represent a new long term average of expected increases in adult production into the future.

Limitation of Optimizing Modeling Runs

The program of implementation for this project allows flow shifting within the February through June time period and also allows for some shifting of water outside of this time period. As modeled, the unimpaired SED flow cases are a representation of a requirement for a certain percentage of unimpaired flow during February through June with a small amount of that water shifted to the fall. In some cases, a percentage of an unimpaired flow event for example, may not be ideal for the ecosystem. However, with flow shifting it is possible to bank water and create the full benefit of certain critical flow and temperature events. The flow shifting cases that were evaluated (SB40%MaxFS and SB40%OPP) represent some shifting and optimizing of flow, and both of these cases improved fish production compared to the non-optimized 40% case. Although these cases represent some optimization, it is likely that real-time optimization on a year-to-year, month-to-month, or day-to-day basis, as is possible with adaptive management, would provide even better results in terms of salmon production. However, optimizing flows and water temperatures in order to optimize SalSim cases, requires optimizing 16 years of flow and temperature on 3 different rivers which equates to a total of 48 years of optimization. This can include trying to time flow and temperature benefits to times and locations that match the timing and movement of fish during individual years. In a real-world management scenario, this type of real-time management can be informed by fish monitoring data like rotary screw traps and passage weirs. Optimizing long-term models on this time scale presents significant challenges; therefore rules that favor salmon on average were used to try to improve the non-optimized 40% case. In a real-world scenario, we expect using “on average” rules that are then informed and slightly modified by real-time information, will provide further improvement than what is represented by the modeling cases shown in this report.

History as a Predictor of the Future

The effectiveness of restoring the natural flow regime in a watershed was demonstrated by Kiernan et al. (2012) in lower Putah Creek where a new flow regime was implemented that mimics the seasonal timing of natural increases and decreases in streamflow. Monitoring of several sites pre- and post- implementation of the new flow regime showed a change in the distribution of the native fish community (Kiernan et al. 2012). At the onset of the study, native fishes were constrained to habitat immediately (<1 km) below the diversion dam, and non-native species were numerically dominant at all downstream sampling sites. Following implementation of the new flow regime, native fish populations expanded and regained dominance across more than 20 km of lower Putah Creek. The authors (Kiernan et al. 2012) proposed that expansion of native fishes was facilitated by creation of favorable spawning and rearing conditions (e.g., elevated springtime flows), cooler water temperatures, maintenance of lotic (flowing) conditions over the length of the creek, and displacement of alien species by naturally occurring high-discharge events.

In addition to the Putah Creek example, at least two real-world examples exist of salmon populations in the Central Valley responding substantially well to flow and non-flow restoration actions. These examples are Clear Creek and Butte Creek. Both of these tributaries to the Sacramento River underwent flow and non-flow restoration beginning in the 1990s, which resulted in dramatic population increases of Chinook salmon. On Butte Creek, the spring-run Chinook salmon estimated yearly natural adult production increased from an average of 1,018 adults per year between 1967 and 1991, to an average of 9,713 adults per year between 1992 and 2011 (USFWS 2013a). This increase in adult abundance occurred after a series of projects were implemented including small dam removals, fish ladder installations, fish screen installations, implementation of 40 cfs of dedicated instream flow from October 1 to June 30, and other flow and temperature management actions to reduce mortality to over-summering adult spring-run Chinook salmon. On Clear Creek, estimated yearly natural production of fall-run Chinook salmon increased from an average of 3,576 adults per year between 1967 and 1991, to an average of 10,685 adults per year between 1992 and 2011 (USFWS 2013a). This increase in adult abundance on Clear Creek occurred after a series of restoration actions were implemented including setting minimum instream flow and temperature targets resulting in significant flow increases throughout each year (CVPIA 2013).

Prior to European influence in California, it is estimated that adult spring-run and fall-run Chinook salmon escapement in the SJR drainage totaled in the hundreds of thousands of fish annually as an estimated lower bound (Yoshiyama et al 1998). In the Tuolumne River, fall-run Chinook salmon escapement has declined from approximately 130,000 adult salmon per year during the 1940s (Mesick 2009) to less than 500 adult salmon per year several times during the last few decades. On the Stanislaus, Tuolumne, and Merced Rivers between 1967 and 1991 (well after significant habitat modifications) there was an estimated average yearly natural production of 38,388 adult fall-run Chinook salmon that returned to spawn each year (USFWS 2013a). During the 1992 to 2011 time period there was an estimated average yearly natural production of 18,703 adult fall-run Chinook salmon that returned to spawn each year on these three rivers combined (USFWS 2013a) indicating continued declines of salmon during the last few decades.

Final SalSim Summary

With the projected temperature and floodplain benefits during the spring time period (as indicated by modeling results in the previous sections of this chapter), and with adaptive implementation, it is expected that there will be substantial increases in fall-run Chinook salmon abundance on these tributaries from unimpaired flows at or greater than 40%. The SalSim results support this expectation, and because of the apparent conservative nature of SalSim, the results are likely a lower bound of potential salmon production increases that could have occurred during the SalSim evaluation time period. Finally, it is important to consider that many other native fish and wildlife species are expected to benefit from improved flow conditions during the February through June time period including other imperiled Bay-Delta species such as steelhead, sturgeon, and splittail.

19.5 Final Discussion of Benefits Analysis

Scientific evidence indicates that reductions in flows and alterations to the flow regime in the SJR Basin, resulting from water development over the past several decades, have negatively impacted fish and wildlife beneficial uses (see Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*). The SJR Basin once supported large spring-run and fall-run (and possibly late fall-run) Chinook salmon populations; however, the basin now only supports fall-run Chinook salmon populations, and these populations are facing a high risk of extinction (Mesick 2009, 2010a, 2010b; Moyle 2002). Currently, the SJR Watershed accounts for approximately 5% of all fall-run Chinook salmon in the Central Valley, and a much smaller percentage of total salmon when winter-, spring-, and late fall-runs are included. The Stanislaus, Tuolumne, and Merced Rivers (individually or combined) have had larger reductions in the natural production of adult fall-run Chinook salmon than any of the other tributaries (or combination of three tributaries) to the Sacramento or San Joaquin Rivers when comparing the 1967-1991 and 1992-2011 time periods (USFWS 2013a). The existing low abundance and diversity of naturally spawning SJR Basin salmon and steelhead stocks increases the sensitivity of these stocks to natural disasters, long-term climate change, increasing human population, and other threats that could lead to extinction (Williamson and May 2005; Mesick 2009; Mesick 2010a; Mesick 2010b; Moyle et al. 2008; Lindley et al. 2009). One of the mechanisms of reducing extinction risk is to increase the number and distribution of viable populations within the historical range of the stocks, and to diversify population structures and life history attributes. For Central Valley fall-run Chinook salmon, Carlson and Satterthwaite (2011) suggested that the most effective means of achieving this would be to restore the SJR Basin populations.

One of the goals of the current Bay-Delta Plan update is to maintain flow conditions from the SJR Watershed to the Delta at Vernalis, sufficient to support and maintain the natural production of viable native SJR Watershed fish populations migrating through the Delta. The State Water Board proposes to use a percentage of unimpaired flow to restore a more natural flow regime during February through June on the Stanislaus, Tuolumne, and Merced Rivers to achieve this goal.

This chapter has presented biologically important and measurable benefits of providing higher and more variable flows during this time period using predicted effects to key evaluation, or “indicator species.” For this analysis, the indicator species used were Central Valley fall-run Chinook salmon (*Oncorhynchus tshawytscha*) and Central Valley steelhead (*Oncorhynchus mykiss*). It is anticipated that habitat benefits relative to the indicator species will also provide habitat benefits to other native fish species, including other imperiled Bay-Delta species such as sturgeon and splittail. The results of the temperature, floodplain, and SalSim analysis presented in this chapter indicate that as the percentage of unimpaired flow is increased during the February through June time period, the flow related benefits to salmon and steelhead also increase. Further, as discussed in Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*, there are likely to be many additional benefits (other than temperature and floodplain) that would result from improved flow conditions in these rivers. Improving flows that mimic the natural hydrographic conditions including related temperature and floodplain regimes to which native fish species are adapted, are expected to provide many juvenile salmonids with additional space, time, and food resources which are necessary for required growth, development, and survival. Extending spatial, temporal, and nutritional opportunities available to juvenile fall-run Chinook salmon and steelhead in the Stanislaus, Tuolumne, and Merced Rivers is expected to improve abundance, productivity, diversity, and spatial structure of the SJR Basin and Central Valley populations. Improving and maintaining these important population attributes should help buffer SJR Basin and Central Valley salmon and steelhead populations from catastrophic events and conditions in the future.

Although increasing flow and providing a more natural flow regime is expected to provide substantial and necessary benefits to native fishes; flow alone cannot solve the many issues that native fish populations face in the SJR Watershed. To reach the goal of achieving and maintaining viable populations of native fish, many other non-flow actions (see Program of Implementation as described in Appendix K, *Revised Water Quality Control Plan*) must be taken. For example, large scale habitat restoration should be completed. Additionally, California’s coldwater fish species require cold water, and there should be considerable effort put forth to efficiently provide cold water downstream of California's reservoirs, and to provide migratory fish access to the cold water above these reservoirs. Improved coldwater management and infrastructure will improve California's native fish populations and may save water compared to the current coldwater management and dam infrastructure.

Chapter 20
Economic Analyses

20.1 Introduction

As described in Chapter 1, *Introduction,* the purpose of this recirculated substitute environmental document (SED) is to present the State Water Resources Control Board's (State Water Board) analysis for potential changes to the Lower San Joaquin River (LSJR) flow and southern Delta water quality (SDWQ) objectives, as well as updates to the program of implementation included in the 2006 Water Quality Control Plan for the San Francisco Bay/Sacramento–San Joaquin Delta Estuary (2006 Bay-Delta Plan). This SED, although not an environmental impact report (EIR), fulfills the requirements of the California Environmental Quality Act (CEQA) to analyze the environmental effects of a proposed regulatory activity and its alternatives. The State Water Board must also comply with Section 13141 and Section 13241 of the Porter-Cologne Act when developing and adopting new water quality objectives.

Project-related social or economic effects are not, as a general rule, required to be analyzed in CEQA documents; however, a lead agency may decide to include an assessment of economic or social effects in an EIR (or, by extension, an SED), particularly if these effects are perceived as being important or substantial. As discussed in Section 15131 of the State CEQA Guidelines, economic or social information may be included in an EIR in whatever form a lead agency desires. The State CEQA Guidelines also indicate that social and economic issues may be discussed in an EIR when they are linked to physical change. (§ 15131, subd. (a).) The intermediate economic or social changes that cause the physical change, however, need not be analyzed in any detail greater than necessary to trace the chain of cause and effect. The focus of the analysis should be on the physical changes. If, for example, a construction project would severely limit access to a business area, and the resultant loss of taxes would reduce an agency's ability to maintain infrastructure and public services, then the fiscal (economic) impacts should be discussed. California courts have held that potential economic and social consequences of a program or project that would cause urban decay or blight (e.g., effects on downtown businesses from developing a suburban shopping center) should be discussed in an EIR (e.g., *Bakersfield Citizens for Local Control v. City of Bakersfield*).

Under the California Water Code, the need for economic analysis associated with State Water Board actions is required by two sections. Water Code Section 13141 states:

> . . . prior to implementation of any agricultural water quality control program, an estimate of the total cost of such a program, together with an identification of potential sources of financing, shall be indicated in any regional water quality control plan.

Water Code Section 13241 states that "economic considerations" should be considered in establishing water quality objectives. In practice, compliance with these statutory provisions typically involves quantifying the costs to affected parties (e.g., farmers and water districts), and assessing potential impacts on local and regional economies affected by changes in economic activity. Evaluation of other potential economic effects, such as water quality benefits, typically is conducted more qualitatively.

To address the dual objectives of the proposed plan amendments,[1] this chapter is separated into the following two geographic parts: Section 20.3, *Lower San Joaquin River and Tributaries*, and Section 20.4, *Southern Delta*.

The resources addressed in the *Lower San Joaquin River and Tributaries* section are as follows:

- 20.3.1, *Changes in Hydrologic Conditions*
- 20.3.2, *Agricultural Production and Related Effects on Economic and Local Fiscal Conditions*
- 20.3.3, *Effects on Municipal and Industrial Water Supplies and Affected Regional Economies*
- 20.3.4, *Effects on Hydropower Generation, Revenues and the Regional Economy*
- 20.3.5, *Effects on Fisheries and Associated Regional Economies*
- 20.3.6, *Effects on Recreational Opportunities, Activity, and the Regional Economy*

In addition to evaluating the economic effects on these resources, Section 20.3.7, *Non-Flow Measures,* identifies the costs associated with other potential compliance actions that could be taken to inform the body of scientific literature and assist with adaptive implementation.

Section 20.4, *Southern Delta*, evaluates the potential costs of complying with salinity water quality objectives in the southern Delta, consistent with requirements in Water Code Section 13241. This section presents the potential effects that higher water treatment costs could have on ratepayers and the regional economy.

The geographic locations or study areas discussed in this chapter vary by topic, depending on the resource being evaluated, the temporal and geographic distribution of that resource, and the geographic extent of potential effects on local and regional economies. As such, evaluations may extend beyond the defined plan area described in Chapter 1, *Introduction*. For example, the evaluation of recreation and commercial fisheries includes the Pacific Ocean marine waters and corresponding coastal areas. This is necessary because anadromous fish migrate to the ocean and develop there for usually 3–4 years before they can be harvested in commercial and recreational fisheries as they return to spawn in the freshwater rivers of their origin. The evaluation of recreational activities related to rivers and reservoirs is generally confined to the Stanislaus, Tuolumne, and Merced Rivers and their respective rim reservoirs, New Melones, New Don Pedro, and Lake McClure. Given the spatial variability among topics discussed in the analyses, each subsection in this chapter describes the geography in which the analysis focuses.

Several important considerations need to be noted concerning the analyses contained in this chapter. The purposes of and the analytical framework for these analyses are (1) to compare potential changes in surface water diversion-related economic effects of the LSJR alternatives, and (2) to describe the potential costs of compliance with updated water quality objectives for the southern Delta. Although the analyses conducted to address these two purposes are presented together in this chapter, this should not be interpreted as an attempt to compare relevant costs and benefits of the LSJR alternatives or of the SDWQ alternatives. While the topic-specific analyses include certain analytical components common to each discussion (e.g., evaluation of potential effects on the regional economy), the reader is strongly discouraged from trying to draw conclusions across topics concerning the overall net benefits of a particular alternative. The study areas often differ among the analyses, and information available to conduct the different analyses (such as

---

[1] These plan amendments are the *project* as defined in State CEQA Guidelines, Section 15378.

estimates of physical impacts on a corresponding resource topic) is highly variable, thereby precluding the conduct of a net benefit-type analysis.

The economic analysis presented in this SED will help inform the State Water Board's consideration of potential changes to the 2006 Bay-Delta Plan related to LSJR flow and southern Delta water quality objectives. Any project-level changes to water rights or other measures that may be needed to implement any approved updates to the 2006 Bay-Delta Plan will be considered in subsequent proceedings and would require project-level analysis, as appropriate. Therefore, the economic analyses presented in this chapter, which also summarize results from resource analyses presented elsewhere in this SED and its appendices, are limited by the programmatic nature of this document.

20.2 Summary of Results

The economic analyses in this chapter assess the potential economic effects of LSJR Alternatives 2, 3, and 4 and SDWQ Alternatives 2 and 3 based on how the use of certain resources may change. The economic analyses mostly rely on impacts presented in corresponding chapters and appendices in this SED.

Under the LSJR alternatives, reductions in diversions would result both in potential cost effects (e.g., from reduced agricultural production) and potential beneficial effects (e.g., from enhanced conditions for salmon and other native fisheries) in the three eastside tributary[2] watersheds and the San Joaquin River (SJR) Basin, relative to baseline conditions. Where appropriate in this chapter, baseline conditions are described using modeled results; in cases where modeled results are not available (e.g., fisheries), historical conditions and general trends are used to establish a point of reference. As described in Chapter 3, *Alternatives Description*, baseline conditions are not representative of the No Project Alternative. The No Project Alternative represents continuation of the existing Bay-Delta Plan, with full implementation of the plan through D-1641 requirements. The anticipated economic effects of LSJR Alternatives 2, 3, and 4, which represent unimpaired flow[3] requirements of 20 percent, 40 percent, and 60 percent, respectively, on the three eastside tributaries, are summarized in Tables 20.2-1 through 20.2-5.

---

[2] In this document, the term *three eastside tributaries* refers to the Stanislaus, Tuolumne, and Merced Rivers.

[3] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.

As described in Chapter 3, *Alternatives Description*, LSJR Alternatives 2, 3, and 4 include adaptive implementation. Four different methods of adaptive implementation are analyzed under each LSJR alternative. These are described in detail in Chapter 3 (Section 3.3.3, *Adaptive Implementation*) and allow instream flow requirements under LSJR Alternatives 2, 3, and 4 to be adjusted. In general, the methods are as follows.

- Method 1, increasing or decreasing the percent of unimpaired flow required by up to 10 percent depending on the LSJR alternative selected
- Method 2, adjusting the timing of the unimpaired flow releases within the period of February–June
- Method 3, allowing some of the required unimpaired flow volume to be shifted outside of February–June, depending on the LSJR alternative selected
- Method 4, maintaining a certain base flow in the SJR at Vernalis.

The operational changes made using the adaptive implementation methods above may take place on either a short-term (e.g., monthly or annually) or a longer-term basis. Where appropriate, this chapter presents a qualitative discussion of adaptive implementation for each of the LSJR alternatives.

The SDWQ alternatives would establish a revised salinity objective to protect the beneficial uses of agriculture in the southern Delta. Revising the objective could involve costs to dischargers complying with a new National Pollution Discharge Elimination System (NPDES) discharge permit, new waste discharge requirements, or complying with a new total maximum daily load (TMDL) that is established for protecting agricultural beneficial uses. New or updated requirements would be established through subsequent actions of the Central Valley Regional Water Quality Control Board (Central Valley Water Board). Potential compliance costs would be expected mostly from increased wastewater treatment costs in various wastewater treatment districts, although costs also could be incurred by agricultural operators for return flow salinity controls. Potential ratepayer effects and regional economic effects resulting from higher treatment costs would also be possible. Because the actual methods of compliance that would ultimately be used are necessarily site- and discharge-specific, only general costs of compliance for agencies could be developed, as described below.

- **Reduce salinity discharges by developing new, higher-quality water supplies.** Based on purchases (i.e., water transfers) of substantial quantities of water in the southern Delta between 1997 and 2005, a reasonable cost for a long-term transfer would be about $310 per acre-foot (AF), whereas the purchase cost for a permanent transfer would have been about $1,716 per AF based on environmental water account (EWA) contract sales between 2002 and 2004. (Note that these are examples of unit costs ($/AF) for developing new water supplies and do not represent potential total costs if all water purveyors in the southern Delta portion of the plan area decide to develop new, higher-quality water supplies.) These cost estimates are based solely on the estimated cost of surface water and do not include capital costs (e.g., conveyance of water from source to point of use), administrative, engineering, or legal costs related to securing the water supply and building the infrastructure. Because water supply, demand, and price conditions have changed substantially since the late 1990s and early 2000s, when these unit cost estimates were developed, further research should be conducted to determine the appropriateness of these unit costs for representing current costs.

Based on examples of more recent and comprehensive cost information for relatively large-scale water supply projects, water supply costs could range from $235 to $337 million to develop between 33,600 and 45,000 AF per year (AF/y) of new surface water resources (see Table 16-24). Higher quality water would be used by water purveyors to reduce reliance on groundwater, which is typically more saline than surface water supplies.

- **Implement salinity pretreatment programs.** A wastewater treatment agency could implement a program that involves, for example, replacing 2,000 salt-regenerating water softeners over 5 years. Under such a program, the wastewater treatment agency could reasonably be expected to pay between $929,000 and $9,000,000 over the life of the program ($185,700 to $1,803,100 per year). In the case when a commercial, industrial, or institutional discharger decides to install a desalination device, costs vary based on what is being discharged, the volume, and the desired water quality entering the wastewater collection system. Costs can range considerably; relatively small systems can cost as little as $1,000 to install and $200 per year to operate, whereas larger systems can cost millions of dollars to install and tens of thousands of dollars to operate annually.
- **Develop desalination processes at the wastewater treatment plant.** Assuming a 10 million gallons per day (mgd) discharger, a wastewater treatment agency could be expected to pay between $5 million and $22 million to construct a reverse osmosis system at a wastewater treatment plant (WWTP).
- **Implement agricultural return flow salinity controls.** Control options include real-time management (e.g., changing the timing of the release of agricultural discharge to receiving waters). Assuming 11 real-time management systems to effectively cover the major water users in the plan area, estimated construction costs could total $4.7 million, with an operations and maintenance budget of $1.1 million per year (excluding costs to construct and operate temporary detention ponds).
- **Continue operating the South Delta Temporary Barriers Program.** Implementation for the SDWQ alternatives requires the continued operation (construction and removal) of the temporary barriers in the southern Delta. A recent DWR contract was awarded to build and then remove the temporary rock barriers for approximately $7.5 million, which accounts for other related construction activities but no environmental studies.
- **Provide additional low lift pumping stations at existing south Delta temporary barriers.** Assuming a two-pumping site alternative with 1,000 cubic feet per second (cfs) pumping capacity and combined pumping at Middle and Old River barriers, estimated construction costs could range from $55.5 to $540.7 million, with annual operating costs ranging from $4.5 to $62.7 million.

Under the SDWQ alternatives, costs for complying with salinity objectives could result in rate increases for ratepayers in wastewater treatment districts that do not currently meet salinity objectives set by the alternatives. Assessing how sewer utility rates could be affected by complying with salinity objectives under the SDWQ alternatives is complicated because of several uncertainties that make it infeasible to estimate rate effects as part of this SED's program-level assessment. However, the following wastewater treatment agencies could face increased compliance costs, potentially resulting in higher costs for ratepayers to offset compliance-related expenditures for development and operation of programs and/or facilities.

- No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)— none, or the City of Tracy, City of Stockton, City of Manteca, and Mountain House Community Services District (CSD) depending on the status of NPDES permits.
- SDWQ Alternative 2: 1.0 dS/m salinity—City of Tracy, the City of Stockton, and Mountain House CSD.
- SDWQ Alternative 3: 1.4 dS/m salinity—none.

From the perspective of the regional economy in the southern Delta area, rate increases could shift a portion of the spending by residential, commercial, and industrial ratepayers from consumer goods and services, business employee wages, and business supplies and services to monthly sewer utility bills. This shift, although somewhat speculative, would not be anticipated to affect a large percentage of overall consumer and business spending in the region, but could cause relatively small reduction in sales, employment, and income in several sectors of the regional economy. To some extent, these adverse regional economic effects would be offset by increased spending by wastewater treatment agencies to construct and operate new and expanded facilities and establish and operate programs to achieve updated salinity objectives established by their NPDES permits.

20.3 Lower San Joaquin River and Tributaries

This section describes the potential economic effects of LSJR Alternatives 2, 3, and 4 based on modeling results from the State Water Board's Water Supply Effects (WSE) model and the interpretation of those results. Potential economic effects of adaptive implementation are also addressed. The LSJR alternatives represent new instream flow requirements on the eastside tributaries to the LSJR (Stanislaus, Tuolumne, and Merced Rivers) that are defined as a percent of each rivers unimpaired flow from February–June. Specific requirements of the LSJR alternatives are presented in Chapter 3, *Alternatives Description*. Changes in flows would result both in potential costs (e.g., reduction in agricultural production due to reduced diversions) and potential benefits (e.g., improved fisheries and the enhancement of river recreation opportunities); however, the analyses in this section focus on presenting the pertinent economic effects of LSJR Alternatives 2, 3, and 4 without attempting to sum values across resource topics. The dollar values reported in each subsection that follows, with the exception of certain costs reported in Section 20.3.3, *Effects on Municipal and Industrial Water Supplies and Affected Regional Economies*, are presented in constant 2008 dollars.

20.3.1 Changes in Hydrologic Conditions

As discussed in Appendix G, *Agricultural Economic Effects of Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*, allowable monthly diversions under LSJR Alternatives 2, 3, and 4 were estimated using the WSE model. The WSE model is a monthly water balance spreadsheet model that estimates allowable surface water diversions and reservoir operations needed to achieve the target flow requirements of LSJR Alternatives 2, 3, and 4 on the three eastside tributaries. For the purposes of this analysis, the monthly diversions were added together for a given year and presented as annual allowable diversions in thousand-acre-foot (TAF) increments. The annual diversion estimates were then used to inform the economic analysis of agricultural production effects, municipal and industrial water supply effects, hydropower generation effects, and recreation effects presented later in this chapter. The CALSIM II model run that was used as a source of information for the WSE model is the CALSIM II "Current Conditions" case used in the California Department of Water Resources (DWR) *2009 Delivery Reliability Report* (DWR 2010).

Table 20.3.1-1 summarizes how the LSJR alternatives may impact surface water diversions on the three eastside tributaries and the plan area as a whole. This table presents the average annual allowable surface water diversions under baseline conditions and the potential change of those diversions for each of the LSJR alternative, in total TAF values and as a percent of baseline diversions. Table 20.3.1-1 also includes results for adaptive implementation method 1 under each of the LSJR alternatives for illustrative purposes. Although the adaptive implementation conditions are not quantitatively analyzed for each economic resource topic addressed in this chapter, these adaptive implementation conditions are considered in assessing the likely direction and/or magnitude of impacts associated with a particular LSJR alternative.

As shown in Table 20.3.1-1, the annual average reductions in surface water diversions for the LSJR alternative without adaptive implementation ranges from 2 to 32 percent on the Stanislaus River, 2 to 35 percent on the Tuolumne River, and 6 to 32 percent on the Merced River. For the entire plan area the annual average reduction in surface water diversions for the LSJR alternatives ranges from 3 to 33 percent. In general, average annual diversions are reduced more, relative to baseline, as the unimpaired flow requirement increases (i.e., the least reduction occurs in LSJR Alternative 2 and the greatest reduction occurs in LSJR Alternative 4, both without adaptive implementation.)

The values presented in Table 20.3.1-1 are averaged over the 82-year time period of modeling results for simple reporting. However, because water supplies and related conditions in the watersheds of the Stanislaus, Tuolumne, and Merced Rivers are highly variable over time, diversion reductions could be higher or lower for a specific year than the value reported in the table, depending on the hydrologic conditions. Diversions would likely receive greater cuts in drier years, while diversions may not be reduced at all in wet years, even under LSJR Alternative 4.

Table 20.3.1-1. Average Annual Baseline Water Supply and Differences from Baseline (Changes in Diversions) in the Eastside Tributaries and Plan Area for LSJR Alternatives 2, 3, and 4 (1922–2003)

	Stanislaus (TAF)/(%)	Tuolumne (TAF)/(%)	Merced (TAF)/(%)	Plan Area (TAF)/(%)
Baseline	637/100%	851/100%	580/100%	2,068/100%
LSJR Alternative 2				
Without Adaptive Implementation	-12/-2	-20/-2	-33/-6	-65/-3
With Adaptive Implementation (30%)[a]	-33/-5	-56/-7	-60/-10	-149/-7
LSJR Alternative 3				
Without Adaptive Implementation	-79/-12	-119 /-14	-95/-16	-293/-14
With Adaptive Implementation (30%)[a]	-33/-5	-56/-7	-60/-10	-149/-7
With Adaptive Implementation (50%)[a]	-136 / -21	-193/-23	-136/ -23	-465/-23

	Stanislaus (TAF)/(%)	Tuolumne (TAF)/(%)	Merced (TAF)/(%)	Plan Area (TAF)/(%)
Baseline	637/100%	851/100%	580/100%	2,068/100%
LSJR Alternative 4				
Without Adaptive Implementation	-206/-32	-298/-35	-185/-32	-689/-33
With Adaptive Implementation (50%)[a]	-136 /-21	-193/-23	-136/-23	-465/-23

TAF = thousand acre-feet

TAF/y = thousand acre-feet per year

[a] LSJR Alternatives 2, 3, and 4 include adaptive implementation. The four methods of adaptive implementation are described in Chapter 3, *Alternatives Description*. Results are presented here for method 1, which could result in an increase or decrease of up to 10 percent of the unimpaired flow, depending on the LSJR alternative. The adaptive implementation conditions are not quantitatively analyzed for each economic resource topic addressed in this chapter; however, reference is made to these adaptive implementation conditions in assessing the likely direction and/or magnitude of impacts associated with a particular LSJR alternative.

20.3.2 Agricultural Production and Related Effects on Economic and Local Fiscal Conditions

20.3.2.1 Introduction

The analysis in this section focuses on the potential economic effects that could result from changes in agricultural production caused by reduced surface water diversions under the LSJR alternatives. The economic variables examined include agricultural production and revenues, including groundwater pumping costs, regional economic output, regional economic jobs, and local fiscal conditions. Agricultural production in the tributary watersheds is dependent on irrigation water supply from various sources, including surface water diversions, groundwater pumping, and deliveries from the State Water Project (SWP) and the federal Central Valley Project (CVP). Implementation of LSJR Alternatives 2, 3, and 4 is expected to affect the amount of allowable surface water diversions and, therefore, the agricultural production dependent on those diversions.

The study area for this evaluation includes the San Joaquin, Stanislaus, and Merced Counties (three-county region). Within the three-county region, there are multiple diverters that regularly receive surface water from the Stanislaus, Tuolumne, or Merced Rivers. The primary water providers within this area are collectively referred to as *irrigation districts* and include: South San Joaquin Irrigation District (SSJID), Oakdale Irrigation District (OID), Stockton East Water District (SEWD), Central San Joaquin Water Conservation District (CSJWCD), Turlock Irrigation District (TID), Modesto Irrigation District (MID), and Merced Irrigation District (Merced ID). SEWD and CSJWCD are also sometimes referred to as *CVP contractors*. Many residents and businesses also rely on water from one of the four groundwater subbasins that underlie the three-county region: the Eastern San Joaquin, Modesto, Turlock, and Merced Subbasins[4]. Irrigation district boundaries, counties in which the districts are located, and key municipalities in this region are identified in Figures ES-2 of the *Executive Summary*, Figures 2-1a, 2-1b, and 2-4 of Chapter 2, *Water Resources*, and Figure G.1-1 of Appendix G, *Agricultural Economic Effects of Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*.

---

[4] As described in Chapter 9, *Groundwater Resources*, the Merced Subbasin was extended for the analysis to include a part of the Chowchilla Subbasin.

As described in Sections G.2, G.4, and G.5 in Appendix G, the analysis of agricultural production and related economic effects follows three primary steps. First, total agricultural applied water for the irrigation districts is estimated based on the allowable surface water diversions calculated by the WSE model and the available groundwater pumping capacities of the irrigation districts. Second, the Statewide Agricultural Production (SWAP) model is used to estimate how changes in applied water directly affect agricultural production and associated revenues. Finally, the Impact Analysis for Planning (IMPLAN) input-output model is used to estimate how changes in agricultural production revenues, predicted by SWAP for the study area, could impact regional economic output and jobs. The IMPLAN analysis considers the effects on all interconnected sectors of the regional economy to estimate the total economic effect, including direct, indirect, and induced effects.

If surface water supplies are reduced, diverters would likely increase groundwater pumping to help mitigate shortage and to meet their demands. Therefore, implementation of LSJR Alternatives 2, 3, and 4 also would be expected to affect the need for and costs of additional groundwater pumping by farm operators. Appendix G describes the groundwater pumping calculations in section G.2.1, *Inputs from the WSE Model*, and G.2.2, *Methodology for Calculating Applied Water*, and summarizes the groundwater pumping results in Tables G.3-3 and G.4-11. Potential economic impacts related to the costs of additional groundwater pumping are summarized below.

This section focuses on three related topics: agricultural production and revenues, including the potential impacts of additional groundwater pumping on farm operators, regional economic effects (total economic output and jobs) in the study area, and effects on local fiscal conditions. For each topic, the modeled baseline conditions are compared to modeled results for LSJR Alternatives 2, 3, and 4 to determine the economic effects.

Baseline Agricultural Production and Revenues and Potential Farmer Effects

Assessment Methods

This section describes application of the SWAP model, including a description of the model inputs. The SWAP model is a widely used agricultural production model for estimating the response of agricultural production and associated revenues to changes in water supply. SWAP uses estimates of applied water (described in Appendix G, Section G.2.4, *Estimates of Total Applied Water*) along with crop distribution information (described in Appendix G, Section G.4.2, *Crop Distribution and Applied Water for SWAP*) to estimate agricultural production and associated revenues under baseline conditions and for LSJR Alternatives 2, 3, and 4. For more detailed description of the SWAP model, see Appendix G, Section G.4.1, *Description of the Statewide Agricultural Production Model.*

The SWAP model optimizes available land and water such that net returns to farmers are maximized. As water becomes more scarce, the crops most affected, in general, are Pasture, Alfalfa, Rice, and Other Field Crops. These crops are affected more because they require relatively high water use and/or generate lower net revenue per acre when compared to annual crops, such as Almonds and Pistachios. In this analysis, the lower net-revenue crops cover large portions of the study area; consequently, the acreages of these crop groups are substantially reduced as a result of the LSJR alternatives, particularly for LSJR Alternative 4.

Agricultural Production and Revenues

Table 20.3.2-1 presents the average annual acreage of irrigated crops under baseline conditions and the average difference (in acres and percent) between LSJR Alternatives 2, 3, and 4 and these baseline conditions, by crop group. As shown, total acreage is reduced by about 6,100 acres (1.2 percent) under LSJR Alternative 2, by about 23,700 acres (4.6 percent) under LSJR Alternative 3, and by about 70,600 acres (13.8 percent) under LSJR Alternative 4.

Table 20.3.2-1. Average Annual Acreage of Irrigated Crops for Baseline and Average Difference (in Acres and Percent) between LSJR Alternatives 2, 3, and 4 and Baseline, by Crop Group

	Baseline	LSJR Alternative 2		LSJR Alternative 3		LSJR Alternative 4	
Crop Group	Acreage	Change	% Change	Change	% Change	Change	% Change
Alfalfa	33,311	-716	11.8	-4,584	19.4	-10,528	14.9

TOTAL	512,229	-6,086	-1.2	-23,679	-4.6	-70,640	-13.8

Source: Derived from Appendix G, Agricultural Economic Effects of Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results, Table G.4-6a to Table G.4-6f.

Note: SWAP results presented in this table assume groundwater pumping similar to what occurred in 2009. If groundwater pumping capacity for 2014 is used instead, the results show an overall decrease in the reduction of average annual crop acreage within all irrigation districts, but particularly MID. See Appendix G for more information related to 2009 versus 2014 groundwater pumping information.

As discussed in Appendix G, *Agricultural Economic Effects of Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results,* the SWAP modeling predicts that pasture and field crops could be nearly eliminated from production in some years of extreme drought, particularly under LSJR Alternatives 3 and 4. On the other hand, higher-value crops, such as Vines, remain unaffected under LSJR Alternatives 2 and 3. The modeling results predict that higher-value crops, such as Tomatoes, are less affected by reduced surface water diversion than lower-value crops because farmers would be expected to fallow lower-value crops first. Perennial crops such as Vines, Almonds, Pistachios, and Sub-Tropical crop groups, are predicted to experience decreases in production only during prolonged extreme droughts, such as occurred in the early 1990s.

Similar to changes in crop acreages, when compared to baseline conditions, average annual crop revenues generated across all irrigation districts are predicted to slightly decrease under LSJR Alternative 2 and to decline more substantially as irrigation water becomes less available under LSJR Alternatives 3 and 4. As shown in Table 20.3.2-2, total average annual crop revenues in the entire region would decrease by an estimated $9 million, or about 0.3 percent, under LSJR Alternative 2, as compared to baseline revenues. Under LSJR Alternatives 3 and 4, crop production revenues are estimated to decline by $36 million (2.4 percent) and $117 million (7.9 percent), respectively, as compared to baseline revenues.

Table 20.3.2-2. Estimates of Annual Average Agricultural Revenues under Baseline Conditions and the Change in Revenues for LSJR Alternatives 2, 3, and 4, by Irrigation District

		LSJR Alternative 2		LSJR Alternative 3		LSJR Alternative 4	
	Baseline	Difference from Baseline		Difference from Baseline		Difference from Baseline

Source: Appendix G, *Agricultural Economic Effects of Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results,* Table G.4-9.

Because water supplies and other conditions important to agricultural production are highly variable over time, effects associated with LSJR Alternatives 2, 3, and 4 on crop revenues also vary. These trends are characterized in Appendix G (Figure G.4-1) by an exceedance plot that shows the magnitude and variability of estimated revenues across the 82 years of model simulation (1922–2003) for LSJR Alternatives 2, 3, and 4 and baseline.

Groundwater Pumping Costs and Potential Impacts on Farmers

As discussed in Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*, additional groundwater pumping needed to offset the loss of surface water supplies could affect the profitability of farming operations. These potential impacts, which are discussed in detail in Appendix G, are summarized below.

Factors affecting the costs of drilling and operating new groundwater wells, or to increase the production of existing wells, include pump efficiency, depth of the well, cost of electricity, volumetric flow, cost of materials for maintenance (lubrication, replacement parts, etc.), proximity to water distribution system, and the staff needed to maintain equipment and facilities. For this analysis, an average energy price of $0.189/kilowatt hour (kWh) over the entire irrigation season was assumed based on information contained in the SWAP model (CH2M Hill 2012). The cost effects of additional groundwater pumping on farming operations are presented in Table 20.3.2-3. The average price used for this analysis is considered a conservative assumption because some of the affected irrigation districts have hydropower projects and/or receive discounted power that would be less expensive than this average price,

The estimated increase in groundwater pumping costs would range from $1.3 million per year under LSJR Alternative 2 to $12.7 million per year under LSJR Alternative 4, when compared to baseline conditions (Table 20.3.2-3). In addition to estimating the cost of additional groundwater pumping on farming operations, an IMPLAN-based analysis of the induced effects on proprietary income (presented in Table 20.3.2-3 as Induced Economic Impact) from additional groundwater pumping are estimated to range from about $1 million per year (LSJR Alternative 2) to about $9.8 million per year (LSJR Alternative 4). Loss in proprietor income also may result in some reductions in employment in the study area, ranging from 7 jobs in in LSJR Alternative 2 to about 74 per year in LSJR Alternative 4, when compared to baseline conditions.

One of the effects of increased pumping costs would be to transfer income from farming to mostly power utilities. Because operations of the power utility entities that serve the area are mostly located outside the plan area, most of the benefits in employment and economic output from this transfer would be expected to occur outside the study area.

Adaptive Implementation

Adaptive implementation would take place based on required evaluation of current scientific information and would need to be approved as described in Appendix K, *Revised Water Quality Control Plan.* Accordingly, the frequency and duration for any use of adaptive implementation methods 1, 2, 3, and 4 cannot be determined at this time. Adaptive implementation method 1 potentially has the greatest likelihood to change economic effects as it would allow the unimpaired flow requirement to be increased or decreased by up to 10 percent from the objective unimpaired flow (with a minimum requirement of 20 percent and a maximum of 60 percent unimpaired flow). For LSJR Alternative 2 an increase from 20 percent to 30 percent of the unimpaired flow would likely result in different effects as compared to those shown above for LSJR Alternative 2, depending upon flow conditions and frequency of the adjustment. As such, under LSJR Alternatives 2 or 3, if the percentage of unimpaired flow is increased with adaptive implementation method 1, crop production would likely shift more toward higher-value crops and away from lower value crops (e.g., Pasture, Row Crops) than is predicted without adaptive implementation. On the other hand, under LSJR Alternatives 3 and 4, if the percent of unimpaired flow is reduced with adaptive implementation method 1, the shift toward higher value crops would not be as great and revenue losses for lower value crops would be smaller than those predicted without adaptive implementation.

Baseline Regional Economic Conditions and Potential Regional Effects

This section addresses potential regional economic effects associated with changes in agricultural production and revenues. Estimates of the total economic output and total employment within the three-county region under baseline conditions and under LSJR Alternatives 2, 3, and 4 are presented. As discussed in Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*, IMPLAN-derived multipliers were applied to the estimated changes in crop production revenues as predicted by SWAP to determine these effects.

Table 20.3.2-3. The Average Annual Cost of Groundwater Pumping in the Irrigation Districts, and its Associated Induced Effects on Total Economic Output and Employment under Baseline Conditions and for LSJR Alternatives 2, 3, and 4

			Change from Baseline		
		Baseline[a]	LSJR Alternative 2	LSJR Alternative 3	LSJR Alternative 4
Average Annual GW Pumping	TAF/y	258	21	104	216
Average Annual Cost of GW Pumping	$Millions/y, 2008	15.3	1.3	6.2	12.7
Induced Economic Effect	$ Millions/y, 2008	11.9	1.0	4.8	9.8
Induced Employment Effect	Jobs/y	89	7	36	74

Source: Appendix G, *Agricultural Economic Effects of Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results,* Table G.4-11.

GW = groundwater

TAF/y = thousand acre-feet per year

[a] The baseline induced effects are approximated using marginal impact multipliers, so these values likely differ to some extent from the actual values.

Assessment Methods

To estimate the regional economic effects of agricultural production under baseline conditions and for LSJR Alternatives 2, 3, and 4, this assessment used multipliers developed from the 2010 IMPLAN database. The IMPLAN model relies on a snapshot of the interrelationships among sectors and institutions in a regional economy; it is widely used to assess the regional economic effects resulting from changes in the availability and use of resources.

For the IMPLAN analysis, direct agricultural revenues from the SWAP model, described above, were "mapped" from the SWAP categories to different IMPLAN crop groups. The economic effect of each LSJR alternative was then estimated in terms of the total annual economic output less estimates of the direct annual revenues under baseline conditions. As described in Appendix G, the majority of the irrigation district areas modeled using IMPLAN is contained within San Joaquin, Merced, and Stanislaus Counties.

Potential effects on economic activity can extend beyond the three-county region used to analyze predicted changes in agricultural production. These changes could affect residents and businesses throughout the state, and beyond. In general, even when a change in agricultural production occurs in a particular region, change in economic activity (sales and purchases) typically extends beyond that area, both directly and indirectly. For example, agricultural inputs, such as seed, fertilizer, insurance services, and fuel and transportation, often originate outside the region where they are used. After accounting for direct sales and purchases, the indirect and induced transactions that result from income changes and secondary effects broaden the boundaries of the originally-affected area.

These potential effects outside of the three-county region, however, are not quantified for this analysis; the analysis focuses on the three-county region where the irrigation districts are located and where the direct effects on agricultural production and associated revenues would occur. Effects on areas outside of this region would be more dispersed, thereby incurring an increasingly smaller effect.

Results

Overview of Regional Economic Effects

Under LSJR Alternatives 2, 3, and 4, reductions in water deliveries to agricultural users would affect several sectors of the economy, in addition to agriculture. When farm production decreases as a result of reduced water availability, farmers often would hire fewer seasonal workers and may lay off some year-round workers. Without jobs, household spending by these workers is likely to decrease, affecting retailers and other businesses in the area. In addition, farmers would likely reduce purchases of equipment, materials, and services from local businesses, reducing jobs and income for these suppliers. The total regional economic effect is the sum of the direct effects on agriculture and the associated indirect and induced effects.

Effects on Total Economic Output in the Study Area

Table 20.3.2-4, presents estimates of average annual effects on total economic output (including direct, indirect, and induced effects) related to agricultural production in the irrigation districts under baseline conditions. Table 20.3.2-4 also presents differences from baseline conditions, both in dollars and as a percent, for each LSJR alternative. The table splits the total sector output into direct effects and indirect and induced effects. As shown, as the unimpaired flow for an LSJR alternative increases, the effect on economic output also increases.

Table 20.3.2-4. Estimates of Total Economic Output Related to Agricultural Production in the Irrigation Districts under Baseline Conditions and Associated with Changes in Agricultural Production under LSJR Alternatives 2, 3, and 4

Economic Output Effects	Baseline Total Economic Output ($ Millions, 2008)[a]	Change from Baseline ($ Millions, 2008)		
		LSJR Alternative 2	LSJR Alternative 3	LSJR Alternative 4
Direct Economic Output	1,477	-9	-36	-117
Indirect and Induced Economic Output	1,109	-7	-27	-89
Total Economic Output	2,586	-17	-64	-206
% of Baseline Total Economic Output	100	-0.6	-2.5	-8.0

Source: Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*, Table G-5.4.

[a] The baseline economic output is approximated using marginal impact multipliers, so these values likely differ to some extent from the actual values.

Effects on Total Employment in the Study Area

Table 20.3.2-5 presents estimates of the number of jobs associated with crop production and affected economic activity in other sectors of the economy under baseline conditions. The table also presents differences from baseline conditions, both in total jobs and as a percent, for each LSJR alternative.

The total effect on jobs associated with the LSJR alternatives are relatively similar to the effects on economic output. The number of jobs within the crop production sector (direct effects) and those within other affected sectors (indirect and induced) are presented.

Table 20.3.2-5. Estimates of Total Employment Related to Agricultural Production in the Irrigation Districts under Baseline Conditions and the Change for LSJR Alternatives 2, 3, and 4

Employment Effects	Baseline Total Employment (# of Jobs)[a]	Change from Baseline (# of Jobs)		
		LSJR Alternative 2	LSJR Alternative 3	LSJR Alternative 4
Direct Employment	8,087	-53	-190	-692
Indirect and Induced Employment	10,514	-64	-242	-782
Total Employment	18,601	-117	-433	-1474
% of Baseline Total Employment	100	-0.6	-2.3	-7.9

Source: Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*, Table G-5.6.

[a] The baseline employment is approximated using marginal impact multipliers, so these values likely differ to some extent from the actual values.

Other Regional Considerations

As described in Appendix L, *City and County of San Francisco Analyses*, and summarized in Section 20.3.3, *Effects on Municipal and Industrial Water Supplies and Affected Regional Economies*, the analysis of potential economic effects on water districts and ratepayers in the San Francisco Public Utilities Commission (SFPUC) service area assumes that water districts and farm operators in the plan area would be willing to sell water to the SFPUC for $1,000 per AF and that existing Tuolumne River water supply infrastructure would be used to transfer this water to the San Francisco Bay Area. These assumed agreements would result in a stream of income from the SFPUC to the willing irrigation districts. As shown in Tables 20.3.3-9a and 20.3.3-9b (Section 20.3.3, *Effects on Municipal and Industrial Water Supplies and Affected Regional Economies*), the income that would be paid in severe drought years to the irrigation districts is estimated to be $14 million or $25 million under LSJR Alternative 2, $27 million or $119 million under LSJR Alternative 3, and $30 million or $208 million under LSJR Alternative 4, depending on which scenario under the Fourth Agreement between CCSF and the irrigation districts is agreed upon. (For more information regarding the Fourth Agreement, see Section 20.3.3.4, *M&I Water Supply Conditions in the SFPUC Service Area and Potential Effects*.) This income would be expected to offset, to some extent, the economic effects in the three-county region caused by reduced agricultural production.

Adaptive Implementation

Adaptive implementation would take place based on required evaluation of current scientific information and would need to be approved as described in Appendix K, *Revised Water Quality Control Plan.* Accordingly, the frequency and duration for any use of adaptive implementation methods 1, 2, 3, and 4 cannot be determined at this time. Adaptive implementation method 1 potentially has the greatest likelihood of changing economic effects as it would allow the unimpaired flow requirements to be increased or decreased by up to 10 percent from the objective unimpaired flow (with a minimum requirement of 20 percent and a maximum of 60 percent unimpaired flow). For LSJR Alternative 2, an increase from 20 percent to 30 percent of the unimpaired flow would likely result in different effects as compared to those shown above for LSJR Alternative 2, depending upon flow conditions and frequency of the adjustment. As such, under LSJR Alternatives 2 or 3, if the percentage of unimpaired flow is increased with adaptive implementation method 1, the regional economic and employment effects could be greater than those predicted without adaptive implementation. On the other hand, under LSJR Alternatives 3 and 4, if the percent of unimpaired flow is reduced with adaptive implementation method 1, the regional economic and employment effects could be less than those predicted without adaptive implementation.

Baseline Local Fiscal Conditions and Potential Fiscal Effects

This section describes how changes in agricultural production could affect local fiscal conditions in the three-county study region. Agricultural production encourages economic activity throughout local economies, generating millions of dollars in revenue for farmers and related industries. Federal, state, and local governments also collect a portion of this income by imposing various taxes. Potential fiscal effects at the state and federal level are described in Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*, along with details of the following assessment on local fiscal conditions.

Overview

Because the amount of tax revenue generated by a community depends on its levels of economic activity, reductions in agricultural production may have fiscal impacts on tax revenue for cities, counties, the state, and the federal government. There could be direct impacts on sales tax revenue associated with the reduction in agricultural production because there is less crop product to sell. Property taxes may decrease slightly as property values decline from fallowing of farmland and reduced economic activity in the area. Tax revenue generated from other industries also could decrease in response to the indirect and induced effects caused by changes in crop production. A significant decline in tax revenue from reduced agricultural production could in turn impact the delivery of public services. Although vital services, such as health and safety, would likely maintain funding by tapping into other available sources of revenue, less critical services, such as public transportation and road systems, could be forced to operate with smaller budgets.

Table 20.3.2-6 presents estimates of total tax revenue received by local governments for each county within the three-county region during 2010, and the contribution of crop farming related production and import tax revenues to each county's total. Taxes on production and imports represent sales tax, property tax, and other miscellaneous taxes (severance, motor vehicle license); it does not include income or corporate taxes, which primarily go to the state and federal governments. Of the three counties in the study area, the agricultural sector makes the greatest percent contribution in Merced County where it generates about 4.5 percent of the tax revenue. Overall, San Joaquin and Stanislaus Counties receive more tax revenue than Merced County, primarily because they have larger urban populations, but agriculture contributes a smaller percent of the total tax revenue.

Table 20.3.2-6. Estimates of Local Government Tax Revenue and Crop Farming Contribution from IMPLAN

	Total Annual Tax Revenue to Local Governments[a]	Total Annual Tax Revenue from Crop Farming to Local Governments[b]	Crop Farming Contribution as % of Total Tax Revenue
County	($ Millions, 2010)	($ Millions, 2010)	(%)
San Joaquin	983	18	1.9
Stanislaus	736	11	1.4
Merced	283	13	4.5

$ Million, 2010 = millions of 2010 dollars.

[a] Local government includes the governments of both the county and cities within the county.

[b] Only includes taxes on production and imports, not personal taxes.

Assessment Methods

Multipliers derived from the IMPLAN input-output model are used to estimate potential local tax revenue effects under LSJR Alternatives 2, 3, and 4. These multipliers are developed for a three-county study region of San Joaquin, Stanislaus, and Merced Counties, and also for each of the three counties individually. Table 20.3.2-7 presents the impact and the fiscal impact multipliers associated with an agricultural revenue loss of $1 million in each county. For example, a 1 million dollar loss in agricultural revenue in San Joaquin County would have a direct loss of $15,691 in tax revenue for local governments. Accounting for the indirect and induced effects of the 1 million dollar loss would increase the tax revenue losses to $44,731. To create fiscal impact multipliers for the different levels of government, the total loss at each level of government is divided by $1 million. In other words, the total federal tax impact is 15.4 percent of the agricultural revenue loss, the total state tax impact is 6.1 percent of the loss, and the total local tax impact is 4.5 percent of the loss.

The county fiscal impact multipliers in Table 20.3.2-7 are used with the SWAP results for crop revenue as described in Appendix G, Section G.4.3, *SWAP Modeling Results,* to estimate the tax revenue losses. Before applying the multipliers, SWAP results for crop revenue in each of the irrigation districts are first totaled by county. For OID and TID, which each overlap portions of two counties, the revenue is divided between the counties based on the relative area of the irrigation districts in each county. According the OID AWMP (2012) 20 percent of OID falls in San Joaquin County and 80 percent falls in Stanislaus County. TID is estimated to have 74 percent of its area in Stanislaus County and 26 percent of it area in Merced County, based on GIS analysis.

Table 20.3.2-7. Fiscal Impacts by County of a Hypothetical $1 Million Crop Revenue Loss

Level of Government	Tax Revenue Impact ($ Million, 2010)		Fiscal Impact Multipliers	
	Direct	Total[a]	Direct	Total
San Joaquin				
Federal	-75,482	-154,003	0.075	0.154
State	-27,156	-61,415	0.027	0.061
Local	-15,691	-44,731	0.016	0.045

$ Million, 2010 = millions of 2010 dollars.

[a] Includes direct, indirect, and induced effects of a $1 million (in 2010 dollars) loss in agricultural revenue.

Results

This section focuses on potential effects for local tax revenues under each of the LSJR alternatives, although results for state and federal tax revenues also are addressed. Table 20.3.2-8 shows the annual average tax revenue related to changes (decreases) in agricultural production for each level of government in the three counties individually and in the three-county region as a whole. Under baseline, the federal government receives about $210 million and the state receives about $85 million in tax revenue from agricultural production over all three counties, which is only 0.01

percent and 0.09 percent of their total tax revenue for 2010, respectively. Both federal and state tax revenues from agricultural production in the three counties decrease by an estimated 0.7 percent under LSJR Alternative 2, up to about 8.1 percent under LSJR Alternative 4; however, these changes are minor compared to the total revenue for 2010.

Table 20.3.2-8. Estimated Change in Tax Revenue Associated with Predicted Changes in Annual Agricultural Production for LSJR Alternatives 2, 3, and 4 Relative to Baseline Conditions

		Tax Revenue Effects of Agricultural Production			
		Baseline ($ Millions, 2008)[a]	Change Relative to Baseline ($ Millions, 2008)		
County	Level of Government		LSJR Alternative 2	LSJR Alternative 3	LSJR Alternative 4
San Joaquin	Federal	91	-0.41	-1.08	-3.29
	State	36	-0.16	-0.43	-1.31
	Local	26	-0.12	-0.31	-0.96
Stanislaus	Federal	77	-0.89	-3.60	-11.88
	State	31	-0.35	-1.42	-4.69
	Local	20	-0.23	-0.95	-3.13
Merced	Federal	42	-0.12	-0.63	-1.98
	State	18	-0.05	-0.27	-0.86
	Local	13	-0.03	-0.19	-0.59

	Local	59	-0.39	-1.45	-4.68

Source: Appendix G, *Agricultural Economic Effects of Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results,* Table G-5.13.

$ Millions, 2008 = millions of 2008 dollars.

[a] The baseline tax revenue is approximated using marginal impact multipliers, so these values likely differ to some extent from the actual values.

Table 20.3.2-9 summarizes the effect of the LSJR alternatives on local governments and how it compares to the total annual tax revenue from Table 20.3.2-6. Under baseline, local governments in San Joaquin, Stanislaus, and Merced Counties receive an estimated $26, $20, and $13 million in tax revenue from annual agricultural production, respectively. These revenues represent about 2.7 to 4.5 percent of the total annual tax revenue for local governments in each of the three counties (Table 20.3.2-9). For the LSJR alternatives, the resulting impact on tax revenue is small compared to the total annual tax revenue. Stanislaus County has the largest reduction in tax revenue of the three counties, but its losses would not exceed an estimated 0.4 percent of the total annual tax revenue under any of the LSJR alternatives.

Table 20.3.2-9. Estimates of Local Tax Revenue Associated with Predicted Changes in Annual Agricultural Production, as a Percent of Total Tax Revenue

County	Estimates of Total Annual Tax Revenue to Local Governments[a,b] ($ Millions, 2008)	Tax Revenue Related to Predicted Annual Agricultural Production, by County: Baseline Value as % of Estimated Total Annual Tax Revenue[c]	Change Relative to Baseline as % of Estimated Total Annual Tax Revenue: LSJR Alternative 2	LSJR Alternative 3	LSJR Alternative 4
San Joaquin	963	2.7	<0.01	<0.01	-0.1
Stanislaus	722	2.8	<0.01	-0.1	-0.4
Merced	278	4.5	<0.01	-0.1	-0.2

Source: Appendix G, *Agricultural Economic Effects of Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results,* Table G-5.14.

$ Million, 2008 = millions of 2008 dollars.

[a] Local government includes the governments of both the county and cities within the county.

[b] Dollar values from IMPLAN are in $2010 and had to be converted to $2008 with a conversion factor of 0.980 derived from BEA data (BEA 2016).

[c] The baseline tax revenue is approximated using marginal impact multipliers, so these values likely differ to some extent from the actual values.

Given the results presented above (and in Appendix G), LSJR Alternatives 2, 3, and 4 would have a minor effect on tax revenue for all levels of government relative to the total tax revenue collected by each level of government. Tax revenue from agricultural production is a larger percentage of income for local governments than for the federal or state government, but it is still relatively small compared to tax revenue from other sources. Although the three counties in the study area account for some of the largest agricultural producing counties in the state[5], the contribution to tax revenue from agriculture is relatively small for most local governments. A recent report similarly concluded that lost agricultural production over the drought from 2012–2014 did not substantially impact the finances of most local governments (MIS 2014). While there could be localized impacts on small towns that primarily rely on agriculture, most cities within the three-county region would not be expected to experience substantial budgetary changes or impacts on public services.

Adaptive Implementation

Adaptive implementation would take place based on required evaluation of current scientific information and would need to be approved as described in Appendix K, *Revised Water Quality Control Plan.* Accordingly, the frequency and duration for any use of adaptive implementation methods 1, 2, 3, and 4 cannot be determined at this time. Adaptive implementation method 1 potentially has the greatest likelihood of changing fiscal effects as it would allow the unimpaired flow requirements to be increased or decreased by up to 10 percent from the objective unimpaired flow (with a minimum requirement of 20 percent and a maximum of 60 percent unimpaired flow). For LSJR Alternative 2, an increase from 20 percent to 30 percent of the unimpaired flow would likely result in different effects as compared to those shown above for LSJR Alternative 2, depending

---

[5] See information in the 2012 Census of Agriculture for California – county data. Can be accessed at: https://www.nass.usda.gov/Statistics_by_State/California/Publications/

upon flow conditions and frequency of the adjustment. As such, under LSJR Alternatives 2 or 3, if the percentage of unimpaired flow is increased with adaptive implementation method 1, tax revenue related to agricultural production would likely decrease slightly more than is predicted without adaptive implementation. On the other hand, under LSJR Alternatives 3 and 4, if the percent of unimpaired flow is reduced with adaptive implementation method 1, tax revenue related to agricultural production would be slightly larger than predicted without adaptive implementation. Overall, given the very small estimated changes in agricultural-related tax revenue, it is not expected that adaptive implementation would substantially change the effects presented above.

20.3.3 Effects on Municipal and Industrial Water Supplies and Affected Regional Economies

Implementation of LSJR Alternatives 2, 3, and 4 could result in surface and groundwater water supply reductions to municipal and industrial (M&I) service providers in the plan area, as described in Chapter 13, *Service Providers*, and Chapter 22*, Integrated Discussion of Potential Municipal and Domestic Water Supply Management Options*. Specifically, M&I service providers that rely on surface water contracts with irrigation districts within the plan area or rely solely on groundwater from the four primary groundwater subbasins under the plan area could be particularly affected if they do not have ready access to alternative supplies (Tables 13-3a and 13-3b).

This section discusses potential costs to municipal and industrial service providers, identified in Chapter 13, concerning different activities they may undertake to secure reliable water supplies.

Potential effects on ratepayers in affected irrigation districts within the plan area also are evaluated. In addition to potential effects within the plan area, implementation of the LSJR alternatives under drought conditions could result in water supply reductions within the SFPUC retail service area, and within the service areas of the 27 agencies in Alameda, San Mateo, and Santa Clara Counties that purchase wholesale water from SFPUC. The analysis presented in this section (and described in greater detail in Appendix L, *City and County of San Francisco Analyses*) assumes that under LSJR Alternatives 2, 3, and 4, during drought periods, SFPUC could meet its potential water supply shortage by buying water from MID and TID. However, due to the uncertainties of this type of water transfer (i.e., price of water, quantity of water available, willingness of parties to enter into an agreement), other actions that SFPUC might undertake to ensure a reliable supply of water for its service area also are considered (primarily in Chapter 16, *Evaluation of Other Indirect and Additional Actions*, and summarized in Appendix L).

This section first describes M&I water supply conditions in the plan area and addresses potential effects that the LSJR alternatives may have on these water districts and their ratepayers. The section then describes M&I water supply conditions in the SFPUC service area and assesses potential indirect effects of the LSJR alternatives on water supply costs and the regional economy within that service area. Additional details of the assessment for potential M&I water supply effects in the SFPUC service area are included in Appendix L.

M&I Water Supply Conditions in the Plan Area and Potential Water District and Ratepayer Effects

This section addresses potential economic effects of reduced surface water diversions on affected water districts and ratepayers within the plan area under LSJR Alternatives 2, 3, and 4. The following assessment uses three of the service providers in the plan area as examples: SSJID, SEWD, and MID. The discussion first presents information on water usage, types of uses served, rate structures, and facility improvement plans for each district, followed by a qualitative assessment of the potential economic effects on these and other districts (and ratepayers) in the plan area using information presented in Chapter 13, *Service Providers*, and Chapter 16, *Evaluation of Other Indirect and Additional Actions*. These districts exhibit certain characteristics that are important to assessing potential economic effects, as they rely on surface water to meet some or all of their demand and they have agreements to either provide surface water to other water users or receive surface water.

Affected Water Districts

Water service providers in the plan area obtain their water supplies by either diverting surface water from one or more of the three eastside tributaries (see Table 13-2) or by pumping groundwater from aquifers (see Tables 13-3a and 13-3b). Some irrigation districts also have contracts or agreements to obtain water supplies from other water users, including water districts or conservation districts. Irrigation districts within the plan area obtain most of their water supply from surface water diversions; other water users primarily rely on groundwater, or a combination of groundwater and surface water, for their water (see Tables 13-3a and 13-3b). As identified in Chapter 13, *Service Providers* (see Table 13-2), five irrigation districts receive surface water from the Stanislaus, Tuolumne, and Merced Rivers, and 13 other water users, including water districts and conservation districts, obtain some of its water from one of the primary surface water diverters.

South San Joaquin Irrigation District

SSJID, together with OID, holds contract rights with the U.S. Bureau of Reclamation (USBR) to divert 600 thousand acre-feet (TAF) of water from the Stanislaus River. Water usage by type of use within the SSJID is identified in Table 20.3.3-1.

Table 20.3.3-1. South San Joaquin Irrigation District Water Usage by Type of Use

Type of Use	Usage (acre-feet)
Treated Water for Cities of Lathrop, Manteca, and Tracy	19,263 (2014)
Groundwater Recharge from Distribution Seepage and Applied Irrigation Water	132,513 (2014)
SSJID Water Transfers	325 (40,150 to San Luis & Delta-Mendota Water Authority in 2013)
Supplemental Water to Improve Flow for Chinook Salmon	(Average of 3,529 from 2000–2010)

Source: SSJID 2015a.

SSJID charges a flat rate of $24 per acre for water service to each parcel performing irrigation, with a $50 minimum charge. In addition, SSJID charges a groundwater recharge fee of $12 per acre for parcels of more than 10 acres with a $25 minimum charge, as long as the parcel is subject to an Irrigation Service Abandonment Agreement (ISAA). In 2013, the district enacted a $3 per AF volumetric charge for water. However, starting in 2016, the district plans to have a two-tier volumetric charge, where it increases to $10 per AF if water use exceeds 48 inches per year (Table 20.3.3-2). Finally, since 2010, the district also has imposed a pressurized water charge of $30/AF for the first 3 AF/y and $40/AF in excess of 3 AF/y for customers served with pressurized water by the District's Irrigation System Improvement Project

Table 20.3.3-2. South San Joaquin Irrigation District2016 Water Rate Structure

Category of Charge	Cost in $/Acre (AC) or $/Acre-Foot (AF)
Fixed Charge	None
Flat Rate	$24/AC (with a $50 minimum)
Groundwater Recharge Fee (for parcels of 10+ acres, subject to an ISAA)	$12/AC (with a $25 minimum)
Volumetric—Tier 1 (water use ≤ 48"/y)	$3/AF
Volumetric—Tier 2 (water use > 58"/y)	$10/AF
Pressurized Water Charge (first 3 AF/y)	$30/AF
Pressurized Water Charge (above 3 AF/y)	$40/AF

Source: SSJID 2015b.

Although the district does not have a fixed capital cost fee, it is allowed by district law to levy assessments for maintenance projects. The district may also collect charges for any services furnished. The second tier volumetric charges (Table 20.3.3-2) were recently enacted to pay for the increased costs of ongoing maintenance and other pipeline costs.

The SSJID's 2011 capital improvement plan includes the following highlights.

- Expanding the Nick C. DeGroot Water Treatment Plant to increase the total output of the plant to 43,000 AF/y of water, which would provide sufficient capacity to supply Escalon with treated water.
- Constructing a new pipeline to Escalon.
- Constructing a 10-mile-long pressurized water delivery system to areas west of Ripon.
- Using newly installed electronic controllers on district groundwater pumps to measure groundwater salinity.
- Implementing a 2011 plan to provide drinking water to Ripon, which requires constructing a new pipeline.
- Supplying a new 80-acre annexation area with irrigation water from existing irrigation facilities.

Stockton East Water District

SEWD provides water to the CalWater Services Company, the Stockton Municipal Utility District, and very small amounts of water to the County of San Joaquin. District surface water is diverted from the Stanislaus River and the Calaveras River. Surface water is stored in two reservoirs and treated at the Dr. Joe Waidhofer water treatment plant. The district provides about 12,400 AF/y of water for urban uses, and about 117,400 AF/y for agricultural uses (SEWD 2014).

As of January 2015, SEWD's rate structure for water included both fixed charges and volumetric charges (Table 20.3.3-3). Also included is a base monthly charge that allocates costs of the Treatment Plant Budget (SEWD 2014). Groundwater production costs are estimated during each update of the water management plan.

Table 20.3.3-3. Stockton East Water District Rate Structure and Units Billed, by Type of Use

Charges	Charge Units	Units Billed During Year	Collected
Fixed Charges			
Urban			
Domestic Groundwater	$37.50/Well	5,042 Wells	$218, 549
Agricultural			
Surface water	$20/AF	4,150 AF	$83,008
Agricultural Groundwater	$4.58/AF	117,434 AF	$537,806
Volumetric Charges			
Urban			
Municipal Groundwater	$164.31/AF	16,122 AF	$2,506,012
Agricultural			
Metered Surface Water	$20/AF	18,965 AF	$379,304

Source: SEWD 2014.

AF = acre-feet

According to the 2014 SEWD Water Management Plan, no new treatment facilities or reservoirs are planned; however, the district has expressed interest in securing additional supplemental supplies from the Calaveras River (SEWD 2014).

Modesto Irrigation District

Water usage by type of use within the MID service area is shown in Table 20.3.3-4. As shown, irrigation water accounts for the largest share (65 percent) of the total water usage in the district.

Table 20.3.3-4. Modesto Irrigation District Water Usage in 2012, by Type of Use

Type of Use	Usage (2012) (acre-feet)
Surface Water—Irrigation	278,800
M&I Treated Surface Water	32,661
Groundwater Pumping—Irrigation (agency wells)	17,300
Groundwater Pumping—M&I (agency wells)	28,700
Groundwater Pumping—Irrigation (private wells)	81,200

Source: MID 2015a.

As of March 2015, MID's water rate structure included both a fixed charge and a four-tier volumetric charge (Table 20.3.3-5). If a customer takes no surface water, the landowner is charged a facilities maintenance fee that is half of the fixed charge, or $20 per acre. Provisions of the Amended and Restated Treatment and Delivery Agreement (ARTDA) reached between MID and the City of Modesto in 2005 allow MID the option to pass higher costs on to water customers, including the City of Modesto, if the state of California levies fees or other charges on MID.

Table 20.3.3-5. Modesto Irrigation District Water Rate Structure

Category	Cost $/Acre (AC) or $/Acre Foot (AF)
Fixed Charge	$40.00/AC
Volumetric—Tier 1 (water use ≤ 24"/y)	$1.00/AF
Volumetric —Tier 2 (24"/y < water use ≤ 36"/y)	$2.00/AF
Volumetric—Tier 3 (36"/y < water use ≤ 42"/y)	$3.00/AF
Volumetric—Tier 4 (42"/y < water use)	$10.00/AF

Source: MID 2015b.

MID is presently moving forward on Phase Two of its Modesto Regional Wastewater Treatment Plant (MRWTP) project, which would expand water treatment capacity to 67,000 AF. As part of the project, new storage tanks and pipelines are expected to be built. During Phase One, MID and the City of Modesto developed a long-term water management plan, which included combining well water with surface water supplies from the Tuolumne River. In addition to water supply, MID also operates an extensive power grid, and the capital costs associated with the power grid are allocated jointly with the water infrastructure costs as part of the Capital Infrastructure Budget (MID 2013).

Potential Effects of the LSJR Alternatives

The LSJR alternatives are expected to result in reduced surface water diversions on the Stanislaus, Tuolumne, and Merced Rivers. The reduced surface water diversion could increase the cost of operations for irrigation and water districts in the plan area. This effect, in turn, could also indirectly affect the customers of the affected water service providers. This section presents an evaluation of these potential effects, including a qualitative assessment on how affected service providers can recover the investment costs of securing other reliable water supplies.

Potential Changes in Water Supply Costs

As discussed in Chapter 13, *Service Providers*, the extent of reduced surface water diversions on the amount of water in the eastside tributaries would vary by alternative. The average percent reduction in water supply on the Stanislaus, Tuolumne, and Merced Rivers is between 2 and 6 percent for LSJR Alternative 2, between 12 and 16 percent for LSJR Alternative 3, and between 32 and 35 percent for LSJR Alternative 4. The extent to which these reductions in surface water diversions would affect water supplies delivered by irrigation and water districts in the plan area would, however, be largely determined based on a number of factors that underlie how each affected service provider obtains its respective water supplies. These factors include a district's established water rights or contracts, the types of uses that water service providers supply, existing (district and others) policies affecting the distribution of water supplies, and local and state regulations. As described in Chapter 13 some water supply contracts include provisions that dictate when and how much surface water can be received by other water users from irrigation districts.

Other important considerations in assessing the extent of potential effects of reduced surface water supplies include a district's ability to expand water production, as needed, from current water sources (e.g., groundwater), its ability to potentially develop alternative water supplies, and the effectiveness of implementing demand-side management measures. As an example, service providers that currently rely on groundwater as their primary source of water (e.g., Central San Joaquin Water Conservation District, Manteca, Ripon, and Escalon) could potentially expand use of groundwater, assuming that additional pumping of groundwater is economically feasible. This situation would be expected to minimize potential cost effects of LSJR Alternatives 2, 3, and 4. Service providers that rely substantially on surface water diversions from the eastside tributaries (e.g., Cities of Modesto and Tracy), however, could experience more substantial cost effects, depending on the factors identified above.

As indicated in Chapter 13, some service providers that cannot expand production from current water sources may need to construct new water supply infrastructure or modify existing infrastructure to obtain water supplies from other sources. Alternatively, water conservation efforts may be effective in offsetting some of the cost effects associated with developing new supplies. According to information recently published by the State Water Board (2016), statewide cumulative water conservation savings in response to Executive Order (EO) B-29-15, State of Emergency Due to Severe Drought Conditions, totaled 23.9 percent between June 2015 and February 2016, compared with the same months in 2013. Ultimately, affected water districts would need to consider the capital and operating costs of acquiring alternative water supplies, including conservation actions, and how these costs could affect the structure of water rates. Estimated costs of developing some presumably feasible alternative water supplies, which are discussed in Chapter 16, *Evaluation of Other Indirect and Additional Actions*, are summarized in Table 20.3.3-6.

Table 20.3.3-6. Cost Estimates for Developing Alternative Water Supplies

Source	Cost Estimate
Water Transfers	$1,716 per AF for an Environmental Water Account contract sale or $310 per AF for a long-term transfer[a]
Substitution of Surface Water with Groundwater	$57–$76 per AF for groundwater pumping electrical costs; $102–$153 per AF annually for total operations and maintenance cost of a groundwater project; $1,938 per AF based on entire operating budget and total groundwater production
Aquifer Storage and Recovery	$158–$238 per AF annually (20-year amortized cost)
Recycled Water Sources:	$400–$2,100/AF for landscape and agricultural irrigation (including capital, operations, and maintenance); $700–$1,200/AF for direct potable reuse (including capital, operations, and maintenance)

Source: Chapter 16, *Evaluation of Other Indirect and Additional Actions*, Section 16.2.

AF = acre-foot

[a] The section below titled *M&I Water Supply Conditions in the SFPUC Service Area and Potential Cost, Ratepayer, and Regional Economic Effects* of the LSJR alternatives discusses the costs associated with a water transfer specific to SFPUC.

Potential Ratepayer Effects

Ratepayers in districts that substantially rely on surface water diversions from the eastside tributaries, and where current rates do not account for unexpected capital costs, would likely be the service providers most affected by the additional costs of replacing lost surface water supplies. Over the long term, most districts would be expected to recover most, if not all, capital costs through rate adjustments. Certain water service provider may consider temporarily halting construction for new treatment facilities, as a project could become less economically viable as a result of reduced surface water diversions; however, over time, districts would be expected to re-spread the fixed costs of its projects, whether completed or not, among their ratepayers to achieve the revenue needed to remain economically viable. The potential impacts of reduced surface water supplies could be largely offset if cost-effective alternative supplies are available, similar to those described in Table 20.3.3-6.

A recent economic analysis of implementing EO B-29-15 (M-Cubed et al. 2015) provides additional insight on the potential economic effects from LSJR Alternatives 2, 3, and 4. Although there are fundamental differences in the actions being taken under the plan amendments and EO B-29-15 (implementation of the EO would result in a substantial reduction in the demand for water by essentially restricting water use, whereas the LSJR alternatives would result in reduced surface water supplies), both actions would not only affect water service providers, but also their ratepayers. Over the long term, any additional net costs to affected water service providers would likely be passed on to the ratepayers, unless specific provisions restrict this action. As presented in the M-Cubed economic impact analysis of EO B-29-15, impacts of restricted water use would principally consist of reduced net revenue for urban water districts and lost benefits for businesses and ratepayers who could have used the water productively. Both types of costs ultimately would be borne by water users, since water utilities would have to adjust their service charges and rates over time to recover the forgone net revenue from ratepayers. Similar actions and ratepayer consequences would be expected from implementing LSJR Alternatives 2, 3, and 4. However, these impacts are expected to vary significantly by district as a result of water use differences, established institutional/legal measures, water rates, and opportunities for obtaining water supplies from other sources.

As highlighted by the differences in sources of water, types of uses and water rates for the three example water providers characterized above, each service provider in the plan area has its own unique set of circumstances (e.g., institutional constraints affected by user types, rate structures, need for new facilities) within which it can react to reduced surface water supplies. As established by state law, the intent of regularly updating water management plans is to provide districts with an opportunity to consider how changes in supply and demand conditions potentially affect each district and its ratepayers. Although water service providers (both primary diverters and other water users) that rely less on surface water would appear to be less vulnerable than other service providers, this is not necessarily the case given the many factors that must be considered. However, service providers with cost effective opportunities to tap alternative sources of water, such as groundwater or water transfers, would be best positioned to minimize potential costs effects of a reduced surface water supply.

Adaptive Implementation

Adaptive implementation would take place based on required evaluation of current scientific information and would need to be approved as described in Appendix K, *Revised Water Quality Control Plan.* Accordingly, the frequency and duration for any use of adaptive implementation methods 1, 2, 3, and 4 cannot be determined at this time. Adaptive implementation method 1 potentially has the greatest likelihood to change economic effects as it would allow the unimpaired flow requirement to be increased or decreased by up to 10 percent from the objective unimpaired flow (with a minimum requirement of 20 percent and a maximum of 60 percent unimpaired flow). For LSJR Alternative 2 an increase from 20 percent to 30 percent of the unimpaired flow would likely result in different effects as compared to those shown above for LSJR Alternative 2, depending upon flow conditions and frequency of the adjustment. As such, under LSJR Alternatives 2 or 3, if the percentage of unimpaired flow is increased with adaptive implementation method 1, water supply costs to affected water districts also would likely increase as these districts would need to develop more costly sources of water supply than those developed without adaptive implementation. On the other hand, under LSJR Alternatives 3 and 4, if the percent of unimpaired flow is reduced with adaptive implementation method 1, water supply costs to affected water districts would be expected to be somewhat less than without adaptive implementation.

M&I Water Supply Conditions in the SFPUC Service Area and Potential Cost, Ratepayer, and Regional Economic Effects

Introduction

SFPUC is a department of CCSF that provides retail drinking water and wastewater services to San Francisco, wholesale water to three Bay Area counties, and green hydroelectric and solar power to San Francisco's municipal departments. The amount of water SFPUC delivers to its service area is largely dependent on water delivered from the Tuolumne River Watershed. LSJR Alternatives 2, 3, and 4 may affect the amount of surface water diversions to the SFPUC service area.

This discussion presents background information on SFPUC's service area and ratepayers. It is followed by an analysis of how the LSJR alternatives could potentially affect water supply costs, the regional economy, and ratepayers in the service area. In addition, the potential economic effects of purchasing water (i.e., water transfers) by SFPUC from willing sellers in the Central Valley are analyzed. Cost information for other actions that SFPUC could take instead of purchasing water can be found in Chapter 16, *Evaluation of Other Indirect and Additional Actions* and summarized in Appendix L, *City and County of San Francisco Analyses*. Where appropriate, sections, tables, and figures from Chapter 16 and Appendix L are cited in this discussion.

Service Area Conditions

CCSF, through the SFPUC, owns and operates a regional water system that provides retail water directly to customers in San Francisco and wholesale water to 27 water agencies and water companies in three Bay Area counties, including those serving parts of Alameda, San Mateo, and Santa Clara Counties. CCSF also delivers water to a small number of isolated retail and wholesale customers along the water system, including customers in Tuolumne County. In 2010, the SFPUC retail and wholesale service areas included service to about 2.6 million residents.

The SFPUC water system has the capacity to deliver about 265 mgd (296,800 AF/y) on average, of which about 85 percent is from the Tuolumne River Watershed through SFPUC's Hetch Hetchy Project, and about 15 percent is from the combined Alameda and Peninsula Watersheds. During drought periods, the water provided by the Hetch Hetchy Project can amount to more than 93 percent of the total water delivered within SFPUC's retail and wholesale service areas.

As Table 20.3.3-7 shows, individual water agencies rely on SFPUC supplies to varying extents. Based on fiscal year 2010–2011 water demands and deliveries, SFPUC provided at least 90 percent of the water used by 19 of the 27 wholesale agencies it served that year. An additional five agencies received at least half their water supply from SFPUC. Water use by customer class also varies widely among the wholesale agencies, as shown in Table 20.3.3-8. Across the entire wholesale service area, about 59 percent was delivered to residential customers, 21 percent to commercial and industrial customers, 11 percent to government and other users, and 9 percent to dedicated irrigation users.

Table 20.3.3-7. SFPUC Water Deliveries to Retail and Wholesale Agencies and Reliance of Agencies on San Francisco Public Utilities Commission Water, 2010

NA = not available.

[a] Includes government uses, recycled water uses, unaccounted-for uses, meter under-registration loses, and other system losses.

[b] Includes dedicated irrigation uses for both private and government customers.

[c] Based on 2010 demands. Does not included city irrigation uses and golf course uses served by groundwater.

[d] Based on fiscal year 2010–2011 demands.

Baseline Ratepayer Conditions

SFPUC funds its water system through two separate budgets, its Hetch Hetchy Water and Power Budget and its Water Enterprise Budget. The Hetch Hetchy Water and Power Budget operates the collection and conveyance of approximately 85 percent of SFPUC's total water supply, employing a system of reservoirs, hydroelectric power plants, aqueducts, pipelines, and transmission lines that carry water and power from Hetch Hetchy to customers in San Francisco and to SFPUC's wholesale customers elsewhere in the Bay Area. The Water Enterprise is responsible for collecting, treating, and distributing SFPUC's water supply to its retail and wholesale customers, as well as operating and maintaining pipelines in San Francisco and throughout the region, 27 pump stations, 28 dams and reservoirs, 9 water tanks, and 3 water treatment plants. An overview of recent budget expenditures under the Water Enterprise Budget and the water portion of the Hetch Hetchy Water and Power Budget are shown in Table L.3-3 in Appendix L, *City and County of San Francisco Analyses*.

SFPUC sets its retail water rates based on an independent rate study conducted at least once every 5 years. Retail water rates consist of a monthly service charge based on meter size and a commodity charge based on usage volumes. Annual rate increases for retail customers are set to meet project costs and debt coverage requirements. SFPUC's water rates for its 27 wholesale customers are based on the Water Supply Agreement established in 2009. In general, costs are apportioned to wholesale customers based on proportionate water use, and rates are reset annually to cover costs as mandated by the Water Supply Agreement. See Table L.3-4 for actual retail and wholesale water rates between 2008 and 2014.

Effects on M&I Water Supply in the SFPUC Service Area

This section addresses how the LSJR alternatives could potentially affect water supply costs, the regional economy, and ratepayers in the SFPUC service area. Regional economic effects are presented within each county in the four-county Bay Area region in which the SFPUC serves retail and wholesale customers. Additional details of the methods and assumptions can be found in Appendix L, *City and County of San Francisco Analyses*.

Potential Change in Water Supply Costs

As discussed in Section L.6 of Appendix L, *City and County of San Francisco Analyses,* LSJR Alternatives 2, 3, and 4 may affect the ability of SFPUC to supply water to its retail and wholesale customers under drought conditions. The magnitude of the effect under drought conditions depends on how the parties involved interpret the Fourth Agreement between CCSF and MID and TID, which currently governs the New Don Pedro Reservoir water bank account on the Tuolumne River. There are two possible scenarios,[6] which are described in Table 20.3.3-9a and referred to throughout the remainder of this evaluation. To assess the effects of additional water supply costs on the four-county Bay Area regional economy, it is assumed that the SFPUC would meet its water demands during severe drought periods (such as within the 6-year drought 1987–1992) by purchasing water from MID and TID. Under this assumption, water costs for SFPUC are estimated based on the predicted annual average water shortage during severe drought years under each of the LSJR alternatives, relative to baseline conditions. The annual average cost for SFPUC to replace lost surface water supplies was then calculated based on the following assumptions.

- During severe drought periods, SFPUC would replace reductions in water supplies by purchasing water at $1,000 per AF.
- No other costs to SFPUC would be required to wheel, treat, or distribute the purchased water beyond existing costs for Hetch Hetchy water. (Note that if the transferred water comes from Cherry or Eleanor Reservoirs instead of passing through Hetch Hetchy Reservoir, the water would need to be filtered, potentially resulting in additional cost.)
- SFPUC operations and maintenance costs to provide water from the Hetch Hetchy water system do not vary based on the amount of water annually delivered by the system. As a result, SFPUC

---

[6] It cannot be predicted whether and how CCSF and the irrigation districts would agree to apportion responsiblity for meeting future flow requirements. In the past, the parties have agreed to either an allocation of storage credits or payments. Nonetheless, Appendix L, *City and County of San Francisco Analyses*, analyzes the potential water supply effects associated with the allocation of responsibility under paragraph (b) of Article 8 of the Fourth Agreement. Under Scenario 1, storage credits would be reallocated only if CCSF has a positive credit balance in the water bank account. Under Scenario 2, storage credits would be reallocated even if CCSF has a negative balance in the water bank account. See Appendix L for more information.

water-production costs do not appreciably decline when less water is delivered during drought conditions. (System facilities still need to be operated and maintained regardless of the amount of water delivered through the system.) As a result, 100 percent of the $1,000 per AF purchase price for water transfers would be added to overall SFPUC costs to provide water from the Hetch Hetchy system.

Based on these assumptions, average annual water-shortage replacement costs for SFPUC are estimated in Table 20.3.3-9a. For the LSJR alternatives, SFPUC's annual severe-drought-period (1987–1992) water transfer costs are estimated to range from about $14 million to $30 million under Scenario 1 and from about $35 million to $208 million under Scenario 2.

Table 20.3.3-9a. Estimated San Francisco Public Utilities Commission Replacement Water Purchase Costs in Severe Drought Years (1987–1992) under the LSJR Alternatives

	Scenario 1[a]		Scenario 2[b]	
Alternative	Required Water Transfer (TAF)	Estimated Purchase Cost	Required Water Transfer (TAF)	Estimated Purchase Cost
LSJR Alternative 2	14	$14,000,000	35	$35,000,000
LSJR Alternative 3	27	$27,000,000	119	$119,000,000
LSJR Alternative 4	30	$30,000,000	208	$208,000,000

Source: Appendix L, *City and County of San Francisco Analyses,* Table L.6-1a.

TAF = thousand acre-feet.

[a] Scenario 1 is defined in Appendix L as: storage credits would be reallocated only if CCSF has a positive credit balance in the water bank account.

[b] Scenario 2 is defined in Appendix L as: storage credits would be reallocated even if CCSF has a negative balance in the water bank account.

Assuming a "worst-case" return period of one severe 6-year drought every 21 years, the mean annual costs to purchase water in drought years shown in Table 20.3.3-9a would be spread over 21 years, instead of over only 6 drought years. The mean annual reduction in water supply compared to baseline would range from 4–9 TAF per year under scenario 1 to 10–71 TAF per year under scenario 2 (Table 20.3.3-9b). The distributed costs would be similarly reduced—long-term annual average costs for the LSJR alternatives are estimated to range from about $4–$9 million under Scenario 1 and from about $10–$71 million under scenario 2.

It should be noted, however, that these estimated costs to be incurred by SFPUC and its wholesale agencies due to a water supply reduction during a severe drought would not be expected to occur evenly over a defined period, either 6 years or 21 years, as suggested by the calculation of an average annual value, based either on the example 1987–1992 drought or on the available 21-year period of record used for assessing water bank deficits. Consequently, while the calculation of an average annual cost is useful for evaluating potential effects (both cost and regional economic effects) relative to ongoing budgetary conditions, the temporal accuracy of calculating an average annual cost is somewhat uncertain. Appendix L, *City and County of San Francisco Analyses*, briefly provides additional consideration of the return interval of such a severe drought.

Table 20.3.3-9b. Estimated Mean Annual (1983–2003) San Francisco Public Utilities Commission Replacement Water Purchase Costs in Severe Drought Years under the LSJR Alternatives

	Scenario 1[a]		Scenario 2[b]	
Alternative	Required Water Transfer (TAF)	Estimated Purchase Cost	Required Water Transfer (TAF)	Estimated Purchase Cost
LSJR Alternative 2	4	$4,000,000	10	$10,000,000
LSJR Alternative 3	8	$8,000,000	34	$34,000,000
LSJR Alternative 4	9	$9,000,000	71	$71,000,000

Source: Appendix L, *City and County of San Francisco Analyses,* Table L.6-1b.

TAF = thousand acre-feet.

[a] Scenario 1 is defined in Appendix L as: storage credits would be reallocated only if CCSF has a positive credit balance in the water bank account.

[b] Scenario 2 is defined in Appendix L as: storage credits would be reallocated even if CCSF has a negative balance in the water bank account.

For assessing regional economic effects of the water supply impacts, the costs in Tables 20.3.3-9a and 20.3.3-9b are distributed to SFPUC water users by agency and user category. The assumptions underlying this distribution are described in Appendix L. After distributing the water replacement cost among SFPUC's different customers, it is totaled by county under each of the LSJR alternatives for scenarios 1 and 2.

It is assumed that SFPUC would purchase and transfer additional water supplies from the Tuolumne River Watershed to offset water shortages during drought periods. This would result in substantially lower estimates of regional impacts than if it is assumed that SFPUC would cut back its water deliveries (i.e., impose shortages) to its retail and wholesale customers, particularly in assessing impacts for commercial and industrial water users. See Sunding 2014 for an assessment of how assumed water shortages, as opposed to the water replacement approach used in this analysis, within the Hetch Hetchy Regional Water System Service Area could impact SFPUC.

Assessment Methods for Potential Effects on the Regional Economy

SFPUC could purchase water to offset water shortages during drought periods (described above) and, in turn, could pass the additional cost on to its retail customers in the form of a temporary rate surcharge and to its wholesale customers in the form of higher wholesale water rates. Wholesale customers could then pass the higher costs to their own retail customers through a temporary rate surcharge. As higher water costs filter through the four-county Bay Area region, less discretionary income would be available for water customers to spend on goods and services, resulting in a reduction of economic output (sales) and employment throughout the region.

The IMPLAN input-output economic model was used to analyze the effects on the regional economy. IMPLAN is widely used for assessing regional economic effects of regulatory and policy actions, despite some limitations in evaluating cost-related impacts. The model was used to estimate the indirect and induced economic activity associated with direct changes in water costs for customers within SFPUC's retail and wholesale service areas. Using 2010 IMPLAN county-level data files, individual IMPLAN models were constructed for Alameda, San Francisco, San Mateo, and Santa Clara Counties.

The regional economic effects of rate surcharges would largely be determined by the reactions of end-use customers to temporarily higher water rates, which includes actions taken by residential customers, commercial and industrial customers, government water users, and dedicated irrigation water users. Predicting how the various classes of water customers would react to temporarily higher water rates is complex. Faced with higher water costs during drought years, residential customers could decrease their water use or they could decrease their spending on other goods and services to compensate for higher water utility bills. If rate increases are relatively small, however, households may not change their spending habits at all by reducing savings and/or investments, by charging purchases using credit cards, or by borrowing money. Commercial and industrial water customers could account for the additional cost of water by reducing profits, purchasing less water and/or decreasing production levels, raising product/service prices, or changing their mix of production inputs to reduce non-water-related costs. For institutional water users responding to temporarily higher water costs, government agencies could lay off staff or reduce spending on other operational inputs. However, the need for agencies to maintain staffing and service levels set through agency budgeting suggests that temporary economic effects of higher water costs would be limited. For the SFPUC retail service area, dedicated city irrigation demands are met using groundwater supplies, which have been excluded from this assessment.

Several assumptions are made to simplify the modeling approach for assessing the regional economic effects of the LSJR alternatives. These assumptions are presented in Appendix L, *City and County of San Francisco Analyses*.

Results for Potential Effects on the Regional Economy

Under Scenario 1 (storage credits would be reallocated only if CCSF has a positive credit balance in the water bank account), decreased spending on goods and services resulting from increased water costs for residential, commercial, industrial, and institutional water users could cause industrial output to decline throughout the Bay Area region during drought periods. The reduction in economic output is estimated to range from $16.2 million under LSJR Alternative 2 to $35.3 million under LSJR Alternative 4 (Table 20.3.3-10). While large, these reductions during severe drought periods (e.g., 1987–1992) would be relatively small in the context of the regional economy, ranging from 0.03 to 0.05 percent of total output.

[a] Scenario 1 is defined in Appendix L as: storage credits would be reallocated only if CCSF has a positive credit balance in the water bank account.

Under Scenario 2 (storage credits would be reallocated even if CCSF has a negative balance in the water bank account) output and job losses during drought periods are predicted to be substantially higher than under Scenario 1 because replacement water needs and related costs to customers would be much larger. Annual output reductions in the Bay Area region are estimated to range from $40.5 million to $243.6 million under LSJR Alternatives 2, 3, and 4 (Table 20.3.3-12). In the context of the overall Bay Area region economy, these reductions would represent 0.06 and 0.38 percent of total output, respectively. Similarly, job losses would be relatively small, ranging from 292 to 1,756 jobs across LSJR Alternatives 2, 3, and 4, which represent 0.01 and 0.06 percent of all regional jobs, respectively (Table 20.3.3-13).

Assessment Methods for Potential Ratepayer Effects

Effects of SFPUC water purchases on water rates are evaluated based on the relative increase in overall SFPUC budget costs attributable to replacement water purchases under each alternative. Existing water rates that are annually established for both the retail and wholesale service areas reflect operating costs, debt service costs, capital costs, programmatic project costs, and reserve considerations. This ratepayer assessment uses the total SFPUC Water Enterprise and Hetch Hetchy Water budgets for fiscal year 2013–2014 as baselines for the assessment. The adopted fiscal year 2013–2014 budgets totaled $483.2 million, as shown in Appendix L, *City and County of San Francisco Analyses,* (Table L.3-3). These budgets account for the cost of producing, conveying, filtering, treating, and distributing water within the SFPUC service areas, as well as to defray the costs of past, current, and future projects. Existing water rates for SFPUC's retail and wholesale customers, which are largely driven by these budget costs, also are shown in Appendix L (Table L.3-4). For purposes of evaluating ratepayer effects, budgetary cost increases for SFPUC to replace water during drought conditions are assumed to result in proportional rate increases in SFPUC's retail and wholesale water rates, relative to the existing rates.

Results for Potential Ratepayer Effects

The budget effects of purchasing replacement water during severe drought periods (e.g. 1987–1992) under the LSJR alternatives are shown in Tables 20.3.3-14a and 20.3.3-14b and 20.3.3-15a and 20.3.3-15b. Compared to adopted fiscal year 2013–2014 SFPUC budget costs of $483.12million, water replacement costs in severe drought years under Scenario 1 would represent an increase in overall costs ranging from about 3 to 6 percent (Table 20.3.3-14a). These additional drought-period costs would presumably result in rate surcharges within the retail and wholesale service areas of about the same percentages, relative to existing water rates. For example, the drought-period rate surcharge in the SFPUC retail service area could cause existing rates for a single-family residential customer to rise by about 3 percent under LSJR Alternative 2, and by about 6 percent under LSJR Alternatives 3 and 4. Existing rates charged by SFPUC to its wholesale customers could increase by similar percentages.

[b] Represents combined Adopted Water Enterprise and Hetch Hetchy Water budgets for fiscal year 2013–2014.

Using a longer-term period of record (1983 to 2003), the annual average water replacement costs (as derived in Table 20.3.3-9b) are much less than the costs within the severe drought period (1987 to 1992) described above. Under Scenario 1, estimated longer-term increases in budget expenditures range from 0.8 to 1.9 percent (Table 20.3.3-14b).

[b] Represents combined Adopted Water Enterprise and Hetch Hetchy Water budgets for fiscal year 2013–2014.

For Scenario 2, the additional expenditures to purchase and transfer water during severe drought periods (e.g. 1987–1992) under the LSJR alternatives would be much higher than in Scenario 1, with cost increases ranging from about 7 to 43 percent of the baseline water budget (Table 20.3.3-15a). As a result, water rate increases during drought periods would be substantially higher than under Scenario 1. Drought-period rate surcharges in the SFPUC retail service area could raise existing rates for a single-family residential customers by about 7 percent under LSJR Alternative 2, by about 25 percent under LSJR Alternative 3, and by about 43 percent under LSJR Alternative 4. Existing rates charged by SFPUC to its wholesale customers could increase by similar percentages. Under Scenario 2, estimated longer-term increases in budget expenditures range from 2.1 to 14.7 percent (Table 20.3.3-15b).

For the 27 individual water agencies that purchase wholesale water from SFPUC, the actual drought surcharges levied on their retail water customers (e.g., residential, commercial and industrial) would vary depending on the percentage of each district's overall water demand met by purchases from SFPUC. As identified in Appendix L, *City and County of San Francisco Analyses* (Table L.3-1), 19 of the water agencies served by SFPUC purchased at least 90 percent of their total water supply from SFPUC in 2010. Within the service areas of those agencies (e.g., the Cities of Hayward, East Palo Alto, Menlo Park), percentage increases in drought-period rates would likely be similar to increases in wholesale water rates under the LSJR alternatives. For water agencies that rely less on SFPUC water deliveries (e.g., the Cities of Santa Clara, Sunnyvale, and San Bruno), the rate surcharges attributable to the LSJR alternatives would presumably be lower. Additionally, rate increases for customer classifications within each agency would vary based on the rate-setting policies of each agency.

Sensitivity Analysis

In the results described above, the cost of water purchases from the irrigation districts (i.e., MID and TID) is assumed to be $1000 per AF. This assumed price is key to the analysis, and is derived based on a review of recent water purchases involving both MID and TID, as well as by other agricultural districts in California. Although this assumption is considered reasonable for the analysis, an argument also can be made for assuming either a higher or lower average cost per AF, given the many site- and time-specific factors that affect water transaction prices.

A limited review of relevant information concerning the cost of water in recent water purchases suggests that a reasonable cost range for agricultural-to-urban water transfers is $500 to $2000 per AF. Although many factors influence the relationship between the price of water and the extent of associated regional economic effects, assuming that this relationship is linear provides an order-of-magnitude approximation for the potential effects under different average water prices. In other words, the resulting economic effects assuming a water transfer price of $500 per AF could approximately halve the impacts discussed above, while a price of $2000 per AF could approximately double the impacts. Approximate impacts on total economic output and employment in the four-county Bay Area region (San Francisco, Alameda, San Mateo, and Santa Clara Counties) using water transfer prices of $500, $1000, and $2000 per AF are shown in Tables 20.3.3-16 and 20.3.3-17 under Scenarios 1 and 2 for the LSJR alternatives.

Adaptive Implementation

Adaptive implementation would take place based on required evaluation of current scientific information and would need to be approved as described in Appendix K, *Revised Water Quality Control Plan.* Accordingly, the frequency and duration for any use of adaptive implementation methods 1, 2, 3, and 4 cannot be determined at this time. Adaptive implementation method 1 potentially has the greatest likelihood to change economic effects as it would allow the unimpaired flow requirement to be increased or decreased by up to 10 percent from the objective unimpaired flow (with a minimum requirement of 20 percent and a maximum of 60 percent unimpaired flow). For LSJR Alternative 2 an increase from 20 percent to 30 percent of the unimpaired flow would likely result in different effects as compared to those shown above for LSJR Alternative 2, depending upon flow conditions and frequency of the adjustment. As such, under LSJR Alternatives 2 or 3, if the percentage of unimpaired flow is increased with adaptive implementation method 1, water supply costs to water districts served by the SFPUC also would likely increase as these districts develop more costly water supply options than those developed without adaptive implementation. On the other hand, under LSJR Alternatives 3 and 4, if the percent of unimpaired flow is reduced with adaptive implementation method 1, water supply costs to SFPUC and affected water districts would be somewhat less than expected without adaptive implementation. Overall, the costs to the SFPUC associated with replacing reduced water supplies from the Tuolumne River Watershed would be expected to increase as the deliveries are reduced.

20.3.4 Effects on Hydropower Generation, Revenues and the Regional Economy

Introduction

The analysis in this section, as explained in Appendix J, *Hydropower and Electric Grid Analysis of Lower San Joaquin River Flow Alternatives*, discusses the potential effects of LSJR Alternatives 2, 3, and 4 for hydropower generation on the three eastside tributaries and the corresponding effects on revenue generation. Implementation of the LSJR alternatives could change reservoir operations, which, in turn, could alter the associated timing of water releases and amount of hydropower generated from hydroelectric facilities on the eastside tributaries. The study area for analyzing hydropower generation includes the three rim dams[7] on the eastside tributaries: New Melones on the Stanislaus River, New Don Pedro on the Tuolumne River, and New Exchequer on the Merced River. The study area also includes areas where connecting transmission systems are located and areas where the balancing authorities for the three hydropower plants—New Melones, New Don Pedro, and New Exchequer—are located, as described in Appendix J, Section J.1 and J.3.

The remaining discussion is organized around a description of baseline conditions and potential effects of each LSJR alternative. The analysis focuses on three related topics: the amount of hydropower generated, generation-related revenues, and effects on regional economic conditions, including ratepayers. Information on hydropower generation and related revenues is presented by tributary area and by hydropower facility. The methods used to assess these related topics are described first.

Assessment Methods

Results from the WSE model provides estimates of the effects of LSJR Alternatives 2, 3, and 4 on reservoir releases and storage (elevations head) and on allowable diversions to off-stream generation facilities; these results are used in this analysis to estimate changes in the generation of monthly and annual amounts of hydropower associated with LSJR Alternatives 2, 3, and 4. It should be noted that changes in hydropower generation at each rim dam differ from changes in total hydropower generation by tributary because other hydroelectric facilities on the tributaries may also contribute to the amount of hydropower generated.

In addition to changes in hydropower generation under LSJR Alternatives 2, 3, and 4, revenues associated with these changes in hydropower generation also are estimated. To derive the effects of LSJR Alternatives 2, 3, and 4 on hydropower revenue, the estimated change in monthly power generated over the 82-year simulation period is multiplied by an assumed monthly price of hydropower.

The monthly price of power used in the assessment is the value at the 80th percentile of average hourly power prices (i.e., the value at which 80 percent of the hourly prices were lower); monthly values available from the California Independent System Operators (ISO) during the 2006 calendar year were used in the assessment. Prices for 2006 were used because, as shown in Figure 20.3.4-1 below, these prices most closely match the median price during years in which price data are

---

[7] In this document, the term *rim dams* is used when referencing the three major dams and reservoirs on each of the eastside tributaries: New Melones Dam and Reservoir on the Stanislaus River; New Don Pedro Dam and Reservoir on the Tuolumne River; and New Exchequer Dam and Lake McClure on the Merced River.

available (1998 to 2008.) The 2006 monthly prices (Table 20.3.4-1) were adjusted to 2008 dollars using *Engineering News-Record* (*ENR*) Building Cost Indices.[8] Note that the use of monthly power prices at the 80th percentile of hourly prices is considered a conservative approach to estimating hydropower revenue impacts because historical power prices have been generally lower than this 80th percentile value. As a result, the estimated revenue impacts of LSJR Alternatives 2, 3, and 4 likely overstate, to some limited extent, the actual effects on hydropower generation revenue.

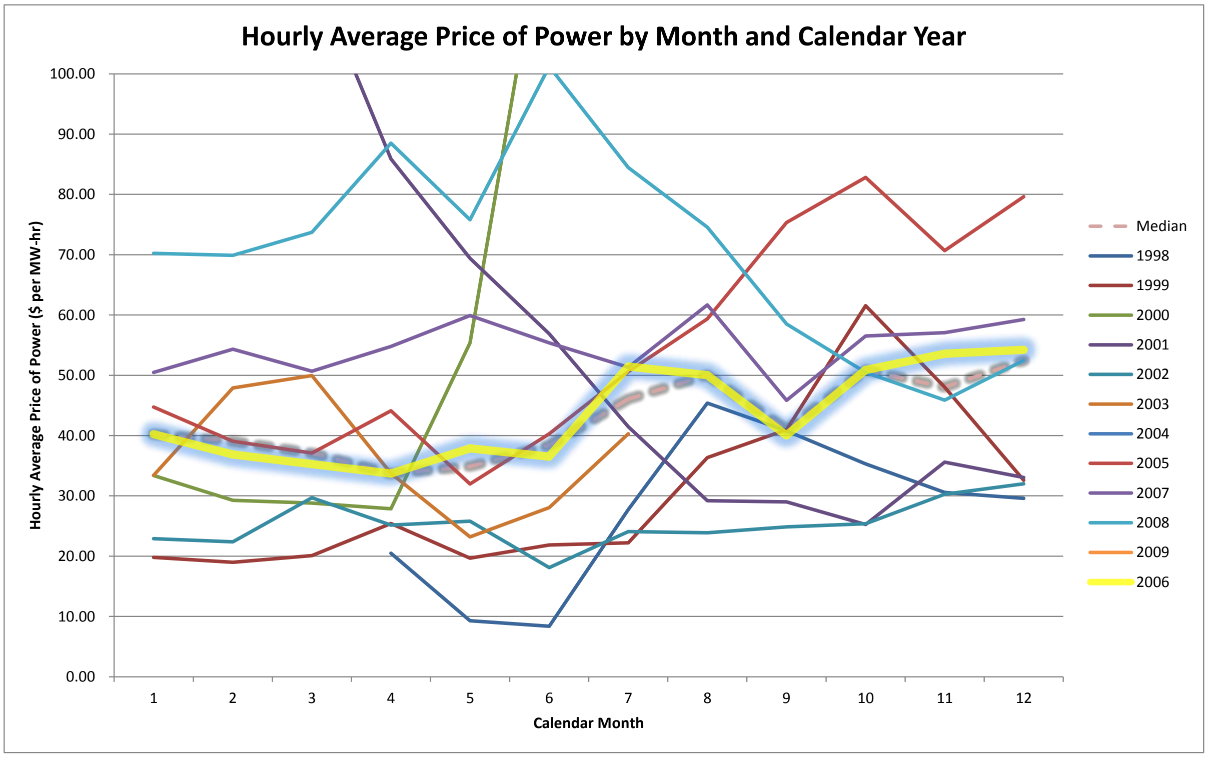

Figure 20.3.4-1. Monthly Average Price and Median Monthly Average Price of Power 1998–2008

---

[8] The *ENR* Building Cost Index, which has been issued since 1915, is widely used throughout the U.S. construction industry as a benchmark for measuring inflation.

Table 20.3.4-1. Selected 80th Percentile of Hourly Prices from 2006 and Factors used to Escalate to 2008 Dollars

	2006 ISO Power Price	Building Cost Index Adjustment Factor	ISO Power Price Adjusted by Building Cost Index Factor
Calendar Month	$/MWh ($2006)		$/MWh ($2008)

Hydropower Generation

Table 20.3.4-2 shows the average annual hydropower generation on the three eastside tributaries under baseline conditions and the relative change associated with each of the LSJR alternatives. Under baseline conditions, hydropower generation plants on the tributaries are estimated to produce 1,650 gigawatt hours (GWh) of energy per year, with 35 percent from facilities on the Stanislaus River, 40 percent from facilities on the Tuolumne River, and 25 percent from facilities on the Merced River. Under LSJR Alternative 2, energy production increases relative to baseline for all three tributaries, but as the unimpaired flow requirements increase under LSJR Alternatives 3 and 4, the amount of power generated annually is reduced. Relative to baseline, total annual hydropower generation on the tributaries increases by 29 GWh under LSJR Alternative 2, decreases by 4 GWh under LSJR Alternative 3, and decreases by 87 GWh under LSJR Alternative 4.

The analysis presented in Appendix J, *Hydropower and Electric Grid Analysis of Lower San Joaquin River Flow Alternatives*, and summarized here, also estimates the amount of hydropower that would be generated at the major rim dam facilities on each of the three eastside tributaries. Table 20.3.4-3 shows the average annual hydropower generation at each of the three rim dam facilities under baseline conditions and the relative change associated with each of the LSJR alternatives. Under baseline conditions, hydropower facilities at the three rim dams are estimated to produce 1,318 GWH per year. New Don Pedro on the Tuolumne River generates the most energy at about 604 GWh annually (46 percent of the total), while New Melones and New Exchequer generate 419 GWh (32 percent of the total) and 295 GWh (22 percent of the total), respectively. Overall energy production at the three rim dams increases relative to baseline under LSJR Alternatives 2 and 3, but the increase diminishes as the unimpaired flow requirement gets larger under LSJR Alternative 3. Under LSJR Alternative 4, hydropower facilities at the three rim dams generate less total power than under baseline conditions, but facilities at New Melones generate slightly more. Relative to baseline, total annual hydropower generation at the rim dams increases by 38 GWh under LSJR Alternative 2 and by 18 GWh under LSJR Alternative 3, but decreases by 33 GWh under LSJR Alternative 4.

Table 20.3.4-2. Average Annual Baseline Hydropower Generation and Difference from Baseline, by Tributary

Alternative	Stanislaus (GWh)	Tuolumne (GWh)	Merced (GWh)	All Tributaries (GWh)

Note: Numbers are rounded.

GWh = gigawatt hours

Hydropower Generation-Related Revenue

Table 20.3.4-4 shows the average annual hydropower revenue on each of the three tributaries under baseline conditions and the relative change associated with each of the LSJR alternatives. Under baseline conditions, total revenue from energy production on the three tributaries is estimated to be $97.5 million per year, with 36 percent from facilities on the Stanislaus River, 39 percent from facilities on the Tuolumne River, and 25 percent from facilities on the Merced River. Under the LSJR Alternatives 2, 3, and 4, the change in revenue from hydropower generation on each of the tributaries is proportional to the change in hydropower generation. Relative to baseline, total annual hydropower revenue over all there tributaries increases by $1.7 million under LSJR Alternative 2, decreases by $0.67 million under LSJR Alternative 3, and decreases by $6.5 million under LSJR Alternative 4. Under LSJR Alternative 2, facilities on the Tuolumne River have the smallest revenue increase, whereas the Tuolumne River facilities have the greatest revenue decrease under LSJR Alternatives 3 and 4.

Table 20.3.4-5 shows the average annual hydropower revenue produced by facilities at each of the rim dams on the three tributaries under baseline conditions and the relative change associated with each of the LSJR alternatives. Under baseline conditions the total revenue from energy production by facilities at all three rim dams is estimated to be $77.8 million per year. Facilities at New Don Pedro on the Tuolumne River produce the most revenue, accounting for $35.4 million annually (46 percent of the total), whereas facilities at New Melones and New Exchequer annually contribute $24.8 million (32 percent of the total) and $17.6 million (22 percent of the total), respectively. Overall, revenue from energy production at facilities at the rim dams increases relative to baseline under LSJR Alternatives 2 and 3, but the increase diminishes as the unimpaired flow requirement gets larger under LSJR Alternative 3. Relative to baseline , annual revenues from the sale of hydropower generated at the rim dams is estimated to increase by $2.2 million under LSJR Alternative 2, increase by $0.72 million under LSJR Alternative 3, and decline by $3.2 million under LSJR Alternative 4.

Table 20.3.4-4. Average Annual Baseline Hydropower Revenue and Difference from Baseline, by Tributary

Alternative	Stanislaus ($)	Tuolumne ($)	Merced ($)	All Tributaries ($)
Baseline	34,711,954	38,509,568	24,288,834	97,510,355
LSJR Alternative 2	1,107,615	107,213	464,967	1,679,795
LSJR Alternative 3	139,363	-479,990	-329,987	-670,613
LSJR Alternative 4	-1,866,071	-2,916,944	-1,765,366	-6,548,380

Note: Revenues shown in 2008 dollars.

Table 20.3.4-5. Average Annual Baseline Hydropower Revenue from New Melones, New Don Pedro, and New Exchequer Hydropower Facilities and Difference from Baseline, by Facility

Alternative	New Melones ($)	New Don Pedro ($)	New Exchequer ($)	Three Facilities ($)
Baseline	24,798,903	35,436,787	17,563,111	77,798,801
LSJR Alternative 2	1,338,481	92,113	782,483	2,213,076
LSJR Alternative 3	738,473	-387,781	377,854	728,546
LSJR Alternative 4	-319,743[a]	-2,414,141	-440,110	-3,173,994

Note: Revenues shown in 2008 dollars.

[a] An increase or decrease in revenue that is contrary to the direction of change in average hydropower generation is explained by the shift in power generation over the year from a lower price to a higher price. Although the overall generation is lower (or higher), the change in price leads to higher (or lower) revenue (e.g., shifting an equal generation January–April to June–October would result in increased revenue due to higher prices charged for energy).

Adaptive Implementation

Adaptive implementation would take place based on required evaluation of current scientific information and would need to be approved as described in Appendix K, *Revised Water Quality Control Plan.* Accordingly, the frequency and duration for any use of adaptive implementation methods 1, 2, 3, and 4 cannot be determined at this time. Adaptive implementation method 1 potentially has the greatest likelihood of changing economic effects as it would allow the unimpaired flow requirements to be increased or decreased by up to 10 percent from the objective unimpaired flow (with a minimum requirement of 20 percent and a maximum of 60 percent unimpaired flow). For LSJR Alternative 2 an increase from 20 percent to 30 percent of the unimpaired flow would likely result in different effects as compared to those shown above for LSJR Alternative 2, depending upon flow conditions and frequency of the adjustment. As such, under LSJR Alternatives 2 or 3, if the percentage of unimpaired flow is increased with adaptive implementation method 1, hydropower revenue could be slightly less than is predicted without adaptive implementation. On the other hand, under LSJR Alternatives 3 and 4, if the percent of unimpaired flow is reduced with adaptive implementation method 1, hydropower revenue could be slightly higher than predicted without adaptive implementation.

In addition, adaptive implementation methods 2 and 3 could also affect hydropower generation, given that hydropower generation is affected by the timing of reservoir releases. Method 2 involves shifting flow between months within the February–June period to improve conditions for fish and wildlife, whereas method 3 involves shifting flow from February–June to later in the year to prevent negative impacts for fisheries. Under both methods for all LSJR alternatives, shifting the timing of reservoir releases could produce small changes in revenue as a result of the fluctuating value of power generation. Changes in reservoir storage levels as a result of adaptive implementation could also affect hydropower generation. For example, retaining water until later in the February – June time frame or until fall, will keep reservoir storage higher for a longer amount of time and thereby increase hydropower generation. However, adaptive implementation is not expected to substantially affect revenues related to hydropower generation.

Baseline Regional Economy Conditions and Potential Regional Effects Related to Hydropower

This section qualitatively evaluates potential regional economic effects associated with predicted changes in hydropower generation and associated revenues under LSJR Alternatives 2, 3, and 4. Predicted changes in hydroelectric power generation could potentially affect residents statewide in terms of electricity rates; however, modeling results presented in Tables 20.3.4-2 and 20.3.4-3 above suggest that the changes in energy generation would be virtually imperceptible at the statewide level.

Potential impacts on the regional economy caused by changes in hydropower generation can be evaluated by describing the underlying relationship between changes in hydropower production and regional economic conditions. From the perspective of the statewide electricity grid, power lost as a result of implementing one of the LSJR alternatives would need to be replaced to meet statewide electricity demand, especially during peak summer months. Presumably, purchasing replacement power from other sources would be more costly to power utilities than purchasing power from hydropower facilities on the three tributaries. Electricity providers could offset the cost of purchasing replacement power by raising utility rates for residential, commercial, and industrial users. For these users, increased spending on higher electricity bills could cause reduced spending on other goods and services, in turn, causing some employment and revenue losses for certain sectors of the state's economy. The extent of these effects would depend on the size of the hydropower losses relative to California's overall supply of electricity.

Hydropower generation on the eastside tributaries under LSJR Alternatives 2, 3, and 4 is estimated to increase by 29 GWh under LSJR Alternative 2, decrease by 4 GWh under LSJR Alternative 3, and decrease by 87 GWh under LSJR Alternative 4 (Table 20.3.4-2). According to the California Energy Commission (2012), California's electricity generating system annually produces more than 296,000 GWh, accounting for 69 percent of the electricity the state uses. Compared to annual statewide electricity production, the hydropower changes potentially caused by one of the LSJR alternatives would range from an increase of less than 0.0001 percent under LSJR Alternative 2 to a reduction of about 0.0003 percent under LSJR Alternative 4. Thus, the impacts of the LSJR alternatives on hydropower related revenues are relatively small and would not likely affect ratepayers in any substantial way. In addition, given the virtually imperceptible effects at a regional and statewide level under each of the LSJR alternatives, adaptive implementation is not expected to have an effect on regional hydropower generation or revenue.

20.3.5 Effects on Fisheries and Associated Regional Economies

Introduction

This section addresses potential economic effects concerning commercial and sport fisheries, with a specific emphasis on Chinook salmon, which could be affected by implementation of the LSJR alternatives. Because biological impacts on fishery resources, such as expected population shifts for key fish species (e.g., Chinook salmon), are highly uncertain and difficult to quantify, the corresponding economic effects also are difficult to evaluate. As a result, this analysis of fisheries-related economic effects is necessarily qualitative.

The study area for this analysis includes areas where there is commercial and sport fishing activity for species that could be affected by the LSJR alternatives. This not only includes the rim reservoirs and three eastside tributaries, but also the greater Bay-Delta region and the more expansive Pacific Ocean, plus coastal fishing areas along the western United States.

As discussed in Chapter 7, *Aquatic Biological Resources*, improving flow conditions in the SJR Watershed to the Delta at Vernalis can be expected to benefit many native fishes. However, relevant information on potential effects on native species is too limited to estimate exact population responses to habitat improvements. It is likely, however, that LSJR Alternatives 2, 3, and 4 would benefit many native plant and animal species (Merz and Moyle 2006) that exist in and adjacent to the Stanislaus, Tuolumne, and Merced Rivers through increased availability of marine derived nutrients and through improved habitat (e.g., riparian and floodplain) conditions. Information is too limited, however, to predict the exact expected positive biological responses and then to assign an appropriate economic value to those responses.

Because information on potential effects on native fish species is limited, a case study approach that focuses on Chinook salmon, a key fish species expected to benefit substantially from LSJR Alternatives 2, 3, and 4, is instructively used to examine potential economic effects associated with aquatic habitat improvements. Although results from evaluating the biological impacts of LSJR Alternatives 2, 3, and 4 on Chinook salmon populations also are limited, historical population and harvest information concerning Chinook salmon are available; this information is used to provide some insight into potential monetary values associated with improving salmon habitat in the three eastside tributaries.

Potential benefits to native fish populations such as Chinook salmon would be expected at spatial scales that extend beyond the plan area. For example, there is the potential to improve the population resiliency and stability to Central Valley fish populations by improving SJR fish populations (Carlson and Satterthwaite 2011).

This section is organized by first presenting relevant background information, including information on game species and associated sport fishing activity, on salmon management and harvest in the study area, and on recent salmon fishery closures in California. This discussion is followed by an assessment of the effects of LSJR Alternatives 2, 3, and 4 on commercial and sport fisheries, focusing on Chinook salmon. The section describes the potential economic effects on use and non-use (passive use) values associated with improving habitat conditions and sustaining salmon populations, and addresses potential effects on the regional economies affected by commercial and sport fishing activity.

Background Fishery Conditions

This section describes historical and recent information on commercial and sport fisheries that could be affected by the plan amendments. Unlike other topics covered in this chapter, the information presented here is not referred to as a baseline, primarily because these conditions characterize historical information, trends, and other dynamic factors that do not serve as an specific point of reference. Overall, there is too much uncertainty concerning the many factors that affect fishery conditions (e.g., population conditions, management actions, harvest rates) to establish a point of reference (or baseline) for evaluating potential effects. This background section describes game and sport fishing activities, salmon management actions, commercial harvest levels, and recent salmon fishery closures within the study area.

Game Species and Sport Fishing Activity

Fishing is a common recreational activity on the rivers and reservoirs of the plan area. As discussed in greater detail in Chapter 7, *Aquatic Biological Resources*, the mainstem LSJR and three eastside tributaries support several warmwater game fish populations, such as smallmouth and largemouth bass, sunfish, and catfish, as well as a variety of native fishes, such as hardhead, Sacramento pikeminnow, Sacramento sucker, sculpin, and lamprey. The mainstem LSJR and the three eastside tributaries also provide habitat for coldwater species, such as trout and Chinook salmon. Historically, the Upper SJR supported abundant populations of spring- and fall-run Chinook salmon and steelhead. Today, however, only small populations of fall-run Chinook salmon and steelhead are found in the three eastside tributaries.

Among the many game fish in the mainstem LSJR and its tributaries (refer to Chapter 7*, Aquatic Biological Resources*), the most commonly caught by sport anglers are as follows.

- LSJR: largemouth bass, striped bass, catfish, and sunfish.
- Stanislaus River: striped bass, largemouth bass, smallmouth bass, American shad, and rainbow trout.
- Tuolumne River: American shad, largemouth bass, smallmouth bass, striped bass, catfish, and sunfish.

- Merced River: largemouth bass, smallmouth bass, American shad, catfish, and sunfish.

The tributary reservoirs support a variety of fish species, including rainbow trout, brown trout, largemouth bass, smallmouth bass, kokanee, catfish, and sunfish. Sport anglers typically fish from the shore or boats for the following species in tributary reservoirs.

- New Don Pedro Reservoir: kokanee, Chinook salmon, brown trout, brook trout, rainbow trout, largemouth bass, smallmouth bass, spotted bass, catfish, and sunfish.
- New Melones Reservoir: rainbow trout, brown trout, kokanee, largemouth bass, smallmouth bass, catfish, and sunfish.
- Lake McClure: kokanee, rainbow trout, Chinook salmon, largemouth bass, spotted bass, catfish, and sunfish.

Historical (1990s and early 2000s) estimates of fishing activity at major recreation areas (rivers and reservoirs) within tributary Watersheds are identified in Section 20.3.6, *Effects on Recreational Oportunities, Activity, and the Regional Economy* (Table 20.3.6-1). As shown, sport fishing activity on the tributaries are approximated to be 5,200 angler days annually along the Lower Stanislaus River and 34,900 angler days annually along the Lower Tuolumne River; no fishing-specific estimates are available for the Merced River. Annual sport fishing activity on the LSJR is approximated at 57,500 angler days.

Salmon Management and Harvest in the Study Area

This section describes salmon management and harvest conditions in the study area. As noted above, the study area includes geographic areas where commercial and sport fishing activity occurs that could be affected by salmon production in the three eastside tributaries.

Ocean Salmon Fisheries in the Pacific Region

Ocean commercial and recreational fishing for salmon originating from Central Valley rivers occurs along the California coast, primarily from Monterey north to central Oregon. Salmon harvest levels for ocean and river fisheries are managed by federal and state agencies. The Pacific Fisheries Management Commission (PFMC) coordinates this process and annually assesses salmon populations to establish sustainable salmon harvest levels for the Pacific Region (California, Oregon, and Washington). The PFMC also sets ocean commercial and recreational fishing seasons for harvesting of salmon in federal waters. Each year, the PFMC recommends ocean fishing regulations designed to meet constraints established by escapement goals and jeopardy opinions for federally listed species. California fisheries are managed, in part, to meet escapement, allocation, and rebuilding goals for Klamath River fall-run Chinook salmon, coastal natural spawning coho salmon, and Sacramento River spring-, fall-, and winter-run Chinook salmon (Boydstun 2001).

In the Pacific region, salmon fisheries are subject to weak stock management, where access to the harvestable surplus of healthier stocks is often restricted to protect weaker stocks with which they co-mingle in the ocean. This makes establishing regulations difficult. For example, in 2008 and 2009 (see *Recent Salmon Fishery Closures in California* section below), virtually all fishing in the ocean off California was closed to protect Central Valley fall-run Chinook, even though Klamath fall-run Chinook salmon returns were large enough to support limited ocean angling (Morse and Manji 2009). Salmon management is further complicated by the need to ensure equitable allocation of harvest among diverse user groups and the need to coordinate with the entities that have jurisdiction over other aspects of salmon management. The PFMC also develops a catch-sharing plan for tribal and non-tribal fisheries conducted in federal waters (NMFS 2014).

Historically, Native American tribes along the West Coast relied on natural resources as a source of food, nutrients, and trading commodities. Over time, the opportunity to engage in traditional use fisheries has been dramatically limited by political forces and human population expansion. Native American natural resource initiatives along the West Coast have resulted in an array of contemporary outcomes, including the sometimes controversial Boldt Decision in the Pacific Northwest (Norman et al. 2007). For California state-managed waters (i.e., those extending 3 nautical miles offshore), the California Fish and Game Commission (Commission) establishes salmon fishing regulations to ensure that California's non-tribal harvest allowances are not exceeded by commercial fishers and recreational anglers.

The California Department of Fish and Wildlife (CDFW), as the state fishery management agency, manages fishery regulations, implements management plans, provides technical expertise, and coordinates the implementation of policy throughout California. CDFW is responsible for providing recommendations to the Commission and for carrying out research that informs these recommendations or other management decisions to be made by the California State Legislature. All of these regulations affect recreational and commercial fishing opportunities and, therefore, the economic value of these fisheries in California (Morse and Manji 2009).

Historical Harvest of Ocean Commercial and Sport Salmon in California

Ocean commercial harvest levels for Chinook salmon in California have varied considerably over the last four decades, as shown in Table 20.3.5-1. Excluding the fishery closure years of 2008 and 2009 (see *Recent Salmon Fishery Closures in California* section below), statewide commercial salmon catch between 1976 and 2013 varied from about 1,317,200 salmon in 1988 down to 15,100 salmon in 2010. During this period, catches could change substantially from year to year. The best 5-year period occurred from 1986–1990, with an average of 794,700 fish caught per year.

Sources: Pacific Fishery Management Council 1997, 2013, 2014, 2015 (Tables A-3 and IV-2).

NA = not available. Note that the commercial salmon fishery was closed in 2008 and 2009.

[a] Nominal prices adjusted to 2014 dollars using the gross domestic product implicit price deflator.

[b] Averages exclude the salmon fishery closure years of 2008 and 2009.

Compared to the 1976–2014 average annual harvest of 426,900 salmon, commercial harvests between 1976 and 1990 were relatively high, averaging 625,300 fish per year. However, commercial harvests then dropped to an average of 364,600 fish from 1990 until 2005, and then further declined to an average of 67,200 fish per year from 2006–2011, excluding 2008 and 2009 when fisheries were closed. Although more recent harvests have shown large improvements, average harvests from 2012 to 2014 were still 47 percent below the 37-year (1976–2014, excluding 2008 and 2009) average. Commercial landings in the San Francisco port area accounted for 45 percent of statewide landings over the 37-year period, followed by the Monterey (22 percent), and Fort Bragg (22 percent) port areas (Table 20.3.5-1). The remainder of the statewide salmon catch was landed in the Eureka (8 percent) and Crescent City (3 percent) port areas. However, annual harvests vary significantly for all ports.

As can be seen by reviewing the harvest data in Table 20.3.5-1, Chinook salmon harvests in the Crescent City and Eureka port areas, and to a lesser extent in the Fort Bragg port area, were eliminated or greatly reduced from 1991–2001. For these port areas, stringent commercial fishing regulations have been imposed in some years to protect Klamath River fall-run Chinook in the PFMC's Klamath Management Zone (KMZ) (encompassing Curry County in Oregon and Humboldt and Del Norte counties in California). By severely constraining harvest in the KMZ, the PFMC is able to maintain fishing opportunities in other areas farther from the KMZ (e.g., San Francisco, Monterey) that have lesser impacts on this stock (Pomeroy et al. 2010). Additionally, the California portion of the KMZ was closed to commercial salmon fishing from 1992–1995 due to several localized factors. These factors include the need to protect Oregon Coastal Natural coho, a determination that the Klamath fall-run Chinook had been overfished, and a court decision allocating 50 percent of Klamath-Trinity River salmon to the Yurok and Hoopa tribes (Pomeroy et al. 2010). Finally, in 2006, failure of Klamath fall-run Chinook to achieve established escapement minimums for the third consecutive year prompted the PFMC to close the commercial fishery in the California KMZ and curtail the season in other areas (Pomeroy et al. 2011). Until recently, Klamath River fall-run Chinook was the constraining stock in the ocean fishery, prompting the restrictive regulations. Since 2007, however, conservation concerns regarding Sacramento River fall-run Chinook have prompted unprecedented recreational season reductions and closures statewide (see *Recent Salmon Fishery Closures in California* section below [Pomeroy et al. 2010]).

In inflation-adjusted 2014 dollars, ex-vessel prices[9] for Chinook salmon averaged $3.99 per pound between 1979 and 2014 (Table 20.3.5-1). Annual inflation-adjusted salmon prices were above $3.00 every year through 1993. From 1994 through 2003, however, average prices did not exceed the 1994 value of $2.81. After 2003, prices rebounded and have not fallen below an inflation-adjusted $3.49 through 2014. The 1979–2014 overall inflation-adjusted average price of $3.99 was exceeded in every year since 2005 (excluding 2008 and 2009 when the California commercial salmon fishery was closed). The 2014 average inflation-adjusted price of $5.54 was 39 percent above the average between 1979 and 2014.

Similar to commercial harvests, ocean sport (or recreational) catch has varied substantially from year to year. Excluding the complete or partial closure years of 2008 and 2009 (see *Recent Salmon Fishery Closures in California* section below), statewide ocean sport catch of Chinook salmon between 1976 and 2014 ranged from 397,200 fish in 1995 to 14,800 fish in 2010, averaging about 128,200 fish per year over the entire period (Table 20.3.5-2). During that time, the best 5-year period for sport catch occurred from 1991–1995, with an average catch of approximately 170,300 salmon per year.

---

[9] The *ex-vessel price* is a measure of the dollar value of commercial landings, usually calculated as the price per pound at first purchase of the commercial landings multiplied by the total pounds landed.

Sources: Pacific Fishery Management Council 2013, 2014, 2015 (Table A-5).

[a] Averages exclude the salmon fishery closure years of 2008 and 2009.

Sport landings from the San Francisco catch area accounted for almost 60 percent of statewide ocean sport landings over the 37-year period (i.e., excluding 2008 and 2009), followed by the Monterey area (21 percent) (Table 20.3.5-2). Sport landings in the Crescent City, Eureka, and Fort Bragg areas, which accounted for 19 percent of statewide ocean sport landings over the period, have been affected by many of the same management considerations that have restricted commercial salmon harvests.

According to historical data maintained by the U.S. Fish and Wildlife Service's (USFWS's) Anadromous Fish Restoration Program (AFRP) (USFWS 2015), between 1967 and 2010, the in-river catch of Chinook salmon in the Central Valley by sport anglers averaged 57,611 fish. Average annual in-river catch has been higher over the past two decades than in the preceding 25 years, with catches from 1992–2010 averaging about 64,900 salmon, compared to an average of 51,200 from 1967–1991.

In addition to commercial and sport fishing, California has approximately 100 recognized tribes, some of which engage in traditional uses of fish (Shilling et al. 2014). Currently, CDFW uses the term "recreational" for fishermen who do not earn revenue from their catch, but fish for pleasure or for personal consumption. Information on subsistence fishing by tribal members in California is captured within the broader scope of sport fishing data (Norman et al. 2007; Shilling et al. 2014).

Contribution of Central Valley Salmon to Ocean and Inland Fisheries

Located within California's Central Valley, the Sacramento-San Joaquin River system is the principal producer of Chinook salmon caught in California's ocean fisheries. Its salmon runs also contribute to the ocean fisheries of Oregon and Washington (CDFW 2014). Historically, the rivers in the SJR Watershed supported abundant populations of spring- and fall-run Chinook salmon and steelhead (discussed in greater detail in Chapter 7, *Aquatic Biological Resources*). However, degradation of habitat and increasing pressures from the human expansion has negatively affected those populations. Today, only a relatively small population of fall-run Chinook salmon remain in the three eastside tributaries to the LSJR. These fish pass through the LSJR during their migrations to and from the Delta and Pacific Ocean, where they contribute to the commercial and sport ocean salmon fisheries.

According to historical data maintained by the AFRP, 1967–2010, the average annual ocean catch of Central Valley Chinook salmon by San Francisco and Monterey port area-based boats was 382,070 fish per year. Of this total, 71 percent of the landings were by commercial fishermen and 29 percent were by sport anglers. Furthermore, based on the historical data, it was estimated that 95 percent of the catch originated from the Sacramento River Watershed, with the remaining 5 percent originating from the SJR Watershed. Based on these estimates, the average annual commercial and sport ocean catch of Chinook salmon originating from the SJR totaled about 13,560 and 5,540 fish, respectively, between 1967 and 2010. Catch data for boats based in the Fort Bragg, Eureka, and Crescent City port areas were not available; however, data from recent years suggest that a large proportion of the commercial and sport salmon harvest in these areas originates from Central Valley watersheds (CDFW 2012, 2013, 2015).

Recent Salmon Fishery Closures in California

As discussed above, in 2008 and 2009 the sudden decline of the Sacramento River Basin fall-run Chinook salmon population led the PFMC to almost completely close salmon fishing seasons for the first time in California's history. In both years, the ocean commercial salmon fishery was completely closed. The ocean recreational salmon fishery also was closed in 2008, but was opened for a 10-day period in 2009 (August 29–September 7) from Horse Mountain (near Shelter Cove) to the Oregon border, allowing fishing along the northernmost portion of the California coast (PFMC 2010). Fishing rebounded beginning in 2010, but still remains below the levels prior to the closures (NMFS 2014.)

Recreational fishing for salmon in Central Valley rivers was also highly restricted in 2008 and 2009 relative to recent years. In 2008, an estimated 650 Sacramento River fall-run Chinook salmon were harvested during a 2-month season lasting from November 1 through December 31, which was only 1 percent of the river run. Angler surveys conducted in the Sacramento River Basin for 9 years between 1991 and 2007, during which harvest regulations were much less restrictive than in 2008, suggested a mean harvest rate of 14 percent of the river run (PFMC 2009). In 2009, the Upper Sacramento River late fall-run fishery was the only Central Valley fishery open to Chinook retention, and in an attempt to decrease harvest and protect Sacramento River fall-run Chinook, the fishery was not opened until November 16, 2009. Preliminary estimates indicated that no Sacramento River fall-run Chinook salmon were harvested by recreational anglers in the 2009 late-fall fishery (PFMC 2010).

The prohibition of commercial and recreational salmon fishing in 2008 and 2009 caused substantial economic effects on California's fishing industry, including direct employment and income losses in the fishing industry and secondary employment and income losses in dependent industries. Additionally, the populations of Columbia River Chinook and coho salmon from Oregon and Washington also declined to near record-low levels. In April of 2008, the Governors of all three states (California, Oregon, and Washington) wrote the Speaker of the House requesting assistance in obtaining emergency appropriations to help mitigate the economic impact, which at the time totaled $290 million and included the loss of more than 4,200 jobs (Schwarzenegger et al. 2008).

Two subsequent studies estimated similar impacts on industrial output and employment in California caused by the closures of the ocean salmon fisheries. The first study as reported in

CDFW's *Outdoor California*[10] magazine (Morse and Manji 2009), estimated that the 2008 closure cost the California economy $255 million in industrial output and 2,263 jobs. The publication also estimated that the 2009 closure resulted in a loss of $279 million in output and 2,690 jobs. The closures put some boat owners and commercial salmon fishermen out of business, causing economic hardships for tackle shops, bait and boat dealers, motels and restaurant owners, and other related businesses during those years (Morse and Manji 2009).

This assessment was corroborated to some extent by a second study of the fishery closure effects conducted by the University of the Pacific Business Forecasting Center (Michael 2010).[11] This study assessed effects relative to 2004 and 2005 salmon fishery production, when annual commercial harvests in California averaged 421,500 salmon. For commercial salmon fishing, the Michael study estimated economic effects for only those directly and indirectly related to salmon harvesting and processing, assuming that no effects would occur at the wholesale, distribution, or retail levels because consumers could switch to substitute products. The Michael study estimated that the fishery closure cost $21.3 million in revenue for the commercial salmon fishing industry, $47.9 million in total income, and 961 total jobs. For recreational salmon fishing, estimated impacts included the loss of $70.5 million in total income and 862 jobs.[12] Combined, the closures of California's commercial and recreational salmon fisheries cost the economy $118.4 million in annual income and 1,823 jobs compared to the income and employment for 2004 and 2005.

The Michael study noted that salmon abundance was much higher in recent decades and that recovery to these levels would generate even larger economic impacts. Additionally, it noted the role of seasonality and dispersion in interpreting the results of its study. For example, the study's employment impacts represent annual averages, whereas an industry with highly seasonal employment patterns such as fishing would have employment impacts at some point during the year higher than those represented by the annual average employment losses. On the other hand, economic effects of salmon fishing are dispersed across hundreds of miles of coastline and inland waterways, somewhat diluting the concentration of effects. However, relatively small fishing communities may feel the effects more acutely than would a larger port area such as San Francisco. These smaller, more-isolated communities, considered somewhat dependent on commercial and recreational fishing, include Crescent City in Del Norte County; Eureka, Trinidad, and Fields Landing in Humboldt County; Fort Bragg, Albion, and Point Arena in Mendocino County; Bodega Bay in Sonoma County; Point Reyes, Marshall, and Bolinas in Marin County; Princeton and Half Moon Bay in San Mateo County; and Moss Landing in Monterey County (Langdon-Pollock 2004; Norman et al. 2007).

The studies above (i.e. Morse and Manji 2009; Michael 2010) did not estimate the potential economic effects caused by curtailment of inland sport fishing for Central Valley Chinook salmon. Although sport anglers can shift their effort to other species when salmon are not available, the

---

[10] *Outdoor California* is an official California fish, wildlife, and habitat magazine published by CDFW that describes noteworthy stories on California's native species and habitat.

[11] A third salmon closure study, conducted by Southwick Associates, produced much higher estimates of economic impacts than did CDFW and Michael studies. However, Michael (2010) concluded that several methodological flaws led to highly exaggerated estimates of commercial fishing-related impacts, particularly for effects in California's retail and salmon distribution sectors.

[12] Note that the modeling of recreational salmon fishing effects used only the expenditures of out-of-state anglers based on the premise that recreational spending by in-state anglers may simply be transferred to fishing effort for different species or entirely out of fishing and directed towards other recreational pursuits in the area, offsetting the effects attributable to decreased salmon fishing.

reduction of salmon fishing opportunities in Central Valley rivers likely adds to the economic effects estimated by the two ocean closure studies.

In 2006, a federal socioeconomic study conducted by PFMC and the National Marine Fisheries Service (NMFS) evaluated the needs of fishing communities. The study identified several Northern California counties and port communities as “most vulnerable” and “vulnerable” with high levels of dependence on commercial fishing and low levels of resilience. For example, the county of Del Norte was classified as "vulnerable," and the counties of Humboldt, and Mendocino were classified as “most vulnerable.” Additionally, the communities of Crescent City, Eureka, Fort Bragg, Point Arena, and Bodega Bay were classified as “vulnerable." These areas may be particularly susceptible to fishery closures and the associated economic losses that occur.

Effects on Commercial and Sport Fisheries

Expected Effects on Salmon in the San Joaquin River Watershed

The impacts of LSJR Alternatives 2, 3, and 4 on aquatic resources are detailed in Chapter 7, *Aquatic Biological Resources*, and summarized in Table 7-1. Reservoirs releases on the LSJR tributaries are made in response to multiple operational objectives, including flood management, downstream diversions, instream flow requirements for fisheries, instream water quality requirements, and water quality and flow objectives at Vernalis. Under LSJR Alternatives 2, 3, and 4, increased flows would largely be confined within existing channels, preventing an increase in flood frequency, and would have similar timing and magnitude compared to historical flows. As a result, increased flows from LSJR Alternatives 2, 3, and 4, with and without adaptive implementation, are not anticipated to have substantial adverse impacts on fish species in the tributary watersheds and LSJR. Specifically, flow alterations would not be sufficient to substantially impact aquatic resources in the tributary rivers or watershed reservoirs. As a result, impacts on fish species in the tributary rivers and reservoirs, and consequently on recreational fisheries, would be less than significant.

The potential benefits of the LSJR alternatives on aquatic resources are detailed in Chapter 19, *Analyses of Benefits to Native Fish Populations from Increased Flow Between February 1 and June 30*, and Chapter 3 of Appendix C, *Technical Report on the Scientific Basis of Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*. The following information is largely taken from those sources and repeated here for ease of reference.

The results shown in Chapter 19 indicate that there would be significant temperature benefits for Central Valley fall-run Chinook salmon and Central Valley steelhead on the eastside tributaries and the mainstem LSJR under some of the alternatives. These fish evolved to spawn and develop at higher elevations where the water temperatures are colder. However, with the construction of the rim dams they can no longer reach these elevations and must spawn in the lower, warmer reaches of the tributaries. Increasing flow in tributaries at the right times can help buffer streamflow temperatures against hotter air temperatures in the late spring and early summer, when young salmon are developing and migrating. Significant temperature improvements are expected on the Stanislaus and Merced Rivers, primarily under LSJR Alternatives 3 and 4, with and without adaptive implementation (i.e., requirements of 40–60 percent unimpaired flow). On the Tuolumne River, significant temperature improvements are expected under all LSJR alternatives, with the least benefit under LSJR Alternative 2, and the most benefit under LSJR Alternative 4, both without adaptive implementation.

In addition to temperature benefits, results indicate that providing more flow of a more natural regime during the February–June time period would significantly increase the amount of floodplain habitat that is available to native fish. Increasing the floodplain area or duration could provide several benefits for young salmon, including cover from predators, greater access to food resources, and low flow zones to rest in. Higher unimpaired flow requirements will produce greater benefit, in terms of floodplain frequency and magnitude (and presumably duration), compared to lower unimpaired flow requirements or baseline conditions. In general, flood inundation will increase the most (compared to baseline) during the months of April, May, and June under the LSJR alternatives.

Potential Effects on Use and Non-Use Values Resulting from Improved Salmon Production

The following assessment focuses on potential use and non-use benefits associated with supporting and maintaining sustainable Chinook salmon populations in the Stanislaus, Tuolumne, and Merced Rivers. The assessment of use benefits focuses on potential commercial and recreational[13] fishing-related economic effects. Information collected by CDFW, PFMC, USFWS, AFRP, and others is used to characterize the economic values of existing commercial and sport fisheries that could be affected by LSJR Alternatives 2, 3, and 4.

Potential non-use benefits (i.e., monetary values associated with just protecting fish resources rather than from directly using fish resources) also are considered in this section. Although this assessment is necessarily more qualitative because of the lack of specific information on potential effects on salmon populations and other native species, estimates of non-use monetary values, as measured in terms of the public's willingness to pay (WTP) for programs or actions designed to restore or enhance fish populations, are presented for context. For this assessment, non-use values (passive use values) are defined as the non-fishing public's perceived values associated were merely knowing that salmon are being protected, even if these individuals have no intention to ever use the resources.

Improving salmon production in the Stanislaus, Tuolumne, and Merced Rivers would improve Central Valley adult escapement rates for salmon and could help avoid salmon fishery closures in the future. Healthier populations and more viable fisheries could have economic benefits for California residents and businesses, as well as for out-of-state visitors or those who reside out of the state but place value on maintaining and improving Central Valley fish species. As discussed above under *Recent Salmon Fishery Closures in California*, the closures of the ocean commercial and sport fisheries in 2008 and 2009 cost the California economy an estimated $255–$275 million in industrial output (sales), $118 million in personal income, and 1,800–2,700 jobs during each year of the closure. If economic effects from curtailment of the freshwater sport salmon fishery also are considered, the total economic impact would be substantially greater. There is also a direct relationship between the prosperity of fishing-dependent communities in the Central Valley and along the Pacific Coast and the viability of commercial and recreational fisheries that contribute economic activity to these communities. Additionally, there is a direct benefit for residents of California and other regions to avoid further extinctions of California's salmon and other native fishes.

---

[13] Recreational and sport fishing refer to the same activity; the term *sport fisheries* is used in this section to refer to marine and freshwater areas where sport fishing activities are managed. This terminology is intended to differentiate fishing activity from more general recreational activities discussed in Section 20.3.6, *Effects on Recreational Opportunities, Activity, and the Regional Economy.*

Non-use values are considered public goods that can be simultaneously enjoyed by millions of people across a region and the country (Loomis 1996). Existence value is a non-use value defined as the benefit received from simply knowing that a resource exists even if no use is made of it. Increasing stocks of Chinook salmon and steelhead in the SJR Watershed to sustainable levels would have associated existence values as it provides assurance that the resource will continue to exist. Although data on salmon recovery rates and associated population levels is too limited to reliably estimate non-use values associated with recovering Chinook salmon in the SJR Watershed, these values are conceptually measurable and would likely differ to some extent among LSJR Alternatives 2, 3, and 4.

Table 20.3.5-3 identifies four salmon restoration programs with studies conducted to estimate non-use values associated with the restoration programs. Typically, non-use values can only be measured reliably by designing and implementing program-specific public surveys; however, the number of such studies is very limited due to the time and costs associated with conducting public surveys of this nature. Although the underlying reason for conducting the four studies referenced in Table 20.3.5-3 was similar (i.e., to estimate the monetary value that the public would place on restoring salmon habitat and populations), each study embodied different actions for achieving the salmon restoration goals of the programs. In the case of the Elwha River and the Klamath River, removing dams that blocked access to habitat important for salmon was central to the program. In the case of the Columbia River, interest in substantially increasing (doubling) salmon runs was the overriding goal. Lastly, the Upper SJR study was part of a broader federal and state program to improve deteriorating habitat conditions for fish and wildlife resources in the San Joaquin Valley.

Acknowledging non-use values similar to those in Table 20.3.5-3 is important to a comprehensive assessment of costs and benefits for LSJR Alternatives 2, 3, and 4. Although difficult to accurately measure without conducting a public survey tailored to the outcomes of specific physical and biological program objectives, the importance of relevant non-use values in an economic assessment of the plan amendments should not be overlooked. Oftentimes, estimates of non-use values can total in the hundreds of millions of dollars or more. However, thoroughly understanding important causal relationships between restoration (e.g., enhanced flows) and the resulting physical and biological outcomes is challenging. As such, the best result that typically can be expected from a review of values similar to those studies identified in Table 20.3.5-3 is to develop a contextual foundation for these values. This foundation provides an understanding about the general magnitude of non-use values and their contribution to the economic calculus.

The evaluation described above is limited to potential use and non-use benefits associated with supporting and maintaining sustainable populations of Chinook salmon in the three eastside tributaries. As noted, improving salmon production in the Stanislaus, Tuolumne, and Merced Rivers would be expected to improve Central Valley adult escapement rates and could help avoid salmon fishery closures in the future, resulting in direct economic benefits to California businesses and residents. There also may be additional benefits to other native fish species and other plant and animal species at spatial scales that extend beyond the scope of the plan amendments; however, uncertainty and lack of information on the potential biological effects preclude a more quantitative evaluation of these benefits.

Table 20.3.5-3. Existing Studies that Estimate the Non-Use Monetary Benefits Associated with Restoring Salmon Populations, as Measured by the Public's Willingness to Pay

	Upper San Joaquin River Study (1990)[a]	Columbia River Study (1989)[b]	Elwha River Study (1996)[c]	Klamath River Study (2012)[d]
Description of Salmon Program Benefits	Increase annual populations of Chinook salmon in the Upper SJR from less than 100 fish to about 15,000 fish as a result of increasing flows in the river	Restore (double) annual salmon and steelhead runs (increase of 2.5 million fish annually) as a result of habitat restoration efforts	Increase pink salmon runs by 200,000 fish annually and chum, steelhead, and Chinook runs by 100,000 fish annually as a result of dam removal/habitat restoration	Increase populations of wild salmonids (Chinook salmon and steelhead), with increases ranging from 30% to 150%; changes in extinction rates for the shortnose and Lost River suckers, and for coho salmon as a result of dam removal/habitat restoration
Estimates of Annual Willingness to Pay (WTP) per Household	Annual WTP benefits ranged from $103 per household (out-of-state residents) to $202 per household (residents of the San Joaquin Valley) (in 1990 dollars)	Monthly WTP benefits range from $2.21 per respondent to $4.88 per respondent (in 1989 dollars), depending on the probability of future use of the river for salmon fishing	Annual WTP benefits vary by location of respondent, ranging from $59 per household for residents of Clallam County, to $73 per household for residents elsewhere in Washington State; out of state residents indicated an average (mean) WTP benefit of $68 annually (in 1996 dollars)	WTP benefits vary by program characteristics; annualized values (discounted) range from $65.82 to $112.28 per household (in 2012 dollars)

Effects of Commercial and Sport Fisheries on Regional Economies

This section addresses potential effects on fishery-dependent regional economies from flow-related effects on recreational and commercial fisheries. The analysis considers potential changes in fisheries associated with improved conditions for native fisheries affected by LSJR Alternatives 2, 3, and 4.

Potential effects on regional economic conditions caused by changes in fishery conditions in the three tributaries and the LSJR can be viewed by tracing the underlying relationship between fishing activity (both commercial and sport fishing activity) and regional economies affected by this activity. Conceptually, local and regional economic activity generated by the use of fishery resources can be followed from the availability of (and changes to) the resources to the generation of employment and income within a region. Management of commercial and sport fishery resources in marine waters, as well as those at freshwater reservoirs and rivers, affects the amount and type of commercial and sport fishing activity at different fishing areas. Changes in the availability and management of fishing facilities result in changes in sport fishing activity, which, in turn, typically alters the location and level of fishing-related spending. For example, a highly developed facility, such as a marina with a resort and restaurants, boat slips, and boat launching facilities, may attract large numbers of anglers from outside the region who spend money on accommodations, restaurant meals, boat rentals, and fuel in the vicinity of the facility. Alternatively, an undeveloped campground on a reservoir may attract relatively few anglers from outside the local area, resulting in fishing-related spending that largely consists of food and gasoline purchases made at home or en route to the site.

As discussed previously in this section, fisheries-related activities in the study area would likely increase under LSJR Alternatives 2, 3, and 4 in response to enhanced populations of salmon and other native fish species. LSJR Alternative 2 would likely have a relatively minor impact on fisheries-related economic activity, but the economic benefits would grow under Alternatives 3 and 4 as salmon populations further increase. However, the overall economic and employment effects for most businesses directly and indirectly linked to fishing activity in the study area would likely not be substantial. Some small, fishing-dependent communities, where fishing-related activity contributes more than just minimally to local economic activity, may see greater economic benefits.

As discussed in Section 20.3.5, *Effects on Fisheries and Associated Regional Economies*, implementation of the San Joaquin River Restoration Program[14] (SJRRP) is expected to have fishery-related benefits, which, in turn, would benefit fishery-dependent communities within the study area. When considered in conjunction with the SJRRP, the plan amendments may have a more substantial effect on economic activity for fishery-dependent communities in the study area. In addition, greater economic activity could also bring additional economic opportunities (i.e., jobs, income) to these areas.

Adaptive Implementation

Adaptive implementation would take place based on required evaluation of current scientific information and would need to be approved as described in Appendix K, *Revised Water Quality Control Plan.* Accordingly, the frequency and duration for any use of adaptive implementation

---

[14] Implementation of the settlement and the Friant Dam release flows required by the San Joaquin River Restoration Program are expected to increase the existing SJR flows at Stevinson in the near future

methods 1, 2, 3, and 4 cannot be determined at this time. Adaptive implementation method 1 potentially has the greatest likelihood of changing economic effects as it would allow the unimpaired flow requirements to be increased or decreased by up to 10 percent from the objective unimpaired flow (with a minimum requirement of 20 percent and a maximum of 60 percent unimpaired flow). For LSJR Alternative 2, an increase from 20 percent to 30 percent of the unimpaired flow would likely result in different effects as compared to those shown above for LSJR Alternative 2, depending upon flow conditions and frequency of the adjustment. As such, under LSJR Alternatives 2 or 3, if the percentage of unimpaired flow is increased with adaptive implementation method 1, regional economic effects related to enhanced fisheries could increase more than conditions without adaptive implementation. Under LSJR Alternatives 3 and 4, if the percent of unimpaired flow could be reduced with adaptive implementation method 1, if there were no effect on fish, and as such, use and non-use benefits and regional economic conditions would not be expected to change much compared to conditions without adaptive implementation.

20.3.6 Effects on Recreational Opportunities, Activity, and the Regional Economy

Introduction

As described in Chapter 10, *Recreational Resources and Aesthetics*, changing flow regimes and reservoir-storage levels may potentially affect the timing, duration, and quality of recreational opportunities. Therefore, implementation of LSJR Alternatives 2, 3, and 4 may affect recreational activities through adoption of new and updated water management practices that could alter reservoir-storage levels and downstream releases.

Changes in reservoir-storage levels could affect recreational activities primarily by reducing access to boat ramps, marinas, and boat-in campgrounds; reducing water surface area for boaters; and exposing large areas of shoreline, negatively affecting aesthetic quality and access for picnickers, swimmers, and shore side users. Changes in downstream flows could affect both water-dependent and water-enhanced recreation in the Stanislaus, Tuolumne, and Merced Rivers and potentially along the LSJR. Furthermore, altering the timing, duration, and quality of recreational opportunities could affect the value that recreationists place on the activities and, in turn, change the frequency with which these recreational resources are used.

As described in Gallo (2002), recreational opportunities can generate economic benefits through two pathways. The first pathway is the value (net benefit) to those participating in the activities, as indicated by their willingness to pay over and above trip expenditures (i.e., transportation and parking fee costs) for these recreational opportunities. This measure of value depends, to a large extent, on the quality of the recreation environment. For example, wildlife watching is more rewarding when there is more viewable wildlife, creating greater value in that environment. Improving the quality of the environment can augment recreational benefits, which is typically measured by the increase in willingness to pay (i.e., monetary value over and above trip-related expenditures) for the recreational activities.

The second pathway to assess the economic contribution of recreational opportunities is the beneficial impacts that recreation-related spending by nonresidents of a region brings to a local economy where the nonresidents are visiting. Nonresidents are particularly important in this regard because their economic activities may not otherwise occur within the region. More frequent trips by visitors means additional spending in the region. These types of economic effects are typically referred to as *regional economic impacts*, where a region can range from a small geographic area (e.g., a county or city) to a large multi-county area. While these effects do not directly affect residents, increased visitor spending does support local economic activity. Although not considered here, those who do not directly use the improved environment for recreational activities may still benefit just from knowing that biodiversity is enhanced and from other environmental enhancements that contribute to amenity values (i.e., non-use value).

The study area for evaluating recreation-related economic effects in this analysis includes the reservoirs (i.e., New Melones, New Don Pedro, and Lake McClure) and the three eastside tributaries (Stanislaus, Tuolumne, and Merced Rivers) extending from the reservoirs, downstream, to the LSJR. (Potential economic effects of LSJR Alternatives 2, 3, and 4 on fishing are discussed in Section 20.3.5, *Effects on Fisheries and Associated Regional Economies.*) This section begins by presenting a description of baseline conditions, including information on recreational activity in the study area and its relationship to river flows and reservoir levels. Then, potential effects of the LSJR alternatives on recreational opportunities, participant benefits and recreation-related spending are assessed. This assessment is followed by a qualitative assessment of potential recreation-related regional economic impacts on the regional economy.

Description of Baseline Conditions

In this analysis, estimates of existing recreational use help establish a baseline of potentially affected recreational activity and associated spending in the study area. Table 20.3.6-1 presents estimates of baseline recreational use, in terms of annual visitor days, at recreation areas in the study area. Approximating recreation activity at the specific locations identified in Table 20.3.6-1 is useful for evaluating the relative economic importance of these recreational areas within the surrounding region. Although some of the values in Table 20.3.6-1 are somewhat dated, these estimates are considered to reasonably characterize existing recreational activity because of the many factors affecting recreational use levels over time, both positively and negatively.

As shown in Table 20.3.6-1, annual recreational use at New Melones Reservoir, Don Pedro Reservoir, and Lake McClure totals about 2.4 million visitor days, of which it is assumed that residents and non-residents each account for about 50 percent of the total. Annual recreational activity along the Stanislaus, Tuolumne, and Merced Rivers and the LSJR totals an estimated 710,200 visitor days. Although the proportion of visitor days to the eastside tributaries made by residents or nonresidents is unknown, it is assumed to be similar to the proportions at the reservoirs (50 percent made by residents and 50 percent made by non-residents of the study area).

For this analysis, recreational activities are grouped according to flow ranges developed by Whittaker and Shelby (2003) to support different types of river recreation activities. Based on this study, low-range flow activities, like swimming, account for about 25 percent of all use; that mid-range flow activities, including motorized boating, rafting, and kayaking, account for about 60 percent of all activities; and that high-range flow activities, such as advanced kayaking and rafting, account for about 15 percent of all activities.

Table 20.3.6-1. Estimated Use (in Visitor Days) of Affected Recreation Areas, by Watershed

Watershed/Recreation Area	Counties	Estimated Visitor Days (Year)	Type of Activities
Stanislaus	San Joaquin, Calaveras, Tuolumne, Stanislaus		
New Melones Reservoir		800,000 (2011)[a]	All activities
Stanislaus River		330,200 (1999)[b]	Fishing, camping, swimming, whitewater boating, water-enhanced activities
		5,200 (average of 1999/2000)[c]	Fishing only
Tuolumne	Tuolumne, Stanislaus		
Don Pedro Reservoir		244,000 (peak season, April through September - 2012)[d]	All activities
Tuolumne River		150,000 (1992)[e]	Boating, fishing, swimming, rafting, wildlife viewing
		34,900 (2000)[f]	Fishing only
Merced	Mariposa, Merced		
Lake McClure		1,400,000 [2010][g]	All activities (camping, boating, swimming, hiking, bicycling, house boating, fishing)
Merced River		73,000 [1999][h]	Kayaking, rafting, canoeing, water-enhanced activities
Lower San Joaquin River	San Joaquin, Stanislaus, Merced	157,000 [2001][i]	Boating and fishing
		57,500 [2000][j]	Fishing only

[e] USBR 1999; use is measured in 6-hour RVDs.

[f] Derived based on information from Gallo 2002. Note that estimates in Table 20 of the Gallo report were adjusted to account for all visitors; as stated in the referenced report, county residents account for an estimated 51 percent of all recreation days.

[g] As cited in Merced ID 2014.

[h] As cited in USBR 1999; use is measured in 6-hour RVDs.

[i] As cited in USBR 2001; use is measured in 6-hour RVDs.

[j] Derived based on information from Gallo 2002. Note that estimates in Table 20 of the Gallo report were adjusted to account for all visitors; as stated in the referenced report, county residents account for an estimated 51 percent of all recreation days.

Residents of the study area who use the rivers and reservoirs for recreational activity are estimated to receive, on average, $25 (in 2007 dollars) per visitor day in net benefits, as measured by their willingness to pay for these recreational opportunities over and above their trip-related expenditures (Hanemann 2005). Non-residents of the region who use the rivers and reservoirs for recreational activity are estimated to spend, on average, $30 (in 2007 dollars) per visitor day (Hanemann 2005). Based on information presented in Table 20.3.6-1, the three eastside tributaries and their upstream rim reservoirs account for about 3.5 million visitor days per year. Assuming that half of the visitors to the region are residents of the region and the other half are non-residents, the residents spend an estimated $43.7 million per year and the non-residents spend about $52.5 million per year, which have additional benefits for residents in terms of generating local economic activity.

Effects of the LSJR Alternatives

This section describes the potential effects on recreational activity and associated economic effects from changes in recreational opportunities in the study area under the LSJR Alternatives 2, 3, and 4. The assessment is based primarily on predicted flow differences between modeled baseline conditions and the LSJR alternatives, as presented in Chapter 10, *Recreational Resources and Aesthetics* (Tables 10-4 through 10-6), and on how changes to reservoir storage levels could impact recreational opportunities and the use of recreational facilities at affected reservoirs (Tables 10-8 through 10-13).

Effects on River Recreational Activities

This analysis uses hydrology modeling results for the LSJR alternatives to measure the frequency of flows within particular ranges that support different types of river recreational activities, as presented in Chapter 10, *Recreational Resources and Aesthetics*, (see Tables 10-4 through 10-6). Although optimal flows vary for each river due to hydrologic and geomorphic conditions, flows can generally be classified into the following flow ranges for purposes of evaluating potential effects on certain types of recreational activities.

- Low-range flows (less than 500 cfs) for supporting swimming, floating, canoeing and kayaking.
- Moderate-range flows (between 500 and 1,500 cfs) for supporting motorized boating, rafting, and kayaking (but may still support swimming, wading, and floating, particularly in certain locations).
- High-range flows (between 1,500 and 2,500 cfs) for supporting advanced rafting or kayaking.

A flow above 2,500 cfs is generally considered unsafe for recreational activities, although advanced whitewater rafting and kayaking often still take place.

Although impacts on recreational opportunities and activities, and associated economic effects, would be relatively minor under all LSJR alternatives, these effects would vary by alternative and river.

Under LSJR Alternative 2, the frequency of low-range, moderate-range, and high-range flows on the Stanislaus, Tuolumne, and Merced Rivers would not substantially change. The Merced and Tuolumne Rivers would experience a slight decrease in the frequency of low-range flows when compared with modeled baseline conditions (see Tables 10-4 and 10-5); however, a slight increase in the frequency of moderate flows could offset the impact of changes in the frequency of low-range flows on recreation activity on these rivers. The Stanislaus River would experience even less change in the frequency of low-range, moderate-range, and high-range flows (see Table 10-6). Overall, changes in flows under LSJR Alternative 2 would not be expected to substantially impact recreational activities on these rivers.

Under LSJR Alternative 3, the frequency of low-range flows on the Merced River would likely decrease, while the frequency of moderate-range and high-range flows would be expected to increase. Overall, recreational opportunities could be slightly greater, primarily because activities associated with the more frequent moderate-range (500–1500 cfs) and high-range (1,500–2,500 cfs) flows could more than offset the expected decrease in recreation activity supported by low-range (<500 cfs) flows (see Table 10-4). Conversely, the frequency of low-range and moderate-range flows on the Tuolumne River would likely decrease, whereas the frequency of high-range flows would be expected to increase. There would also be an increased frequency of flows over 2500 cfs that do not support most recreational activities. Overall, recreational opportunities on the Tuolumne River could slightly decrease as recreation activity supported by low-range and mid-range flows could more than offset the increased activity supported by high-range flows (see Table 10-5). Finally, on the Stanislaus River there would be minor shifts in the frequency of low-range, moderate-range, and high-range flows and, therefore, recreation activity would be more or less unchanged under LSJR Alternative 3 (see Table 10-6).

Under LSJR Alternative 4, flow frequency impacts would be similar to those under LSJR Alternative 3. On the Merced River, the frequency of low-range flows would likely decrease while the frequency of moderate-range and high-range flows would increase, resulting in slightly greater recreational opportunities and activity (see Table 10-4). On the Tuolumne River, the frequency of low-range and moderate-range flows would likely decrease slightly, while the frequency of flows over 2500 cfs would increase. In response, recreational opportunities and activities could slightly decrease on the Tuolumne River because activities that rely on low-range and moderate-range flows could not be performed as often (see Table 10-5). Finally, on the Stanislaus River the frequency of low-range and moderate-range flows would slightly decrease, whereas the frequency of flows over 2500 cfs would increase. As a result, recreational opportunities on the Stanislaus River may slightly decrease, as activities that rely on low-range and moderate-range flows could not be performed as often (see Table 10-6).

In summary, flow changes associated with LSJR Alternatives 2, 3, and 4 would be expected to result in minor increases or decreases in recreational opportunities and activities in the three eastside tributaries. Low-range flows would likely occur less frequently under the LSJR alternatives, while high-range flows would likely occur more frequently. In turn, there may be slight shifts in the types of recreational activities performed, depending on historical use of each river. As flows shift higher more people may participate in boating rather than wading, but overall recreational opportunities should remain more or less unchanged. Consequently, benefits to local residents and potential effects on visitor spending in the region associated with recreational activity on the tributaries would be relatively unchanged under LSJR Alternatives 2, 3, and 4.

Effects on Reservoir Recreational Activities

As discussed in Chapter 10, *Recreation Resources and Aesthetics*, operational changes at the three rim reservoirs (New Melones Reservoir, Don Pedro Reservoir, and Lake McClure) under LSJR Alternatives 2, 3, and 4 would be expected to have less than significant (and presumably slight) effects on recreational opportunities and associated activity. Overall, recreational opportunities and use at all three reservoirs would be expected to decrease slightly or remain generally unchanged under LSJR Alternatives 2, 3, and 4 (see Tables 10-8 through 10-13). Under LSJR Alternative 2, the relatively small changes in reservoir elevations would not be expected to affect levels of recreational activity at any of the reservoirs. Under LSJR Alternative 3, the predicted changes in reservoir elevations would not be expected to substantially affect recreational use levels at any of the three rim reservoirs; however, elevation shifts at New Don Pedro Reservoir would be more noticeable than at the other two reservoirs, although recreation opportunities and associated activities still would not be expected to decrease substantially (see Tables 10-10 and 10-11). Finally, under LSJR Alternative 4, predicted changes in reservoir elevations would still not be expected to substantially affect recreational use levels at any of the three rim reservoirs.

Because water levels in all three reservoirs would not change significantly under the LSJR alternatives, the impacts on recreational opportunities at the reservoirs would likely be small. Consequently, benefits to local residents and effects on visitor spending in the region associated with reservoir recreation activity would be relatively unchanged under LSJR Alternatives 2, 3, and 4.

Potential Effects on the Regional Economy

Management of recreational resources in the plan area, including reservoir-elevation levels and river flows, affects recreational opportunities and the number of visitors and types of activities that they take part in. For example, a highly developed recreation area, such as a reservoir that includes a resort with restaurants, boat slips, and boat launching facilities, may attract a large number of visitors from outside the region who spend money in the vicinity of the recreation area. Alternatively, an undeveloped campground may attract relatively few visitors from outside the local area, while local visitors will primarily purchase food and gasoline at home or en route to the site. Conceptually, local and regional economic activity generated by recreational spending can be traced from the use of recreational resources to the generation of employment and income by recreational activities within the region.

Although not quantified for this analysis, potential regional economic effects associated with changes in recreational activity on the three tributaries and rim reservoirs are expected to be minor. LSJR Alternatives 2, 3, and 4 would likely have only minor effects on recreational activity and spending at the eastside tributaries and their associated rim reservoirs. The greatest potential effects would be associated with recreational activity on the Tuolumne and Merced Rivers where implementation of the LSJR alternatives could reduce the frequency of low range flows (<500 cfs), which are optimal for relatively calm water activities such as swimming and wading. In turn, LSJR Alternatives 2, 3, and 4 could also have relatively minor impacts on regional economic activity, as the number of non-local visitors may slightly decrease.

As identified in Section 20.3.5, *Effects on Fisheries and Associated Regional Economies,* implementation of the SJRRP is expected to provide additional recreational opportunities in the SJR Watershed that would benefit the local and regional economy. It has been estimated that the additional recreational activity (including fishing) provided by the SJRRP could support 475 recreation industry jobs annually by 2025 (Kantor 2012). The stimulus of economic activity from the SJRRP would result in a cumulative economic benefit to the local and regional economy within the SJR Watershed.

Adaptive Implementation

Adaptive implementation would take place based on required evaluation of current scientific information and would need to be approved as described in Appendix K, *Revised Water Quality Control Plan.* Accordingly, the frequency and duration for any use of adaptive implementation methods 1, 2, 3, and 4 cannot be determined at this time. Adaptive implementation method 1 potentially has the greatest likelihood of changing economic effects as it would allow the unimpaired flow requirements to be increased or decreased by up to 10 percent from the objective unimpaired flow (with a minimum requirement of 20 percent and a maximum of 60 percent unimpaired flow); however, this would likely result in tradeoffs between river and reservoir recreation economic effects. Methods 2 and 3 could change the timing of the flows and if more water is held in the reservoirs for later release, this might help reservoir and maybe river recreation. Overall, given the very small changes in recreational opportunities, it is not expected that adaptive implementation would substantially change the effects presented above.

20.3.7 Non-Flow Measures

This section provides cost estimates associated with implementing non-flow measures that affected entities or resource agencies (e.g., CDFW) may undertake between the rim dams on the Stanislaus, Tuolumne, and Merced Rivers and the confluence of the LSJR. These measures would inform the body of scientific information potentially used to make adaptive implementation decisions under LSJR Alternatives 2, 3, and 4. The costs described are based on reference projects and incorporate standard assumptions regarding the type and potential location of non-flow measures. These measures, which are grouped into habitat restoration, fish passage improvements, and other actions, include the following.

Habitat Restoration

- Floodplain and riparian habitat restoration.
- Gravel augmentation.
- Enhanced in-channel complexity.
- Improve temperature conditions.

Fish Passage Improvements

- Fish screens (screen unscreened diversions in tributaries and LSJR).
- Permanent physical barrier in the southern Delta.

Other

- Predatory fish control.
- Invasive species control (i.e., plant control).

The cost information described below is summarized from information presented in Chapter 16, *Evaluation of Other Indirect and Additional Actions*. The availability of information pertaining to the costs associated with several of the non-flow measures identified in Chapter 16 is very limited as such is not presented here. This includes reduction of vegetation disturbing activities and removal of human-made barriers to fish migration. In particular, the costs associated with the removal or modification of human-made barriers to fish migration are not presented below because the feasibility of this non-flow measure is unknown, as discussed in Chapter 16.

Floodplain and Riparian Habitat Restoration

Floodplain and riparian habitat restoration can be achieved through different approaches. While site specific conditions influence the cost of each approach, removal of riprap or other bank protection and active plantings are considered generally lower cost approaches, as compared to creating or expanding natural or engineered floodways, modifying river and floodplain geometry, or hydrologic reconnection of historical floodplains through levee breaches and/or setbacks. Removal of riprap and active plantings typically require fewer feasibility and design studies, fewer permits, and the involvement of fewer responsible agencies, and require limited adaptive management and mitigation monitoring plans to evaluate the effectiveness of the projects. In addition, removal of riprap and active plantings are less likely to require the purchase of property, which can be a substantial cost associated with floodplain and riparian habitat restoration.

Examples of floodplain and habitat restoration projects include the following.

- The Lower San Joaquin River Floodplain Protection and Restoration Project that acquired a total of 223.54 acres of wildlife habitat adjacent to the SJR and eastside tributaries for preservation and future enhancement of riparian and wetland habitats for an estimated cost of $1.1 million.
- The Basso Bridge Ecological Reserve and Merced River Ranch Land Acquisitions on the Merced River were purchased for approximately $830,000 in 1997 to protect spawning riffles and enhance riparian species. At the time, the purchase was simply to secure the land, with no active restoration planned. Depending on the size, scale, and location of a project, levee breaches can be very costly.
- The Cosumnes River floodplain restoration project where the U.S. Army Corps of Engineers breached and abandoned 5.5 miles of levees to allow the river to flow into the floodplain as a result of the 1997 floods. This project cost an estimated $1.55 million.

Gravel Augmentation

The cost of gravel augmentation is substantially influenced by site specific conditions. Generally, gravel injection is a low cost approach, whereas hydraulic structure installation is a higher cost approach. The costs associated with gravel injection primarily relate to fuel costs for gravel delivery. These costs are estimated at $15–$20 per ton, plus $0.16–$0.20 per mile to transport. Gravel injection is typically used where flows are high enough to mobilize the material, such as downstream of a reservoir or at locations with easy access to the river for gravel placement.

Spawning bed enhancement is more expensive than gravel injection as it typically requires engineering design. The cost of spawning bed enhancement, which does not include engineering design, is estimated at $25–$33 per ton ($19–$25 per cubic yard). Choosing an appropriate location and gravel mix is crucial for successful augmentation.

Hydraulic structure installation is generally the most expensive gravel augmentation approaches because it requires engineering analysis and in-stream work with heavy equipment that requires permits from different agencies that can take 6–18 months to obtain. Project costs for this approach can range from $1,500 to $100,000 depending on the complexity of the project, project length and materials.

The costs associated with the gravel augmentation approaches described above do not include maintenance and monitoring costs, which depend on the approach selected. Examples of gravel augmentation projects are shown in Table 20.3.7-1.

Table 20.3.7-1. Central Valley Project Improvement Act[a] Spawning and Rearing Habitat Restoration Projects

Project	Description	Construction/ Implementation[b]	Monitoring + Adaptive Management[c]
Sacramento River Project	Annual placement of 10,000 tons of gravel for spawning and rearing habitat restoration – between Clear Creek & Keswick Dam	$795,000	$120,000
American River Project	Annual placement of 7,000 tons of gravel at Nimbus Basin on the American River	$745,000	$6,000 + $100,000
Stanislaus River Project	Annual placement of 3,000 tons of gravel at the Two Mile Bar or Upper Honolulu Bar along the Stanislaus River	$670,000	$15,000
Program Management & Support (for three projects over 2 fiscal years)		$450,000	

Source: Hannon et al 2013.

[a] The Central Valley Project Improvement Act of 1992 (CVPIA) created a collaboration of agencies, including the Department of the Interior, USBR, and U.S. Fish and Wildlife Service in collaboration with state and local governments, tribes and stakeholders.

[b] Costs provided represent the requested funding for fiscal year 2015–2016. Costs represent the amount being cost-shared between the state and federal agencies involved in implementing the CVPIA.

[c] The adaptive management cost is intended for building a model and assembling information to develop model parameters for identifying restoration actions and monitoring priorities for the American River Project.

Enhanced In-Channel Complexity

The costs for enhancing in-channel complexity through the installation of cover structures, boulder structures and log structures depend primarily on the size of the stream, channel hydrology, complexity of the design, site accessibility, cost of materials, and equipment needed to transport and install the material. One of the primary costs associated with enhancing in-channel complexity is that cost for large woody materials (e.g., logs), which is highly dependent on the type of tree selected. For example, Washington Douglas Fir is $100 per 1,000 board feet (ft), whereas the cost for California Redwood is about $510 for the same amount. The National Resources Conservation Services cost share practice standard estimates that the material cost for large woody material ranges between approximately $1,900 per acre and $924 per acre (Guhin and Hayes 2015). The range in approximate costs (low–high) based on stream size is shown in Table 20.3.7-2.

Table 20.3.7-2. Engineered Log Structures and Large Woody Debris—Cost Estimates

Stream Size (cfs)	Cost[a] ($ Thousands) (Low–High)
Small stream (1–100)	10–40
Medium stream (101–2000)	20–70
Large stream (2000+)	10–80

Source: Thomson and Pinkerton 2008.

cfs = cubic feet per second

[a] Estimates identified above include construction, design, permitting, basic monitoring and routine maintenance (up to 2 years), reestablishing site to prior conditions and project management costs. These estimates assume purchased materials.

As part of the Lower Mokelumne River Joint Settlement Agreement (JSA) between East Bay Municipal Utilities District, the USFWS and CDFW, $25,663 in funding to the University of California, Davis was approved in 2008 to conduct a study along the Lower Mokelumne River to determine the effectiveness of large woody materials in aiding fish habitat. The project consisted of placing 542 large wood pieces along 4.8 miles on the Lower Mokelumne River directly below the Camanche Dam where the flows averaged 350 cfs.

Improve Temperature Conditions

Cost information concerning actions to improve temperature conditions, such as installation or modification of selective withdrawal structures, is limited. One factor that substantially affects the cost is construction. Examples of the costs of temperature improvement projects include the following.

- The Lake Natoma Temperature Curtains Pilot Project estimated the cost to be $1,960,196 for a 3-year study that included the installation of 2 curtains (one 700-ft long with a depth of 15-20 ft, second curtain 600-ft long with a depth of 20–25 ft). The costs associated with this pilot project included: design, permitting and environmental review, project management, temperature monitoring, project installation and removal, and project analysis and reporting.
- A temperature curtain was installed at Whiskeytown Lake in 2011 for a cost of $3 million. The new temperature curtain replaced a curtain from 1993 that had deteriorated and was no longer functional. The temperature curtain is 2,400 ft long and drops into the lake 110-ft and is anticipated to achieve a 2–4 degree drop in water temperature.

Fish Screens (Screen Unscreened Diversions in Tributaries and Lower San Joaquin River)

The costs for fish screens vary considerably depending on the size of the existing intake. Typically, screening smaller or private intakes that primarily serve agricultural uses are less costly as compared to the costs for screening large intake projects that primarily serve municipal and industrial uses. Agricultural diversions (with an average diversion rate of 10 cfs) have an estimated cost of $75,000 per diversion (unit cost of $7,500/cfs). Capital costs for agricultural diversion screens in the western United States can range between $3,000 and $20,000 per cfs, with maintenance and operations costs ranging between $3,000 and $5,000 per year.

The Anadromous Fish Screen Program (AFSP) established under the CVPIA has funded several fish screen projects in California. Recent projects include the following.

- Natomas Mutual Sankey Fish Screen Project (total cost of about $46.0 million) located off the left bank of the Sacramento River replaced existing unscreened diversions with a consolidated 434 cfs fish screen and intake facility.
- RD2035/Woodland Davis Clean Water Agency Joint Intake and Fish Screen (estimated cost of $44 Million) located off the right bank of the Sacramento River replacing unscreened diversion with a consolidated 400 cfs fish screen and intake facility to provide water to irrigate approximately 15,000 acres of crops and serve the cities of Davis, Woodland, and the University of California, Davis campus.

Another large municipal intake in the Central Valley that has been screened is the Davis Ranches Fish Screen Project, located in Colusa County at river mile 132.5. This fish screen consists of installing a self-cleaning, cylindrical, brushed intake fish screen with a retrieving system. The cost for this project is an estimated $414,900, which includes planning, design, project management, construction, installation, and monitoring. Table 20.3.7-3 provides a more detailed breakdown of the costs for the Davis Ranches Fish Screen Project.

Table 20.3.7-3. Design and Construction Costs for Davis Ranches Site 2, Pumps 4 & 5 Project

Cost Category	Davis Ranches Site 2, Pumps 4 & 5[a] ($)
Design & Construction of fish screen	310,964
Eng. Review, Inspection & documentation, permit costs	24,000
Accounting & project management & monitoring	79,940
Total	**414,904**

Source: Griffith 2001.

a Costs represent the total costs over 2 years.

Physical Barrier in the Southern Delta

A permanent operable barrier (gate) at the Head of Old River (HOR) is currently proposed as part of the California WaterFix to prevent out-migrating salmonids from entering Old River in the spring and improve adult passage conditions and water quality (dissolved oxygen) in the SJR (particularly the Stockton Deep Water Ship Channel) in the fall. DWR (2015) produced a report in response to requirements of the NMFS 2009 Biological Opinion on the long-term operations of the CVP and SWP, discussing engineering solutions to reduce diversion of emigrating salmonids. This report discusses the potential engineering solutions for HOR and four other areas in the Delta. The permanent, operable HOR gate is estimated to cost $43,200,000 for construction and $200,000 for operation and maintenance.

Predatory Fish Control

Predatory fish control can be accomplished through direct removal, or by the elimination/modification of habitat conducive to predators. Direct removal of predators is generally less expensive than the elimination/modification of habitat, as described below.

No long-term predator removal programs are in effect in the Delta; however, such programs have been implemented in rivers located in the western U.S. One example is the Upper Colorado Endangered Fish Recovery Program (Recovery Program), which was established in 1988 and is a partnership of local, state, and federal agencies, water and power interests, and environmental groups working to recover endangered fish in the Upper Colorado River. The Recovery Program implements long-term nonnative fish management by removing the most problematic nonnative fish predators from rivers. Among the nonnative fish management projects funded within the Recovery Program are the middle Yampa River northern pike and smallmouth bass removal and evaluation project; and the removal of smallmouth bass in the Upper Colorado River between Price-Stubb Dam near Palisade, Colorado and Westwater, Utah project. The total annual cost of each project from 2010 to 2015 ranged between $157,000 and $214,000.

The costs of habitat modification projects designed to reduce predator habitat in the Delta and upstream tributaries have been estimated as part of several recovery programs including: the Golden Gate Salmon Association Salmon Rebuilding Plan, the NMFS Final Recovery Plan (Recovery Plan), the Tuolumne River Corridor Restoration Plan, and the San Francisco Estuary Project 2007 Comprehensive Conservation and Management Plan. The costs of these projects are influenced by site-specific conditions and depend on the extent of modifications needed. Costs can vary from $100,000–$300,000 per site for reducing predator habitat at large screen structures, to more than $4.6 million for filling a gravel pit to reduce/eliminate habitat favored by predatory bass species, and replacing with high quality chinook salmon habitat. On a broader scale, the costs associated with Recovery Plan implementation projects designed to minimize predation at weirs, diversions, and related structures in the Delta are about $50 million over a period of 50 years.

Invasive Aquatic Vegetation Species Control

The California Department of Boating and Waterways (DBW) implements an Aquatic Weed Control Program, which includes a program to control water hyacinth. Established in 1982, the California state legislature designated DBW as the lead state agency to cooperate with other state, local, and federal agencies in controlling water hyacinth in the Delta, its tributaries, and Suisun Marsh. The total annual cost of DBW's Aquatic Weed Control Program for the years of 2001 through 2007 was between $6.2 and $7.9 million.

20.4 Southern Delta

Consistent with requirements in Water Code Section 13241, this section presents results from evaluating potential costs of compliance with salinity water quality objectives in the southern Delta. Potential effects on ratepayers and the regional economy resulting from higher treatment costs also are considered.

20.4.1 Costs of Methods of Compliance

This section includes a summary of information presented in Chapter 16, *Evaluation of Other Indirect and Additional Actions,* on the costs for WWTPs to comply with salinity objectives in the southern Delta. Because the actual methods of compliance ultimately used are necessarily site- and discharge-specific, only general estimates of compliance costs can be developed for this assessment; as such, this section presents cost ranges. A more precise evaluation of the actual costs is neither required in this plan-level analysis, nor is it feasible without specific information about projects that would be selected by project proponents as they move toward compliance.

As discussed in Chapter 16 and in Chapter 13, *Service Providers,* compliance costs in the southern Delta would be attributable to complying with NPDES based on salinity objectives that could be developed and applied to WWTP dischargers as a result of implementing the southern Delta water quality (SDWQ) alternatives. The Cities of Tracy and Stockton and Mountain House CSD may need to modify wastewater treatment processes or domestic water supply cycles to comply with SDWQ Alternative 2 and those service providers, plus the City of Manteca, may need to modify treatment processes to comply with the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1). The following three methods of compliance, which are not intended to be limiting but rather as a sampling of methods available during different stages of the domestic water supply cycle or wastewater treatment cycle, are considered the most likely methods to be implemented by WWTPs to comply with potential NPDES.

- **Developing new source water supplies**. By reducing reliance on highly saline groundwater for potable water demand, salinity discharged to the southern Delta would decrease.
- **Implement salinity pretreatment programs.** Target salinity loading in the sewer collection systems by removing water softeners and reducing salinity discharged to the sewer collection system from commercial, industrial, or institutional dischargers.
- **Desalination at the WWTP.** Remove salts at the WWTP to improve treated water quality and meet waste discharge permit limits.

Additionally, under the program of implementation for SDWQ Alternatives 2 or 3, agricultural dischargers may implement agricultural return flow salinity controls, such as changing the timing of current releases of discharges into the southern Delta. Furthermore, SDWQ Alternatives 2 or 3 could require additional studies of circulation and monitoring of water levels in the southern Delta. Additional studies and monitoring may indicate the continued need for modifying the temporary barriers in the southern Delta. Alternatively, under the program of implementation for SDWQ Alternatives 2 or 3, the State Water Board may determine that installing low-lift pumping stations at the temporary barriers is feasible. These potential costs of these additional methods of compliance are described below.

New Source Water Supplies

Water supplies with high salinity content can contribute to elevated salinity discharges to the southern Delta. Generally, water purveyors in the plan area (e.g., the Cities of Stockton, Tracy, Manteca, and Modesto) rely on a combination of surface water and groundwater to meet potable water demand. Groundwater is typically more saline than surface water in the SJR Basin.

One method to reduce salinity discharges is to use more high quality water (i.e., surface water) to meet water demands. To obtain more surface water, a water purveyor may need to enlarge existing structures (water intake, treatment facility, and pipelines and pumps), or build new structures.

One comparable project is the Davis-Woodland Water Supply Project (DWWSP). The DWWSP will construct a surface water intake, water treatment plant, pump stations, storage tanks, and associated transmission lines to develop 45,000 AF/y of new, high quality water resources on the Sacramento River. The DWWSP is in the construction phase, which began in April 2014, and is estimated to be completed in September 2016. The estimated project costs are detailed in Table 20.4.1-1.

A second comparable project is the Delta Water Supply Project (DWSP), which is being completed by the City of Stockton and will divert water pursuant to Water Code, Section 1485. Water Code, Section 1485 allows any municipality disposing of treated wastewater into the SJR to seek a water right to divert a like amount of water, less losses, from the river downstream of the point of its wastewater discharge. The DWSP will develop 33,600 AF/y of new water resources in the Delta. A new surface water intake, water treatment plant, pump stations, and pipelines have been constructed. The estimated costs for this project are also detailed in Table 20.4.1-1.

Table 20.4.1-1. Design and Construction Costs for the Davis-Woodland Water Supply Project and Delta Water Supply Project

Cost Category	DWWSP (millions)	DWSP (millions)
Design and Construct Intake	$15.6	$22.3
Design and Construct Treatment Facilities and Pipelines	$236.9	$176.6
Project Administration[a]	$33.1	$14.2
Other Local Costs[b]	$51.4	$21.6
Total	$337	$234.7

Source: Price pers. comm.

Note: All costs in 2010 dollars.

DWWSP = Davis-Woodland Water Supply Project

DWSP = Delta Water Supply Project

[a] Project Administration includes environmental and construction permitting, land acquisitions, rights of way, pre-design, agency administration and contingency, program management, water rights permits, and water supply acquisition.

[b] Other Local Costs includes costs to the water purveyor not included in the project, but necessary to integrate the project into the existing infrastructure.

Based on the estimated costs of these two projects, the planning, design, management, and construction of facilities needed to develop 33,600 AF/y (DWSP) and 45,000 AF/y (DWWSP) of new surface water resources in the Delta would be an estimated $337 million and $234.7 million, respectively. These examples of costs for developing new water supplies do not represent potential total costs if all water purveyors in the southern Delta portion of the plan area were to develop new, higher-quality water supplies. To potentially offset or reduce total project costs, the regional water boards (e.g., Central Valley Regional Water Board) and the California Department of Public Health offer grants and low-interest financing.

Salinity Pretreatment Programs

A salinity pretreatment program would target salinity loading from domestic (residential) and industrial and commercial sources in a wastewater service provider's wastewater collection system. It would provide salinity source controls at different locations within a service district to reduce the overall salt loading into the sewer system.

Domestic water similar to that found in the southern Delta may have a high concentration of minerals (typically magnesium and calcium). Water softeners are frequently used in residences to remove these minerals. During a water softener's recharge cycle, brine is used to clean the system and remove magnesium and calcium that accumulate in the mineral exchange tank. The recharge water, with suspended minerals, is then discharged to the wastewater collection system. This brine[15] and mineral solution is rarely treated at a wastewater treatment facility. By removing self-regenerating (or "automatic") water softeners and reducing salinity discharged to the wastewater collection system, salinity in the southern Delta would be expected to be reduced. Many wastewater treatment agencies operate a water softener buy-back program to remove water softeners from domestic use.

Salts also can enter the wastewater collection system as a byproduct of commercial activities, industrial processes, and food preparation activities, which can contribute to elevated salt loads entering the wastewater collection system and discharging into the southern Delta. Some commercial and industrial sources of salinity are commercial laundry facilities, food processing operations, and industrial fabrication shops. To address salinity loading by commercial and industrial dischargers, many wastewater treatment agencies prohibit commercial and industrial users from discharging to the wastewater collection system or strictly regulate the quality of wastewater entering the wastewater collection system. To improve the water quality of commercial and industrial dischargers, a variety of pollution-control methods can be used, such as best management practices (BMPs) and desalination devices, depending on the activities conducted by the commercial and industrial discharger. These methods are typically applied at the industrial or commercial business generating the wastewater.

Many wastewater treatment agencies offer rebate programs for removal of water softeners. Currently, the Inland Empire Utilities Agency (IEUA), and the Los Angeles County Sanitation Districts (LACSD) offer $206–$2,000 to homeowners to remove water softeners. Rules for each agency's programs differ, but in general, once a homeowner certifies that the water softener is removed (and it is later verified by the wastewater treatment agency), the wastewater treatment agency will reimburse the homeowner for the cost of removal.

If a wastewater treatment agency anticipates replacing 2,000 water softeners over 5 years, the agency can reasonably expect to pay between $928,600 and $9,015,400 over a period of 5 years ($185,720–$1,803,080 per year). If a commercial and industrial discharger decides to install a desalination device, costs would vary based on what is being discharged, the volume, and the desired water quality entering the wastewater collection system. For example, some light commercial reverse osmosis (RO) filtration systems cost as little as $1,000 to install and $200 per year to operate.

Desalination

Some wastewater treatment agencies may opt to remove salts at the WWTP before treated effluent is discharged to the southern Delta. Conventional wastewater treatment processes do not significantly remove salts from the wastewater treatment stream. To remove salts, a discharger must desalinate treated wastewater effluent. Methods to desalinate water at WWTPs include thermal separation, electro-dialysis, and RO. RO is analyzed here because it is the most common

---

[15] *Brine* is the saline solution prevented from traveling through an RO filter.

desalination technology in California and is comparable or less expensive than other desalination methods (e.g., ion exchange, distillation).

The costs of RO include the costs associated with constructing the RO facilities and operating and maintaining facilities associated with energy and brine disposal. Brine's salinity is a function of the quality and volume of the influent into the RO filter and the efficiency of the RO filter. For example, if the influent water had 75,000 pounds of salt per 10 million gallons per day, and the RO filter was 85 percent efficient, the brine would contain 75,000 pounds of salt per 1.5 million gallons of RO filter reject water (or a 5 percent saline brine solution).

The cost to install a desalination system at a WWTP is highly variable. Important factors include: the quality and quantity of water entering the desalination system, the desired water quality leaving the desalination system, energy costs, the chosen method of desalination, and the brine disposal method. Some WWTPs only would need to treat a portion of the influent wastewater to achieve effluent limitations for salinity, which would reduce costs.

DWR's California Water Plan Update 2009 discusses the costs of desalination, which are summarized in Table 20.4.1-2.

Table 20.4.1-2. California Water Plan Update 2009 Unit Cost of Desalination

	Total Water Cost ($/AF)	
Type of Desalting	Low	High
Groundwater	500	900
Wastewater	500	2,000
Seawater	1,000	2,500

Source: Chapter 16, *Evaluation of Other Indirect and Additional Actions,* Table 16-29.

AF = acre-feet.

Using the unit cost approximations in Table 20.4.1-2, a 10 million-gallon-per-day discharger could expect to pay between $5 and $22 million to construct an RO system at a WWTP. The unit cost for constructing and operating different desalination systems are not linear, however, because the associated administrative, engineering, and legal costs do not generally decrease for smaller projects. Larger RO facilities cost more, but the typical unit price of water produced decreases due to the scale of construction costs compared to administrative, engineering, and legal costs.

Agricultural Return Flow Salinity Control

Real-time management of agricultural return flow, such as changing the timing of the release of agricultural discharge to receiving waters, is the potential method of compliance for agricultural water users that must comply with numeric salinity objectives. This method may reduce salinity entering the southern Delta.

Agricultural dischargers could monitor receiving water's assimilative capacity on a real-time basis, and time discharges to coincide with periods of high flow (i.e., more assimilative capacity). This potential method of compliance with proposed salinity standards would require dischargers to establish a network of monitoring stations and a discharge schedule. When there is no assimilative capacity, irrigators would either recycle water that would otherwise be discharged or would discharge to a detention pond until discharges to the receiving waters are permitted. This method of compliance could be integrated with other BMPs (such as water recycling or use of evaporation ponds) to reduce salinity entering the plan area.

Enhanced monitoring equipment, modeling, and forecasting capability would be needed to forecast assimilative capacity in the LSJR. Control gates and conveyance systems would also be needed to divert drainage from river discharge to permanent treatment structures when assimilative capacity is not available. Personnel would be needed to manage real-time systems and coordinate discharges from multiple subareas in the LSJR Watershed. It is assumed that there would be multiple subareas within the plan area that would manage discharges in real time, creating a real-time monitoring system. Table 20.4.1-3 estimates the components needed and costs associated with constructing a real-time management system.

Table 20.4.1-3. Costs and Components of a Real-Time Management System

Construction	
Computer and Software	$5,000
Control Gates (10)	$100,000
Floats, Weirs, and EC Monitoring Equipment	$50,000
Installation of Monitoring Components	$75,000
Conveyance to River	$100,000
Subtotal	$330,000
Contingency (30%)	$99,000
Total Construction Cost	$429,000
Operations and Maintenance	
Operations and Maintenance (Including Coordinating Discharges)	$100,000 per year

Source: Chapter 16, *Evaluation of Other Indirect and Additional Actions*, Table 16-31.

EC = electrical conductivity (salinity).

In this document, EC is *electrical conductivity*, which is generally expressed in deciSiemens per meter (dS/m). Measurement of EC is a widely accepted indirect method to determine the salinity of water, which is the concentration of dissolved salts (often expressed in parts per thousand or parts per million).

Based on the costs identified in Table 20.4.1-3, the total estimated construction cost for 11 systems to cover the plan area is $4,719,000, with an operations and maintenance budget of $1,100,000 per year. This cost is in addition to the costs to construct and operate temporary detention ponds.

Southern Delta Temporary Barriers

The program of implementation for the SDWQ alternatives requires continued operations of the agricultural barriers at Grant Line Canal, Middle River, and Old River at Tracy, or other reasonable measures, to address the impacts of the CVP or SWP export operations on water levels and flow conditions that might affect salinity. The existing temporary barriers would likely to continue to operate in the southern Delta under the program of implementation. The purpose of operating the temporary barriers is to protect salmon migrating through the Delta and provide an adequate agricultural water supply in terms of quantity, quality and channel water levels to meet the reasonable and beneficial needs of water users in the southern Delta area. The program is operated by DWR, which also takes actions to protect agricultural diversions that do not benefit from the adverse effects of operations of the barriers. As described in Chapter 16, *Evaluation of Other Indirect and Additional Actions*, the program consists of four rock barriers across southern Delta channels that primarily benefit migrating fish or agricultural water users. DWR posts a standing schedule for the operation of the barriers.

According to DWR, water levels and water circulation in the southern Delta have improved since installation of the agricultural barriers. Migration conditions for salmon have improved since the HOR barrier was installed. As such, DWR determined it is essential to continue barrier installations.

As indicated in Chapter 16, DWR recently awarded a contract to construct and remove the temporary rock barriers, including other related construction activities for approximately $7.5 million; this cost does not include preparation of environmental studies.

Low-Lift Pumping Stations

The program of implementation for the SDWQ alternatives requires additional studies and monitoring of the southern Delta circulation and water levels. It is possible that additional study and monitoring would determine the need for modifying the existing South Delta Temporary Barriers Project. If this determination is made by the State Water Board, DWR may be required to install low lift pumping stations at the temporary barriers as a method of compliance.

As described in Chapter 16, *Evaluation of Other Indirect and Additional Actions,* a cost and environmental evaluation was prepared by DWR in 2011 for the Low-Head Pumping Conceptual Plan that identifies installation of either permanent or temporary pumps at the southern Delta temporary barriers. Estimated cost ranges were based on different site layout configurations. The site layout that would provide the greatest reduction in water quality violations is a two-pumping site alternative with 1,000 cfs combined pumping capacity at Middle and Old River barriers. The capital cost of this layout is estimated to range from $55.5–$540.7 million, and annual operation and maintenance costs are estimated to range from $4.5–$62.7 million.

20.4.2 Effects on Ratepayers and the Regional Economy

As discussed more fully in Chapter 13, *Service Providers*, existing WWTPs are point source dischargers of salt into the southern Delta, influencing the southern Delta salinity. The following WWTPs,[16] all of which are required to comply with effluent limitations established by the NPDES permits, discharge into the southern Delta. These WWTPs, their NPDES wastewater discharge permit order numbers, and their receiving water bodies are identified in Table 13-7 in Chapter 13.

- City of Tracy WWTP: 16 mgd permitted discharge.
- Manteca Wastewater Quality Control Facility: 17.5 mgd permitted discharge.

---

[16] As discussed in Chapter 13, *Service Providers*, while Discovery Bay Community Services District (CSD) is very close to the southern Delta, it is not expected to result in any modifications or new construction to its facility. This is because of the large dilution in Old River and the good quality water in Old River coming down from the Sacramento River (Marshall pers. comm. 2012). Therefore, the Central Valley Water Board has determined the discharge from Discovery Bay CSD does not have reasonable potential to cause or contribute to an exceedance of the Bay-Delta water quality objectives in Old River (Marshall pers. comm. 2012). Thus, they can comply with the water quality objectives and do not need effluent limits based on the Bay-Delta water quality objectives (Marshall pers. comm. 2012). Accordingly, Discovery Bay CSD is not further included in the analysis.

- Stockton Regional Wastewater Control Facility: 55 mgd permitted discharge.
- Mountain House CSD WWTP: 5.4 mgd permitted discharge.

Ratepayer Effects

Costs to WWTP operators to comply with NPDES permit discharge limitations could result in rate increases for utility ratepayers. Assessing how sewer utility rates could be affected by compliance with salinity objectives is complicated by several uncertainties. To assess potential ratepayer impacts, the specific actions to be taken by each wastewater treatment agency to meet salinity objectives must be determined. As discussed previously, the decision that each discharger might make could include some or all of the following actions: (1) developing new surface water supplies, (2) developing and enforcing a salinity pretreatment program, and/or (3) developing desalination processes at WWTPs. These decisions, which have different cost implications, would be made by individual wastewater treatment agencies based on numerous considerations, including the needs of their service districts, availability of surface water and land, and specific operation of their wastewater facilities. Regional Water Boards are precluded from specifying the manner of compliance under Water Code Section 13360, so each wastewater treatment agency must choose for itself the appropriate mix of actions to meet its discharge requirements.

Once individual wastewater treatment agencies have decided on the proper combination of salinity control measures and the design and scale of the actions, the costs to implement an agency's compliance program to address salinity objectives under each SDWQ alternative would become apparent. Without knowing which actions an agency would take as part of its compliance strategy, estimating compliance costs is not feasible. However, once total costs associated with the compliance actions have been estimated, each individual agency would need to determine how these costs would be recovered (e.g., increasing utility rates for customers)

For example, as described in the City of Manteca's *Draft Sewer Rate Study* (2008), sewer rates for ratepayers are determined based on a systematic analysis of the contribution of sewerage made by different land uses and of the costs required to collect and treat sewer influent. The allocation of collection and treatment costs between customer categories is based on a combination of estimated usage and actual sewer influent. Sewer expenditures generally include the following categories.

- Collection operating and maintenance costs.
- Treatment operating and maintenance costs.
- Debt service (existing and projected).
- Capital replacement.
- Depreciation.
- Operating reserves/contingency.

Once the collection and treatment costs are allocated to the different customer categories, rates are determined by dividing the allocated costs by the number of users in each category. Customer categories generally include residential, commercial, industrial, and public users.

The southern Delta dischargers that could be affected by the SDWQ salinity alternatives are communities that, to varying extents, serve a mix of residential, commercial, and industrial users, with service area populations ranging from the relatively small residential community of Mountain

House (population 10,000) to the relatively large urban service area of the Stockton Regional Wastewater Control Facility (population 280,000). For each wastewater treatment agency, potential rate increases attributable to compliance with salinity objectives would be spread among user groups depending on each group's contribution to sewer system influent. Generally, rates for each user group could be expected to increase similar to the percentage increase in wastewater treatment agency budgets to achieve salinity objectives under the SDWQ alternatives, as described below.

No Project Alternative (LSJR/SDWQ Alternative 1)

Under existing conditions, the following existing wastewater treatment plant dischargers (service providers), meet amended NPDES permit requirements or are currently exempted from requirements, as described in Section 13.2.3, *Southern Delta,* of Chapter 13, *Service Providers:* the City of Tracy, the City of Stockton, the City of Manteca and Mountain House CSD. Two possible scenarios could occur under the No Project Alternative for these providers: no change to NPDES permits or a change. If, under the No Project, there would be no change to the NPDES permits the No Project Alternative would not cause the need for expansion of existing facilities or infrastructure and would not cause significant environmental effects. However, if the litigation in City of *Tracy v. California State Water Resources Control Board* is resolved in a manner that allows for the application of the Delta salinity objectives to municipal wastewater dischargers, existing wastewater treatment plant dischargers, such as the City of Tracy, the City of Stockton, the City of Manteca, and Mountain House CSD would likely be unable to meet the current 2006 Bay-Delta Plan salinity objective of 0.7 dS/m from April to August based on current effluent discharge concentrations and past violations (Tables 13-8, 13-9, and 13-20). City of Tracy, City of Stockton, and Mountain House CSD would also likely not meet the current 2006 Bay-Delta Plan salinity objective of 1.0 dS/m from September – March (Tables 13-8, 13-9, and 13-20. Therefore, it is expected that these wastewater treatment providers would potentially exceed wastewater treatment requirements during some parts of the year such that new wastewater treatment facilities, or expansion of existing facilities or infrastructure could result, the construction or operation of which could result in increased costs to ratepayers.

SDWQ Alternative 2

As discussed in Chapter 13, *Service Providers*, the City of Tracy, the City of Stockton, and Mountain House CSD would not be expected to meet the salinity objectives under SDWQ Alternative 2. As such, SDWQ Alternative 2 is anticipated to require or result in the construction of new water or wastewater treatment facilities or expansion of existing facilities, the construction or operation of which could result in increased costs to ratepayers.

SDWQ Alternative 3

As discussed in Chapter 13, *Service Providers*, all of the WWTPs would be expected to comply with the SDWQ Alternative 3 without new or modified facilities. Consequently, there would be no effects on ratepayers.

Regional Economic Effects

Although the amount that sewer rates could increase in response to expenditures by wastewater treatment agencies to achieve salinity objectives under SDWQ Alternative 2 is uncertain, any increase in sewer utility rates could shift a portion of the spending by residential ratepayers from purchases of consumer goods and services to monthly sewer utility bills. From the perspective of the regional economy of the southern Delta region, this shift, while somewhat speculative and not anticipated to be a large percentage of overall consumer spending in the region, could result in relatively small reductions in sales, employment, and income in consumer-serving sectors of the regional economy, such as retail stores and consumer-service businesses. Similarly, increases in sewer utility rates for commercial and industrial ratepayers could shift business spending from wages, supplies, and services to expenditures on higher sewer utility bills. This shift in spending could result in slightly higher prices for goods and services provided by commercial and industrial businesses, and potential reductions in employment by affected businesses. In both cases, reductions in consumer and business spending on goods and services could have ripple effects throughout the regional economy. These effects would be concentrated within the service areas of the City of Tracy, the City of Stockton, and Mountain House CSD, which are potentially affected by the SDWQ Alternative 2 and the City of Tracy, the City of Stockton, the City of Manteca, and Mountain House CSD, which could potentially be affected by the No Project Alternative.

To some extent, the adverse effects on the regional economy would be offset by increased employment generated by wastewater treatment agencies as these agencies spend to construct and operate facilities, and to establish and operate programs to achieve salinity objectives under the alternatives. These agencies and its employees would contribute to economic activity in the regional economy, directly and indirectly generating sales, employment, and income in businesses that provide good and services in the region.

The net change in regional economic activity from potentially higher sewer utility rates and from increased agency spending is not anticipated to be substantial because changes would largely represent regional shifts in sales, employment, and income rather than overall reductions in regional economic activity.

Chapter 21
Drought Evaluation

21.1 Introduction

All Californians have confronted numerous challenges associated with the reduced water supplies available during the current drought. The State Water Resources Control Board (State Water Board) has taken extraordinary actions in response to the drought, including curtailing water rights, imposing statewide urban water conservation measures, and issuing Temporary Urgency Change Petition (TUCP) orders to modify flow and other requirements in the Delta and elsewhere under various water rights. This chapter uses Water Supply Effects (WSE) model simulations to compare drought years during the 1922–2003 analysis period to the more recent period of 2004–2015, specifically to the recent drought years of 2012–2015, to assess the severity of water supply effects during recent drought conditions compared to the severity of water supply effects during the 1922–2003 analysis period. In addition, this chapter includes a comparison of water supply availability and other water parameters during drought periods under baseline conditions and under the Lower San Joaquin River (LSJR) alternatives. These analyses show that: (1) water supply effects during drought conditions are adequately characterized by the WSE model during the 1922–2003 analysis period, (2) the runoff and water supply effects during the recent period of 2004–2015 are not inconsistent (i.e., more extreme) than drought conditions during the prior historical record, and (3) there are reductions in water supply diversions in many years under the different LSJR alternatives compared to baseline, particularly during dry years.

The following definitions are provided to understand the discussion in this chapter.

- A *dry year* or *dry period* is described as one or more years with less-than-average runoff. More than half of the years in California are identified as dry years because much greater than average runoff in a few wet years increases the average runoff compared to the median runoff (half of the years with less runoff).
- The *runoff deficit* is the difference between the average runoff and the annual runoff within a single water-year (e.g., October–September). Each dry year has a runoff deficit.
- A *water supply diversion deficit* is the difference between the normal full water supply diversions and the available water supply diversions during the water year (WY).
- A *drought year* or *drought period* is defined as one or more years with less-than-normal full diversions for water supply, reflecting a dry year or dry year period that is severe enough to cause a water supply deficit of a specified magnitude (e.g., <80 percent of full diversions).
- *Carryover storage* is the quantity of water remaining in storage in a reservoir at the end of the WY (end-of-September), before refilling from rain and snowmelt begins, and after the end of the primary water use period. Carryover storage is an important metric for evaluating water supplies during a series of dry year(s) because reservoir storage is typically reduced during dry years to provide normal full water supply deliveries. Multiple dry years may result in a cumulative runoff deficit severe enough to reduce carryover storage such that there is also a water supply diversion deficit.

- The *maximum carryover storage* is defined as the maximum end-of-September storage that provides adequate storage capacity for flood control purposes, and the *carryover storage drawdown* is defined as the maximum carryover storage minus the actual carryover storage.

This chapter identifies dry years and dry periods from 1922–2015 and evaluates how they affect water supply. The severity of a multi-year dry period depends on two factors: (1) the duration of the dry period (i.e., consecutive years with less-than-average runoff), and (2) the cumulative runoff deficit (total of runoff deficits during the dry period). The severity of dry periods was, therefore, identified by the duration, in years, and the cumulative runoff deficit, in thousand acre-feet (TAF). Each tributary was evaluated separately, but the similarities in the dry year periods for the three tributaries were identified and described. The effects of dry years on water supply were different for each tributary because the average runoff, reservoir storage, normal full diversions for water supply, and required flow releases were different for each tributary. Generally, the ratios of factors, such as storage/runoff, water supply/runoff, and required flow releases/runoff, govern the severity of the reservoir storage drawdowns and water supply deficits on the three tributaries. The historical reservoir operations and historical water supply diversions were reviewed to compare to WSE baseline reservoir operations and water supply diversions during dry year periods. The WSE baseline results for carryover storage and water supply diversions generally match historical conditions for the years post-construction of the major reservoirs. As such, the WSE model results adequately characterize the ability of reservoir storage in each tributary to reduce drought effects, with different drought effects depending on the storage/runoff and normal full diversion/runoff ratios for each tributary. The comparison of historical conditions is described in Sections 21.6 to 21.9 in this chapter.

As described in Appendix F.1 *Hydrologic and Water Quality Modeling*, the WSE model was developed to evaluate the effects of changed instream flow requirements on water supply and other parameters. Some inputs to the WSE model were based on information from the San Joaquin Module of CALSIM between 1922 and 2003. To better understand the effects for the more recent time period (from 2004–2015), the WSE model was extended using the historical reservoir inflows and estimated monthly data for downstream local inflows, return flows, and water supply diversions, using CALSIM inputs from years with similar hydrology. Adding this time period to the WSE-simulated time period allowed two additional dry periods to be included, 2007–2009 and 2012–2015. The incorporation of 2004–2015 allowed an evaluation of the effects of the LSJR alternatives on reservoir operations, water supply, and river temperatures for the most recent years, including conditions during the recent dry periods. The 2012–2015 dry year period was similar to other 4-year dry year periods in the historical record, with drought effects (reduced normal full water supply diversions) increasing in each year of the dry period. Historical and WSE-simulated operations during the two recent dry periods (2007–2009 and 2012–2015) were similar, and the WSE-simulated operations for dry periods between 1922 and 2003 were also similar to the WSE-simulated operations for the two recent dry periods.

Chapter 2, *Water Resources*, and Chapter 5, *Surface Hydrology and Water Quality*, provides additional hydrological information for each tributary. The sections below focus on the analysis and discussion of water supply effects in drought years (less than full normal water supply diversions).

21.2 Tributary Runoff and Droughts

This section compares the tributary dry periods and droughts (water supply effects) by evaluating the annual runoff and the corresponding February–June runoff for the 1921–2015 period of record. It also describes the different water user's (i.e., water or irrigation districts) responses to recent dry year periods (i.e., droughts).

The California Department of Water Resources (DWR) has published a summary of the monthly unimpaired runoff for the Central Valley streams for WY 1921–2014 (DWR 2016). California Data Exchange Center records were used to update the monthly runoff through September 2015 (WY 2015).

Table 21-1 presents a summary of the cumulative distributions of the annual runoff, February–June runoff, and February– June fraction of annual runoff for the three eastside tributaries.[1] This information is used to summarize and compare runoff and dry year periods, particularly for the February– June period that is subject to the LSJR alternatives. This chapter describes years with lower than average runoff. The average runoff is between the 50th and 60th cumulative distribution percentiles for each of the tributaries.

Table 21-1. Cumulative Distributions of Annual (WY) and February–June Unimpaired Runoff and the February–June Fraction of Runoff for the LSJR Tributaries for 1921–2015 (95 years)

Source: DWR 2016.

---

[1] In this document, the term *three eastside tributaries* refers to the Stanislaus, Tuolumne, and Merced Rivers.

The cumulative distributions of annual unimpaired runoff for the three eastside tributaries, expressed as a fraction of the mean annual runoff for 1921 to 2015, are shown in Table 21-2. The water supply conditions, defined using the fraction of average runoff, are nearly identical for the three eastside tributaries. The full water supply diversions and the maximum carryover storage can be expressed as the fraction of average runoff; the effects of dry year periods on water supply reductions (diversion deficits) depend on these diversion/runoff and carryover storage/runoff fractions.

The Stanislaus River average WY runoff was 1,107 TAF, and the average February–June runoff was 857 TAF. The reduced runoff in dry years is of particular interest for the drought analysis; the minimum runoff was 14 percent of average runoff; runoff in 10 percent of the years was less than 45 percent of average runoff; runoff in 20 percent of the years was less than 53 percent of average runoff; runoff in 30 percent of the years was less than 59 percent of average runoff; and runoff in 40 percent of the years was less than 74 percent of average runoff. The WSE model showed average full water supply diversion for the Stanislaus River was 651 TAF (59 percent of average runoff), and the maximum carryover storage in New Melones Reservoir is 2,000 TAF (180 percent of average runoff).

The Tuolumne River average WY runoff was 1,829 TAF, and the average February–June runoff was 1,384 TAF. The minimum runoff was 21 percent of average runoff; runoff in 10 percent of the years was less than 45 percent of average runoff; runoff in 20 percent of the years was less than 56 percent of average runoff; runoff in 30 percent of the years was less than 58 percent of average runoff; and runoff in 40 percent of the years was less than 75 percent of average runoff. Because the City and County of San Francisco (CCSF) diversions of 250 TAF are upstream of New Don Pedro Reservoir, the downstream diversions and carryover storage are expressed as the fraction of the average annual inflow to New Don Pedro Reservoir (i.e., average annual runoff minus 250 TAF). The WSE model showed average full water supply diversion for the Tuolumne River was 901 TAF (57 percent of average runoff to New Don Pedro Reservoir), and the maximum carryover storage is 1,700 TAF (108 percent of average runoff to New Don Pedro Reservoir).

The Merced River average WY runoff was 946 TAF, and the average February–June runoff was 731 TAF. The minimum runoff was 16 percent of average runoff; runoff in 10 percent of the years was less than 41 percent of average runoff; runoff in 20 percent of the years was less than 51 percent of average runoff; runoff in 30 percent of the years was less than 59 percent of average runoff; and runoff in 40 percent of the years was less than 68 percent of average runoff. The WSE model showed average full water supply diversion for the Merced River was 632 TAF (67 percent of average runoff) and the maximum carryover storage in Lake McClure is 850 TAF (90 percent of average runoff).

Table 21-2. Cumulative Distributions of Annual (WY) and February–June Unimpaired Runoff as Fraction of Average Runoff for the for the LSJR Tributaries for 1921–2015 (95 years)

Max	2.67	2.33	2.53	2.09	2.95	2.50
Average (TAF)	1,107	857	1,829	1,384	946	731
Average Full Water Supply Diversions	651 (59%)		901 (57% of effective inflow[a])		632 (67%)	
Carryover Storage	2,000 (180%)		1,700 (108% of effective inflow[a])		850 (90%)	

Source: Calculated from DWR 2016.

[a] For the Tuolumne River, effective inflow is 1,829 TAF/y minus 250 TAF/y removed upstream of New Don Pedro Reservoir by City and County of San Francisco.

Table 21-2 shows that unimpaired runoff in each tributary was less than 75 percent of average runoff in 4 out of 10 years (40 percent of years), and the runoff was less than 50 percent of average runoff in 2 out of 10 years (20 percent of years). Potential drought consequences under the baseline and LSJR alternatives would be different for each tributary because of different average full diversions and different maximum carryover storages relative to the average runoff. The annual baseline water supply deficits (i.e., droughts) were, therefore, slightly different for each tributary. The runoff and dry year periods for each river are described below using information from Tables 21-1 and 21-2 and graphically depicted in several figures. The potential for drought (water supply deficits), as a result of reduced runoff and reduced carryover storage in the reservoirs, is also discussed below.

The ability of surface water users in the three eastside tributaries to manage drought conditions varies and depends on numerous factors including, but not necessarily limited to, reservoir carryover storage and availability of non-surface water sources. Typically, the potential consequences for drought are more severe as the cumulative runoff deficits increase over a longer duration. Numerous dry years typically leads to greatly reduced storage and diversions. The sections that follow document some of the recent actions that water users in the three tributaries have taken during the 2012–2015 drought period. For more information regarding the water users and various applicable groundwater management plans and agricultural water management plans

(AWMPs), please refer to Chapters 2, *Water Resources*, Chapter 5, *Surface Hydrology and Water Quality*, Chapter 9, *Groundwater Resources,* and Chapter 13, *Service Providers*.

21.3 Stanislaus River

21.3.1 Runoff

The average runoff on the Stanislaus River (1921–2015) was 1,107 thousand acre feet per year (TAF/y) and the runoff was less than average in about half the years (50 out of 95 years), was less than 50 percent of average in 16 years, and was less than 25 percent of average in 2 years (1924 and 1977) (Table 21-1). The WY runoff could be used to classify five categories (20 percent of years in each). As an example, critical years (lowest 20 percent of years) would have runoff of less than 591 TAF/y (0.53 average); dry years (next lowest 20 percent of years) would have runoff of less than 823 TAF/y (0.74 average); below-normal years (middle 20 percent of years) would have runoff of less than 1,236 TAF/y (1.12 average); above-normal years (second highest 20 percent of years) would have runoff of less than 1,570 TAF/y (1.42 average); and wet years (highest 20 percent of years) would have runoff of greater than 1,570 TAF/y. The runoff in 2014 (370 TAF) and 2015 (330 TAF) were both less than half of average, but runoff has been lower in a few previous years. In lower runoff years, the February–June runoff was more than 80 percent of the total Stanislaus River runoff (Table 21-1). In wet years, rainfall runoff in December or January and snowmelt in July reduced the fraction of runoff in February–June to about 70 percent in some years.

Figure 21-1 shows the annual WY Stanislaus River runoff and February–June runoff, with the annual runoff deficits and the cumulative runoff deficits (consecutive years with runoff deficits, less than average runoff) shown as negative values for WY 1921–2015. About half of the years had greater than average runoff. There were several multi-year periods with less than average runoff (cumulative runoff deficits). The major dry year periods were 1924-1934, 1947-1949, 1959–1962, 1976–1977, 1987–1992, 2001–2004, 2007–2008, and 2012–2015. For the years with less than average runoff, the runoff deficits averaged about 50 percent of the average runoff (550 TAF).

For the Stanislaus River the average runoff was 1,107 TAF, and the cumulative runoff deficits generally increased by about 50 percent of average runoff for each year in the dry-year sequence (550 TAF runoff deficit per dry year). A 2-year dry period generally had a cumulative runoff deficit of about 1,100 TAF (although 1976–1977 had a deficit of 1,700 TAF); a 4-year dry period generally had a cumulative runoff deficit of 2,200 TAF (e.g., 2012–2015 had a deficit of 2,475 TAF); and a 6-year dry period generally had a cumulative runoff deficit of 3,300 TAF (e.g., 1987–1992 had a deficit of 3,600 TAF). The dry year period of 2007-2008 was typical of other historical dry periods with a cumulative runoff deficit of 1,020 TAF (46 percent of average runoff per year) and the dry year period during 2012–2015 (4 years) was typical of other historical dry periods, with a cumulative runoff deficit of 2,475 TAF, about 55 percent of average runoff each year.

Therefore, although there were more dry years with less than average runoff during the last 12 years (8 out of 12), the severity of these dry year periods (i.e., cumulative deficits) were similar to other dry year periods in the historical period of 1922–2003 used for the environmental assessment of the LSJR alternatives.

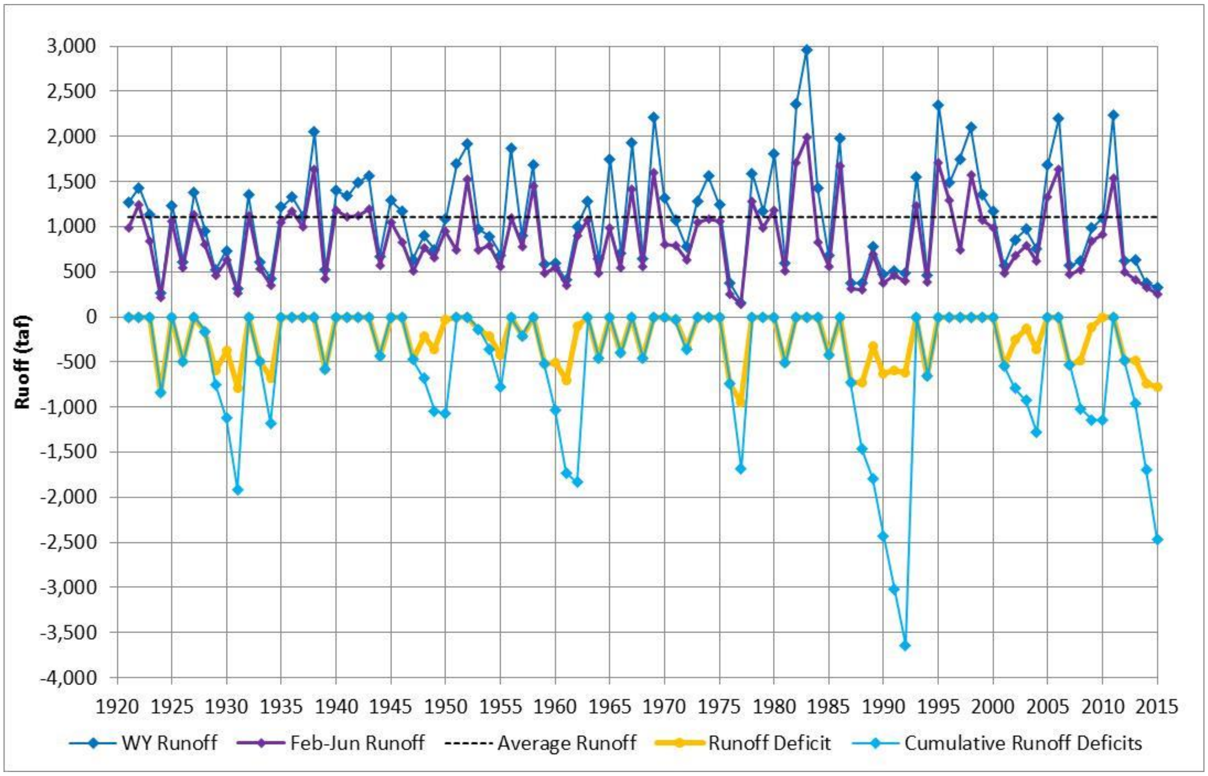

Figure 21-1. Stanislaus River Annual (WY) and February–June Unimpaired Runoff (TAF) with Annual and Cumulative Runoff Deficits for 1921–2015

21.3.2 Potential for Drought

The New Melones Reservoir has substantial carryover storage capacity of 2,000 TAF (180 percent of average runoff). Therefore, the WSE model showed average full water supply diversions of 651 TAF (59 percent of average runoff) can be maintained for several years during dry periods (Table 21-2). The upstream reservoirs on the Stanislaus River are generally operated for seasonal storage to maintain hydroelectric energy generation through the summer months. The annual inflow to New Melones Reservoir is, therefore, similar to the annual runoff.

Prior to the construction of New Melones Reservoir, minimum streamflow requirements were specified in the State Water Board's Water Right Decision 1422 (D-1422). After this decision, minimum streamflow requirements have been increased on the Stanislaus River by various agencies through different mechanisms, including: the California Department of Fish and Wildlife (formerly the California Department of Fish and Game) as part of the 1987 fisheries agreement; the Central Valley Project Improvement Act Anadromous Fish Restoration Program (AFRP); the Vernalis Adaptive Management Program (VAMP) (2000–2012), that modified the D-1641 Vernalis flows during April and May; and the National Marine Fisheries Service (NMFS) as part of its 2009 biological opinion (BO) Stanislaus River reasonable and prudent alternative (RPA), including Action 3.1.3 (NMFS BO). The five flow schedules identified by NMFS in Appendix 2E of the BO (NMFS 2009) are applied depending on a combination of runoff and storage; the minimum release flows require 185 TAF (dry years), which is 17 percent of the average runoff, and the maximum release flows require 590 TAF (wet years), which is 54 percent of the average runoff.

The recent drought (2012–2015) provides evidence of the importance of the New Melones Reservoir carryover storage for full water supply diversions on the Stanislaus River. The carryover storage was full (2,000 TAF) in 2011 and was reduced by about 500 TAF in 2012, 2013, and 2014 (with relatively high diversions of about 550 TAF each year). The carryover storage at the end of WY 2014 was about 520 TAF. The low runoff conditions again in 2015 resulted in reduced diversions (425 TAF) and very low carryover storage (267 TAF).

Allocating more of the Stanislaus River runoff for streamflow requirements over time has generally reduced the potential refilling of New Melones reservoir in normal and wet years. This has generally caused greater carryover storage drawdowns in dry years. The baseline drought conditions assessed with the WSE model were small (less than 5% of years with less than 80 percent of full diversions), but increased flows under the LSJR alternatives and deliveries of full contract amounts in more years would likely increase the severity of drought conditions (more years with greater diversion deficits) for the Stanislaus River (Table 21-3).

21.3.3 Drought Water Management

The Oakdale Irrigation District (OID) and South San Joaquin Irrigation District (SSJID) both have prepared AWMPs that include the efficient water management practices required by the 2009 Water Conservation Bill. They both have water resources plans to improve the operational efficiency and encourage water conservation measures within the districts. OID and SSJID have developed drought bulletins in 2015 for informing their users of activities related to the drought. The emergency drought bulletin explains,

> The two districts have been in negotiations with the federal Bureau of Reclamation (which operates New Melones Reservoir), the National Marine Fisheries Service and the State Water Resources Control Board (SWRCB), urging the approval of a Temporary Urgency Change Petition to…provide for springtime ‘pulse flows’ for steelhead and salmon on the Stanislaus, base flows for the fish in the river through December, and adequate supplies of water for each district, given serious conservation measures both districts are taking (SSJID 2015).

This type of management proposal is anticipated to maintain enough water in New Melones Reservoir at the end of September (irrigation season) to meet flows for spawning salmon through December 31 (SSJID 2015). The plan would also help the districts to keep Lake Tulloch (the regulating reservoir downstream of New Melones Reservoir) at normal operational levels (for recreation) through September (SSJID 2015).

SSJID drought bulletins also encourage water conservation and facilitate water allocation and private groundwater transfers within the district. The drought bulletin of April 6, 2015 includes this summary of conditions in 2015:

> The water supply picture looks increasingly grim for the coming growing season. California’s governor declared a State of Emergency throughout the state due to severe drought conditions on April 1, 2015. With very little precipitation this past winter, farmers will be relying more on pumping groundwater, having to severely conserve whatever surface water they may have available to them, potentially fallowing crops, and when possible and/or necessary, transferring water allocations between their own parcels, or to other growers’ farm operations. A limit of 36 inches of irrigation water per parcel will be in effect because the ongoing drought threatens the District’s water supply in 2015, and will most likely worsen in 2016. A 10-day rotation schedule was also confirmed. SSJID’s drought task force has already met with many of our growers to review their past year’s water consumption history (SSJID 2015).

Table 21-3. Cumulative Distribution of WSE Baseline Annual (WY) Water Supply Diversions for 1922–2015

Average Runoff (TAF)		1,107	Average Inflow (TAF)	1,577	Average Runoff (TAF)	945
Average Full Diversion (TAF)		651	Average Full Diversion (TAF)	901	Average Full Diversion (TAF)	632

Average	635	98	840	93	574	91

Water received by the Stockton East Water District (SEWD)/Central San Joaquin Water Conservation District (CSJWCD) from New Melones Reservoir through their contract with the U.S. Bureau of Reclamation (USBR) and their temporary contracts with OID/SSJID (2000–2010) has been used to reduce some of the need for groundwater pumping for irrigation and urban water supply in the SEWD/CSJWCD service areas (including the City of Stockton). SEWD/CSJWCD have developed conjunctive water management facilities in order to reduce groundwater pumping in normal years so that additional groundwater pumping can provide full water supply in drought years without reducing long-term average groundwater levels (i.e., sustainable pumping). CSJWCD, for example, has developed surface irrigation facilities for about 10,000 acres that are normally irrigated from groundwater pumping. This irrigated land uses about 30 TAF per year and reduces groundwater pumping by approximately this amount.

SEWD worked with Calaveras County to obtain additional surface water supply from Hew Hogan Reservoir on the Calaveras River. This reservoir (317 TAF storage) was completed in 1964 and provides an average yield of about 150 TAF, which reduces groundwater pumping for the land irrigated with surface water (SEWD 2014). Some fraction of this surface water infiltrates from the conveyance channels and from the irrigated lands; SEWD installs check dams along the Calaveras River, Mormon Slough, and other channels to increase the infiltration area. SEWD has developed about 50 acres of recharge ponds that have an infiltration rate of 0.5 foot/day, providing 9 TAF of annual recharge. The most recent recharge project involves winter spreading on irrigated lands downstream of the Farmington flood control dam; the full project could include 1,200 acres of land that would be flooded for 60 days each winter and provide about 35 TAF of infiltration (SEWD 2014). These conjunctive water management facilities have better prepared SEWD and CSJWCD water users for the limited surface supplies during this drought (e.g., No New Hogan Reservoir supplies were available in 2015).

Given the information provided in drought bulletins by SSJID, and as discussed in Chapter 9, *Groundwater Resources*, reductions in the surface water supply during drought years would likely result in a return to groundwater pumping for some users within the SSJID and OID service areas, and for most users within SEWD/CSJWCD. The 1998 agreement with SSJID/OID includes a drought provision; the full contract amount (600 TAF) is reduced to inflow plus 1/3 of the inflow deficit, when the inflow is less than 600 TAF. The 2014 runoff was 370 TAF, the water supply diversions were 515 TAF, and the carryover storage was 520 TAF. The 2015 runoff was 329 TAF, the water supply diversions were 425 TAF and the carryover storage was 267 TAF. No water was available for the SEWD/CSJWCD contract in 2014 or 2015.

21.4 Tuolumne River

21.4.1 Runoff

The average runoff for the Tuolumne River was 1,829 TAF/y, and the runoff was less than average in about half of the years (50 out of 95 years), was less than 50 percent of average in 15 years, and was less than 25 percent of average in 1 year (1977) (Table 21-1). The WY runoff could be used to classify five categories (20 percent of years in each). For example, critical years (lowest 20 percent of years) would have runoff of less than 1,026 TAF/y (0.56 average); dry years (next lowest 20 percent of years) would have runoff of less than 1,368 TAF/y (0.75 average); below-normal years (middle 20 percent of years) would have runoff of less than 2,022 TAF/y (1.11 average); above-normal years (second highest 20 percent of years) would have runoff of less than 2,519 TAF/y (1.38 average); and wet years (highest 20 percent of years) would have runoff of greater than 2,519 TAF/y. The runoff in 2014 (601 TAF) and 2015 (602 TAF) were less than 40 percent of average; runoff has been similar in a few previous years. In lower runoff years, the February–June runoff provided more than 80 percent of the total Tuolumne River runoff (Table 21-1). In wet years, rainfall runoff in December or January and snowmelt in July reduced the fraction of runoff in February–June to about 75 percent in some years.

Figure 21-2 shows the annual WY Tuolumne River runoff and February–June runoff, with the annual runoff deficits and the cumulative runoff deficits (consecutive years with runoff deficits) shown as negative values for WYs 1921–2015. About half of the years had greater than average runoff. There were several multi-year dry periods with less-than-average runoff (cumulative runoff deficits). The major dry periods were 1924–1934, 1947–1949, 1959–1962, 1976–1977, 1987–1992, 2001–2004, 2007–2008, and 2012–2015. For the years with less than average runoff, the runoff deficits averaged about 50 percent of the average runoff (915 TAF). These were the same dry years as identified for the Stanislaus River because the precipitation patterns (i.e., rainfall and snowfall) are nearly identical for these two watersheds.

For the Tuolumne River the average runoff was 1,829 TAF, and the cumulative runoff deficits generally increased by about 50 percent of average runoff for each year in the dry-year sequence (915 TAF runoff deficit per dry year). A 2-year dry period generally had a cumulative runoff deficit of about 1,830 TAF (although 1976–1977 had a deficit of 2,600 TAF); a 4-year dry period generally had a cumulative runoff deficit of 3,660 TAF (e.g., 2012–2015 had a deficit of 4,150 TAF); and a 6-

year dry period generally had a cumulative runoff deficit of 5,500 TAF (e.g., 1987–1992 had a deficit of 5,400 TAF). The dry year period of 2007–2008 was typical of other historical dry periods with a cumulative runoff deficit of 1,675 TAF (46 percent of average runoff per year) and the dry year period during 2012–2015 (4 years) was typical of other historical dry periods, with a cumulative runoff deficit of 4,143 TAF, about 55 percent of average runoff each year.

Therefore, although there were more dry years with less than average runoff during the last 12 years (8 out of 12), the severity of these dry year periods (i.e., cumulative deficits) were similar to other dry year periods in the historical period of 1922–2003 used for the environmental assessment of the LSJR alternatives.

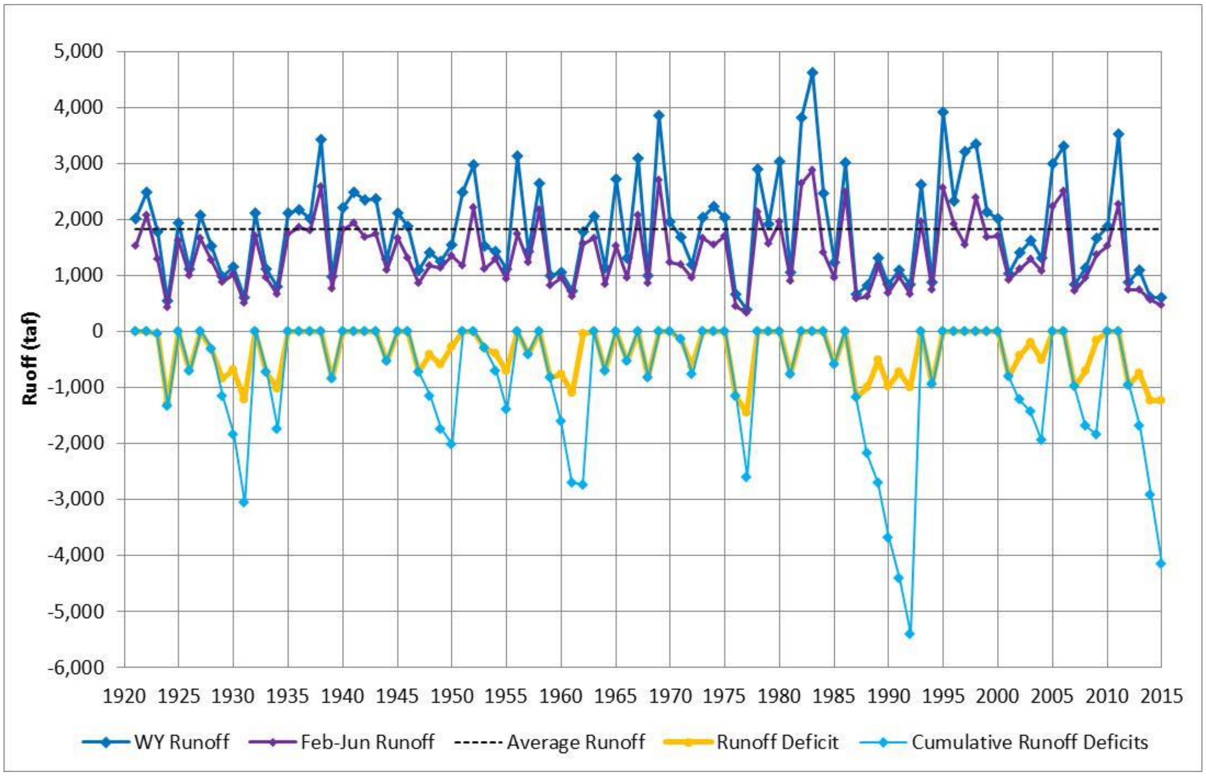

Figure 21-2. Tuolumne River Annual (WY) and February–June Unimpaired Runoff (TAF) with Annual and Cumulative Runoff Deficits for 1921–2015

21.4.2 Potential for Drought

The New Don Pedro Reservoir has a large carryover storage maximum of 1,700 TAF (93 percent of average runoff). Because the CCSF water supply diversions of about 250 TAF/y are upstream of New Don Pedro Reservoir, this drought evaluation for the Tuolumne River assumes that the effective runoff (New Don Pedro inflow) was reduced each year by the 250 TAF upstream diversion. Therefore, the average annual inflow to New Don Pedro Reservoir was 1,579 TAF, the maximum carryover storage is about 108 percent of average inflow, and the WSE model showed average full water supply diversion was 901 TAF, about 57 percent of average effective inflow (Table 21-2).

Required New Don Pedro Reservoir releases for required flows were specified in the original Federal Energy Regulatory Commission (FERC) license (1966) and modified in the 1995 settlement agreement. The original FERC license required 118 TAF (8 percent of average New Don Pedro inflow) in normal years and 64 TAF (4 percent of average inflow) in dry years. The 1995 settlement (based on FERC-mandated fish investigations) increased the required flow releases to 95 TAF (6 percent of average inflow) in the driest years to a maximum of 310 TAF (20 percent of average inflow) in years with greater-than-average runoff.

Allocating more of the Tuolumne River runoff for minimum streamflow requirements has generally reduced the potential refilling of New Don Pedro Reservoir in normal and wet years, and has caused greater carryover storage drawdown in dry years. The combination of average full water supply diversions (57 percent of average inflow) and increased required flows (41 percent of average runoff for WSE baseline conditions) has increased the WSE baseline drought years (with less than 80 percent of average full diversions) to about 15 percent of the years (Table 21-3). The baseline drought conditions assessed with the WSE model were moderate (15 percent of years with less than 80 percent of average full diversions), and increased flows under the LSJR alternatives would likely increase drought conditions (more years with greater diversion deficits) for the Tuolumne River.

21.4.3 Drought Water Management

Both Turlock Irrigation District (TID) and Modesto Irrigation District (MID) have AWMPs (TID 2012; MID 2012), and both participate in regional groundwater management plans (for additional information regarding regional groundwater management plans and the irrigation districts' AWMPs see Chapters 9, *Groundwater Resources*; 11, *Agricultural Resources*; and 13, *Service Providers*). Water shortage procedures for these two irrigation districts are described in their AWMPs. The normal surface irrigation allocation for both TID and MID is 48 inches; however, these allocations were reduced in years with less-than-full water diversions. Both districts use increased groundwater pumping to augment the surface deliveries, but they have a limited number of district wells or rented (private) wells (TID 2012; MID 2012). Both districts describe their water operations as conjunctive (i.e., combination of surface water diversions and groundwater pumping), because the seepage from canals, regulating reservoirs, and infiltration from the irrigated lands results in a substantial groundwater recharge in most years (TID 2012; MID 2012).

TID's AWMP indicates that beginning in 2013, allotments were no longer to be used in water-short years; the TID Board of Directors would determine if the dry year rate schedule should be used and the amount of water available on a per-acre basis. This determination would be based on projected runoff, including the possibility of the occurrence of consecutive dry years, carryover storage, flows required to be delivered to the lower Tuolumne River, and the availability of rented pumps. Groundwater pumping was expected to increase progressively in each drought year as surface supplies decreased. TID's AWMP acknowledged that even with conjunctive water management in the service area, groundwater was not an unlimited supply, and the availability of groundwater may decline over time due to declining water levels from increased pumping and reduced recharge from irrigation canals. The 2014 runoff was 601 TAF, the water supply diversions were 560 TAF, and the carryover storage was 780 TAF. The 2015 runoff was 602 TAF, the water supply diversions were 450 TAF and the carryover storage was 644 TAF.

21.5 Merced River

21.5.1 Runoff

The average runoff was 946 TAF/y, and the runoff was less than average in more than half of the years (54 out of 95 years), was less than 50 percent of average in 18 years, and was less than 25 percent of average in 1 year (1977) (Table 21-1). The WY runoff could be used to classify five categories (20 percent of years in each). For example, critical years (lowest 20 percent of years) would have runoff of less than 479 TAF/y (0.51 average); dry years (next lowest 20 percent of years) would have runoff of less than 644 TAF/y (0.68 average); below-normal years (middle 20 percent of years) would have runoff of less than 1,037 TAF/y (1.10 average); above-normal years (second highest 20 percent of years) would have runoff of less than 1,414 TAF/y (1.50 average); and wet years (highest 20 percent of years) would have runoff of greater than 1,414 TAF/y. The runoff in 2014 (239 TAF) and 2015 (175 TAF) were less than 25 percent of average; the runoff has only been this low in 1924 and 1977. In lower runoff years, the February–June runoff provided more than 80 percent of the total Merced River runoff (Table 21-1). In wet years, rainfall runoff in December or January and snowmelt in July reduced the fraction of runoff in February–June to about 75 percent in some years.

Figure 21-3 shows the annual Merced River WY runoff and February–June runoff, with the annual runoff deficits and the cumulative runoff deficits (consecutive years with runoff deficits) shown as negative values for WY 1921–2015. About half of the years had greater than average runoff. There were several multi-year periods with less-than-average runoff (cumulative runoff deficits). The major dry year periods were 1924–1934, 1947–1949, 1959–962, 1976–1977, 1987–1992, 2001–2004, 2007–2008, and 2012–2015. For the years with less than average runoff, the runoff deficits averaged about 50 percent of the average runoff (475 TAF). These were the same dry years as identified for the Stanislaus and Tuolumne Rivers because the precipitation patterns (*i.e.,* rainfall and snowfall) are nearly identical for these three watersheds.

For the Merced River, the average runoff was 945 TAF, and the cumulative runoff deficits generally increased by about 50 percent of average runoff for each year in the dry-year sequence (475 TAF runoff deficit per dry year). A 2-year dry period generally had a cumulative runoff deficit of about 950 TAF (although 1976–1977 had a deficit of 1,500 TAF); a 4-year dry period generally had a cumulative runoff deficit of 1,900 TAF (e.g., 2012–2015 had a deficit of 2,450 TAF); and a 6-year dry period generally had a cumulative runoff deficit of 2,850 TAF (e.g., 1987–1992 had a deficit of 3,000 TAF). The dry year period of 2007–2008 was typical of other historical dry periods, with a cumulative runoff deficit of 860 TAF (46 percent of average runoff per year), and the dry year period from 2012–2015 (4 years) was more severe than most historical dry periods, with a cumulative runoff deficit of about 2,460 TAF (65 percent of average runoff each year) on the Merced River.

Therefore, although there were more dry years with less than average runoff during the last 12 years (8 out of 12), the severity of these dry year periods (i.e., cumulative deficits) were similar to other dry year periods in the historical period of 1922–2003 used for the environmental assessment of the LSJR alternatives.

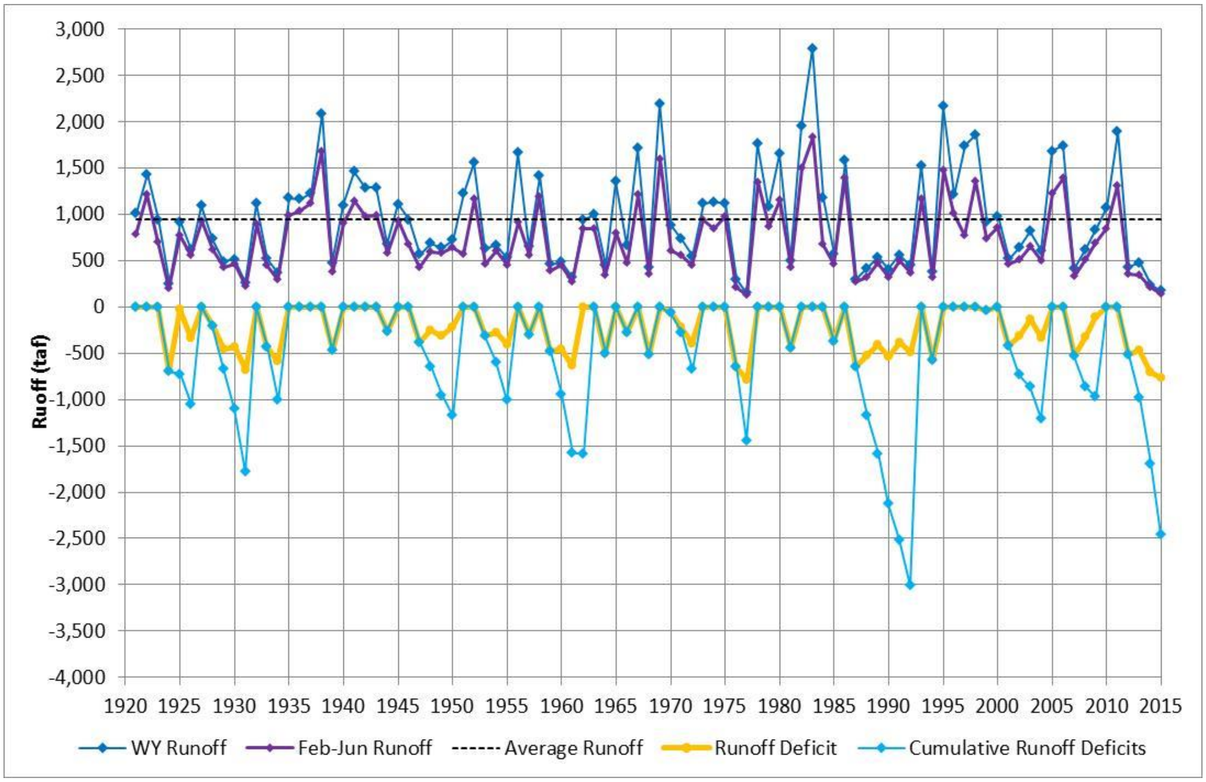

Figure 21-3. Merced River Annual (WY) and February–June Unimpaired Runoff (TAF) with Annual and Cumulative Runoff Deficits for 1921–2015

21.5.2 Potential for Drought

Lake McClure has a maximum capacity of 1,024 TAF, but the carryover storage is limited to 850 TAF (90 percent of average runoff) by the COE maximum flood-control storage. The WSE model showed average full water supply diversion for the Merced River was 632 TAF (67 percent of average runoff) (Table 21-2). Three separate agreements jointly control required minimum flows (FERC license, Cowell Diversions, and Davis-Grunsky contract). Normal year fish flow requirements are about 175 TAF (18 percent of average runoff) and dry year flow requirements are about 100 TAF (10 percent of average runoff).

The combination of average full water supply diversions (67 percent of average runoff), moderate carryover storage (90 percent of average runoff) and relatively low required release flows (17 percent of average runoff for WSE baseline conditions) increased the WSE baseline drought years (with less than 80 percent of full diversions) to about 10 percent of the years (Table 21-3). The baseline drought conditions assesses with the WSE model were moderate (15 percent of years with less than 80 percent of average full water supply diversions) and increased flows under the LSJR alternatives would likely increase drought conditions (more years with greater diversion deficits) for the Merced River.

21.5.3 Drought Water Management

The general water supply strategy for Merced ID and Merced County, to maximize surface water deliveries in order to minimize the groundwater pumping for agricultural water supply in normal years, is described in the Merced Integrated Regional Water Management Plan (RMC 2013). This plan covers approximately 600,000 acres in the northeast portion of Merced County, including the 490,000-acre Merced groundwater subbasin. The Integrated Regional Water Management Program (IRWMP) suggests that Merced ID and Merced County rely on more groundwater pumping in dry years to provide as much of the full agricultural and urban supplies as possible for all water users.

The Merced IRWMP includes several water conservation measures (urban and agricultural) and several projects to increase surface water deliveries (new pipelines and pumps) or to increase groundwater recharge (spreading basins). Two of these, the Highlands Groundwater Conservation Project and the expanded Cressey Groundwater Recharge Project were included in the 2014 IRWMP Drought Grant Application (Merced ID 2014). These two projects, which provide good examples of how Merced ID responds during dry periods, are summarized below.

The Highland Groundwater Conservation Project would deliver surface water to about 700 acres instead of pumping groundwater in normal years. During dry years when surface water diversions are limited, the existing wells would be available for pumping (i.e., conjunctive use). Merced ID has surface water supply that could be provided in this area, but infrastructure is currently not sufficient to convey water to the entire area. The water supply for this area is about 2,500 AF/y (e.g., 3.5 AF/acre); increased diversions from the Merced River would reduce groundwater pumping by this amount in most years (8 out of 10). During drought years (2 out of 10), groundwater pumping would be resumed. (Merced ID 2014.)

The Cressey Groundwater Recharge Project would expand an existing recharge basin to provide drought relief by increasing groundwater supplies in normal years in the Merced groundwater subbasin. The Cressey Recharge Basin Enlargement Project, sponsored by Merced ID, is the second phase of an ongoing recharge project. The project would enlarge the existing recharge basin from 8 acres to 13 acres. The existing recharge basin began operations in 2011 and is capable of recharging 2.75 acre-feet per acre per day (AF/y); the existing ponds recharge about 24 AF/y and the expanded ponds could recharge about 38 AF/y. The annual recharge depends on the number of days when surface water can be delivered to the ponds. The existing operations of the main canal are limited to the irrigations months. (Merced ID 2014.) The 2014 runoff was 239 TAF, the water supply diversions were 210 TAF, and the carryover storage was 122 TAF. The 2015 runoff was 175 TAF, the water supply diversions were 20 TAF, and the carryover storage was 87 TAF.

21.6 Evaluation of Recent Historical Reservoir Operations 1970–2015

The reservoirs on each of the SJR tributaries provide seasonal and multi-year storage to support seasonal water supply diversions. The reservoirs allow seasonal and carryover storage of the runoff, provide flood control benefits (temporary storage of high inflows with subsequent releases to maintain the seasonal flood control storage), allow diversions of the seasonal irrigation demands, and provide required river releases for fish habitat and downstream riparian diversions. The historical reservoir operations are described with the allocation of annual runoff for water supply diversions and carryover storage. In many years, the runoff is greater than the water supply diversions, and carryover storage is increased. Additional water can be released as flood-control releases or required river releases, as needed. In years when runoff is less than the water supply diversions, the carryover storage is reduced to supply the required river releases and water supply diversions. In years when the runoff and carryover storage is not sufficient, the water supply diversions are reduced.

The monthly WSE baseline results for 1922–2003 provide estimates of the reservoir operations for the historical runoff with the existing reservoir releases for water supply diversions, required flows for fish habitat, downstream riparian diversions, and flood control. The WSE extended baseline results (1922–2015) provide a longer period for drought evaluation, with the existing water supply diversions and fish habitat flows calculated up to 2015. The WSE baseline results are expected to more closely match the historical reservoir operations in the most recent years, when the required release flows and water supply diversions were similar to those specified in the WSE model. Because this chapter is focused on drought conditions, the extended WSE baseline water supply diversions are summarized for each tributary to indicate the potential for drought conditions. Because the WSE model calculates a different full water supply diversion for each year based on each year's water demand, the annual diversions were compared to the full diversions for each year to determine water supply deficits.

Table 21-3 summarizes the extended WSE baseline diversions for 1922–2015 for each tributary, with the diversions expressed as a fraction of the specified WSE-modeled full diversion for each year (varies by about +/- 10 percent from year to year). The cumulative distributions of the annual diversions are given in 10 percent increments (i.e., 1 out of 10 years). The average runoff and the average full diversion for each tributary are given for reference. The frequency of diversion deficits greater than 10 percent of full diversions (moderate), 20 percent of full diversions (substantial) or 30 percent of full diversions (severe) can be compared. For example, the fraction of years with less than 80 percent of full diversions (>20 percent deficit) can be compared: the Stanislaus River diversions were less than 80 percent of full diversions in about 20 percent of the years; the Tuolumne River diversions were less than 80 percent of full diversions in about 15 percent of the years (interpolated from the 20 percent and 10 percent values); and the Merced River diversions were less than 80 percent of full diversions in about 15 percent of the years (interpolated from the 20 percent and 10 percent values). The recent historical reservoir operations and extended WSE baseline results for 1970–2015 for each tributary are described and discussed in the sections that follow.

21.7 Stanislaus River Diversions and Carryover Storage

21.7.1 Historical

Figure 21-4 shows the Stanislaus River runoff and average runoff along with historical diversions and end-of-September reservoir carryover storage drawdown for WY 1970–2015. Drought years are identified as years with substantial diversion deficits (e.g., <80 percent full diversions). The historical diversions from WY 1970–2015 were generally above 500 TAF, with a maximum of about 600 TAF in a few years. The full contract diversions were increased from 600 TAF to 755 TAF in 1997 (as a result of SEWD and CSJWCD receiving water). The historical diversions were often less than the contract maximum, but historical records do not provide an explanation for this difference, which could include water transfers between users. The historical reservoir carryover storage drawdown was generally effective in minimizing diversion deficits in most years. The historical reservoir operations in 2012–2015 show reduced diversions to about 515 TAF in 2014, and reduced carryover storages to about 520 TAF in 2014. The low Stanislaus River runoff of 329 TAF in 2015 and reduced carryover storage in 2014 resulted in low diversions (425 TAF) and low carryover storage (267 TAF) in 2015.

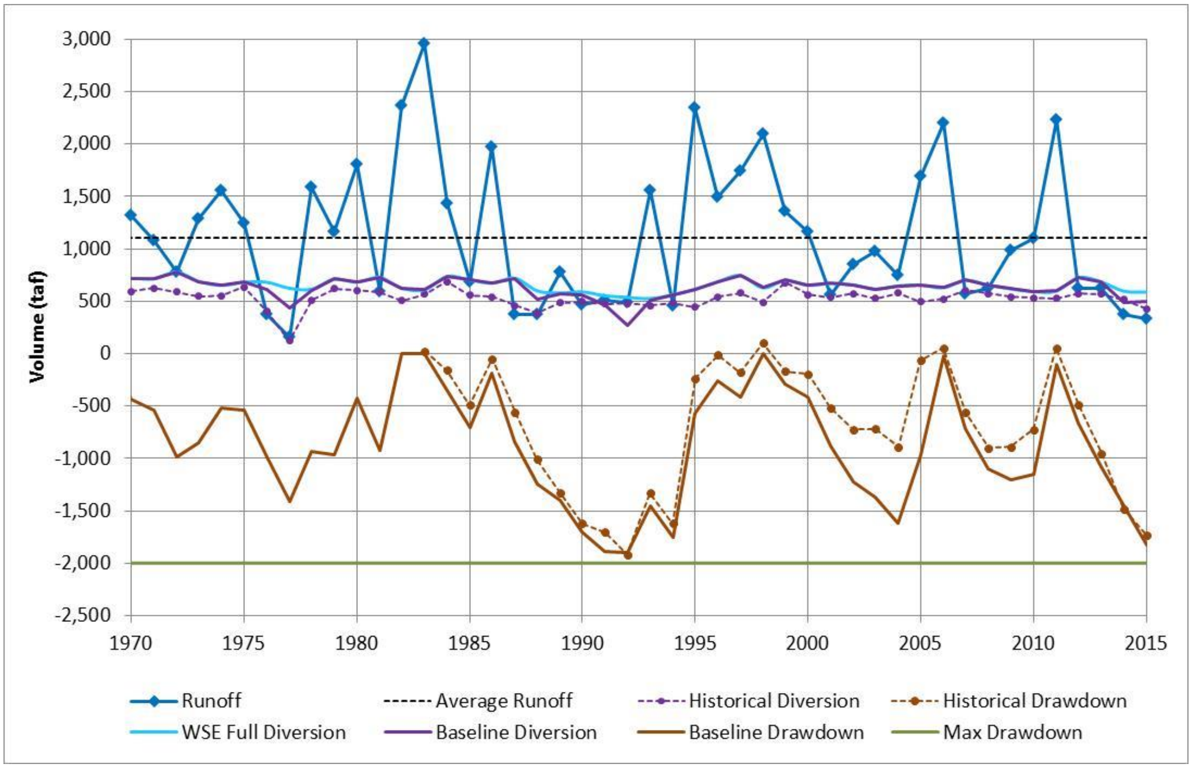

Figure 21-4. Stanislaus River Runoff with Historical and WSE Baseline Diversions, Diversion Deficits and Carryover Storage Drawdowns for WY 1970–2015

21.7.2 WSE Baseline

The Stanislaus River WSE-modeled full diversions averaged 651 TAF, and annual diversions were 100 percent of full diversions in 70 percent of the years (Table 21-3). The annual WSE baseline diversions were less than 92 percent of full diversions in 10 percent of the years, were less than 80 percent of full diversions in less than 5 percent of the years. The minimum Stanislaus River WSE baseline diversions (in 1992) were 50 percent of average full diversions.

The WSE model baseline results are also shown in Figure 21-4. The WSE baseline results were higher than the historical diversions and lower than the historical carryover storage patterns. The WSE baseline diversions were often higher than historical diversions because the full contract diversions of 755 TAF were included in the WSE baseline. The WSE baseline required release flows (e.g., flows required by the RPA) were considerably higher than the historical release flows. The WSE baseline carryover storage pattern was almost identical to the historical carryover storage for 1987–1994, but the WSE carryover storage was much less than historical carryover storage for 2000–2005, was slightly less than historical in 2007–2010, and was very similar for 2012–2015. The differences in the carryover storage can be caused by differences in diversions, differences in the required releases, or differences in the flood control releases; the differences in New Melones Reservoir storages appear to be caused by slightly higher WSE diversions during these recent dry year periods. Generally, the WSE baseline provides a very accurate calculation of drought conditions for the Stanislaus River, caused by the combination of dry year periods, with higher full water supply diversions and higher required flow releases.

Historical operations and the extended WSE baseline results demonstrate that New Melones Reservoir storage can sustain full water supply diversions through several dry years. The severity of drought years for the Stanislaus River can be determined by the distribution of diversion deficits as a percentage of full diversions. For the extended WSE baseline diversions in 1922–2015, there were 10 years (11 percent of years) with a deficit of >65 (10 percent of average full diversions), and 3 years (3 percent of years) with a deficit of >130 TAF (20 percent of average full diversions). If greater than a 20 percent water supply diversion deficit is used to identify drought years, the Stanislaus River extended WSE baseline diversions were reduced to less than 80 percent of full diversions in about 3 percent of the years.

21.7.3 Tuolumne River Diversions and Carryover Storage

21.7.4 Historical

Figure 21-5 shows the Tuolumne River runoff and average runoff along with historical diversions and carryover storages for WY 1970–2015. Drought years are identified as years with substantial diversion deficits (e.g., <80 percent full diversions). The historical diversions from La Grange Dam for MID/TID from WY 1970–1995 were generally about 1,000 TAF, with a maximum of 1,100 TAF in a few years. A full diversion target of 1,000 TAF for the MID/TID canals was assumed for the historical analysis.

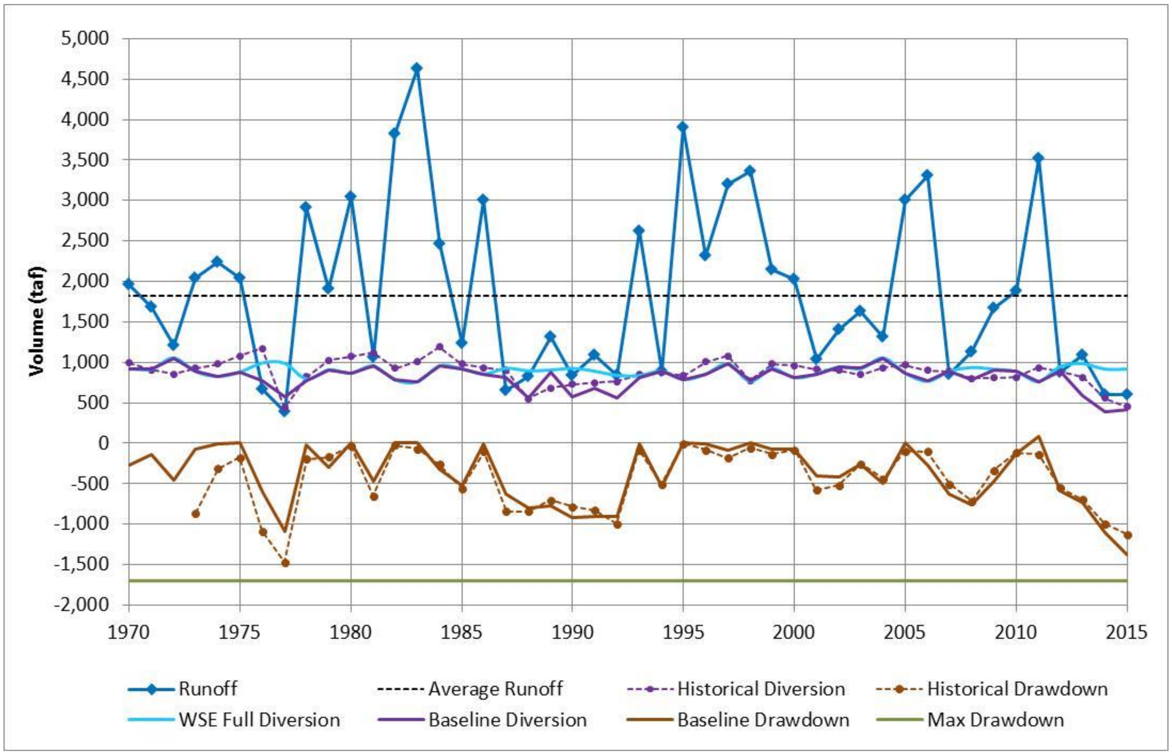

Figure 21-5. Tuolumne River Runoff with Historical and WSE Baseline Diversions, Diversion Deficits and Carryover Storage Drawdowns for WY 1970–2015

The historical diversions were less than 1,000 TAF in 1977 and 1978, in 1988–1994, and in 1998. The historical New Don Pedro Reservoir carryover storage was reduced in most of the dry years. However, because the CCSF has a large water bank in New Don Pedro Reservoir, and because MID/TID also maintain a moderate carryover storage, the carryover storage was only rarely less than 1,000 TAF (carryover storage deficit of more than 750 TAF). The minimum historical carryover storage was 250 TAF in 1977, and was 750 TAF in 1992.

The historical reservoir operations during 2012–2015 showed reduced diversions to about 560 TAF in 2014 and reduced carryover storage to 780 TAF in 2014. The low Tuolumne River runoff of 602 TAF in 2015 and reduced carryover storage in 2014 resulted in low diversions (450 TAF) and low carryover storage (644 TAF) in 2015.

21.7.5 WSE Baseline

The Tuolumne River WSE model full diversions averaged 901 TAF, and annual diversions were 100 percent of full diversions in 60 percent of the years (Table 21-3). The annual WSE baseline diversions were less than 92 percent of full diversions in 20 percent of the years, were less than 67 percent of full diversions in 10 percent of the years, and the minimum diversions were 43 percent of full diversions in 2014 (Table 21-3).

The extended WSE baseline results are also shown in Figure 21-5. The WSE model showed average full diversions were 901 TAF, which generally matched the historical MID/TID diversions for 1970–2015. The WSE baseline diversions averaged 840 TAF (93 percent of full diversions) with diversion deficits in most of the same years as historical diversion deficits. The WSE baseline carryover storage pattern was nearly identical to the historical New Don Pedro Reservoir storage; the WSE diversions and carryover storage for the Tuolumne River was very close to the historical operations. The general agreement between the historical operations and the WSE model results indicate that the new Don Pedro reservoir operations have not changed substantially during the 1970–2015 period. Although the historical and WSE model diversions fluctuated somewhat differently, the average diversions were similar (882 TAF for historical and 813 TAF for WSE model results) and the required flows were also similar, so the reservoir drawdown in dry year periods was similar. Generally, the WSE baseline provides a very accurate calculation of drought conditions for the Tuolumne River.

Historical operations and the extended WSE baseline results demonstrate that New Don Pedro reservoir storage can sustain full water supply diversions through several dry years. The severity of drought years for the Tuolumne River can be determined by the water supply diversion deficits as a percentage of full diversions. For the extended WSE baseline diversions in 1922–2015, there were 19 years (20 percent of years) with a deficit of >90 (10 percent of average full diversions), and 13 years (14 percent of years) with a deficit of >180 TAF (20 percent of average full diversions). If greater than a 20 percent water supply diversion deficit is used to identify drought years, the Tuolumne River extended WSE baseline diversions were reduced to less than 80 percent of full diversions in about 14 percent of the years (1 or 2 out of 10).

21.8 Merced River Diversions and Carryover Storage

21.8.1 Historical

Figure 21-6 shows the Merced River runoff and average runoff along with historical diversions and carryover storages for WY 1970–2015. Drought years are identified as years with substantial diversion deficits (e.g., <80 percent full diversions). The historical diversions from the Merced River for the Merced ID canals were about 550 TAF; this was assumed as the full diversion for the historical analysis. The historical diversion were less than 500 TAF in 1977, 1988–1993, 2008, and in 2012–2015. The historical Lake McClure carryover storage (maximum of 850 TAF) was reduced in most of the dry years. The historical carryover storage was 100 TAF in 1977, was about 100–200 TAF in 1988–1992, was reduced to 120 TAF in 2014, and was 87 TAF in 2015.

The historical reservoir operations during 2012–2015 showed reduced diversions of 210 TAF and reduced carryover storage of 122 TAF in 2014. The low Merced River runoff and reduced carryover storage in 2014 resulted in very low diversions (20 TAF) and very low carryover storage (87 TAF) in 2015.

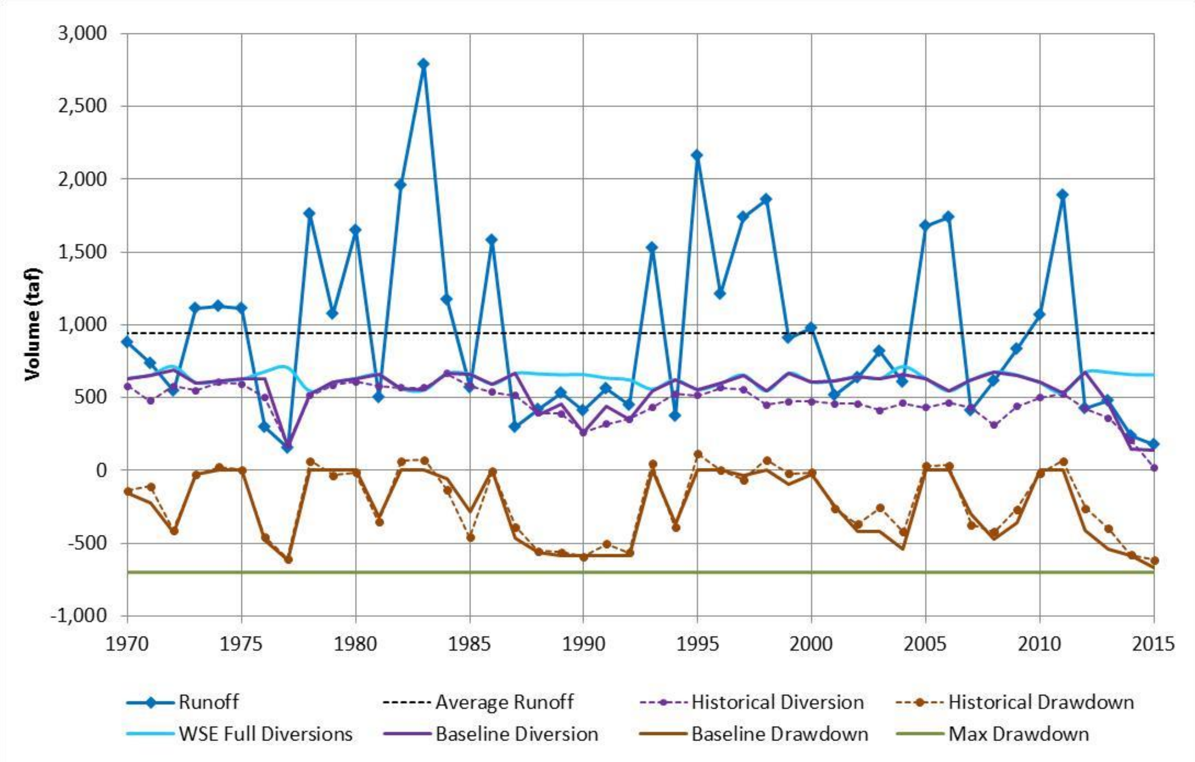

Figure 21-6. Merced River Runoff with Historical and WSE Baseline Diversions, Diversion Deficits and Carryover Storage Drawdowns for WY 1970–2015

21.8.2 WSE Baseline

The WSE model showed Merced River full diversions averaged 632 TAF, and annual diversions were 100 percent of full diversions in 60 percent of the years (Table 21-3). The annual WSE baseline diversions were less than 92 percent of full diversions in 20 percent of the years, were less than 63 percent of full diversions in 10 percent of the years, and the minimum Merced River WSE baseline diversions of 137 TAF (in 2015) were 21 percent of full diversions.

The extended WSE baseline results are also shown in Figure 21-6. The WSE model showed average full diversions were 632 TAF (including the riparian diversions of about 50 TAF) and the WSE baseline diversions averaged 574 TAF (91 percent of full diversions). The WSE baseline diversions were higher than the historical diversions, with diversion deficits in most of the same years. The WSE baseline carryover storage pattern was also nearly identical to the historical carryover storages. Overall the extended WSE baseline provides an accurate match with the historical Lake McClure operations for 1970–2015.

Historical operations and the extended WSE baseline results demonstrate that Lake McClure storage can sustain full water supply diversions through only a few dry years. The severity of drought years for the Merced River can be determined by the diversion deficits as a percentage of full diversions. For the WSE baseline diversions in 1922–2015, there were 18 years (19 percent of years) with a deficit of >63 (10 percent of average full diversions), and 14 years (15 percent of years) with a deficit of >126 TAF (20 percent of average full diversions). If greater than a 20 percent water supply diversion deficit is used to identify drought years, the Merced River extended WSE baseline diversions were less than 80 percent of full diversions in about 15 percent of the years (1 or 2 out of 10).

21.9 LSJR Alternatives and Water Supply Operations

The monthly WSE model used for this recirculated substitute environmental document (SED) evaluation of the LSJR flow objective alternatives calculated the reservoir operations and diversions for the 1922–2003 monthly runoff (or reservoir inflow). The extended WSE model matched the recent historical operations for 2004–2015 very well, as described in the previous section. The extended WSE model-calculated annual results for water supply diversions, required river releases, flood-control releases, reservoir evaporation, and carryover storage for each LSJR alternative are summarized and compared with the baseline results for each tributary.

The WSE model results indicate that implementing the LSJR alternatives would result in more years with drought conditions (i.e., reduced water availability and thus reduced water supply diversions). Increasing the February–June flows under the LSJR alternatives would reduce the reservoir carryover storage in dry years and would reduce the water supply diversions in dry year periods. Although some years with high runoff (and flood-control spills) would still provide full diversions and maximum carryover storage, most years would have reduced storage and/or reduced diversions. This section summarizes the extended WSE baseline and LSJR alternative annual results, showing and describing the likely release flows under each LSJR alternative and corresponding changes in carryover storage and water supply diversions for each tributary. The increased drought years and increased diversion deficits are summarized as the cumulative distribution of water supply diversions for each alternative (Tables 21-7a, 21-b, 21-c, 21-d, and 21-e) for each of the tributaries.

21.9.1 Stanislaus River Operations

Figure 21-7a shows the Stanislaus River annual runoff and extended WSE modeled annual results for the baseline flow requirements[2] and the baseline flows at Ripon that includes reservoir spills in a few years, for 1922–2015. The baseline release flows are a relatively large fraction of the runoff because the baseline required flows include the RPA flow schedules. The WSE baseline required flows averaged 484 TAF (44 percent of runoff); the flows at Goodwin (with spills) averaged 437 TAF (40 percent of runoff); and the flows at Ripon, with about 100 TAF (9 percent or runoff) of local inflows, averaged 536 TAF (48 percent of runoff). The Stanislaus River baseline flows were substantially higher than the required flows (because of reservoir spills) in a few years. The flow requirements were about 500 TAF/y (range of 250 TAF/y to 750 TAF/y) and the release flows were greater than 1,000 TAF in only 5 years (about 1 out of 20 years). The WSE baseline New Melones reservoir spills averaged 52 TAF (5 percent of inflow); spills were infrequent because of the large carryover storage capacity of New Melones Reservoir (180 percent of average runoff).

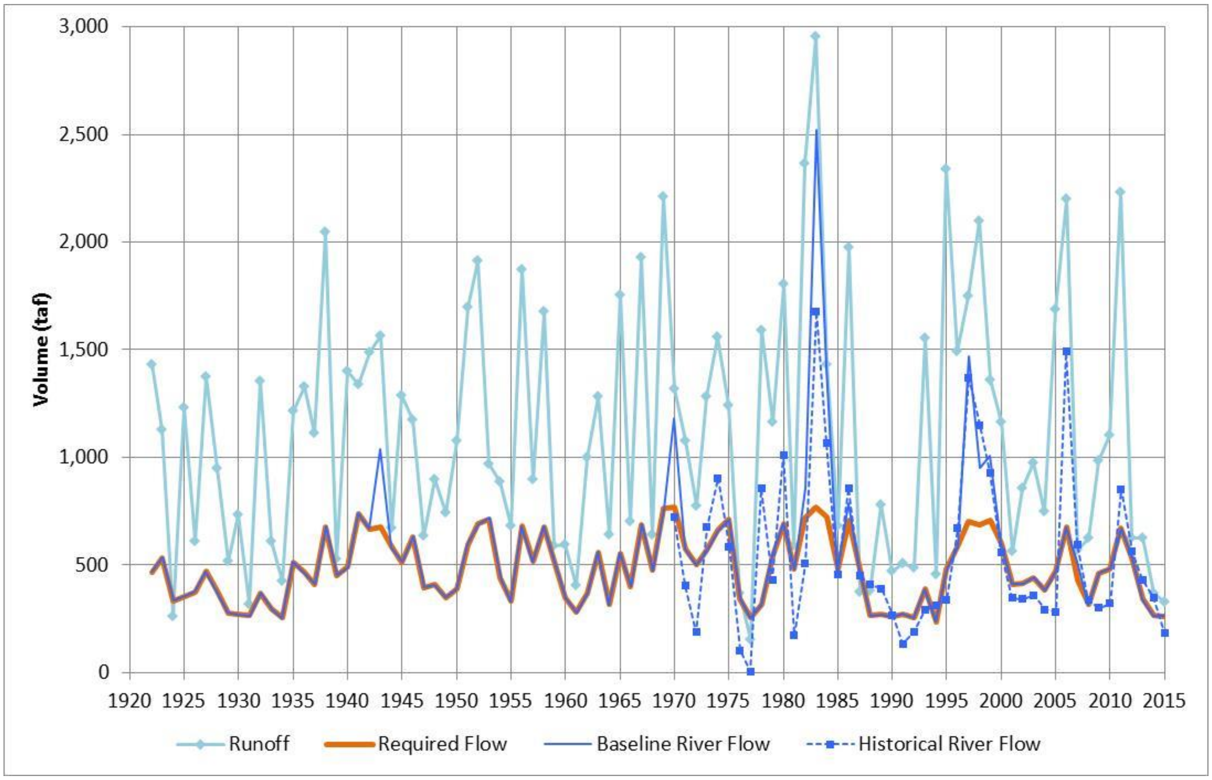

Figure 21-7a. WSE Baseline Required Flows and Release Flows at Ripon Compared with Stanislaus River Runoff and Recent Historical Flows

Figure 21-7b shows the extended WSE-modeled annual results for the baseline and flow objective alternatives release flows for the Stanislaus River at Ripon for 1922–2015. The existing flow requirements are specified at Goodwin, while the LSJR flow objectives were specified in the WSE model at Ripon, where the flows included the local inflow of about 100 TAF/y. LSJR Alternative 2

---

[2] Note the term flow requirements or required flows is used in this section and on several figures to define those flows that are either required under previous or existing agreements (e.g., flow requirements for VAMP) or would be required under the different LSJR alternatives (e.g., LSJR Alternative 3 would have a flow requirement of 40 percent unimpaired flow).

required flows averaged 482 TAF (44 percent of runoff), and release flows (including a few years with reservoir spills) averaged 444 TAF (40 percent of runoff) at Goodwin and 543 TAF (49 percent of runoff) at Ripon. LSJR Alternative 3 required flows averaged 576 TAF (52 percent of runoff) and release flows averaged 512 TAF (46 percent of runoff) at Goodwin and 610 TAF (55 percent of runoff) at Ripon. LSJR Alternative 4 required flows averaged 720 TAF (65 percent of runoff) and release flows averaged 640 TAF (58 percent of runoff) at Goodwin and 739 TAF (67 percent of runoff) at Ripon. All of the LSJR alternatives increased the fraction of runoff released for required flows, but LSJR Alternative 2 was similar to the baseline flows, because the baseline required flows (e.g., RPA schedules) were generally about 20 percent of the February–June runoff. LSJR Alternatives 3 and 4 increased the annual required flows and released flows in almost every year for the Stanislaus River because the New Melones Reservoir storage is large and reservoir spills occurred in only a few years under baseline.

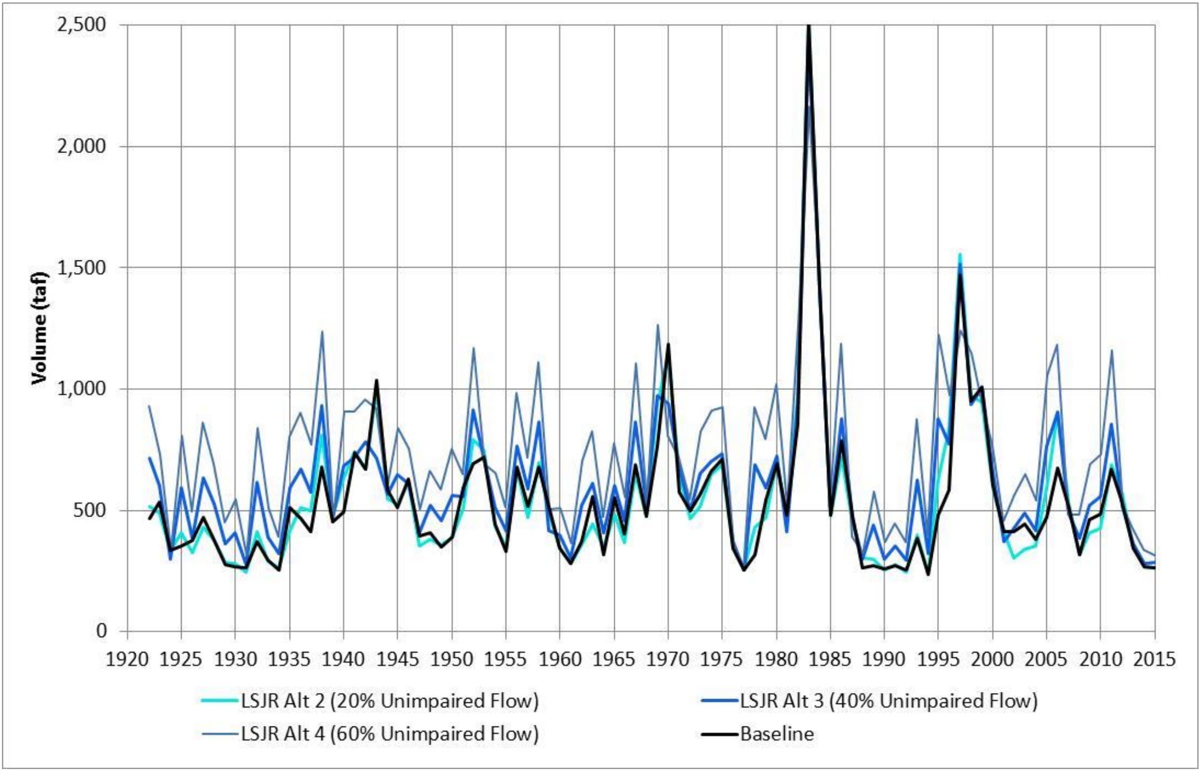

Figure 21-7b. WSE Baseline and LSJR Flow Objective Alternative Results for Stanislaus River Annual Flows at Ripon (TAF) for 1922–2003

Figure 21-7c shows the WSE-modeled annual results for New Melones carryover storage for the baseline and flow objective alternatives for 1922–2015. The baseline carryover storage was rarely full (2,000 TAF maximum) because the reservoir storage is almost twice the average runoff and several dry years are generally needed to reduce the storage, while several wet years are generally needed to refill the storage. The WSE baseline carryover storage was nearly full in only 6 years (1969, 1982, 1983, 1998, 2006, and 2011). The baseline carryover storage was low (<750 TAF) at the end of each major dry year period (e.g., 1929–1936, 1949–1950, 1961–1964, 1977, 1988–1994, 2002–2004, and 2014–2015). The New Melones Reservoir storage was large enough to provide nearly full diversions in many dry years, even with the relatively high required flows (e.g., RPA schedules). The WSE model showed carryover storages with LSJR alternatives were sometimes lower than the baseline storages, but the WSE-modeled carryover storages for the LSJR alternatives remained above 700 TAF[3]. This reduced the water supply diversions in years when the baseline carryover storage was less than 750 TAF. LSJR Alternatives 2 and 3 had similar carryover storage patterns, but LSJR Alternative 4 caused the carryover storage to be much less when compared to LSJR Alternatives 2 and 3 in several years (e.g., 1939–1946, 1952–1953, and 1969).

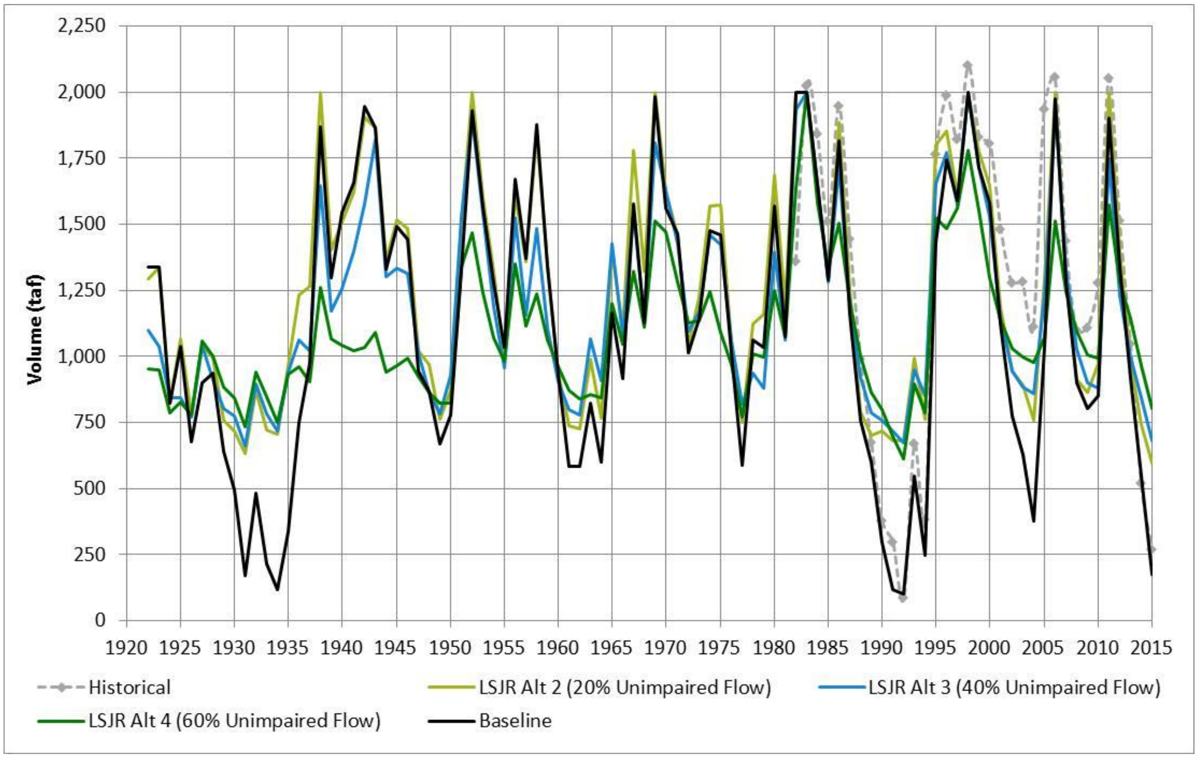

Figure 21-7c. WSE Baseline and LSJR Flow Objective Alternative Results for New Melones Carryover Storages for 1922–2015

Figure 21-7d shows the extended WSE-modeled annual results for Stanislaus River water supply diversions for the baseline and flow objective alternatives for 1922–2015. The baseline diversions fluctuated with the WSE-model full diversions (full water supply demands), generally between 550 TAF and 750 TAF. Baseline diversions were reduced in the major dry year periods (e.g., 1929–1936, 1976-1977, 1988–1994, 2002–2005 and 2013–2015). The average baseline Stanislaus River diversions were 635 TAF (57 percent of runoff). Under the LSJR alternatives, reduced diversions were largely the result of the increased flow requirements and the increased minimum carryover storage between the baseline and LSJR alternatives. The average annual diversion under LSJR Alternative 2 was reduced to 619 TAF (56 percent of runoff). The average annual diversion for LSJR Alternative 3 was reduced to 553 TAF (50 percent of runoff), and the average annual diversion for LSJR Alternative 4 was reduced to 426 TAF (39 percent of runoff). Whereas the baseline diversions were reduced only after several dry years once the carryover storage was reduced (to about 250 TAF), the increased minimum carryover storage (750 TAF) and the increased flow objectives reduced the diversions in more years. The increased carryover storage and increased required flows under the LSJR alternatives reduced the diversions to a smaller fraction of the average runoff (57

---

[3] This was because the WSE model included an assumption that the carryover storage would not be reduced below 750 TAF.

percent of runoff for the baseline, 56 percent of runoff for LSJR Alternative 2, 50 percent of runoff for LSJR Alternative 3, and 39 percent of runoff for LSJR Alternative 4).

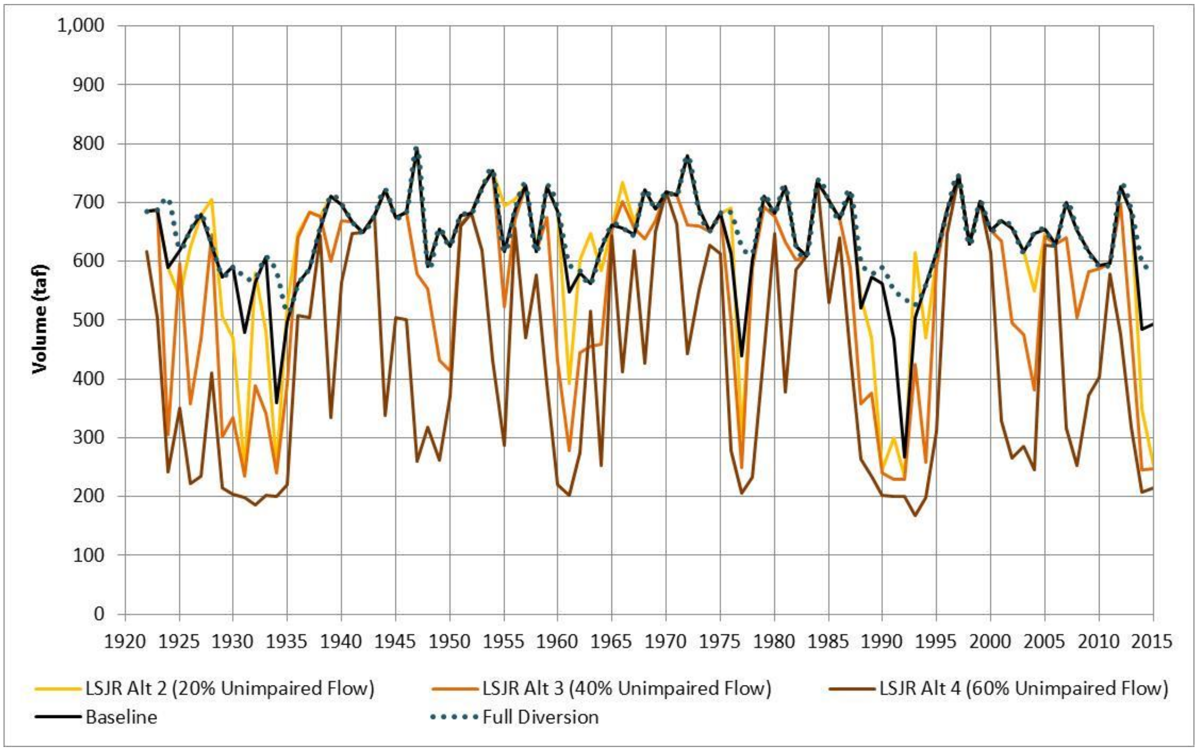

Figure 21-7d. WSE Baseline and LSJR Flow Objective Alternative Results for Stanislaus River Water Supply Diversions for 1922–2015

Table 21-4a gives a comparison of the cumulative distribution of the extended WSE model Stanislaus River water supply diversions for the LSJR alternatives for 1922–2015. There are many years with higher-than-average runoff that allowed full Stanislaus River water supply diversions under baseline conditions, even with the relatively high baseline required flows (44 percent of average runoff). The large storage capacity of New Melones Reservoir allowed full diversions in several dry year periods; reduced water supply diversions were calculated in about 10 percent of the years and the average annual diversion was 635 TAF for the WSE baseline. The LSJR Alternative 2 diversions were reduced in about 20 percent of the years; the increased minimum carryover storage requirement caused diversion deficits earlier in each dry year period, but the average annual diversion for LSJR Alternative 2 was only slightly reduced (619 TAF). The LSJR Alternative 3 diversions were reduced in about 50 percent of the years. The increased minimum carryover storage requirement shifted some of the diversion deficits, and the higher required flows reduced the diversions substantially (more than 20 percent of full diversions) in about 10 percent of the years. The average annual diversion for LSJR Alternative 3 was reduced by 12 percent of the average full diversions to 553 TAF. The LSJR Alternative 4 diversions were reduced in about 80 percent of the years. The increased minimum carryover storage requirement shifted some of the diversion deficits, and the higher required flows reduced the diversions substantially (more than 20 percent of full diversions) in about 65 percent of the years. The average annual diversion for LSJR Alternative 4 was reduced by 30 percent of the average full diversion to 426 TAF. The largest reductions in diversions for the LSJR alternatives occurred in drought years, when the baseline diversions were already reduced.

Table 21-4a. Cumulative Distributions of WSE Model Stanislaus River Diversions for LSJR Alternatives for 1922–2015

Average Runoff (TAF)	1,107
Average Full Diversion (TAF)	651

Average	635	98	619	95	553	85	426	65
Average Deficit (TAF)		16		32		98		225

Figure 21-7e shows the overall effects of the extended WSE baseline and LSJR alternatives on the Stanislaus River diversion deficits. This graph illustrates the basic concept that reservoir operations are a three-way balance between the runoff and: (1) required release flows, (2) full water supply diversions, and (3) carryover storage. The sum of the annual LSJR alternatives release flow requirements (TAF) and full diversions (TAF) are plotted as a function of the runoff (TAF). The sum of the average full water supply diversions and the required flows represents the total water demands for each year. The WSE model-calculated diversion deficits are also plotted as a function of runoff. The sum of the baseline flow requirements and full diversions were generally higher than runoff, until the runoff was greater than 1,000 TAF. When the runoff was less than the average runoff, full water supply diversions required carryover storages to be reduced to supplement the runoff. The baseline diversion deficits generally increased with lower runoff, and there were some diversion deficits when runoff was less than about 1,500 TAF. The LSJR alternatives increased the water needed for required release flows and full water supply diversions, and generally resulted in larger diversion deficits. The sum of the full diversions and the required flows for LSJR Alternative 3 were generally higher than runoff until runoff was greater than 1,500 TAF. The sum of the full diversions and the required flows for LSJR Alternative 4 were generally higher than runoff until runoff was greater than 1,750 TAF.

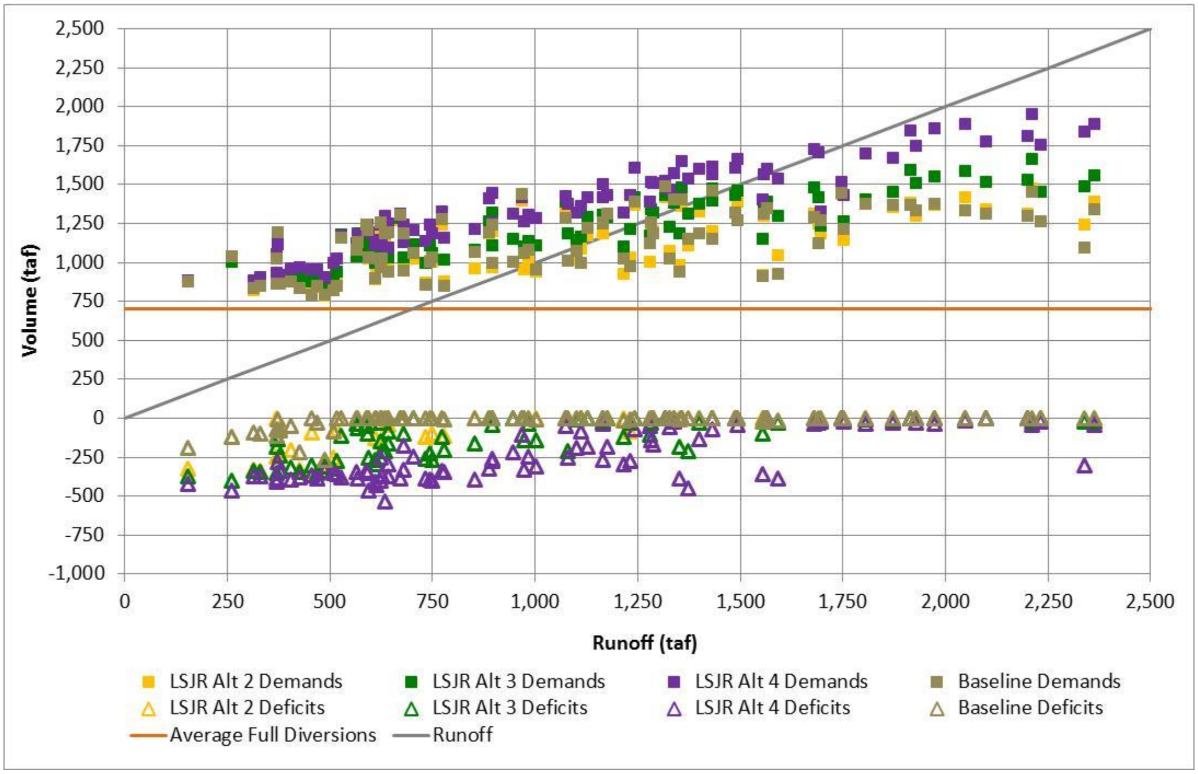

Figure 21-7e. Relationships between Stanislaus River Runoff, Sum of Alternative Flow Requirements and Full Water Supply Diversions, and Diversion Deficits for 1922–2015

21.9.2 Tuolumne River Operations

Figure 21-8a shows the Tuolumne River annual runoff and extended WSE-modeled annual results for the baseline required flows at La Grange and the baseline flows at Modesto that included reservoir spills in about half of the years (58 out of 94), for 1922–2015. The WSE baseline required flows averaged 443 TAF (28 percent of inflow), the release flows at La Grange (with spills) averaged 683 TAF (43 percent of inflow) and the total flows at Modesto, with about 215 TAF (14 percent of inflow) of local inflows, averaged 897 TAF (57 percent of inflow). The Tuolumne River baseline flows are substantially higher than the required flows (because of reservoir spills) in many years. The baseline required flows were about 500 TAF/y (range of 200 TAF/y to 800 TAF/y) and the release flows were greater than 1,000 TAF in about 38 years (4 out of 10 years). The WSE baseline New Don Pedro Reservoir spills averaged 454 TAF (29 percent of inflow).

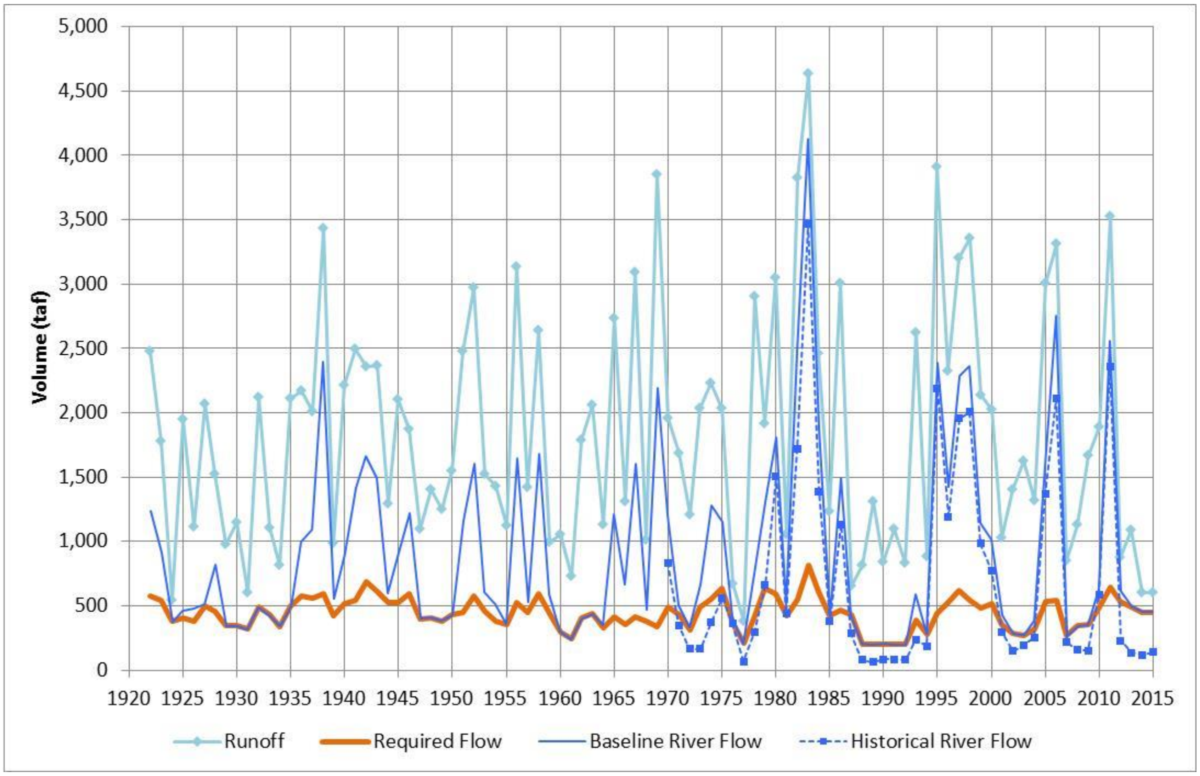

Figure 21-8a. WSE Baseline Required Flows and Release Flows at Modesto Compared with Tuolumne River Runoff and Recent Historical Flows

Figure 21-8b shows the extended WSE-modeled annual results for the baseline and LSJR alternative release flows at Modesto compared to the annual New Don Pedro Reservoir inflow (i.e., runoff minus 250 TAF) for the Tuolumne River for 1922-2015. The baseline minimum flows are required at La Grange, while the required flows for the LSJR alternatives were specified in the WSE model at Modesto, where the flows included the local inflow of 215 TAF/y. The LSJR Alternative 2 required flows averaged 525 TAF (33 percent of inflow) and the LSJR Alternative 2 release flows (including reservoir spills) averaged 702 TAF (45 percent of inflow) at La Grange and 916 TAF (58 percent of inflow) at Modesto. Spills were reduced to an average of 392 TAF (25 percent of inflow). The LSJR Alternative 3 required flows averaged 774 TAF (49 percent of inflow) and the LSJR Alternative 3 release flows averaged 802 TAF (51 percent of inflow) at La Grange and 1,016 TAF (64 percent of inflow) at Modesto. Spills were reduced to an average of 242 TAF (15 percent of inflow). The LSJR Alternative 4 required flows averaged 1,048 TAF (66 percent of inflow) and the LSJR Alternative 4 release flows averaged 978 TAF (62 percent of inflow) at La Grange and 1,192 TAF (76 percent of inflow) at Modesto. Spills were reduced to an average of 143 TAF (9 percent of inflow). The LSJR alternatives increased the fraction of runoff released for required flows and reduced the fraction of the reservoir inflow that was released for flood control (spills).

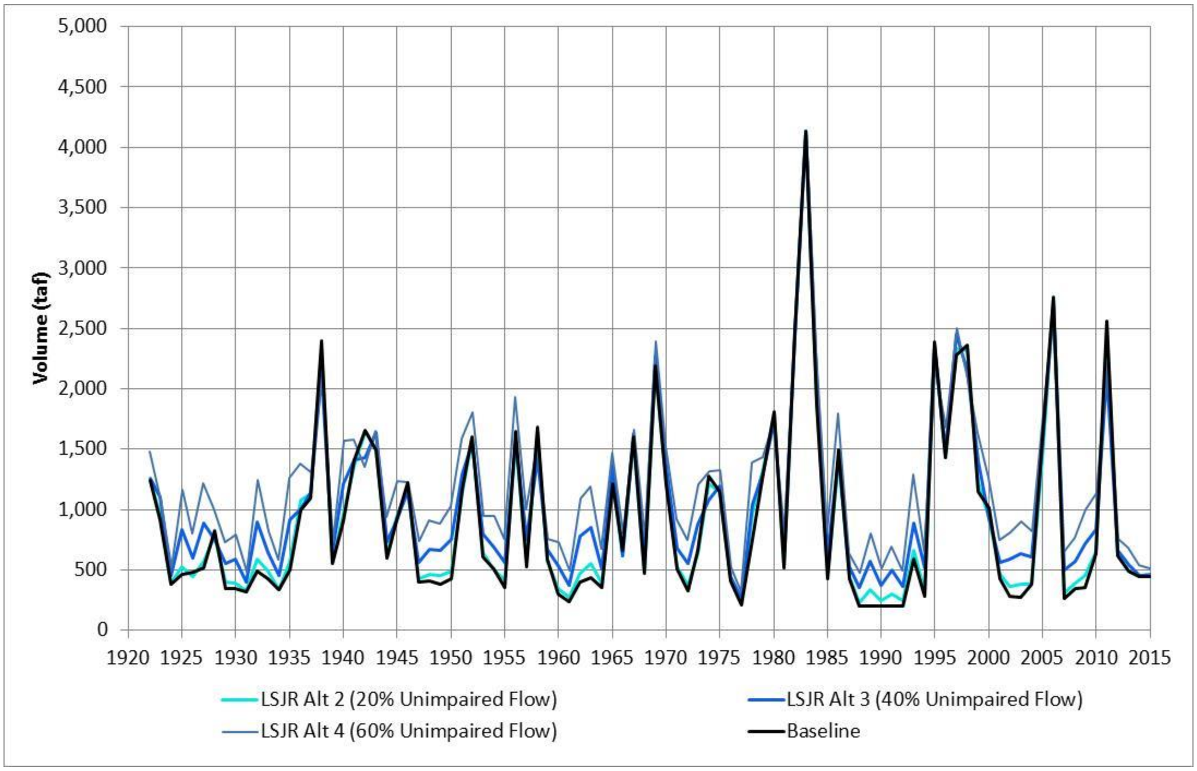

Figure 21-8b. WSE Baseline and LSJR Flow Objective Alternative Results for Tuolumne River Annual Flows at Modesto (TAF) for 1922–2015

Figure 21-8c shows the extended WSE-modeled annual results for New Don Pedro Reservoir carryover storage for the baseline and flow objective alternatives for 1922–2015. The baseline carryover storage was full (1,700 TAF maximum) in about 25 percent of the years. The baseline carryover storage was low (<1,000 TAF) at the end of each major dry year period (e.g., 1929–1934, 1947–1950, 1960–1962, 1977, 1988–1992, 2008, and 2013–2015). The New Don Pedro Reservoir storage was large enough to provide nearly full diversions in many dry years. The WSE model carryover storages with the flow objective alternatives were sometimes lower, because the higher required flows reduced the carryover storage in some years; but many other years had similar carryover storages because although the alternative flow objectives increased the required flows from February–June, the higher release flows reduced reservoir spills and so the carryover storages remained similar.

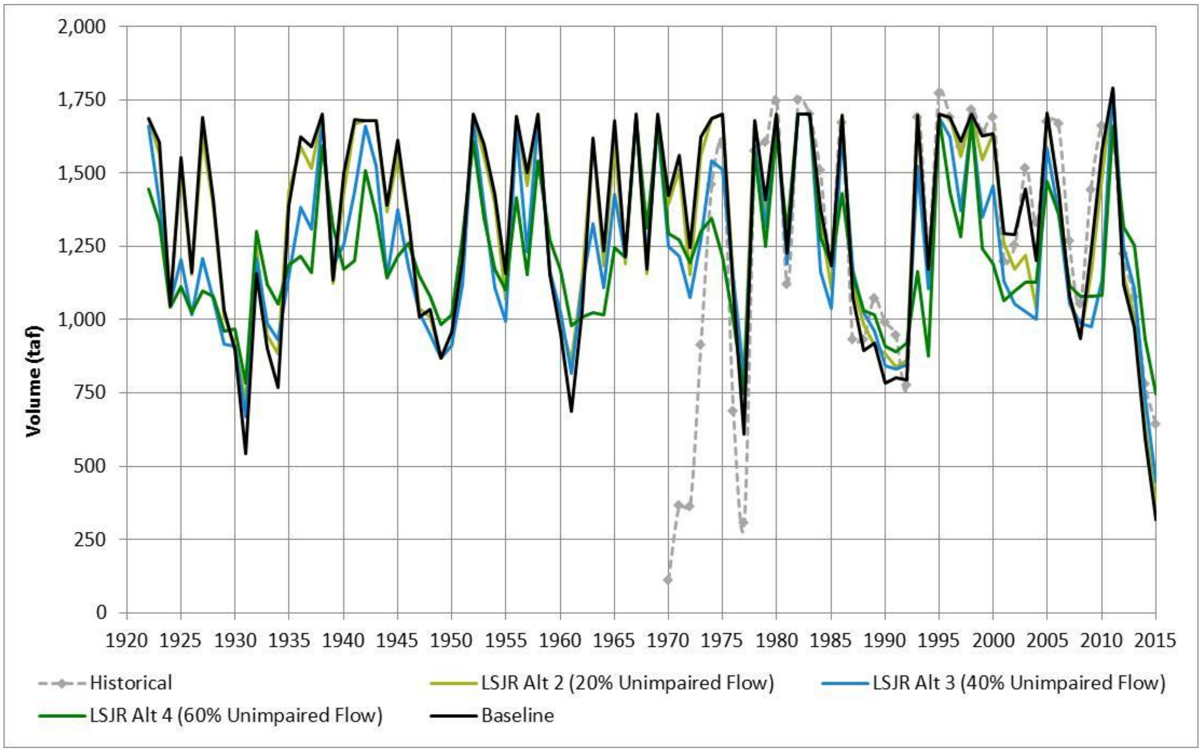

Figure 21-8c. WSE Baseline and LSJR Flow Objective Alternative Results for New Don Pedro Carryover Storages for 1922–2015

Figure 21-8d shows the extended WSE-modeled annual results for Tuolumne River water supply diversions for the baseline and LSJR alternatives for 1922–2015. The baseline diversions fluctuated with the WSE model full diversions (full water supply demands), generally between 800 TAF and 1,000 TAF. Baseline diversions were reduced to less than 800 TAF in a few years. The average baseline Tuolumne River diversions were 840 TAF (53 percent of inflow). The average annual diversion for LSJR Alternative 2 was reduced to 820 TAF (52 percent of inflow). The average annual diversion for LSJR Alternative 3 was reduced to 722 TAF (46 percent of inflow) and the average annual diversion for LSJR Alternative 4 was reduced to 545 TAF (35 percent of inflow).

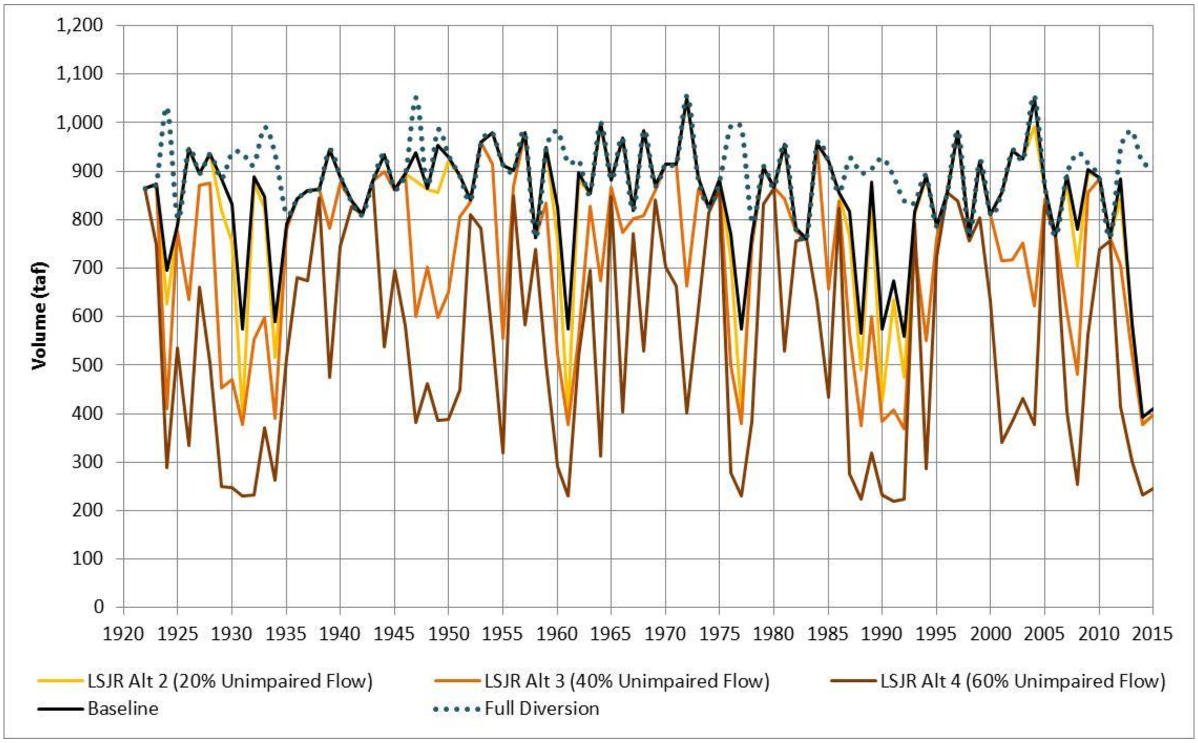

Figure 21-8d. WSE Baseline and LSJR Flow Objective Alternative Results for Tuolumne River Water Supply Diversions for 1922–2015

Table 21-4b gives a comparison of the cumulative distribution of WSE-modeled Tuolumne River water supply diversions for the LSJR alternatives for 1922–2015. There were many years (approximately half of the years) with higher than average runoff that allowed full Tuolumne River water supply diversions under baseline conditions. The large storage capacity of New Don Pedro Reservoir allowed full diversions in several dry year periods; reduced water supply diversions were calculated in about 20 percent of the years, and the average annual diversion for the baseline was 840 TAF. The LSJR Alternative 2 diversions were reduced in about 25 percent of the years; the average annual diversion for LSJR Alternative 2 was reduced slightly to 820 TAF. The LSJR Alternative 3 diversions were reduced in about 50 percent of the years; the diversions were reduced substantially (more than 20 percent of full diversions) in about 40 percent of the years. The average annual diversion for LSJR Alternative 3 was reduced to 722 TAF. The LSJR Alternative 4 diversions were reduced in about 80 percent of the years the diversions were reduced substantially (more than 20 percent of full diversions) in about 65 percent of the years; the diversions were less than half of full diversions in 45 percent of the years. The average annual diversion for LSJR Alternative 4 was reduced to 545 TAF.

Table 21-4b. Cumulative Distributions of WSE Model Tuolumne River Diversions for LSJR Alternatives for 1922–2015

Average Deficit (TAF)		61		81		179		356

Figure 21-8e shows the overall effects of the WSE baseline and LSJR alternatives on the Tuolumne River diversion deficits. This graph illustrates the basic concept that reservoir operations are a three-way balance between the runoff and: (1) required release flows, (2) full water supply diversions, and (3) carryover storage. The sum of the annual LSJR alternatives release flow requirements (TAF) and full diversions (TAF) are plotted as a function of the runoff (TAF). The sum of the average full water supply diversions and the required flows represents the total water demands for each year. The full diversions include the 250 TAF upstream diversions to CCSF. The WSE model calculated diversion deficits are also plotted as a function of runoff. The sum of the baseline flow requirements and full diversions were generally higher than runoff, until the runoff was greater than 1,500 TAF. When the runoff was less than the average runoff, full water supply diversions required carryover storages to be reduced to supplement the runoff. The baseline diversion deficits generally increased with lower runoff, and there were some diversion deficits when runoff was less than about 1,250 TAF. The LSJR alternatives increased the water needed for required release flows and full water supply diversions, and generally resulted in larger diversion deficits. The sum of the full diversions and the required flows for LSJR Alternative 3 were generally higher than runoff until runoff was greater than 2,000 TAF. The sum of the full diversions and the required flows for LSJR Alternative 4 were generally higher than runoff until runoff was greater than 2,500 TAF.

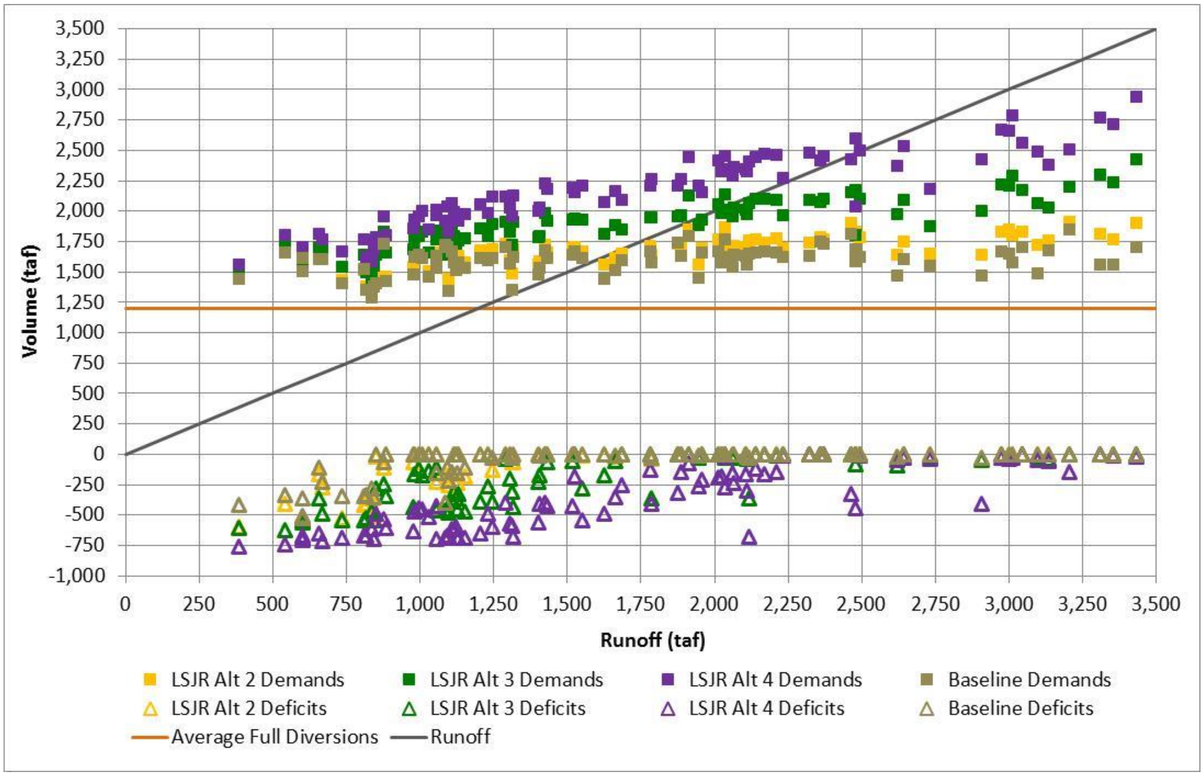

Figure 21-8e. Relationships between Tuolumne River Runoff, Sum of Alternative Flow Requirements and Full Water Supply Diversions, and Diversion Deficits for 1922–2015

21.9.3 Merced River Operations

Figure 21-9a shows the Merced River annual runoff and extended WSE-modeled annual results for the baseline required flows at the Crocker-Huffman Dam and the baseline flows at Stevinson that included reservoir spills in many years, for 1922–2015. The baseline release flows at Stevinson were a relatively small fraction of the runoff in years without reservoir spills, and a larger fraction of runoff in years with spills. The WSE baseline required flows averaged 229 TAF (24 percent of runoff); the release flows at Crocker-Huffman Dam (with spills and about 50 TAF for Cowell Agreement diversions) averaged 382 TAF (40 percent of runoff); and the total flows at Stevinson, with 118 TAF (13 percent of runoff) of local inflows minus 50 TAF for riparian diversions, averaged 450 TAF (48 percent of runoff). The Merced River baseline flows were substantially higher than the required flows (because of reservoir spills) in several years. The required flows were about 200 TAF/y (range of 100 TAF/y to 400 TAF/y) and the release flows were greater than 500 TAF in about 25 years (3 out of 10 years). The WSE baseline Lake McClure spills averaged 222 TAF (23 percent of runoff).

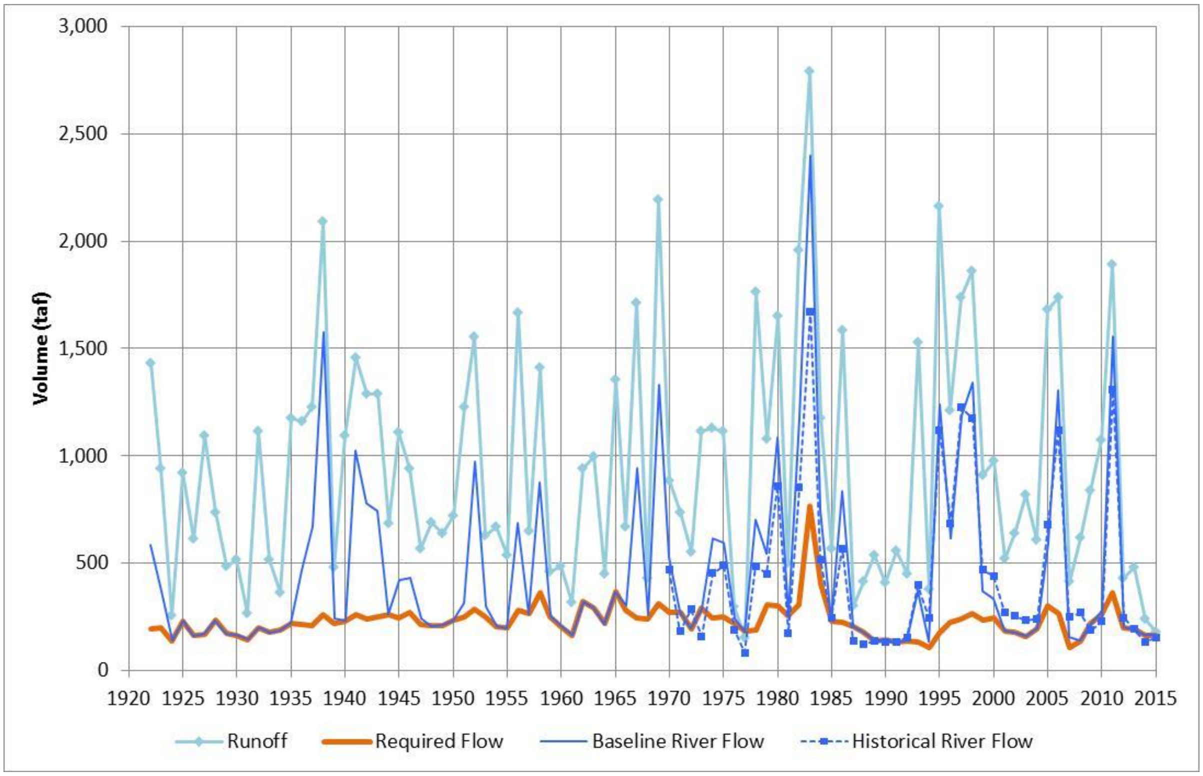

Figure 21-9a. WSE Baseline Required Flows and Release Flows at Stevinson Compared with Merced River Runoff and Recent Historical Flows

Figure 21-9b shows the extended WSE-modeled annual results for the baseline and LSJR alternatives release flows for the Merced River at Stevinson for 1922–2015. The LSJR Alternative 2 required flows averaged 288 TAF (30 percent of runoff), and the LSJR Alternative 2 release flows (including a few years with reservoir spills) averaged 414 TAF (44 percent of runoff) at Crocker-Huffman Dam and 482 TAF (51 percent of runoff) at Stevinson. The spills were reduced to 195 TAF (21 percent of runoff).The LSJR Alternative 3 required flows averaged 420 TAF (44 percent of runoff), and the LSJR Alternative 3 release flow averaged 475 TAF (50 percent of runoff) at Crocker-Huffman Dam and 543 TAF (57 percent of runoff) at Stevinson. The spills were reduced to 123 TAF (13 percent of runoff). The LSJR Alternative 4 required flows averaged 562 TAF (59 percent of runoff), and the LSJR Alternative 4 release flows averaged 561 TAF (59 percent of runoff) at Crocker-Huffman Dam and 630 TAF (67 percent of runoff) at Stevinson. The LSJR Alternative 4 spills were reduced to 68 TAF (7 percent of runoff).

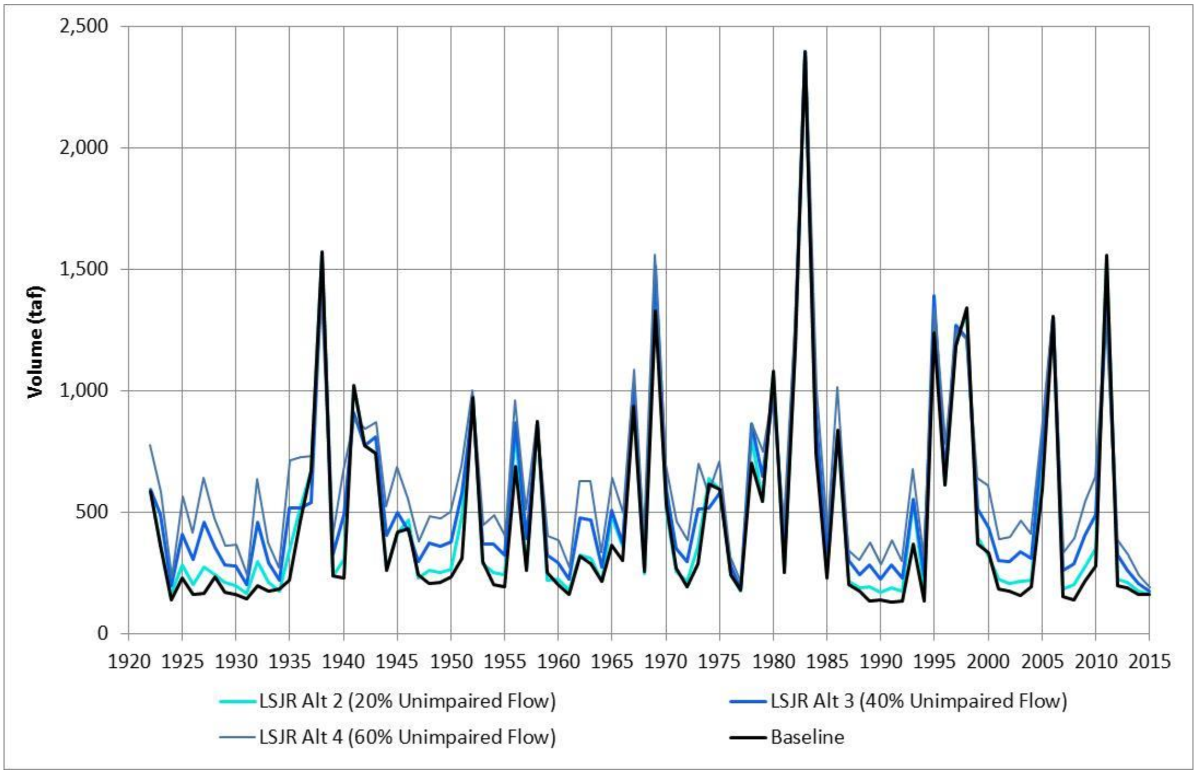

Figure 21-9b. WSE Baseline and LSJR Flow Objective Alternative Results for Merced River Annual Flows at Stevinson (TAF) for 1922–2015

Figure 21-9c shows the extended WSE-modeled annual results for Lake McClure carryover storage for the baseline and flow objective alternatives for 1922–2015. The baseline carryover storage was often full (700 TAF maximum) because the reservoir storage is less than the average runoff. The baseline carryover storage was low (<125 TAF) at the end of each major dry year period. The Lake McClure storage was large enough to provide nearly full diversions in some dry years, with reduced carryover storage, but the carryover storages for the LSJR flow objective alternatives were higher in some years, because a minimum carryover of about 250 TAF was assumed in the WSE model.

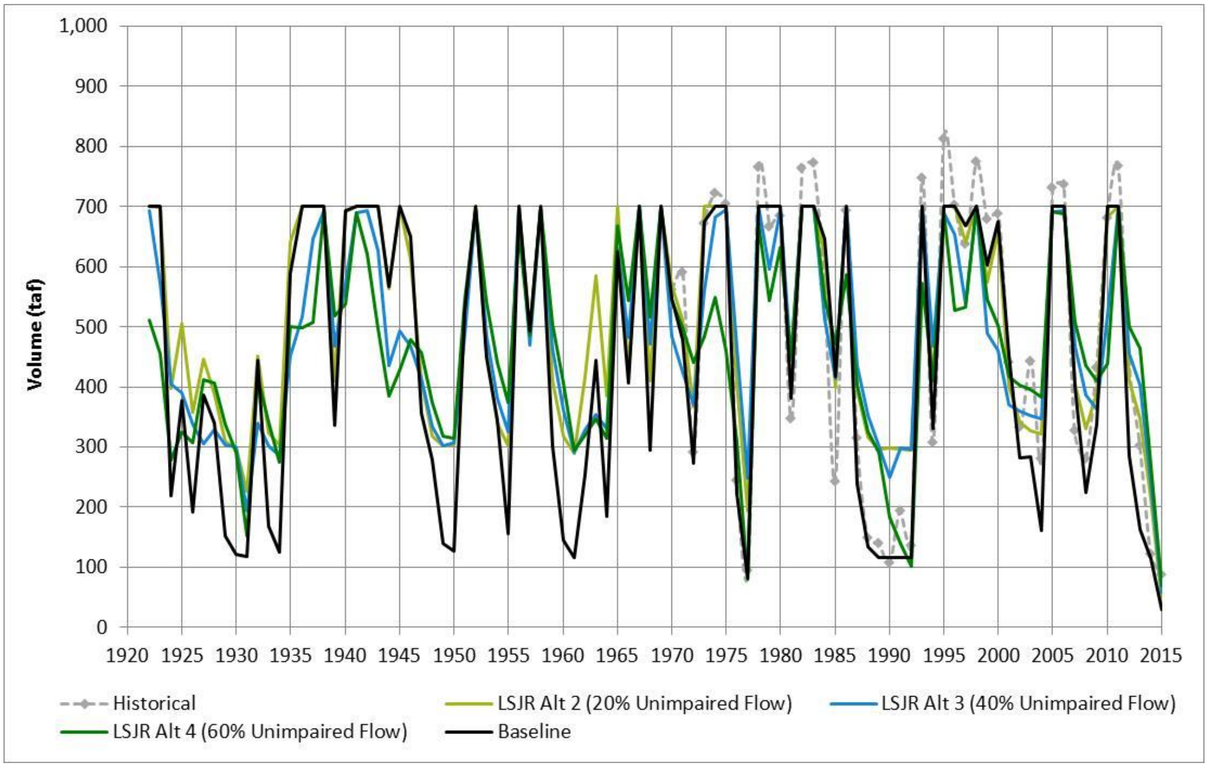

Figure 21-9c. WSE Baseline and LSJR Flow Objective Alternative Results for Lake McClure Carryover Storages for 1922–2015

Figure 21-9d shows the extended WSE-modeled annual results for Merced River water supply diversions for the baseline and LSJR flow objective alternatives for 1922–2015. The baseline diversions fluctuated with the WSE-modeled full diversions (water supply demands), generally between 550 TAF and 700 TAF. Baseline diversions were reduced in about 20 percent of the years. The average annual baseline Merced River diversion was 574 TAF (61 percent of runoff). The average annual diversion for LSJR Alternative 2 was reduced to 540 TAF (57 percent of runoff). The average annual diversion for LSJR Alternative 3 was reduced to 480 TAF (51 percent of runoff) and the average annual diversion for LSJR Alternative 4 was reduced to 395 TAF (42 percent of runoff).

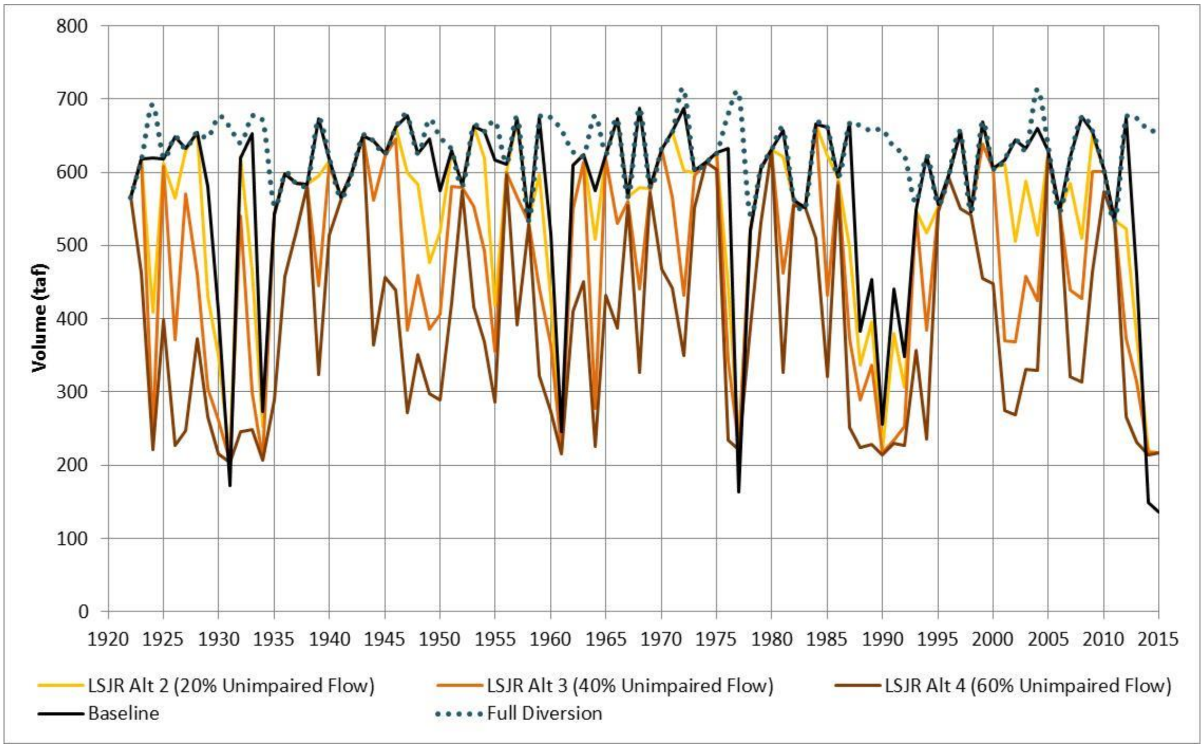

Figure 21-9d. WSE Baseline and LSJR Flow Objective Alternative Results for Merced River Water Supply Diversions for 1922–2015

Table 21-4c gives a comparison of the cumulative distribution of extended WSE model Merced River water supply diversions for the LSJR flow objective alternatives for 1922–2015. There were many years with higher-than-average runoff that allowed full Merced River water supply diversions under baseline conditions. The moderate storage capacity of Lake McClure allowed full diversions in some dry years but reduced water supply diversions were calculated in about 20 percent of the years and the average annual diversion was 574 TAF for the WSE baseline. The LSJR Alternative 2 diversions were reduced in about 40 percent of the years; the average annual diversion for LSJR Alternative 2 was reduced to 540 TAF. The higher required flows reduced the diversions substantially (more than 20 percent of full diversions) in about 25 percent of the years. The LSJR Alternative 3 diversions were reduced in about 50 percent of the years. The higher required flows reduced the diversions substantially (more than 20 percent of full diversions) in about 45 percent of the years. The average annual diversion for LSJR Alternative 3 was reduced to 480 TAF. The LSJR Alternative 4 diversions were reduced in about 75 percent of the years. The higher required flows reduced the diversions substantially (more than 20 percent of full diversions) in about 70 percent of the years; the diversions were less than half of full diversions in 40 percent of the years. The average annual diversion for LSJR Alternative 4 was reduced to 395 TAF.

Figure 21-9e shows the overall effects of the WSE baseline and LSJR alternatives on the Merced River diversion deficits. This graph illustrates the basic concept that reservoir operations are a three-way balance between the runoff and: (1) required release flows, (2) full water supply diversions, and (3) carryover storage. The sum of the annual LSJR alternatives release flow requirements (TAF) and full diversions (TAF) are plotted as a function of the runoff (TAF). The sum of the average full water supply diversions and the required flows represents the total water demands for each year. The WSE model calculated diversion deficits are also plotted as a function of runoff. The sum of the baseline flow requirements and full diversions were generally higher than runoff, until the runoff was greater than 800 TAF. When the runoff was less than the average runoff, full water supply diversions required carryover storages to be reduced to supplement the runoff. The baseline diversion deficits generally increased with lower runoff, and there were some diversion deficits when runoff was less than about 600 TAF. The LSJR alternatives increased the water needed for required release flows and full water supply diversions, and generally resulted in larger diversion deficits. The sum of the full diversions and the required flows for LSJR Alternative 3 were generally higher than runoff until runoff was greater than 1,000 TAF. The sum of the full diversions and the required flows for LSJR Alternative 4 were generally higher than runoff until runoff was greater than 1,250 TAF.

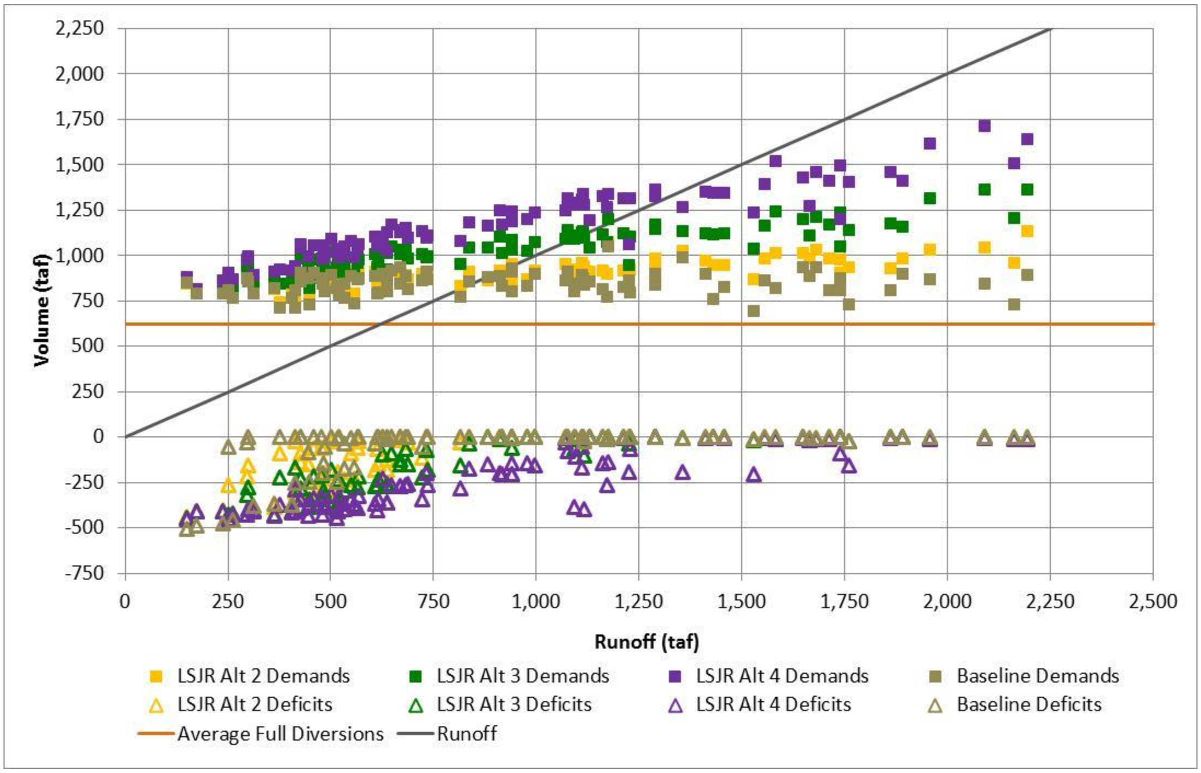

Figure 21-9e. Relationships between Merced River Runoff, Sum of Alternative Flow Requirements and Full Water Supply Diversions, and Diversion Deficits for 1922–2015

21.10 Adaptive Implementation Measures for Consideration

The adaptive implementation methods described in Chapter 3, *Alternatives Description*, could potentially be implemented in all years, including during dry years (less than average runoff), to manage flows in a manner that allows consideration of other beneficial uses, such as water supply for agricultural and municipal uses, as long as intended benefits to fish and wildlife beneficial uses are not reduced. Below is a summary of the four adaptive implementation methods, each of which allows changes based on best available scientific information.

1. Adjust the specified annual February–June unimpaired flow[4] requirement by either increasing or decreasing the requirement to a percentage within the specified range. For LSJR Alternative 2 (20 percent unimpaired flow), the percent of unimpaired flow may be increased to a maximum of 30 percent. For LSJR Alternative 3 (40 percent unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 30 percent or increased to a maximum of 50 percent. For LSJR Alternative 4 (60 percent unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 50 percent.

---

[4] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.

2. Allow the total amount of water during February through June period to be managed as a total volume and released at varying rates, rather than maintaining a constant percentage of unimpaired flow.
3. Release a portion of the February through June unimpaired flow volume after June to prevent adverse effects to fisheries from implementation of the February through June unimpaired flow requirement. The volume of water to be shifted to later in the year would be limited as described in Chapter 3.
4. Modify the February–June Vernalis base flow requirement of 1,000 cfs to a rate between 800 and 1,200 cfs.

The flexibility afforded by adaptive implementation using the four methods may be especially useful during dry years as a means of reasonably protecting fish and wildlife beneficial uses. As described in this chapter, dry years with less than 75 percent of the average runoff occur in about 40 percent of the years (4 out of 10 years). All beneficial uses would likely face water deficiencies in dry years, but adaptive implementation may allow flexibility in managing limited water supplies for fish and wildlife while considering other beneficial uses, provided that these other considerations do not reduce benefits for fish and wildlife.

Chapter 22
Integrated Discussion of Potential Municipal and Domestic Water Supply Management Options

22.1 Introduction

This chapter provides an integrated discussion of potential municipal and domestic water supply management options in response to implementation of the Lower San Joaquin River (LSJR) alternatives. Southern Delta water quality (SDWQ) alternatives are not discussed in this chapter, because a substantial degradation of water quality affecting service providers diverting drinking water from the southern Delta would not occur. This chapter incorporates information from Chapter 9, *Groundwater Resources*, and Chapter 13, *Service Providers*, in order to illustrate how potential impacts from LSJR alternatives would affect water supply to urban and rural populations in the San Joaquin Valley under current regulatory conditions. Current regulatory conditions include the Sustainable Groundwater Management Act (SGMA) (Wat. Code, § 10720 et seq.), which took effect January 1, 2015, and requires the formation of local agencies to protect and manage groundwater resources. SGMA is discussed in more detail below. This chapter also references project overview information from Chapter 1, *Introduction*; water resources and management descriptions from Chapter 2, *Water Resources*; project alternative descriptions from Chapter 3, *Alternatives Description*; and, cost information from Chapter 16, *Evaluation of Other Indirect and Additional Actions*.

This chapter summarizes: water use; the regulatory background for current and future groundwater management; potential impacts on public water supplies and domestic (i.e., private) wells; costs of potential management responses by municipal and domestic users; and the availability of financial and technical assistance programs to help address potential impacts. This chapter also discusses public health, with a special emphasis on disadvantaged communities (DACs)[1] and schools.

This chapter relies on the analyses in Chapters 9 and 13. Chapter 9 analyzes the potential impacts on groundwater as a resource as determined by reductions in groundwater levels and the risk of subsidence. Chapter 13 includes an examination of whether implementation of the LSJR alternatives could potentially require or result in: (1) construction of new water supply facilities or wastewater treatment facilities, or the expansion of existing facilities; or (2) violation of any drinking water quality standards. The study area as used in this chapter is the primary area likely to experience groundwater effects associated with the LSJR alternatives (i.e., the four main groundwater subbasins—the Eastern San Joaquin, Modesto, Turlock, and the “Extended" Merced Subbasin[2]), as defined in Chapter 9 (Figure 9-1).

---

[1] *Disadvantaged communities* are defined as those communities with an annual median household income (MHI) that is less than 80 percent of the statewide annual MHI. (Public Resources Code, § 75005 subd. (g).)

[2] As described in Chapter 9, *Groundwater Resources*, the Merced Subbasin was extended for the analysis to include a part of the Chowchilla Subbasin.

The impacts of the LSJR alternatives on groundwater resources cannot be determined with certainty because groundwater conditions vary within each aquifer subbasin and water users would have varied responses to reduced surface water deliveries and any decrease in groundwater elevations. In addition SGMA, mentioned above, will improve groundwater management as it places a mandatory duty upon local agencies in high and medium priority groundwater basins, including those in the study area, to form groundwater sustainability agencies (GSAs) by June 30, 2017 and adopt and implement groundwater sustainability plans (GSPs) to sustainably manage groundwater resources.[3] Upon GSP adoption, SGMA grants the local GSA specific authorities to manage and protect its groundwater basin including, but not limited to, the ability to require reporting of groundwater withdrawals and to control groundwater extractions by regulating, limiting, or suspending extractions from wells. (Wat. Code, § 10726.4.) If a local agency is unwilling or unable to manage its groundwater resources to prevent undesirable results as defined under SGMA, which include but are not limited to chronic lowering of groundwater levels or migration of contamination, then SGMA empowers the state to provide interim management until local agencies are able to assume management. SGMA is discussed in more detail in Section 22.3, *Regulatory Background.*

22.2 Water Supply

This section summarizes the two major uses of water in the study area (Figure 9-1): irrigation and drinking water. This section focuses on drinking water supply from both surface water and groundwater, but also describes agricultural water use, mainly in the form of irrigation, to put competing water demands in the study area in context.

22.2.1 Water Use

Irrigation districts and water districts (collectively referred to as irrigation districts hereafter) supply water for multiple uses (i.e., agricultural, municipal and industrial) within the study area. They obtain water by either diverting surface water from the three eastside tributaries (Stanislaus, Tuolumne, and Merced Rivers), pumping groundwater from aquifers, or both. Irrigation districts primarily deliver water to a distribution system for crop irrigation. Although these districts serve primarily agricultural supplies, in some cases they also supply local municipalities through existing agreements. Additionally, these districts may also provide hydropower to their service areas. There are also individuals and entities in the study area that use domestic wells to meet their water needs, and riparian diverters that directly deliver water for crop irrigation. A summary of the irrigation district and riparian diversions from the LSJR tributaries is presented in Table 2-3.

A significant portion of California's water supply needs is met by groundwater. Typically, groundwater supplies about 30 percent of California's urban and agricultural uses. In dry years, groundwater use increases to about 40 percent statewide and 60 percent or more in some regions (DWR 2003a). In the San Joaquin River Hydrologic Region, groundwater contributed approximately 38 percent (3.2 million acre-feet [MAF]) to the 2005–2010 average annual total water supply.

---

[3] The Modesto and Turlock Subbasins are listed as high-priority basins, and the Eastern San Joaquin, Merced, and Chowchilla Subbasins are listed as high-priority and critically overdrafted basins. Plans for critically overdrafted basins subject to SGMA must be adopted by January 31, 2020. The deadline to adopt plans for all other basins subject to SGMA is January 31, 2022. See the Sustainable Groundwater Management Act discussion in Section 22.3, *Regulatory Background.*

Groundwater supplies, based on average annual estimates for 2005–2010, contribute 36 percent of the total agricultural water supply, 58 percent of the total urban water supply, and 38 percent of the total managed wetlands supply in the San Joaquin River Hydrologic Region (DWR 2015a).

Irrigation districts pump groundwater to supplement their water supply when surface water is in shortage. Many private growers who are not served by an irrigation district also pump groundwater to irrigate their crops. More than half of all land within the subbasins is irrigated agriculture, which is the largest user of groundwater. Many cities and towns in the study area also rely on groundwater either wholly or partially to for their drinking water supply.

While surface water is the major source of irrigation and provides significant contribution to groundwater recharge, groundwater levels in the San Joaquin Valley Groundwater Basin have generally declined as a result of extensive pumping. As discussed in Chapter 9, *Groundwater Resources*, the Modesto, Turlock, and Merced Subbasins have experienced varying degrees of overdraft and recharge conditions between 1970 and 2000. Each subbasin experienced a net overdraft condition between 1970 and 2000, as indicated by average declines in groundwater elevation of approximately 15, 7, and 30 feet (ft), respectively, with the eastern portion of the subbasins experiencing more severe overdraft (DWR 2003c, 2003d, 2003e). It is estimated that the groundwater storage in the Turlock Subbasin decreased by an average of 21.5 thousand acre-feet per year (TAF/y) during the period of 1997–2006 (TGBA 2008). The Eastern San Joaquin Subbasin has been in a consistent overdraft condition (approximately 1.7 ft/yr) for the same time period. It is estimated that the overdraft has reduced storage in the Eastern San Joaquin Subbasin by 2 MAF over a 40-year period (DWR 2003b), 50 TAF/y on average. According to a recent California Department of Water Resources (DWR) review, two of the four groundwater subbasins underlying the study area (Eastern San Joaquin and Merced) are critically overdrafted (DWR 2016). Groundwater pumping in the region continues to increase in response to growing demand and reduced surface water deliveries. Additional pumping in any of these subbasins could reduce the average groundwater level (i.e., drawdown), with a noticeable effect on groundwater levels over a number of years.

22.2.2 Water Quality

As discussed in Chapter 5, *Surface Hydrology and Water Quality*, surface water quality is very good in the three eastside tributaries,[4] with an average salinity (as measured by electrical conductivity [EC][5]) value of less than 0.1 deciSiemens per meter (dS/m) near the confluence with the San Joaquin River. The water quality of the Stanislaus, Tuolumne, and Merced Rivers is primarily affected by reservoir operations and agricultural return flow. EC generally increases as water moves downstream in all three rivers due to the relatively high EC in agricultural drainage and groundwater discharges to the river. Chloride, bromide, sulfate, and boron are specific ions that contribute to overall salinity and are constituents of concern. However, of these constituents of concern, in the plan area only boron is included on California's statewide list of impaired

---

[4] In this document, the term *three eastside tributaries* refers to the Stanislaus, Tuolumne, and Merced Rivers.

[5] In this document, EC is *electrical conductivity*, which is generally expressed in deciSiemens per meter (dS/m). Measurement of EC is a widely accepted indirect method to determine the salinity of water, which is the concentration of dissolved salts (often expressed in parts per thousand or parts per million). EC and salinity are therefore used interchangeably in this document.

waterbodies (303(d) list).[6] Boron and salinity can affect multiple beneficial uses, including the yield of crops that are sensitive to these constituents. Additionally, high EC values in source water may limit the ability to utilize recycled water. The presence of bromide in municipal water sources is also a concern because bromide is the precursor to the formation of harmful byproducts of the water disinfection process. However, there are no 303(d) listings for bromide. In addition, the Stanislaus, Tuolumne, and Merced Rivers are identified on the 303(d) list for constituents associated with agricultural uses, including pesticides (e.g., chlorpyrifos and diazinon), and temperature (State Water Board 2011).

As discussed in Chapter 9, *Groundwater Resources*, groundwater quality can be affected by many factors, both natural (e.g., substrate material) and anthropogenic (e.g., land use). Therefore, groundwater quality varies substantially throughout the San Joaquin Valley Groundwater Basin. In general, groundwater in the San Joaquin River Hydrologic Region is suitable for most urban and agricultural uses. Groundwater in shallower aquifers generally contains higher concentrations of anthropogenic contaminants, such as nitrates and pesticides, than in deeper aquifers (DWR 2015a). In addition to agricultural and industrial sources, trace elements (such as arsenic, manganese, vanadium and uranium) that naturally occur in rocks and soils can come in contact with the water and present water quality problems. See Chapter 13, *Service Providers*, for further information on quality of groundwater used as a drinking water source.

In general, municipal drinking water wells do not exceed federal and state maximum contaminant levels (MCLs). This is because municipal wells are generally deep, and water quality tends to be better in deeper aquifers. Furthermore, water quality is managed such that if drinking water standards are violated at a public well, the well will be brought offline and corrective actions will be taken to ensure the water will meet the MCL requirement before it is delivered the consumers. For example, dibromochloropropane (DBCP) was detected over the MCL at two of the City of Atwater's wells. Granular activated carbon filtering systems were installed on these water sources to remove the contaminant prior to introduction of water into the City's water system (City of Atwater 2015). The City of Livingston, located in the Merced Subbasin, recently improved filtration in order to reduce arsenic concentrations that were above the state MCL (Giwargis 2014).

Water quality in community water systems is frequently monitored by the State Water Board and the service providers pursuant to various regulatory requirements (discussed in Chapter 13, Section 13.3, *Regulatory Background*). Community water systems must provide annual drinking water quality reports, known as consumer confidence reports (CCRs), to their customers. Table 13-5 of Chapter 13 provides information from CCRs of select municipalities in the groundwater subbasins during representative non-drought and drought years.

Private drinking water wells may have more significant water quality issues than municipal wells because they are often shallower than municipal wells and, therefore, are more susceptible to surface contaminants. However, the State does not regulate the water quality of private drinking water wells, and does not require private drinking water well owners to test for water quality. As such, there is a lack of water quality data for private drinking water wells in the study area.

---

[6] Clean Water Act section 303(d) requires states, territories, and authorized tribes to develop a ranked list of water quality limited segments of rivers that do not meet water quality standards.

22.2.3 Municipal Water Use and the Current Drought

There are approximately 1.2 million people living in the four groundwater subbasins (U.S. Census Bureau 2010). Of this population, approximately 1.1 million people, or 89 percent, receive some portion of their water supply from a public water supplier (California Environmental Health Tracking Program 2016). The remaining 11 percent, equivalent to approximately 133,000 people, rely solely on domestic wells for their water supply. However, due to a lack of records, it is difficult to determine the actual number of people currently relying on domestic wells. Using 635,000 scanned well-completion reports provided by DWR in 2011, and based on a spatially distributed and randomized survey, Johnson and Belitz (2015) estimated that there are 37,386 domestic wells in the six counties that are within or intersect the study area (Table 22-1).

Ninety-three public water suppliers were identified within the four groundwater subbasins (California Environmental Health Tracking Program 2016; State Water Board 2016). Table 13-3a, in Chapter 13, *Service Providers*, lists those public water suppliers, the population served in 2014, and the reliance on groundwater supply (as a percentage of total water supply) in 2014. Many of these water suppliers rely solely or partially on groundwater for their water supply. In 2014, groundwater supplied 52 percent of the 91 public water suppliers’ total water production; the remaining 48 percent of the total water production came from surface water or recycled water. California’s current drought (2012–present) has left many public water suppliers struggling to deliver water to their customers and caused many domestic wells to go dry. The following are examples of public water supplier responses to ensure adequate water supplies during the drought.

Stockton East Water District (SEWD)

SEWD, a water wholesaler, used surface water solely between 2010 and 2014. During this time, SEWD had two inactive drinking water wells intended only for use as emergency or dry year supplies. In February, 2015, the U.S. Bureau of Reclamation (USBR) announced its zero initial water allocation for many agricultural users north and south of the Delta, including SEWD, which received zero percent of their contract quantity due to a lack of available Central Valley Project (CVP) supplies out of New Melones Reservoir (Martineau 2015). In response, SEWD reactivated the two wells, built a new well, and converted two old irrigation wells into drinking water wells in 2015. The changes were permitted by the State Water Board. SEWD now has five active wells, and uses both surface water and groundwater as its sources of water supply (Sahota pers. comm.).

Le Grand Community Service District

Le Grand Community Service District, which serves 1,700 people in Merced County, has three wells. In 2014, one well, which was drilled in 1966, collapsed due to its age, and another well had a valve failure With financial assistance from the State's Drought Emergency Fund, the district rehabilitated the two wells and was able to extract groundwater again. Repairing the wells alleviated the emergency situation; however, water shortages are still a problem. The third well capacity has dropped to 200 gallons per minute and requires new equipment to achieve its maximum production of 1,000 gallons per minute (Giwargis 2014; Chauhan pers. comm.). Furthermore, the District Superintendent, Richard Kilgore II, stated that the local water table (in the Merced Subbasin) was dropping fast (Giwargis 2014).

Plainsburg Elementary School

Plainsburg Elementary School, located near Le Grand, has one well. In 2014, the well went dry and was abandoned. With financial assistance from the State's Drought Emergency Fund, the school constructed a new, deeper well near the old well. The old well was approximately 250 ft deep and the new well is 600 ft deep (Chauhan pers. comm.).

22.2.4 Domestic Wells and Household Water Shortages

In general, public wells are deeper than domestic wells, because private entities do not have the resources to drill deep into the ground. Due to their shallower depth, under drought conditions, domestic wells tend to go dry before public wells. In California, water systems with fewer than 15 household connections, including individual household wells or water supplies, are regulated at the county level. Counties vary in their practices, but rarely do counties collect data regularly from these very small and individual household water supplies. Even where data is collected it is entirely voluntary. As the drought developed, local and state agencies began receiving anecdotal reports of household water shortages. In 2014, DWR led an effort to put these reports in a centralized database. Table 22-1 shows the cumulative numbers of well outages[7] reported to DWR between January 2014 and April 5, 2016 (DWR 2016), and the percentage of outages for each county that intersects the study area. Most reported outages are for wells that serve 1-2 households (Fencl pers. comm.).

Table 22-1. Number of Domestics Wells and Number of Well Outage Reported

County	Number of Domestic Wells	Number of Well Outage Reported[a]	% of Outage
Calaveras	4,873	1	0.02
Mariposa	5,276	172	3.3
Merced	6,209	160	2.6
San Joaquin	7,666	25	0.3
Stanislaus	8,980	227	2.5
Tuolumne	4,382	234	5.3
Total	37,386	819	2.2

22.3 Regulatory Background

This section discusses current and future regional or local program, policies, and regulations related to managing current and future water supplies. Regulations related to managing groundwater resources are in Chapter 9, *Groundwater Resources*; regulations related to service providers are in Chapter 13, *Service Providers*. Select regulations from these chapters are presented below.

---

[7] Outage means the well has gone completely dry, is experiencing very low flow, or has pump issues such that no water can be pumped out of the well.

22.3.1 Current Planning Efforts

It is the state's policy that every human being has the right to safe, clean, affordable, and accessible water adequate for human consumption, cooking, and sanitary purposes. (Wat. Code, § 106.3.) In addition, it is the state's policy that "groundwater resources be managed sustainably for long-term reliability and multiple economic, social, and environmental benefits for current and future beneficial uses" and that sustainable groundwater management "is best achieved locally through the development, implementation, and updating of plans and programs based on the best available science." (Wat. Code, § 113.) Referenced below are relevant state and regional policies and plans related to current planning efforts to ensure a reliable water supply in the future.

Sustainable Groundwater Management Act

As discussed in Section 22.1, *Introduction,* and Chapter 9, *Groundwater Resources*, SGMA provides the framework to implement the state's sustainable groundwater management policy by requiring that local agencies in high- and medium-priority basins[8] form GSAs by June 30, 2017 that will develop and implement GSPs that achieve sustainable groundwater management within 20 years. The four main groundwater basins in the plan area—the Eastern San Joaquin, Modesto, Turlock, and Merced subbasins—are all high-priority subbasins, as is the Chowchilla Subbasin. Basins in a critical condition of overdraft, including the Eastern San Joaquin, Merced, and Chowchilla Subbasins, must achieve sustainability by 2040; all other high- and medium-priority basins must achieve sustainability by 2042. Importantly, SGMA does not require GSP approval at the state level before a GSA can implement measures to protect groundwater resources. SGMA's management and enforcement powers attach upon adoption of a GSP by the local GSA.

SGMA is intended to promote coordinated management of a groundwater basin through GSA formation and requires GSAs to consider the interests of all beneficial uses and users of groundwater, including domestic well owners, municipal well operators, public water systems, disadvantaged communities, and tribes in developing and implementing a GSP. SGMA requires a GSP to provide for "the management and use of groundwater in a manner that can be maintained during the [50-year] planning and implementation horizon without causing 'undesirable results.'" (Wat. Code, § 10721 subd. (v).) *Undesirable results* include, but are not limited to:

- Chronic lowering of groundwater levels (not including overdraft during a drought if a basin is otherwise managed).
- Significant and unreasonable reduction of groundwater storage.
- Significant and unreasonable seawater intrusion.
- Significant and unreasonable degraded water quality, including the migration of contaminant plumes that impair water supplies.

---

[8] One hundred twenty-seven of California's 515 alluvial groundwater basins, which account for 96 percent of California's annual groundwater pumping, were identified as high- or medium-priority (DWR 2014). Prioritization factors include, but are not limited to, the level of population overlying the basin or subbasin, the projected rate of population growth for the basin or subbasin, the number of public supply wells dependent on the basin or subbasin, the irrigated acreage overlying the basin or subbasin, and the degree of reliance on groundwater (Wat. Code, § 10933, subd. (b).)

- Significant and unreasonable land subsidence that substantially interferes with surface land uses.
- Depletions of interconnected surface water that have significant and unreasonable adverse effects on beneficial uses of the surface water.

If local agencies are unwilling or unable to manage their groundwater resources, SGMA authorizes the State Water Board to step in to protect a groundwater basin in limited circumstances: (1) if no agency has opted by June 30, 2017 to serve as a GSA for a basin, (2) when a GSA does not complete a GSP by the relevant deadline (2020 or 2022), or (3) when the GSP is inadequate or the GSP is not being implemented in a manner that is likely to achieve the plan's sustainability goal(s), and the basin is either in a condition of long-term overdraft or, after January 31, 2025, the State Water Board determines that the basin is in a condition where groundwater extractions result in significant depletions of interconnected surface waters.

Integrated Regional Water Management Planning

Integrated Regional Water Management (IRWM) Planning is a collaborative stakeholder process that promotes sustainable water use. IRWM Planning identifies and implements water management efforts on a regional scale to ensure sustainable water uses, reliable water supplies, better water quality, efficient urban development, protection of agriculture, environmental stewardship, and a strong economy. IRWM plans (IRWMPs) acknowledge that regions have distinct identities and hydrologic and ecologic conditions, and that water supply reliability should be a primary water management objective to be considered in these integrated plans.

Urban Water Management Plans

The California Urban Water Management Planning Act (UWMPA) requires California's urban water suppliers[9] to initiate planning strategies to ensure the appropriate level of reliability in their water service to meet the needs of the various categories of customers during normal, dry, and multiple dry years. To do this, urban water suppliers must prepare an UWMP every 5 years. UWMPs serve as a resource for planners and policy makers over a 25-year planning time fame, and include information about groundwater and surface water supplies, historic and projected water use, recycled water, water use efficiency programs in a contracting water district's service area, and contingency planning for the possibility of water shortages.

2015 UWMPs (due to DWR by July 1, 2016) do not reflect new requirements for groundwater management under SGMA. However, DWR recommended that 2015 UWMPs include a discussion of current or planned activities to meet anticipated SGMA requirements (DWR 2016). 2010 UWMPs that are relevant to the irrigation districts and four subbasins are summarized in Table 9-11; 2010 UWMPs that are relevant to the urban water suppliers are summarized in Chapter 13, *Service Providers*. UWMPs vary in terms of water shortage management responses and implementation methods included.

---

[9] Urban water suppliers are defined as suppliers that have 3,000 or more water connections or provide over 3,000 acre-feet of water annually.

Water Shortage Contingency Plan

A reliable water supply is essential and its importance highlights the necessity to prepare for the possibility of drought. Contingency planning before a water shortage allows for a selection of appropriate responses consistent with the varying severity of shortages. To prepare for the possibility of water shortages, UWMPs include a Water Shortage Contingency Plan (WSCP). The WSCP enables the urban water supplier to provide water for public health and safety and minimize impacts on economic activity, environmental resources, and the region's economic health. Examples of priorities for use of available water include the following.

- Health and Safety – interior residential and firefighting.
- Commercial, Industrial, and Institutional – maintain economic base, protect jobs.
- Permanent Crops – takes 5 to 10 years to replace.
- Annual Crops – protect jobs.
- Landscaping – direct water to trees and shrubs.
- New Demand – typically, 2 years of construction projects that are already approved.

Several WSCPs have been developed in the counties that intersect the plan area. While WSCPs vary in terms of water shortage management responses and implementation methods included, all WSCPs include: (1) a description of the stages of action an agency will take in response to water shortages; (2) an estimate of supply for three consecutive years; (3) a plan for dealing with a catastrophic supply interruption; (4) a list of the prohibitions, penalties, and consumption reduction methods to be used; (5) an analysis of expected revenue effects of reduced sales during shortages and proposed measures to overcome those effects; and (6) how the supplier will monitor and document cutbacks.

Water Conservation Act of 2009 (Senate Bill X7-7)

SBX7-7, the water conservation bill passed as part of the 2009 Comprehensive Water Package, requires urban and agricultural water suppliers to increase water use efficiency. SBX7-7 requires urban water suppliers to achieve an interim goal of achieving at least a 10 percent reduction in per capita water usage by 2015 and a 20 percent reduction in per capita water usage by 2020. Additionally, all suppliers were required to determine baseline water use and set reduction targets according to specified requirements.

Several urban and agricultural water suppliers in the counties that intersect the plan area are required to report on progress towards the savings goal. Implementation methods and the level of savings achieved varies by supplier.

22.3.2 Managing Water Supplies under Reduced Water Availability Conditions

Emergency Urban Water Conservation

In April 2015, Governor Edmund G. Brown Jr issued Executive Order (EO) B-29-15, which called for a statewide 25 percent mandatory conservation by urban water suppliers in preparation for the possible continuation of the drought. In response to EO B-29-15, the State Water Board adopted

Resolution 2015-0032, which assigned each of the state's urban water suppliers a conservation standard that ranged between four percent and 36 percent, based on the supplier's residential gallons per capita per day (R-GPCD). The tiered conservation standards accounts for water conservation already achieved by communities based on relative per capita water usage. The compliance period for achieving the statewide mandatory 25 percent savings goal and supplier-specific conservation standards was June 2015 through February 2016. Water use for the same months during 2013 acted as the baseline for calculating water savings. In response to EO B-37-16, issued in May 2016, the State Water Board adopted a modified version of the emergency urban water conservation regulations, extending revised conservation standards through January 2017.

There are 15 urban water suppliers in the study area that were required to achieve water conservation standards for the compliance period. In response to reporting associated with mandatory statewide water conservation regulations, detailed per capita residential water use information is available for 15 water suppliers in the counties that intersect the study area. The residential water use reported by these 15 water suppliers accounted for, on average, approximately 68 percent of their total water production (172 thousand acre-feet [TAF] out of their total production of 253 TAF in 2013). During the compliance period (June 2015-February 2016), the 15 suppliers reported an average cumulative savings of 26 percent, as compared to the total water use for the same months in 2013, with individual supplier savings ranging from 8 to 42 percent (Table 22-2). While supplier success towards achieving their conservation standard varied, all 15 urban water suppliers reported reduced residential water use between 2013 and 2015/16. Average residential water use declined from 148 R-GPCD in 2013, to 106 R-GPCD during the 2015/16 compliance period. This decline represents an overall annual reduction of 47 TAF/y for these 15 water suppliers. If applied to all residential use in the plan area, this represents a potential reduction of 61 TAF/y.

22.3.3 Planning for Future Water Needs

Water is critical to future population and economic growth, and can also be the major limiting factor to growth. Planning for future water needs requires examining current demand and supply pressures, looking at trends within each, and promoting and implementing sustainable and efficient water management practices. However, water management does not happen in isolation. A coordinated, integrated approach is essential to ensure adequate water supplies for future needs. This is accomplished through urban planning (including city and county general plans, water master plans, recycled water master plans, integrated resources plans, IRWMPs, UWMPs, and groundwater management plans). New planning efforts are greatly enhanced when they rely upon the information found in all planning documents within their service area and neighboring service areas.

Meeting future water needs includes ensuring adequate supplies for projected urban population growth, current and future projects, and preparing for climate change impacts on water supplies and possible water shortages. As highlighted by the recent drought, the unreliable nature of municipal water supplies emphasizes the need for communities to develop and manage local resources through strategies such as water use efficiency and conservation, recycled water, and groundwater recharge.

Table 22-2. Urban Water Conservation and Residential Water Use

Urban Water Supplier	Principal County Served	Groundwater Subbasin	Groundwater Reliance in 2014 (%)	Population Served	% Cumulative Water Savings (Jun-15–Feb-16, compared to 2013)	Conservation Standard (Jun-15 – Feb-16; %)	Average R-GPCD (Jun-15 – Feb-16)	Average R-GPCD (Jan-Feb 2013)[a]

R-GPCD = Residential Gallons Per Capita Per Day

NA = Not Applicable

WSD = Water Service District

[a] 2013 R-GPCD is calculated using residential gallons and population from Jun-14 through Feb-15 reports.

[b] As described in Chapter 9, *Groundwater Resources*, the Extended Merced Subbasin includes a portion of the Chowchilla Subbasin.

[c] Based on Jun-15—Nov-15 monthly water conservation reports.

[d] Missing Aug-14 monthly water conservation report.

UWMPs provide a framework for long-term water planning and ensuring adequate water supplies for existing and future demands. These plans require urban water suppliers to coordinate with local planning agencies to assess future growth and related water demand growth. Planning for future water demands may be based on projected development, population growth, and expected future projects and programs during average, single-dry, and multi-dry years. Plans also need to include, to the extent practicable, a description of any constraints on the agency's water supply, such as inconsistent availability or water quality issues, that the water agency has identified, as well as the management strategies that have been, or will be, employed to address the constraint (DWR 2015b).

22.4 Impact Analysis

This section describes the potential impact the LSJR alternatives may have on drinking water supply.

22.4.1 Potential Impacts of LSJR Alternatives

Implementation of the LSJR alternatives would reduce surface water available for diversion. Table 22-3 shows the average annual surface water diversion in baseline and the expected reduction in each LSJR alternative relative to baseline. See Appendix F.1, *Hydrologic and Water Quality Modeling*, for a detailed description of the hydrologic modeling that produces this result.

Table 22-3. Average Annual Change in Surface Water Diversion Compared to Baseline in the Plan Area

River	Average Baseline SW Diversion (TAF/y)	Change in SW Diversion Relative to Baseline (TAF/y)		
		LSJR Alt 2	LSJR Alt 3	LSJR Alt 4
Stanislaus	637	-12	-79	-206
Tuolumne	851	-20	-119	-298
Merced	580	-33	-95	-185
Total	2,068	-65	-293	-689

SW = surface water
TAF/y = thousand acre-feet per year

As discussed in Chapter 9, *Groundwater Resources*, LSJR Alternative 2 would have a less-than-significant impact on groundwater as a resource, while LSJR Alternatives 3 and 4 would have significant and unavoidable impacts on groundwater as a resource. That is, under LSJR Alternatives 3 and 4, the average annual groundwater balance is expected to be reduced by more than the equivalent of 1 inch in three subbasins (Modesto, Turlock, and Extended Merced) and all four subbasins, respectively. Exceeding the 1-inch threshold would eventually result in a measurable decrease in groundwater elevations in the basins. Therefore, it is expected that LSJR Alternatives 3 and 4 would result in a substantial depletion of groundwater supplies or substantial interference with groundwater recharge.

As discussed in Chapter 13, *Service Providers*, under LSJR Alternative 2, there would not be a substantial reduction of surface water or a substantial depletion of groundwater supplies. Therefore, LSJR Alternative 2 would have a less-than-significant impact on service providers.

However, under other LSJR alternatives (Alternative 2 with adaptive implementation, and LSJR Alternatives 3 and 4 with and without adaptive implementation), there would be substantial reductions of surface water and depletion in groundwater supplies. For details of which subbasin and service providers would be impacted under each alternative, see Chapter 13. These LSJR alternatives would potentially require service providers to construct new water supply facilities or wastewater treatment facilities or expand existing facilities, the construction of which could cause significant environmental effects. In this regard, these alternatives would have a significant and unavoidable impact on the environment related to the construction of new or expanded facilities.

Furthermore, due to increased groundwater pumping as a result of implementation of LSJR Alternative 2 with adaptive implementation, and LSJR Alternatives 3 and 4 with and without adaptive implementation, the quality of groundwater as a source of drinking water in the study area could potentially be degraded. However, a substantial increase in groundwater pumping would not necessarily result in an increase in violations of drinking water quality standards. During the recent drought, the amount of groundwater pumped for drinking purposes and the service providers' reliance on groundwater greatly increased and yet there was not a greater number of MCL violations as compared to a wet year based on CCRs prepared by the service providers (Table 13-5). In addition, public water systems are regulated by the state; if a drinking water quality problem is detected, the service provider would have to take corrective actions to ensure that the water is in compliance with relevant drinking water standards before it is served to the public. Therefore, under these alternatives, it is not expected that the quality of groundwater used for public water systems would be affected such that violations of water quality standards would occur. Accordingly, impacts would be less than significant.

In contrast to drinking water served by public water systems, LSJR Alternative 2 with adaptive implementation, and LSJR Alternatives 3 and 4 with and without adaptive implementation may result in the use of contaminated groundwater for drinking water by domestic wells. While it is true that pumping greatly increased during the drought and yet there was not a greater number of MCL violations as compared to a wet year based on CCRs provided by service providers, there is a lack of information to support that this was also the case for private domestic wells. In addition, domestic well users are largely unregulated and are under no state requirements to monitor, test, and treat their water to meet the state and federal Safe Drinking Water Act (discussed in Chapter 13, Section 13.3, *Regulatory Background*). Therefore, there is no required mechanism to prevent private domestic wells from using groundwater that exceeds MCLs. Thus, under these alternatives, there is a potential for the quality of groundwater used in private domestic wells to be affected such that violations of water quality standards would occur. Accordingly, impacts would be significant.

Groundwater Pumping

Pumping within each irrigation district typically increases in dry years when surface water availability is reduced. Therefore, it is expected that, if surface water availability is reduced due to the LSJR alternatives, irrigation districts will respond by increasing groundwater pumping to compensate for a portion of the reduced surface water diversions. In the short-term, the amount of pumping would be limited by the existing capacity of the pumping facilities. However, in the long-term, irrigation districts might respond by deepening their wells or building more wells.

Public water suppliers are also expected to turn to groundwater to compensate for the loss of surface water available to them before additional water treatment or water recycle facilities are commissioned. The cities and communities that currently rely partially on groundwater would have to rely more heavily on groundwater. Such an increase in groundwater reliance will exacerbate the problem of declining groundwater level. The cities and communities that currently solely rely on groundwater might find their groundwater levels reduced and face the increased risk of wells going dry. They might have to deepen their wells or construct new wells to obtain the same groundwater production they currently have.

Dry well issues would affect both domestic and public supply wells. However, domestic wells, which are usually shallower than public wells, would be more likely to be affected by declining groundwater level than public wells. Additionally, because private well owners typically have fewer resources to deepen or construct new wells than public water suppliers, private well owners are likely to be more severely impacted by LSJR alternatives than public water suppliers. There could be more cases of dry wells or more well outages reported, as mentioned in Section 22.2, *Water Supply*.

Table 22-4 shows the expected annual increase of groundwater pumping relative to baseline in each of the LSJR alternatives assuming maximum groundwater pumping based on 2009 infrastructure. Average annual groundwater pumping for agricultural and residential uses by all entities (in and out of districts) in the study area is 2,038 TAF/y in baseline, and it is expected to increase by 23 TAF/y, 109 TAF/y and 224 TAF/y under LSJR Alternatives 2, 3, and 4 respectively.

Table 22-4. Estimated Effect of LSJR Alternatives on Average Annual Groundwater Pumping in the Study Area (Assuming Maximum Groundwater Pumping Based on 2009 Infrastructure)

GW Subbasin	Average Baseline GW Pumping (TAF/y)[a]	Average Change in GW Pumping Relative to Baseline (TAF/y)[b] LSJR Alt 2	LSJR Alt 3	LSJR Alt 4
Eastern San Joaquin	705	-4	23	69
Modesto	191	1	8	15
Turlock	507	2	16	30
Merced	635	23	61	110
Total	2,038	23	109	224

GW = groundwater

TAF/y = thousand acre-feet per year

[a] The average baseline pumping numbers are larger than those presented in Table G.3-3 because the numbers here are estimated for both in-district and out-of-district irrigation, but the numbers in Table G.3-3 are for in-district irrigation only.

A reduction in surface water supply would also affect the groundwater aquifer by simultaneously causing a reduction in groundwater recharge (due to a reduction in conveyance losses from the distribution system and in deep percolation from irrigated fields). Table 22-5 shows the expected annual net change in groundwater balance due to the surface water reduction under the LSJR alternatives. The groundwater balance for each subbasin is calculated as the sum of off-stream reservoir seepage, conveyance losses, and deep percolation from irrigation, minus total groundwater pumping. These components are not all of the inflows and outflows in a groundwater balance model. They are the only inflows and outflows that would be changed under the LSJR alternatives. Other inflows and outflows (such as infiltration from precipitation, recharge from out-of-district irrigated land, and net flux from/to the stream channels) are not included because they are assumed to remain unchanged in the alternatives. The total groundwater balance for the four subbasins in baseline is -994 TAF/y (positive means net recharge and negative means net pumping).

However, this is an over estimate and should not be used as an estimate of the overdraft in the four subbasins, because this groundwater balance does not take into account all components needed for a complete groundwater balance model. The key information is the difference in the groundwater balance between the baseline and the LSJR alternatives as shown in Table 22-5. The groundwater balance is expected to increase by 41, 186 and 411 TAF/y under LSRJ Alternatives 2, 3 and 4 respectively. As previously discussed in Section 22.2, the four groundwater subbasins underlying the study area have experienced varying degrees of overdraft. Increases in pumping due to the LSJR alternatives would exacerbate this problem.

Table 22-5. Estimated Effect of LSJR Alternatives on Average Annual Groundwater Pumping in the Study Area

	Average Change in GW Balance Relative to Baseline (TAF/y)		
GW Subbasin	LSJR Alt 2	LSJR Alt 3	LSJR Alt 4
Eastern San Joaquin	2	-36	-101
Modesto	-6	-25	-57
Turlock	-7	-43	-100
Merced	-30	-82	-152
Total	-41	-186	-411

Note: Positive values mean increase in net recharge; negative values mean increase in net pumping.

GW = groundwater

TAF/y = thousand acre-feet per year

As previously discussed in Section 22.2, groundwater overdraft in the Eastern San Joaquin Subbasin has been estimated to be 50 TAF/y (DWR 2003a) and groundwater storage in the Turlock Subbasin decreased by an average of 21.5 TAF/y (TGBA 2008). These numbers suggest a mean annual rate of groundwater overdraft of approximately 72 TAF/y for the combined Eastern San Joaquin and Turlock Subbasins. The current rate of overdraft in the Merced and Modesto Subbasins is not known, but if a similar combined rate of overdraft is assumed, the current rate of groundwater overdraft is approximately 144 TAF/y (2 x 72) in the subbasins. The 186 TAF/y increase in overdraft under LSJR Alternative 3 would slightly more than double this rate of overdraft to 330 TAF/y (144+186).

It is extremely difficult to provide perspective on the implications of these groundwater overdraft. The numbers beg the question of how long such levels of overdraft can be sustained. Estimates of groundwater storage made in the 1960s suggest that total aquifer storage in the four subbasins is on the order of 125 MAF (Williamson et al. 1989). This suggests that the current assumed rate of overdraft of 144 TAF/y represents approximately 0.12 percent of the total storage. The rate of overdraft under LSJR Alternative 3, 330 TAF/y, represents 0.26 percent of the total storage. These low percentages of total storage should not be taken to mean that these rates of groundwater overdraft do not pose a long-term problem with regard to sustainability. A number of other factors should be considered to make estimates and determinations of sustainability, including:

- It is difficult to quantify groundwater storage for a particular basin and essential data to make an accurate estimate are lacking (Faunt 2009). Even in basins where many studies have been completed, there are still many unknowns and conflicting findings.

- The estimates of storage in Williamson et al. (1989) are based on data collected in the 1960s and may not reflect current storage. No comprehensive estimate of groundwater storage for the four groundwater subbasins has been undertaken since 1961.
- These numbers assume that there is no groundwater movement between adjacent subbasins, and no changes in groundwater-surface water interactions.
- It is impossible to remove all water from storage by pumping. The deeper the well, the more difficult and expensive is it to drill and extract groundwater. At some point, it becomes economically infeasible to drill deeper.
- There will be very large associated effects, including subsidence and loss of recharge capacity, that occur long before all water in an aquifer could be removed.

This means that actions are needed now to address groundwater overdraft in this area, with or without the LSJR alternatives. This highlights the importance of implementing SGMA in areas in which there is already significant groundwater overdraft. This analysis also suggests that the timelines provided under SGMA afford sufficient time for water users in the plan area to develop and implement groundwater sustainability plans.

Groundwater Quality

As discussed in Chapter 9, *Groundwater Resources*, substantial additional groundwater pumping and reduction in groundwater level could occur in the subbasins under LSJR Alternative 2 with adaptive implementation, and LSJR Alternatives 3 and 4 with and without adaptive implementation. Lowering the groundwater table could alter the direction and rate of the groundwater flow and create a hydraulic gradient between the well and surrounding saturated zone. This could potentially accelerate migration of surface contaminants to the well, cause saline water intrusion to the aquifer, mobilize naturally-occurring trace elements in the substrate, and elevate their concentrations in the aquifer (see Chapter 13, *Service Providers*, for a discussion of these processes).

However, the impact of groundwater pumping on groundwater quality depends on a number of different variables including, but not limited to, location and depth of the well, the amount of groundwater pumped and the frequency at which pumping occurs, number and proximity of nearby wells, hydrogeological characteristics of the aquifer, distance between the well and the contaminant(s), contaminant characteristics (e.g., highly mobile in water or adhering primarily to soil), and land use near the well. In addition, it is not possible to predict how the affected parties would respond to the reduction of surface water due to the LSJR alternatives. They may deepen existing wells or build new wells. If they build new wells, it is impossible to determine the number of new wells and their location. Thus while groundwater pumping can affect groundwater flow and quality, for all of the foregoing reasons, it is speculative to determine what that change in groundwater flow and its impact on groundwater quality would be from increased groundwater pumping.

The reduction in surface water supply would therefore affect entities that rely upon groundwater as their principal source of drinking water by: (1) increasing the need to deepen their wells or construct more wells to continue to access groundwater, (2) increasing groundwater pumping costs, (3) degrading groundwater quality, and (4) making groundwater unavailable in some areas in the long term as the groundwater level drops to a level that makes groundwater no longer accessible economically.

If LSJR Alternative 2 with adaptive implementation is implemented in a long term, or LSJR Alternatives 3 or 4 with and without adaptive implementation is implemented, it is expected that service providers relying on surface water supplies may need to find alternative supplies (e.g., groundwater). This could result in a potential degradation in groundwater quality and could impact those service providers (see Tables 13-3a and 13-3b in Chapter 13) and domestic well users relying on groundwater as source of drinking water.

However, a substantial increase in groundwater pumping would not necessarily result in contamination of groundwater used for drinking water for several reasons as described below.

1. During the recent drought, the amount of groundwater pumped for drinking purposes and the service providers' reliance on groundwater greatly increased and yet there was not a greater number of MCL violations as compared to a wet year based on the CCRs prepared by the service providers (Table 13-5 in Chapter 13).
2. While drinking water quality standard exceedances have been detected at the wellhead in different locations in the area of potential effects, these exceedances reflect raw, untreated groundwater quality. Service providers would have to take actions to ensure that the water is in compliance with relevant drinking water standards before it is served to the public. Such actions include monitoring groundwater quality regularly, and if any exceedances are detected, bringing the well offline until the problem is rectified (Chapter 13, Section 13.3, *Regulatory Background*). Treatment options include blending, large-scale treatment systems, wellhead treatment systems, or Point-of-Use/Point-of-Entry water treatment systems used in homes or residences.
3. While increased groundwater pumping may expedite the migration of contaminants introduced at the land surface into the water table and flow towards the well, the effect would be localized, i.e., at the well (see Chapter 13, Section 13.2, *Environmental Setting*). Hence, it would be unlikely that such contamination would spread to other parts of the aquifer.

Therefore, under LSJR Alternative 2 with adaptive implementation, and LSJR Alternative 3 and 4 with and without adaptive implementation, it is not expected that the quality of groundwater used for public water systems would be affected such that violations of water quality standards would occur. Accordingly, impacts would be less than significant.

An additional factor that would keep this impact less than significant is that SGMA would provide controls on the degradation of groundwater quality. As discussed in Section 22.3.1, *Current Planning Efforts*, under SGMA, local agencies in high- and medium-priority basins are required to form groundwater sustainability agencies by June 30, 2017, that will develop and implement GSPs that achieve sustainable groundwater management within 20 years. Sustainable groundwater management includes not causing chronic lowering of groundwater levels and significant and unreasonable degradation of water quality, including the migration of contaminant plumes that impair water supplies. GSPs must be adopted by January 31, 2020, for Eastern San Joaquin and Merced Subbasins. GSPs for Modest and Turlock Subbasins must be adopted by January 31, 2022. Upon GSP adoption, SGMA grants the local GSA specific authorities to manage and protect its groundwater basin including, but not limited to, the ability to require reporting of groundwater withdrawals and to control groundwater extractions by regulating, limiting, or suspending extractions from wells. If a local agency is unwilling or unable to manage its groundwater resources to prevent undesirable results as defined under the SGMA, which include but are not limited to chronic lowering of groundwater levels or migration of contamination, then SGMA empowers the state to provide interim management until local agencies are able to assume management.

Thus, under SGMA, groundwater subbasins will be managed both in terms of over-pumping and groundwater quality degradation from migrating contaminant plumes.

In contrast to drinking water served by public water systems, a substantial increase in groundwater pumping and decrease in groundwater levels may result in contamination of groundwater used for drinking water by private domestic wells under LJSR Alternative 2 with adaptive implementation, and LSJR Alternatives 3 and 4 with and without adaptive implementation. While it is true that pumping greatly increased during the drought and yet there was not a greater number of MCL violations as compared to a wet year as reported by service providers, there is a lack of information to support that this was also the case for private domestic wells. Importantly, private domestic well users are largely unregulated and are under no state requirements to monitor, test, and treat their water to meet the state and federal Safe Drinking Water Act. Therefore, there is no required mechanism to prevent private domestic wells from using groundwaters that may exceed MCLs.

Therefore, under LSJR Alternative 2 with adaptive implementation, and LSJR Alternatives 3 and 4 with and without adaptive implementation, there is a potential for the quality of groundwater used in private domestic wells to be affected such that violations of water quality standards would occur. Accordingly, impacts would be significant.

The State Water Board does not have authority to require implementation of mitigation that could reduce this impact to a less-than-significant level, because it does not regulate private domestic wells. It can and does assist in identifying water quality threats through the Groundwater Ambient Monitoring and Assessment (GAMA) Program, the Board’s comprehensive groundwater quality monitoring program for California, and GeoTracker GAMA, which provides water quality data in California via the internet. For example, using the publicly available data collected in GAMA since 2000, State Water Board provides an online, map-based, tool, called “Is My Property Near a Nitrate-Impacted Water Well?,” which domestic owners can use to evaluate the risk of nitrate contamination to their well. The tool can be accessed at http://www.waterboards.ca.gov/water_issues/programs/nitrate_project/nitrate_tool/.

Possible mitigation measures owners and operators of private domestic wells should undertake to avoid or reduce potential drinking water impacts at private domestic wells include the following.

- Having a licensed contractor construct wells in accordance with well construction standards.
- Choosing a location for a well to make sure it is free of potential sources of contamination.
- Testing well water at certified drinking water laboratories to ensure its quality.
- Installing, if necessary, a water treatment system tailored to the overall water chemistry and constituents that need to be removed. Example systems include activated alumina filters, activated charcoal filters, air stripping, anion exchange, and ultraviolet radiation.
- Drilling, if necessary, a new well that taps into a cleaner aquifer or finding an alternative water source.
- Destroying properly of unused and abandoned wells to prevent contamination.

In addition, local agencies can and should exercise their police powers and groundwater management authority under SGMA, described above, to address groundwater contamination so as to prevent and/or mitigate drinking water impacts on private domestic wells. Specifically, under SGMA, local agencies in high- and medium-priority basins must form GSAs by June 30, 2017, that will develop and implement GSPs that achieve sustainable groundwater management within

20 years. Each GSP must also include measureable objectives as well as milestones in increments of 5 years, to achieve the sustainability goal in the basin within 20 years of the implementation of the plan. (Wat. Code, § 10727.2.) If local agencies are unwilling or unable to manage their groundwater resources, SGMA authorizes the State Water Board to step in to protect a groundwater basin, as discussed above.

Thus, at this time, local agencies are vested with the mandatory duty to achieve sustainable groundwater management, which includes preventing significant and unreasonable degradation to water quality. These agencies, therefore, can and should exercise their full authorities to address degradation of groundwater quality, both under SGMA and their police powers. Doing so would prevent and/or mitigate private domestic well drinking water supply impacts. Due to inherent uncertainty in the degree to which this mitigation and those listed above may be implemented by local agencies and owners and operators of private domestic wells, drinking water impacts on private domestic wells under LSJR Alternative 2 with adaptive implementation, and LJSR Alternatives 3 and 4 with and without adaptive implementation would remain significant and unavoidable.

22.4.2 Potential Impacts on Public Health

All Californians have a right to safe, clean, affordable, and accessible water adequate for human consumption, cooking, and sanitary purposes. Safe water is necessary for public health and community prosperity. The reduction in surface water supply could affect all entities that rely upon groundwater as a partial or primary source of drinking water, including end-users of municipal and public water systems, DACs, domestic well owners, and schools. The public health impacts associated with the LSJR alternatives on groundwater resources cannot be determined with certainty because groundwater conditions vary within each groundwater subbasin, and water users would have varied responses to reduced water deliveries. Communities and individuals will be affected differently by reduced water supply conditions, depending on several variables, including the following.

- Structure and capacity of existing water system.
- Economic development.
- At-risk populations living within the affected area.
- Local governance of water use.
- Other societal factors, such as the presence of local social networks.

Reduction in potable water supplies could results in directly observable and measurable health effects, such as compromised quality or quantity of potable water, diminished living conditions pertaining to sanitation and hygiene in the short term. Other, long-term chronic impacts, such as increased risk of mental or behavioral health issues, such as anxiety and other conditions and disorders (especially among persons who rely on water for their economic survival), increased risk to vulnerable people (e.g., persons suffering from chronic health conditions or immune disorders), and increased disease incidence for infections, chronic, and vector borne or zoonotic diseases are not always easy to anticipate or monitor (CDC et al. 2010).

The analysis of the plan amendment's[10] potentially significant impacts on service providers is in Chapter 13, *Service Providers*. That analysis includes an examination of whether implementation of the LSJR alternatives would lead to drinking water that exceeds standards and the potential for service providers to have to construct new or expanded facilities due to water quality or issues associated with reduced surface water diversions (i.e., reduced water supply). This section moves beyond the Chapter 13 analysis of impacts on service providers and to the environment, and discusses the potential public health impacts on various water users. Implementation of the LSJR alternatives may have some public health impact, with potential public health impacts increasing as the percent unimpaired flow[11] increases. Thus, as LSJR Alterative 2 would have the lowest percentage of unimpaired flow (at 20 percent), it would have the lowest impact on municipal and domestic water supplies, and therefore the least potential impact on public health. The risk of potential public health impacts would increase with LSJR Alternatives 3 and 4. However, because water supply conditions vary by service providers, and because service providers and end users would have varied responses to reduced surface water deliveries, the impacts of the LSJR alternatives on public health cannot be determined with certainty.

The following sections discuss potential public health impacts that specific water users could experience under the LSJR alternatives.

Municipalities and Public Water Systems

Under reduced surface water supply conditions, such as those associated with the LSJR alternatives, California's reliance on groundwater increases, which in turn increases groundwater pumping and lowers groundwater levels. In addition to potentially resulting in reduced groundwater levels, increasing pumping also raises the risk of groundwater contaminant transport and public supply wells going dry, both of which impact water supplies and pose a potential public health threat to public water systems. Contaminated groundwater requires additional treatment and could pose a threat for water systems that could not afford additional treatment to remove contaminants from groundwater prior to serving it to customers. Additionally, lowering groundwater levels may require suppliers to deepen existing wells or construct new wells to ensure adequate groundwater supplies, which could result in higher costs for ratepayers and consumers. As mentioned above, impacts on public health would vary by public water supplier, based on local groundwater contaminants, the system's reliance on groundwater, and groundwater resource management. However, while the LSJR alternatives could have public health impacts, public water systems are required to prepare for reduced water supply scenarios, including reducing or preventing public health impacts.

Disadvantaged Communities

Potential public health impacts associated with the LSJR alternatives are similar to those discussed under Municipalities and Public Water Systems. However, as highlighted during the recent drought, the effects of reduced surface water supplies are not felt by communities equally. In California,

---

[10] These plan amendments are the *project* as defined in State CEQA Guidelines, Section 15378.

[11] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.

communities of color and low-income people living in tribal, rural, and farming communities often disproportionately experience impacts on drinking water supplies. While the public water systems serving DACs are still required to maintain essential public health and resources, public water systems serving DACs are less likely to have the resources to adequately respond to water supply or water quality emergencies.

As discussed above, responding to contaminated or reduced groundwater resources is expensive. The systems serving DACs are more likely to have a difficult time responding to impacts on their water supply because they lack the infrastructure and financing that exists for the water systems serving more affluent communities, which may make them unable to afford treating or finding alternative supplies for a contaminated drinking water source. As a result, DACs may be more vulnerable than other municipalities and cities to impacts associated with the LSJR alternatives.

Domestic Well Users

As discussed earlier in this chapter and in Chapter 9, *Groundwater Resources*, due to their shallower depths, domestic wells are more susceptible to the impacts associated with the LSJR alternatives—such as groundwater contaminant transfer and dry wells—than public water systems wells. Additionally, domestic well owners lack the resources of public water systems to respond to reduced drinking water supplies. Domestic well users represent a small percentage of water users within the four groundwater subbasins, which means that potential public health impacts are more likely to occur as isolated cases. However, given their limited resources, it is possible that individual users would experience more significant impacts than would be experienced by a public water system under the same supply reductions. Given the lack of data regarding both the exact number of domestic well users and the groundwater quality of domestic wells, it is not possible to assess the potential public health impacts on domestic well users.

Schools

With students typically spending at least six hours at school each day, ensuring safe, clean drinking water at schools is an important factor in contributing to overall good health. Like the other water users discussed above, public health impacts associated with the LSJR alternatives will vary by school. However, because schools receive water from either a public water system or a private well, the potential public health impacts would be similar to those impacts discussed in the sections above.

22.4.3 Costs of Potential Management Options

As discussed previously, service providers could respond to reduced surface water supplies associated with LSJR alternatives by deepening their wells and constructing more wells. Additionally, service providers could reduce overall water use by implementing water efficiency and conservation programs, create alternative water supplies through groundwater recharge programs and recycled water programs, or purchase water from other agencies. Domestic well owners might deepen their wells or construct new wells. This section describes potential actions affected entities could take to replace surface water that may be reduced due to implementing the LSJR alternatives. Such actions include the following.

- Substitute groundwater for surface water by deepening wells and constructing more wells – The costs of well projects can vary substantially depending on the geology of the well location, well depth and diameter, well type, pump efficiency, level of water treatment required, size of the distribution system, and cost of electricity and staff needed to maintain equipment and facilities. Table 22-6 shows the two well projects that were funded by the State Water Board. As shown in the table, the cost ranged widely among the projects. One of the dominant cost categories in the operations and maintenance budget for groundwater wells is the cost for electricity. Based on information presented in Chapter 16, *Evaluation of Other Indirect and Additional Actions,* it can reasonably be estimated that groundwater pumping electrical costs in the plan area are between \$57.36 and \$76.48/AF. According to Flex Your Power (2012), energy costs may represent 50–75 percent of a water utility's budget. Using the upper end electricity cost calculated above (\$76.48/AF), it can reasonably be estimated that annual total operations and maintenance cost of a groundwater project would be between \$101.97–\$152.96/AF.

- Purchase water from parties that have extra water through contracts or transfers – The duration and cost for purchasing water are subject to many factors. A short-term transfer is a transfer of 1 year or less; a long-term transfer is a transfer longer than 1 year. A water transfer may change the place of use, the point(s) of diversion, or the purpose of use. A water transfer cannot increase the amount of water a diverter is permitted to use, nor can it change the season when water is diverted. According to USBR (2006), average costs for a short-term water transfer is \$1,716/AF and \$310/AF for a long-term water transfer.
- Recharge groundwater basins – Recharging groundwater basins by storing "extra" available surface water in the aquifer allows it to be extracted for use later, when the water would otherwise be unavailable. This process is known as aquifer storage and recovery (ASR), which typically includes: (1) gravity recharge basins or injection wells that move water under pressure from the surface to an underground aquifer, and (2) wells that pump groundwater from the aquifer and send the water to an existing treatment plant or directly into a distribution system for use. The costs of ASR projects are highly variable and depend on many factors. Table 16-8 identifies recently funded groundwater recharge projects. Annual costs are typically between \$158 and \$238/AF; this includes planning, design, permitting, land acquisition/rights of way, construction, and administrative costs, in 2010 dollars (DWR 2012).
- Use recycled water – Recycled water is wastewater that has been treated to a desired water quality standard, and then distributed and used for another purpose. Typically, recycled water costs less than potable water because it does not need to meet the same water quality standards. For example, cities and municipalities could offset potable water by using recycled water to irrigate parks, golf courses, gardens and other landscaping areas, and agricultural fields. Thus more potable water could be made available for municipal uses. The complexity and cost of a recycled water project depends on many factors, such as the level of treatment needed, the desired water quality for the secondary beneficial use, and the distance between the treatment location and the use location. Recycling wastewater for landscape and agricultural irrigation typically costs between \$400-\$2,100/AF, including capital, treatment, operations, and maintenance costs (WRF 2011). With advanced treatment technology, recycled water could also be used to replace potable water for domestic use. Direct potable reuse is practiced in areas where supply water is extremely scarce, such as Singapore and Namibia (WRF 2011). Direct potable reuse of recycled water typically costs \$700–\$1,200/AF, including capital, treatment, operations, and maintenance (WRF 2011). Recycled water can be used by the commercial, institutional, or industrial sector as process water. For example, cooling towers at power plants could use recycled water to offset the need for potable water. Water quality required for process

water is similar to that for potable water. Process water recycling projects typically cost the same as direct potable reuse projects due to the need for higher water quality.

The cost of each of these options is summarized in Table 22-7. See Chapter 16, *Evaluation of Other Indirect and Additional Actions,* for more information on these potential substitution options.

Table 22-6. Example New Groundwater Well Projects Funded by the State

Applicant	Project	Construction Cost ($)	Production Capability (AFY)	Depth (ft)	Cost per foot of depth ($)
City of Ceres	Replacement of well due to uranium and nitrate contamination	155,598 [a]	1,936	324	480
Plainsburg Elementary School	New water supply well	165,000 [b]	242	600	275

Source: Orellana pers. comm.

[a] Well is equipped with a 100 horsepower submersible pump. It is unclear whether the cost of distribution pipelines is included.

[b] This cost includes the cost of the labor and equipment to drill and install well casing to 600 feet, installation of a submersible pump, pressure tank and electrical system, E-log, potholing for existing utilities, water for drilling, access to the job site as well as a survey.

Table 22-7. Costs of Potential Management Options

Option	Cost ($)
Deepen existing wells	Variable, range between $15–$50/foot
Construct new wells	Highly variable (Table 22-6) Operations and maintenance (O&M) annual costs range between $101.97–$152.96/AF
Purchase water from another party (short-term water transfer)	$1,716/AF on average
Purchase water from another party (long-term water transfer)	$310/AF on average
Treat recycled water	$400–$2,100/AF for irrigation including capital and O&M costs (WRF 2011) $700–$1,200/AF for direct portable reuse and process water, including capital and O&M costs (WRF 2011)
Aquifer storage and recovery (ASR) projects	Highly variable (see Table 16-8), depends on the scale of the project and the level of O&M required

22.5 Assistance Programs

Sustainable water supply solutions must strike a balance between the need to provide for public health and safety (e.g., safe drinking water, clean rivers and beaches, flood protection), protect the environment, and ensure a stable California economy. There are many state, county, and local assistance programs available that may be leveraged to support and improve water supplier planning and supply efforts. This section highlights select State Water Board programs that provide financial and technical assistance to agencies for implementing water supply and quality projects.

22.5.1 Financial Assistance

There are many state and federal financial assistance programs designed to assist public water systems. Over the last 15 years, four major state public funding sources have been made available for public drinking water or water quality improvement projects: Proposition 50, Proposition 84, the Drinking Water State Revolving Fund (DWSRF), and Proposition 1. Often, these funding programs leverage each other to make a project more feasible. A brief description of some applicable funding programs is included in Chapter 16, Section 16.5, *Sources of Funding*.

The State Water Board works with local, state, and federal partners to provide financial assistance to at-risk drinking water systems. This includes a broad range of funding sources for new wells, interties, and emergency drinking water supplies. Through propositions 50 and 84, the State Water Board has provided funding for projects intended to improve water security, as well as infrastructure improvement and groundwater quality projects, and emergency and urgent funding for projects that ensure safe drinking water supplies. The DWSRF continues to provide funding assistance to public water systems for infrastructure improvements to correct public water system deficiencies that pose public health risks and improve drinking water quality, or both.

The passing of Proposition 1 expanded upon existing funding programs, making an additional $260 million available for the DWSRF projects. Proposition 1 also provided $260 million to the Small Community Grant Fund to provide financial assistance to small communities (i.e., population of 20,000 persons, or less) for the planning, design, and construction of publicly owned wastewater treatment and collection facilities. Proposition 1 provided $800 million for projects intended to prevent and clean-up contamination of groundwater that serves (or has served) as a source of drinking water. Additionally, Proposition 1 provided $625 million for water recycling projects and $200 million for storm water projects that will improve regional water supply resiliency.

During the recent drought emergency, the State Water Board made $19 million in funding available to meet interim emergency drinking water needs for those communities, including DACs, with a contaminated water supply or that suffered drought-related water outages or threatened outages (State Water Board 2016). The State Water Board's Drought Response Outreach Program for Schools (DROPS) made $30.2 million in funding available to schools to encourage water conservation education and projects. DROPS provides grants to school districts to create opportunities for storm water retention and reuse, and to raise awareness of sustainability. All DROPS-funded projects include an educational and outreach element to increase student and public awareness of water conservation.

Many financial assistance programs include additional assistance for eligible DACs. During the recent drought, many county and non-profit programs have provided financial assistance to communities with impacted drinking water supplies.

22.5.2 Technical Assistance

Complying with state and federal drinking water regulations is essential for protecting public health and ensuring safe drinking water. There are many technical assistance programs designed to assist agencies implementing water supply and water quality projects. These programs are designed to ensure access to a safe, clean, and affordable water supplies and maintain compliance with all applicable water laws and regulation. The State is committed to identifying and monitoring the status of drought-vulnerable public water systems to help prevent or mitigate any anticipated shortfalls in supply and to secure alternative sources of water for the communities when needed. In 2013, the State Water Board released a report that identified communities relying on a contaminated groundwater source for drinking water (State Water Board 2013). The state also works with local governments and agencies to identify drought-vulnerable areas served by domestic wells and collaborate to prevent or mitigate any anticipated shortfalls.

The State Water Board provides technical assistance to DACs and at-risk drinking water systems and works with the water systems to identify potential solutions. State technical assistance programs provide help with: preparing financial assistance applications; performing compliance audits; reviewing proposed projects alternatives; planning and preparing budgets; and performing community outreach, awareness, and education. DWSRF and Proposition 1 eligible projects can assist publicly owned water systems (e.g., counties, cities, districts), privately owned community water systems (e.g., for-profit water utilities, non-profit mutual water companies), and non-profit or publicly owned non-community water systems (e.g., public school districts) with the planning/design and construction of drinking water infrastructure projects that will improve the community's water efficiency and ensure a drought-resilient water supply. Potential solutions include, but are not limited to, stringent conservation measures, interconnections with other water systems (i.e., consolidation), development of new water sources, expansion of existing sources (e.g., deepen wells, extend reservoir intakes), and treatment of sources that produce water that does not meeting drinking water quality standards. Locally-implemented cost-effective and technically feasible strategies such as urban and agricultural water conservation and efficiency, water reuse and recycling, and storm water capture. Triggers and responses are developed and implemented at the local level.

Sometimes, the best solution for ensuring a safe drinking water supply is for a small, failing water system to join a larger public water system. Senate Bill (SB) 88 authorizes the State Water Board to require public water systems that consistently fail to meet standards to consolidate with, or obtain service from, a public water system. Consolidating public water systems and extending service from existing public water systems to communities and areas which currently rely on under-performing or small, failing water systems, as well as domestic wells, reduces costs and improves reliability (State Water Board 2015).

During the recent drought, many county and non-profit programs have provided technical assistance to communities and private well owners with impacted drinking water supplies, including providing free water quality testing for domestic wells.

Chapter 23
Antidegradation Analysis

23.1 Overview of Antidegradation Policies

The State Water Board and the United States Environmental Protection Agency (USEPA) have adopted antidegradation policies intended to protect existing high quality waters. Both the state and federal antidegradation policies, which are independently enforceable, require the high quality of these waters to be maintained unless otherwise provided by the policies.[1]

In 1968 the State Water Board adopted California's antidegradation policy by Resolution 68-16, "Statement of Policy with Respect to Maintaining High Quality of Waters in California." The state policy applies to surface water and groundwater whose quality meets or exceeds water quality objectives and establishes the intent to maintain high quality waters of the State to the maximum extent possible.

Whenever existing water quality is better than the quality established in applicable policies or plans, Resolution 68-16 provides that the high water quality must be maintained unless it can be demonstrated that any change in water quality will have the following results.

1. Will be consistent with the maximum benefit to the people of the State.
2. Will not unreasonably affect present and anticipated beneficial uses of such water.
3. Will not result in water quality less than that prescribed in applicable water quality control policies or plans.

Further, any activity that results in a discharge to high quality waters must use the best practicable treatment or control necessary to avoid a pollution or nuisance and to maintain the highest water quality consistent with the maximum benefit to the people of the state.

The federal antidegradation policy was included USEPA's first water quality standards regulation in 1975[2] (See 40 Fed. Reg. 55340-41, November 28, 1975). The federal antidegradation policy applies to surface water, regardless of the quality of the water. (40 C.F.R. § 131.12) Under the federal policy, "existing instream water uses and the level of water quality necessary to protect the existing uses shall be maintained and protected." (40 C.F.R. § 131.12, subd. (a)(1)) In addition, where the quality of waters exceeds levels necessary to support the protection and propagation of fish, shellfish, and wildlife and recreation in and on the water, that quality of water must be maintained and protected unless the state finds that

1. allowing lower quality is necessary to accommodate important economic or social development in the area in which the waters are located;

---

[1] While the consideration of state and federal antidegradation policies is included as a chapter in this recirculated substitute environmental document (SED), it is not a requirement under CEQA.

[2] The federal antidegradation policy was originally based on the Clean Water Act's objectives, including the objective to "restore and maintain the chemical, physical, and biological integrity of the Nation's waters." (33 U.S.C. § 1251(a)) In 1987, the Clean Water Act was amended to expressly require satisfaction of antidegradation requirements for revisions of certain effluent limitations. (33 U.S.C. § 1313(d)(4)(B))

2. water quality is adequate to protect existing beneficial uses fully; and
3. the highest statutory and regulatory requirements for all new and existing point sources and all cost-effective and reasonable best management practices for nonpoint source control are achieved. (40 C.F.R. § 131.12, subd. (a)(2))

The federal regulations further require that if a state determines it is necessary to lower the water quality of high quality waters, this determination will be based on both an analysis of alternatives that would lessen or prevent degradation and an analysis related to economic or social development in the area in which the waters are located. (40 C.F.R. § 131.12, subd. (a)(2)(ii); 80 Fed. Reg. 51032 (August 21, 2015)) However, the federal policy applies to reductions in water quality after the policy was adopted in November, 1975 (State Water Board 1994). The federal regulations also require that state water quality standards[3] include an antidegradation policy consistent with the federal policy. (40 C.F.R. § 131.12, subd. (a)) The State Water Board has interpreted Resolution 68-16 to incorporate the federal policy where the federal policy applies under federal law[4] (State Water Board 1986; State Water Board 1994).

The proposed amendments to the 2006 *Water Quality Control Plan for the San Francisco Bay/Sacramento-San Joaquin Delta Estuary* (2006 Bay-Delta Plan) will fully protect existing beneficial uses and will not result in a lowering of water quality. Instead, the analysis of the proposed plan amendments[5] indicates it will likely result in water quality improvements in the San Joaquin River (SJR) Watershed and the southern Delta. As such, a complete antidegradation analysis is not required. (See, e.g., State Water Board, Administrative Procedures Update, Antidegradation Policy Implementation for NPDES Permitting, 90-004 (State Water Board 1990) Nonetheless, by raising the salinity water quality objective in the Southern Delta, the proposed plan amendments may appear to relax the objective and authorize a lowering of water quality. Accordingly, the State Water Board provides the analysis in this chapter, with respect to salinity, to show how existing uses will be fully protected and how water quality will be maintained or improved, consistent with the principles contained in the state and federal antidegradation policies, under the proposed Bay-Delta Plan amendments. In addition, the following analysis demonstrates how there will not be a lowering of water quality with respect to other affected parameters. The analyses are based on available water quality data, modeling, and other analyses contained elsewhere in the recirculated substitute environmental document (SED).

23.2 The 2006 Bay-Delta Plan

The 2006 Bay-Delta Plan defines beneficial uses of water and establishes water quality objectives to reasonably protect these beneficial uses. The plan also includes a program of implementation to achieve the objectives. The requirements of the 2006 Bay-Delta Plan are primarily implemented

---

[3] Together, the beneficial uses and the water quality objectives established to reasonably protect the beneficial uses are called water quality standards under the terminology of the federal Clean Water Act.

[4] The State Water Board continues to reserve its arguments regarding the USEPA's authority to adopt standards for flow and operations, including standards for salinity intrusion. (See Bay-Delta Water Quality Control Plan, footnote 3.) To the extent the proposed flow and salinity water quality objectives are state-only standards, the federal antidegradation policy would not apply.

[5] These plan amendments are the *project* as defined in State CEQA Guidelines, Section 15378.

through water right actions and other measures, such as Clean Water Act hydropower water quality certifications. The beneficial uses protected by the 2006 Bay-Delta Plan include the following.

- Agricultural supply (AGR)
- Cold freshwater habitat (COLD)
- Commercial and sport fishing (COMM)
- Contact water recreation (REC-1)
- Estuarine habitat (EST)
- Groundwater recharge (GWR)
- Industrial process supply (PRO)
- Industrial service supply (IND)
- Migration of aquatic organisms (MIGR)
- Municipal and domestic supply (MUN)
- Navigation (NAV)
- Non-contact water recreation (REC-2)
- Rare, threatened, or endangered species (RARE)
- Shellfish harvesting (SHELL)
- Spawning, reproduction, and/or early development (SPWN)
- Warm freshwater habitat (WARM)
- Wildlife habitat (WILD)

23.3 San Joaquin River Water Quality Objectives for Fish and Wildlife Beneficial Uses

23.3.1 Current San Joaquin River Flow Objectives

The State Water Board first established the SJR flow objectives at Vernalis to protect fish and wildlife beneficial uses in the 1995 Bay-Delta Plan. The State Water Board set different flow objectives for three time periods: February through June, excluding April 15 through May 15 (spring flows); April 15 through May 15 (pulse flows); and October (fall flows). The flow objectives vary depending on the water year type, with higher flows required in wetter years. The spring flow objective was intended to provide minimum freshwater flows in the SJR to address habitat concerns caused by reduced tributary inflows and poor water quality. The pulse flows were principally developed to aid in cueing fall-run Chinook salmon juvenile out-migration in the spring from the SJR. The fall flows were developed to provide attraction flows for fall-run adult salmon returning to the watershed to spawn. The objectives were based on the limited scientific information available at the time. To obtain additional scientific information, the State Water Board in Revised Decision 1641 (2000) approved conducting the Vernalis Adaptive Management Plan (VAMP) experiment proposed in the San Joaquin River Agreement (SJRA) until 2012, in lieu of meeting the pulse flow objectives included in the 1995

Bay-Delta Plan. In 2006, the Bay-Delta Plan was amended to allow the VAMP experiment to be conducted in lieu of the pulse flows.

23.3.2 Proposed Lower SJR Flow Objectives

The proposed Lower San Joaquin River (LSJR) flow objectives would replace the existing water quality objectives for fish and wildlife beneficial uses at Vernalis during the February–June time frame. The proposed objectives call for inflow conditions from the SJR Watershed to the Delta at Vernalis sufficient to support and maintain the natural production of viable native fish populations migrating through the Delta. Inflow conditions include those that more closely mimic the natural hydrographic conditions to which native fish species are adapted, including the relative magnitude, duration, timing, and spatial extent of flows as they would naturally occur. Indicators of fish population viability include abundance, spatial extent, distribution, structure, genetic and life history diversity, and productivity. In addition to the narrative objective, the flow objectives will require from each of the three eastside tributaries to the LSJR, the Merced, Tuolumne, and Stanislaus Rivers, to release a percent of unimpaired flow[6] to the LSJR. The flow objectives evaluated in this SED and this chapter range from 20 percent to 60 percent of the unimpaired flow on each tributary. In addition, a minimum base flow value between 800–1,200 cubic feet per second (cfs), based on a maximum 7-day running average, will be required at Vernalis from February–June.

As described in Appendix K, *Revised Water Quality Control Plan*, the program of implementation will allow the unimpaired flow objective to be adjusted, or adaptively implemented. Specifically, the flow objectives may be adjusted if information produced through the monitoring and review processes, as described in Appendix K, or other best available scientific information indicates that such changes will be sufficient to support and maintain the natural production of viable native SJR Watershed fish populations migrating through the Delta and meet any existing biological goals approved by the State Water Board. Adaptive implementation options include: (1) adjusting the percentage of unimpaired flow within an adaptive range (30 to 50 percent for LSJR Alternative 3), (2) managing the required percentage of unimpaired flow as a total volume that may be released on an adaptive schedule during the February–June period, and (3) shifting flow from the February–June period for release later in the year to prevent adverse impacts on coldwater pool and related fisheries impacts. These measures would be implemented based on real-time circumstances and available scientific information to achieve the narrative objective for the protection of LSJR fish and wildlife. The Vernalis base flow objective may also be adaptively implemented within the allowed range of 800–1200 cfs.

Appendix K describes the coordination actions and approvals needed to manage the flows from the tributaries to the LSJR. This includes the creation of a Stanislaus, Tuolumne, and Merced Working Group (STM Working Group) whose purpose is to assist with implementation, monitoring and effectiveness assessment activities for the LSJR flow objectives. The State Water Board will seek recommendations from the STM Working Group on biological goals to inform adaptive implementation actions and the effectiveness of the program of implementation, among others.

---

[6] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.

23.4 Southern Delta Salinity Water Quality Objectives to Protect Agricultural Beneficial Uses

23.4.1 Current Southern Delta Salinity Objectives

The current salinity objectives for agricultural beneficial uses in the southern Delta are found in Table 2 of the 2006 Bay-Delta Plan (and shown below in Table 23-1). The salinity objectives apply in all water year types and compliance is determined at the following four locations: (1) SJR at Airport Way Bridge, Vernalis (Station C-10); (2) SJR at Brandt Bridge (Station C-6); (3) Old River near Middle River (Station C-8); and (4) Old River at Tracy Road Bridge (Station P-12)[7]. While the salinity objectives for the southern Delta apply to all locations in the general area, these specific locations are used to determine compliance with the objectives.

Table 23-1. Current South Delta EC[8] Standards

EC Objective (30-day running average)	Time Period
0.7 dS/m EC (mmhos/cm)[9]	April 1–August 31
1.0 dS/m EC (mmhos/cm)	September 1–March 31

dS/m = deciSiemens per meter
mmhos/cm = millimhos per centimeter

Agricultural beneficial use is the most sensitive use requiring protection for the range of salinity conditions encountered in the southern Delta. The current salinity standards for the southern Delta were originally adopted in the 1978 *Water Quality Control Plan for the Sacramento-San Joaquin Delta* (1978 Bay-Delta Plan) to protect agricultural beneficial uses. These standards were based on the water quality needs of the different crops grown, predominant soil types, and irrigation practices in the southern Delta. The salinity objectives did not take immediate effect, but instead were to become effective on completion of suitable circulation and water supply facilities. In addition, a year-round total dissolved solids (TDS)[10] standard of 500 milligrams per liter (mg/L) (equivalent to approximately 0.83 dS/m EC) at Vernalis was also included in the 1978 Delta Plan, which became effective in 1980 when New Melones Dam was completed. Prior to adoption of the 1978 Bay-Delta Plan, the Central Valley Regional Water Quality Control Board adopted in its June 1971 *Interim Water Quality Control Plan, San Joaquin River Basin 5C*, a TDS standard of 500 mg/L as a maximum 30-day running average at Vernalis. Water Right Decision 1422 adopted by the State Water Board in 1973, which addressed the U.S. Bureau of Reclamation's (USBR) application to appropriate water from the

---

[7] Although the 2006 Bay-Delta plan identifies this compliance station as Tracy Road Bridge, the actual location is Tracy Boulevard Bridge, consequently Tracy Blvd. will be used here for accuracy.

[8] In this document, EC is *electrical conductivity,* which is generally expressed in deciSiemens per meter (dS/m). Measurement of EC is a widely accepted indirect method to determine the salinity of water, which is the concentration of dissolved salts (often expressed in parts per thousand or parts per million). EC and salinity are therefore used interchangeably in this document.

[9] The text in this chapter and elsewhere in this SED primarily describes salinity using deciSiemens per meter (dS/m), while the units of millimhos/cm (mmhos /cm) are used in the 2006 Bay-Delta Plan. These units are interchangeable in that EC equivalent to 1.0 mmhos/cm is the same as an EC of 1.0 dS/m.

[10] Total dissolved solids is another way to measure dissolved salts in water that has been replaced by electrical conductivity (EC) due to the relative ease in measuring EC.

Stanislaus River, assigned responsibility to USBR for meeting the 500 mg/L TDS salinity standard at Vernalis.

Updates to the Bay-Delta Plan in 1991 and 1995 did not substantively change the southern Delta salinity objectives, except for removal of the 500 mg/L TDS standard at Vernalis beginning with the 1991 plan. Both plans again provided for the staged implementation of the EC water quality objectives. The 1991 Bay-Delta Plan required implementation of the Vernalis and Brandt Bridge salinity standards by 1994, while the Old River near Middle River and Old River at Tracy Boulevard were to be implemented by 1996. Water Right Order 95-6, adopted by the State Water Board in 1995, assigned to USBR the responsibility for meeting the April–August 0.7 dS/m and the September–March 1.0 dS/m EC salinity objectives at Vernalis, which replaced USBR's previous requirement to meet the 500 mg/L TDS standard at Vernalis. Water Right Order 95-6 did not assign responsibility to meet the salinity standards at the other three compliance stations. The 1995 Bay-Delta Plan delayed the compliance date of the agricultural salinity objectives at Old River near Middle River and Old River at Tracy Boulevard from 1996 to December 31, 1997.

In 2000, the State Water Board adopted a water right decision (Revised Decision 1641) that assigned responsibility for meeting the southern Delta salinity objectives by amending the California Department of Water Resources' (DWR) State Water Project (SWP) water rights and the USBR's Central Valley Project (CVP) water rights to require compliance with the 1995 Bay-Delta Plan salinity objectives. In Revised Decision 1641, the State Water Board, however, further delayed the effectiveness of the 0.7 dS/m EC water quality objective set forth in the 1995 Bay-Delta Plan at the Brandt Bridge and the two Old River compliance locations until April 2005. It also allowed for the 0.7 dS/m EC objective to be replaced by the 1.0 dS/m EC objective after April 1, 2005, if permanent barriers were constructed, or equivalent measures were implemented, in the southern Delta and an operations plan that reasonably protected Delta agriculture was prepared by USBR and DWR and approved by the State Water Board Executive Director. In 2006, the Court of Appeals held that the State Water Board did not adequately implement the 1995 Bay-Delta Plan because the plan did not allow further delay in the implementation of the 0.7 dS/m EC water quality objective at the three compliance locations or replace the 0.7 EC objective with the 1.0 EC objective. (State Water Board Cases (2006) 136 Cal.App.4th 674–735 (39 Cal. Rptr. 3d 189)) Currently, SWP and CVP water rights are conditioned on implementation of the EC objectives at the three southern Delta stations downstream of Vernalis and the CVP permits under which USBR delivers water to the SJR Basin are conditioned on meeting the salinity objectives in the SJR at Vernalis.

23.4.2 Proposed Southern Delta Salinity Objectives

The proposed amendments to the Bay-Delta Plan will establish a year-round salinity objective to protect agricultural beneficial uses in the southern Delta of 1.0 dS/m as a maximum 30-day running average of mean daily EC to replace the current seasonal objective of 0.7 dS/m from April–August. The September–March 1.0 dS/m water quality objective will remain unchanged. The compliance locations will include (1) the SJR at Airport Way Bridge, Vernalis; (2) the SJR from Vernalis to Brandt Bridge: (3) Middle River from Old River to Victoria Canal; and (4) Old River/Grant Line Canal from the Head of Old River to West Canal. The program of implementation requires the development of a monitoring plan to assess compliance with the proposed salinity objective, which may lead to changes in the specific locations where compliance is determined. Until the plan is developed, compliance will be assessed at the four locations contained in the 2006 Bay-Delta Plan.

The proposed change to the salinity objective to protect agricultural beneficial uses is based on scientific information and analysis described in Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*, and contained in Appendix E, *Salt Tolerance of Crops in the Southern Sacramento–San Joaquin Delta*. Appendix E examines current agricultural practices, soil characteristics, and crop patterns in the southern Delta to perform its analysis. The analysis in Appendix E concludes that the proposed 1.0 dS/cm EC objective provides for 100 percent yields under most hydrological conditions, and 95 percent yields for the most salt-sensitive crop grown in the region (i.e., dry beans) under dry year conditions and, therefore, adequately protects agricultural beneficial use in the southern Delta. Consequently, the existing April – August water quality objective of 0.7 dS/m, which has never been consistently achieved at all of the required locations, is over protective.

To meet the revised salinity objective downstream of Vernalis, the proposed program of implementation will require the continued conditioning of USBR's water rights pursuant to Revised Water Right Decision 1641. Specifically, USBR's water rights will continue to require the USBR to meet salinity levels of 0.7 dS/m at Vernalis from April 1–to August 31 and 1.0 dS/m from September 1–March 31, as has been the condition since State Water Board adoption of Water Right Order 95-6 in 1995. This will provide assimilative capacity for salinity inputs downstream of Vernalis and help maintain salinity levels that meet the revised objective and reasonably protect agricultural beneficial uses in the southern Delta. Continuation of this requirement will assure that the proposed change to the salinity objective will not result in the lowering of water quality at and downstream of Vernalis in the southern Delta.

The proposed program of implementation requires that DWR and USBR develop and implement a comprehensive operations plan to address the impacts of SWP and CVP export operations on flow and salinity conditions in the southern Delta, including the availability of assimilative capacity for local sources of salinity. DWR's and USBR's water rights will be conditioned to required continued operations of the agricultural barriers at Grant Line Canal, Middle River, and Old River at Tracy Boulevard, or other reasonable measures, to address the impacts of the export operations. In addition, DWR's and USBR's water rights would be conditioned to require monitoring, modeling, special studies, and reporting activities, in coordination with other monitoring programs, to ensure that the salinity objectives are effectively implemented. The proposed program of implementation also includes recommendations to other agencies that would assist in meeting the southern Delta salinity objective (Appendix K, *Revised Water Quality Control Plan*).

23.5 Antidegradation Analysis

The proposed changes to the LSJR flow objectives and southern Delta salinity objective in the Bay-Delta Plan would not result in a lowering of water quality in the Stanislaus, Tuolumne, and Merced Rivers, the LSJR, and the southern Delta. As such, a complete antidegradation analysis is not required (State Water Board 1990). The State Water Board, nevertheless, provides one for salinity because raising the April–August 0.7 dS/m salinity water quality objective to 1.0 dS/m may appear to allow water quality degradation. In addition, the analysis below explains why there will not be a lowering of water quality with respect to other parameters. The analysis evaluates the State Water Board's preferred alternatives: Southern Delta Water Quality (SDWQ) Alternative 2 (1.0 dS/m EC as a running 30-day average year-round) and LSJR Alternative 3 (40 percent unimpaired flow with adaptive implementation); however, this analysis also considers unimpaired flows ranging from 20 percent to

60 percent in order to evaluate a broad range of the LSJR flow objectives alternatives on water quality.

23.5.1 Salinity

Although many factors influence water quality, the new LSJR flow objectives proposed as part of the updated Bay-Delta Plan could affect salinity concentrations in the southern Delta. Salinity, therefore, is evaluated under varying flow objectives (the LSJR alternatives) proposed to revise the Bay Delta Plan. This analysis uses modeling results from the Water Supply Effects (WSE) model to examine whether the proposed changes to the southern Delta salinity and flow objectives for the LSJR would result in a lowering of water quality. Appendix F1, *Hydrologic and Water Quality Modeling*, and Chapter 5, *Surface Hydrology and Water Quality*, of this SED provide explanation and details regarding the analyses and models used to assess the impacts of the proposed plan amendments on water quality. Chapter 5 also evaluates whether the LSJR and SDWQ alternatives would degrade water quality by increasing salinity concentrations at Vernalis or elsewhere in the southern Delta, such that agricultural beneficial uses are impaired. The analysis in Chapter 5 concludes that all LSJR alternatives would reduce average EC values at Vernalis and in the southern Delta channels from April–September and maintain agricultural beneficial uses.

Historical Conditions and Factors Affecting Salinity

Salinity patterns in the southern Delta began to change from their natural state early in the Twentieth Century as a result of increasing agricultural diversions in and around the Delta. Salinity conditions were further altered by the completion of the state, federal, and local water projects, which together have reduced flow entering the Delta at Vernalis. Historical water quality in the southern Delta is discussed in Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta*. Appendix F.2 also describes the high annual and seasonal variability of southern Delta salinity and the strong correlation between salinity and streamflow at Vernalis.

Salinity levels in the southern Delta are affected primarily by the salinity of water flowing into the southern Delta from the SJR near Vernalis and evapoconcentration of salt in water that is diverted from and discharged back into southern Delta channels for agricultural purposes. Point sources of salt in the southern Delta have a small overall salinity effect. High Vernalis flows generally reduce the salinity of water entering the southern Delta from the SJR by diluting salt loads from upstream areas. Municipal treated wastewater discharges[11] have a relatively small effect on the southern Delta salinity. Higher CVP and SWP pumping also has an effect on southern Delta salinity by bringing more low-salinity Sacramento River water across the Delta to the export pumps. In addition, periods of low Delta outflow (in the fall months) can cause increased seawater intrusion and higher EC at the southern Delta export facility and Contra Costa Water District intakes.

In the early 1970s, salinity conditions at Vernalis did not always meet water quality standards for salinity, as evident in the discussion provided in Water Right Decision 1422, issued in 1973. Water Right Decision 1422 states that the water quality objective of 500 mg/L TDS (~0.83 dS/m EC) was

---

[11] Municipal dischargers in the southern Delta are currently not subject to the existing numeric salinity water quality objectives in the 2006 Bay-Delta Plan as a result of a superior court decision in *City of Tracy v. California State Water Resources Control Board*, Sacramento Superior Court, Case No. 34-2009-80000392. In order for municipal dischargers to be subject to salinity standards, the decision requires the consideration of Water Code section 13241 factors for any new salinity standards and a program of implementation.

exceeded 38 percent of the time during the irrigation season. After adoption of the first salinity objectives at Vernalis in the June 1971 Interim Water Quality Control Plan, San Joaquin River Basin 5C, the LSJR was identified as impaired due to salinity in 1975 (1975 303[d] list). Implementation of the April–August 0.7 dS/m salinity objective for the southern Delta, first adopted in the 1978 Bay-Delta Plan, was delayed repeatedly under the assumption that infrastructure would be built to better meet the objective; however, these actions never occurred. Salinity conditions did not improve in the 1980s or early 1990s, as indicated by historical water quality data presented in the final environmental impact report to support implementation of the 1995 Bay-Delta Plan, which shows that the April–August 0.7 dS/m salinity objective at Vernalis was exceeded 62 percent of the time between 1986 and 1995 (State Water Board 1999).

Salinity conditions improved after 1995 when Water Right Order 95-6 assigned USBR responsibility to meet the Vernalis salinity objectives of 0.7 dS/m EC from April–August and 1.0 dS/m EC from September–March. In addition, regulatory requirements for discharge of agricultural drainage upstream of Vernalis were put in place in 1996, in particular for the Grasslands drainage area, which have helped reduce the salinity load and improved water quality in the LSJR. As of 2015, the salinity discharges from the Grasslands drainage area have been reduced by 83 percent between 1995 and 2015 (SLDMWA 2015).

There is a strong relationship between EC values at Vernalis and EC at downstream monitoring locations under most flow regimes. Therefore, as conditions at Vernalis have improved since 1995, so have conditions at the other southern Delta salinity compliance stations. However, despite the improvement, compliance with the interior southern Delta salinity objectives has not always been achieved. The standards at the interior south Delta stations are more difficult to achieve because of high salinity runoff from agricultural land downstream of Vernalis. There are also additional sources of salinity between Vernalis and the other locations, as well as diversions and other hydrodynamic factors that may increase salinity concentrations at the interior locations compared to Vernalis.

Figure 23-1 is an exceedance chart of observed monthly average EC values collected for April–August from 1995–2015 at the four southern Delta compliance locations (Old River at Tracy Boulevard Bridge, Old River near Middle River, SJR at Vernalis, and SJR at Brandt Bridge). Figure 23-1 shows the percent of months during the irrigation season that the monthly average EC values exceeded the 0.7 dS/m EC standard for each of the southern Delta stations. From 1995 to 2015, the monthly average EC at Vernalis exceeded 0.7 dS/m EC only once during April–August, just barely in July of 2015. However, for the other three locations, the average monthly EC exceeded 0.7 dS/m more frequently over the last 2 decades. For the SJR at Brandt Bridge and the Old River near Middle River locations, the average monthly EC remained below 0.7 dS/m approximately 85 percent and 83 percent of months, respectively. Conditions for Old River at Tracy Boulevard Bridge are often worse than the other stations, and the average monthly EC remained below 0.7 dS/m only about 55 percent of the time (DWR 2016a, 2016b).

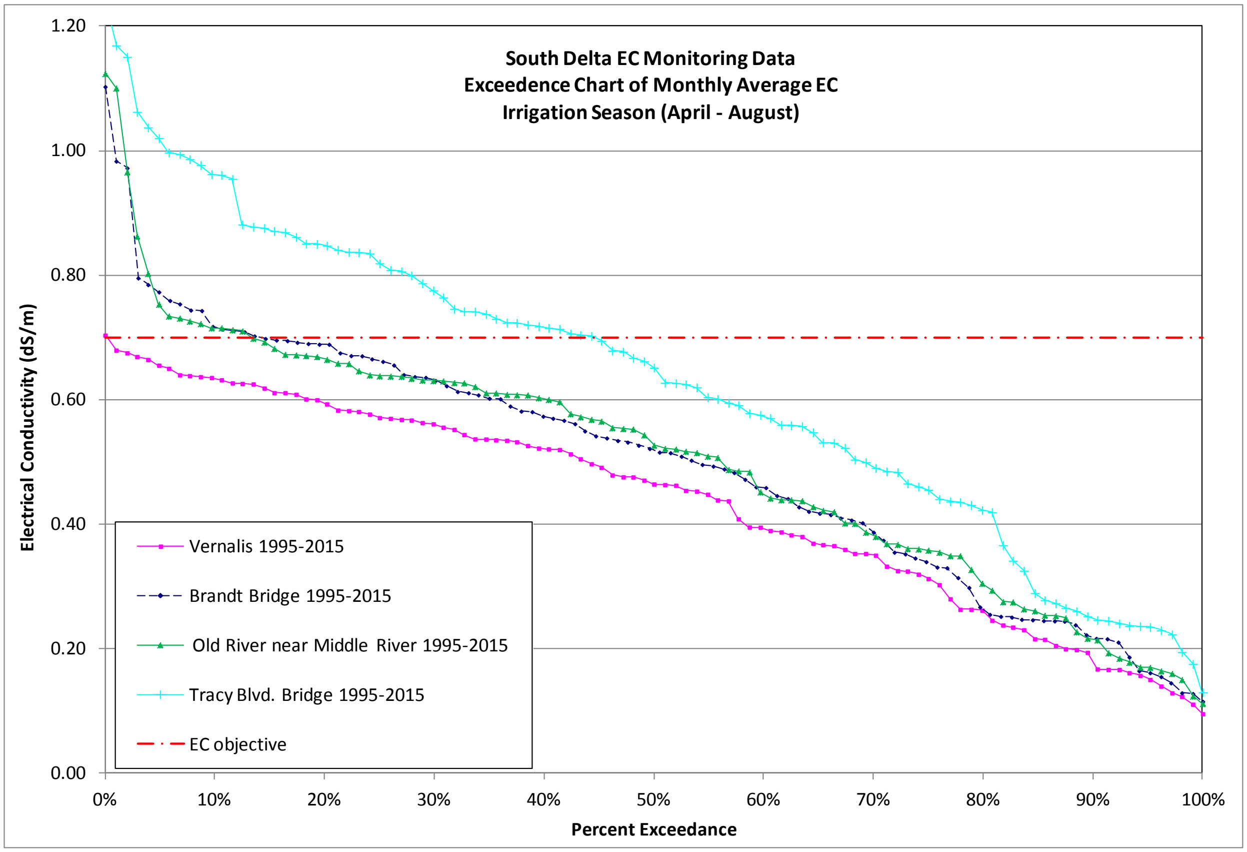

Figure 23-1. Exceedance Chart of Monthly Average EC (dS/m = deciSiemens per meter) Values at South Delta Monitoring Locations for Irrigation Months from 1995–2015

Figure 23-2 shows an exceedance chart for observed monthly average EC values collected for September–March from 1995–2015 at the four southern Delta compliance locations. Similar to Figure 23-1, this chart indicates the percent of months outside of the irrigation season that the monthly average EC values exceeded the 1.0 dS/m EC standard for each of the southern Delta stations. From 1995–2015 the monthly average EC at Vernalis never exceeded 1.0 dS/m from September–March. For the SJR at Brandt Bridge and the Old River near Middle River locations, the average monthly EC remained below 1.0 dS/m approximately 97 percent and 95 percent of months, respectively. Finally, The EC for Old River at Tracy Boulevard Bridge is less than 1.0 dS/m about 85 percent of the time.

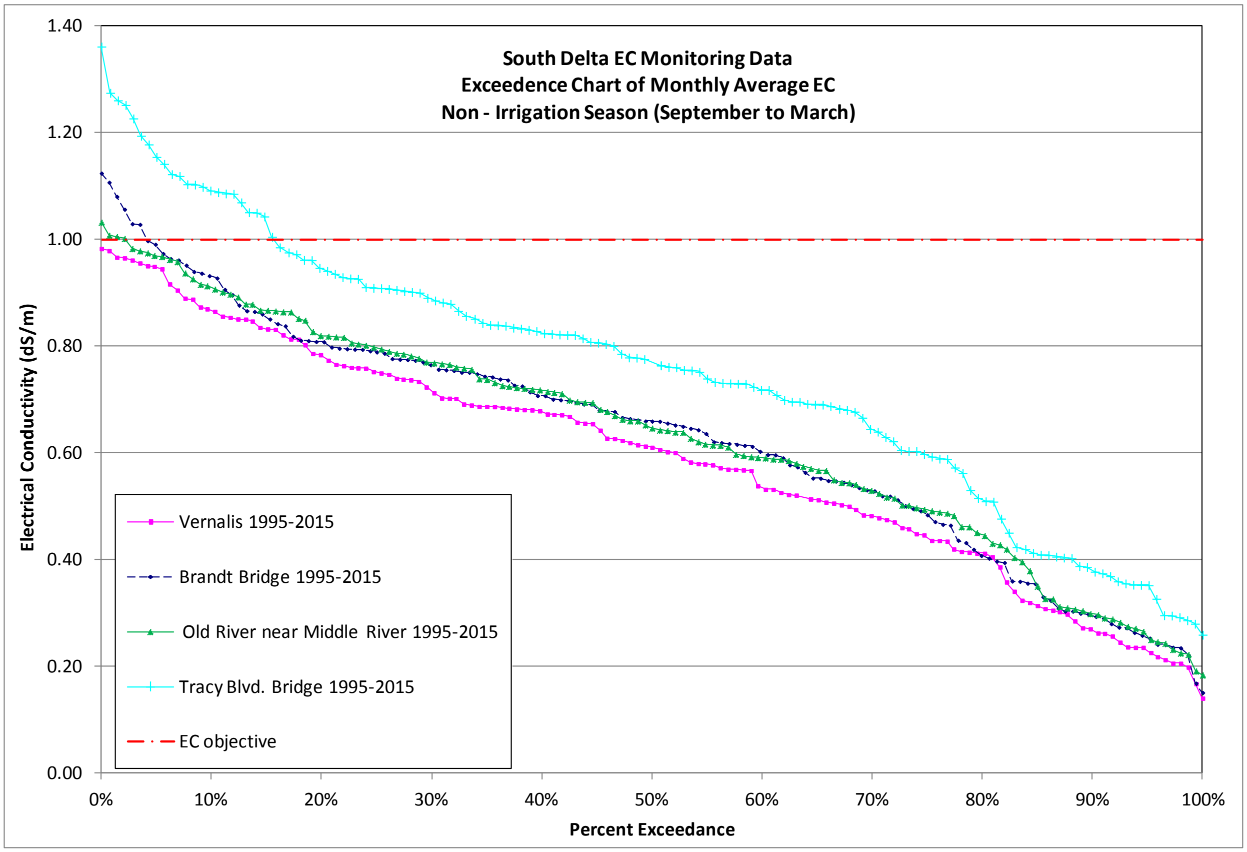

Figure 23-2. Exceedance Chart of Monthly Average EC (dS/m = deciSiemens per meter) Values at South Delta Monitoring Locations for Non-Irrigation Months from 1995–2015

Baseline Water Quality

Establishing the baseline receiving water quality for salinity determines the level of water quality protection. Baseline water quality for the purposes of the antidegradation analysis is the best quality of water measured since 1968, considering the state antidegradation policy, or 1975, considering the federal antidegradation policy, unless a subsequent lowering of water quality was allowed consistent with state and federal antidegradation policies. Under the state antidegradation policy, where a water quality objective for a particular constituent was adopted after 1968, the baseline for that constituent is the highest water quality achieved since the adoption of objective (Resolution 68-16, Resolve 1). If the baseline water quality is equal or less than the water quality objective, it must be maintained at the objective or improved to a level that achieves the objective (State Water Board 1990). If the baseline water quality is better than the water quality objective, it must be maintained unless poorer water quality is necessary to accommodate important economic or social development and is considered to be the maximum benefit to the people of the State (State Water Board 1990).Based on information and salinity data described above, 1995–2015 represents the period of highest water quality, with respect to salinity, since adoption of the state and federal antidegradation policies and establishment of the first salinity objectives. Therefore, this period represents the baseline water quality for salinity.

Salinity concentrations in the southern Delta vary widely over months and years, driven largely by changes in hydrology. The baseline water quality that is representative of salinity conditions must therefore be assessed based on a sufficiently long time frame that takes into consideration this variability. The historical variation in salinity and its relation to hydrological conditions is illustrated in Figure 23-3, which compares the monthly averages of EC and flow at Vernalis from 1995–2015 (DWR 2016b). This time period represents water quality conditions for a range of wet and dry water years. Using a 20-year baseline period is consistent with State Water Board guidance that baseline water quality should be representative of the water body, accounting for temporal and spatial variability (State Water Board 1990). Therefore, the 1995–2015 time period is appropriate for this antidegradation analysis.

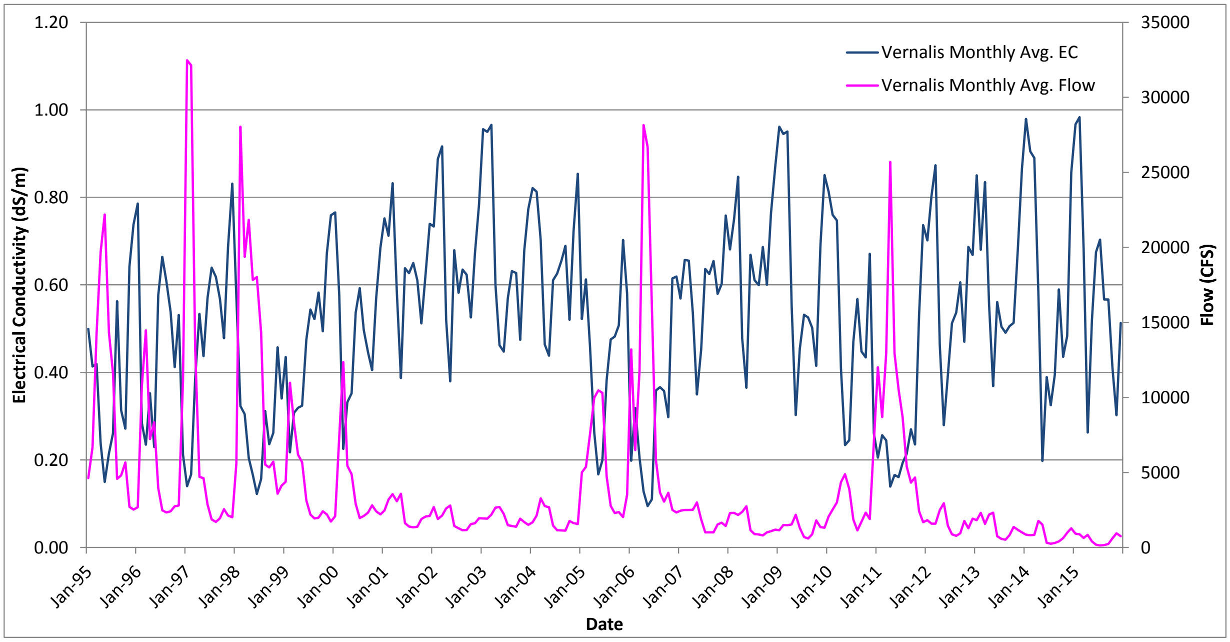

Figure 23-3. Monthly Average EC (dS/m = deciSiemens per meter) Observed at Vernalis Compared to Monthly Average Flow (cfs = cubic feet per second) Observed at Vernalis from 1995– 2015

Comparing the receiving water quality during the 1995–2015 baseline period to the existing water quality objectives (Figures 23-1 and 23-2) indicates that at Vernalis, the baseline water quality is equal to or better than the objective; at the other southern Delta locations, the baseline water quality is equal to or less than the existing objective. Where the baseline water quality is equal or less than the water quality objective, the water quality must be maintained or improved to a level that achieves the objective (State Water Board 1990). Where the baseline water quality is better than the water quality objective, the baseline water quality must be maintained unless poorer water quality is necessary to accommodate important economic or social development and is considered to be the maximum benefit to the people of the State. (State Water Board 1990) The analysis below explains why the baseline water quality will be maintained or improved under the proposed salinity objectives.

Analytic Approach

The WSE model results must be compared to the baseline water quality conditions before they can be used to make determinations about potential changes in salinity conditions. Though the WSE model simulates water operations using historical hydrology, operations are based on current infrastructure development and regulations. WSE model results, therefore, may be different than historical conditions. In addition, the modeling period used in the WSE model does not match the period observed to have the best water quality (i.e., the baseline water quality period). The WSE model uses the same modeling period as the CALSIM II model, water years from 1922–2003, which provides a robust representation of the varying conditions that have occurred in the SJR Watershed. There is only a relatively short period of time overlapping between the period of highest baseline water quality and the modeling results, 1995–2003, and this period is too short to adequately represent long-term variations in water quality.

To determine if modeled results for the LSJR alternatives show degradation in water quality, they must be compared to the model baseline. The *model baseline* represents the water infrastructure and regulatory conditions as of 2010. Due to operations to meet only the Vernalis salinity objective, periodic exceedances of interior southern Delta salinity objectives occur in the historical record and likewise remain in the modeled baseline conditions. A comparison of EC results for the LSJR alternatives and the model baseline will, therefore, show if the proposed flow objectives could cause an increase or decrease in EC at Vernalis and the interior southern Delta compliance locations. This analysis focuses on conditions in the southern Delta since salinity standards upstream are not changing. These results can then be qualitatively applied to the 1995–2015 baseline water quality; if there is an increase in EC compared to the model baseline, it is likely EC would increase compared to baseline water quality conditions as well, and there would be degradation.

As described in Appendix F.1, *Hydrologic and Water Quality Modeling*, the WSE model estimates of monthly EC are based on the Vernalis EC results extracted from a version of the CALSIM II SJR Module. Since EC is highly dependent on flow volume, the WSE model calculated EC at Vernalis is the CALSIM II estimate adjusted by the ratio of flow at Vernalis in CALSIM II compared to the WSE model. EC values predicted in the WSE model for Brandt Bridge, Old River near Middle River and Old River at Tracy Boulevard Bridge are based on the empirical relationship between flow conditions and the observed incremental increase in EC between Vernalis and these downstream locations. The relationship between flow and the incremental increase in EC was found to be the same for both the Brandt Bridge and Old River near Middle River compliance locations (see Appendix F.1 for more details). Consequently, the distribution of EC values predicted under the LSJR alternatives is the same for Brandt Bridge and Old River near Middle River.

CALSIM II EC values were used as a starting point for the WSE model because the CALSIM II results include a suitably long time period to account for long term variation in salinity (82-year period) and because CALSIM II closely matches recent historical salinity at Vernalis. Figure 23-4 compares the monthly average time series of observed EC data (from CDEC) at Vernalis with the CALSIM II estimates of EC at Vernalis from January 1995– September 2003. Figure 23-4 shows that CALSIM II calculated EC is very similar to the historical EC from 1995–2003.

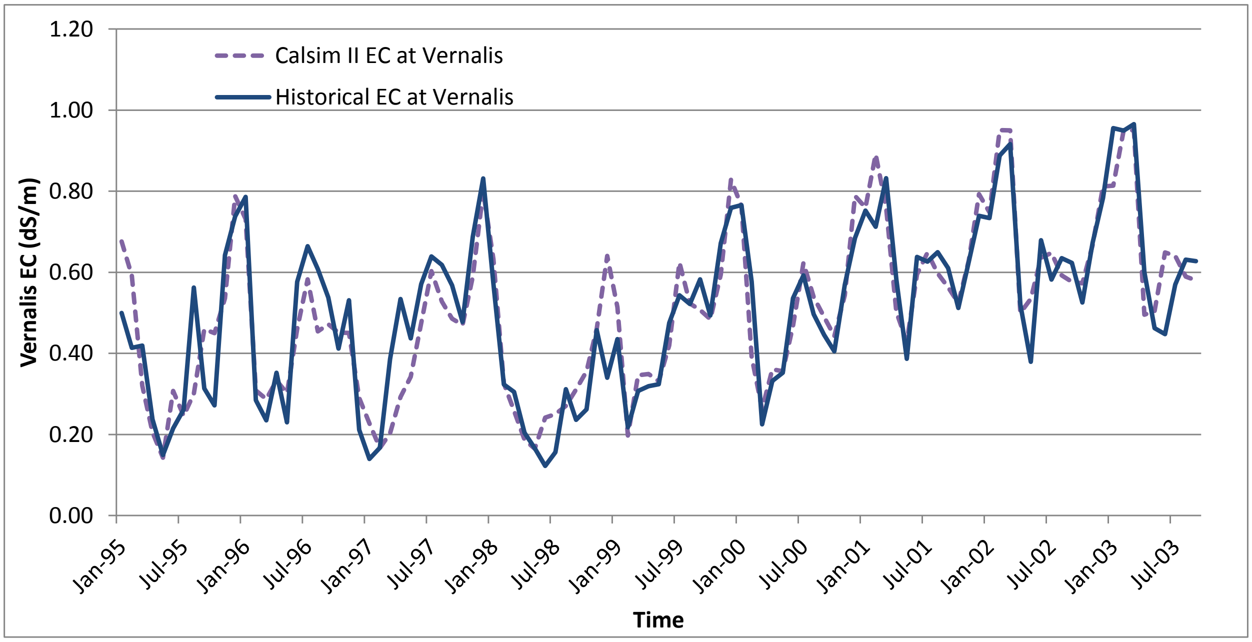

Figure 23-4. Monthly Average EC (dS/m = deciSiemens per meter) Observed at Vernalis Compared to CALSIM II Monthly Estimate of EC at Vernalis from 1995–2003

Effects of the Proposed LSJR Flow and SDWQ Objectives on Salinity

The EC results of the modeled LSJR alternatives are compared with the modeled baseline results for EC to assess whether a reduction in water quality is expected due to implementation of the proposed LSJR flow and EC water quality objectives. The modeled impacts on water quality can then be qualitatively applied to the baseline water quality, 1995–2015, to determine if there could be a degradation of water quality. The analysis shows that, overall, the baseline salinity in the southern Delta would not only be maintained under the proposed plan amendments, consistent with antidegradation requirements, but would generally improve during the irrigation season.

Table 23-2 presents the average annual EC values for each of the southern Delta compliance locations under the modeled baseline conditions and the change in those values for the LSJR flow objectives ranging from 20 to 60 percent unimpaired flow. Model results are provided for 30 and 50 percent unimpaired flow because adaptive implementation may, at times, result in a percentage of unimpaired flow that falls between proposed LSJR Alternatives 2, 3, and 4. As described above, the EC conditions as modeled in WSE are the same for the SJR at Brandt Bridge and for Old River near Middle River. All four stations experience an overall decrease in EC under each of the alternatives, with the least decrease under 20 percent unimpaired flow and the largest decrease under 60 percent unimpaired flow. The compliance location on Old River at Tracy Boulevard Bridge has the greatest reduction in EC for all alternatives but still has the highest modeled EC overall.

Table 23-2. Annual Average EC at Southern Delta Compliance Locations under Modeled Baseline Conditions and the Change in Value based on Percent of Unimpaired Flow

	Annual Average EC (dS/m)					
		Change from Baseline EC				
	Baseline	20% UF	30% UF	40% UF	50% UF	60% UF
SJR at Vernalis	0.57	-0.01	-0.02	-0.04	-0.06	-0.07
SJR at Brandt Bridge	0.61	-0.01	-0.02	-0.05	-0.06	-0.08
Old River near Middle River	0.61	-0.01	-0.02	-0.05	-0.06	-0.08
Old River at Tracy Boulevard Bridge	0.70	-0.01	-0.03	-0.06	-0.07	-0.09

EC (dS/m) = electrical conductivity (salinity) as measured in deciSiemens per meter
UF = unimpaired flow

Although there are individual months in some years when EC increases, in other months EC decreases much more substantially, particularly during the irrigation season. EC increases in the LSJR alternatives correspond to times when flow at Vernalis is lower than under modeled baseline. When the flow at Vernalis decreases it can usually be attributed to a change in the timing and magnitude of flood control releases (there are a few times when it is also caused by the elimination of VAMP and D1641 flow releases or by changes in the New Melones Index, which partially determines instream flow objectives on the Stanislaus River). The increases in EC merely represent shifts in salinity concentrations as water is moved from one period to another. Figures 23-5 through 23-7 show the exceedance plots for the change in monthly EC values under the LSJR flow objectives ranging from 20 to 60 percent unimpaired flow, relative to modeled baseline, at each of the southern Delta compliance locations. Depending on the alternative, about 10–20 percent of months show an increase in EC as water is moved around, while between 25 and 50 percent of months show a much more substantial decrease in EC. Overall, salinity concentrations would improve under the LSJR alternatives. Figures 23-8 through 23-10, discussed below, further illustrate the extent to which the predicted EC values under the LSJR alternatives would be substantially lower than the modeled baseline for the April–August irrigation season.

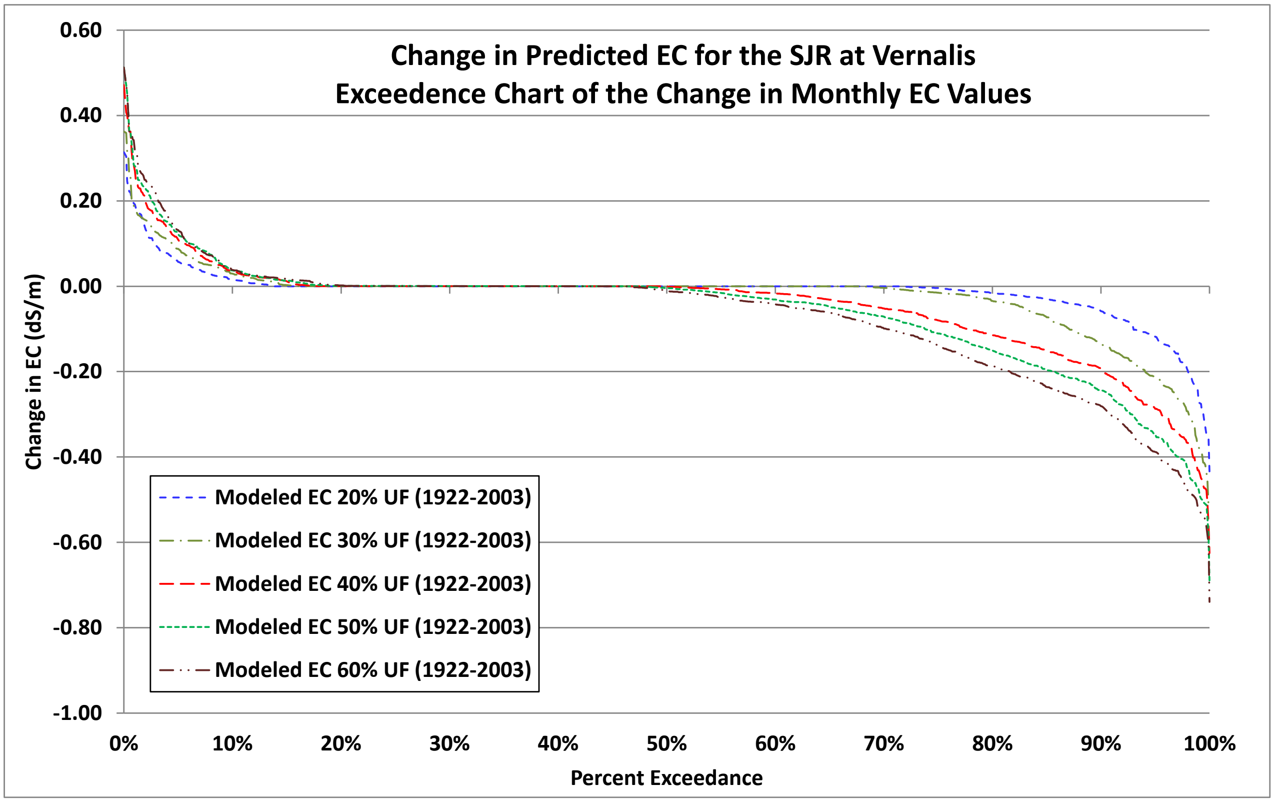

Figure 23-5. Exceedance Chart of the Change in Monthly EC Values for the SJR at Vernalis Based on Percent of Unimpaired Flow, Relative to Modeled Baseline

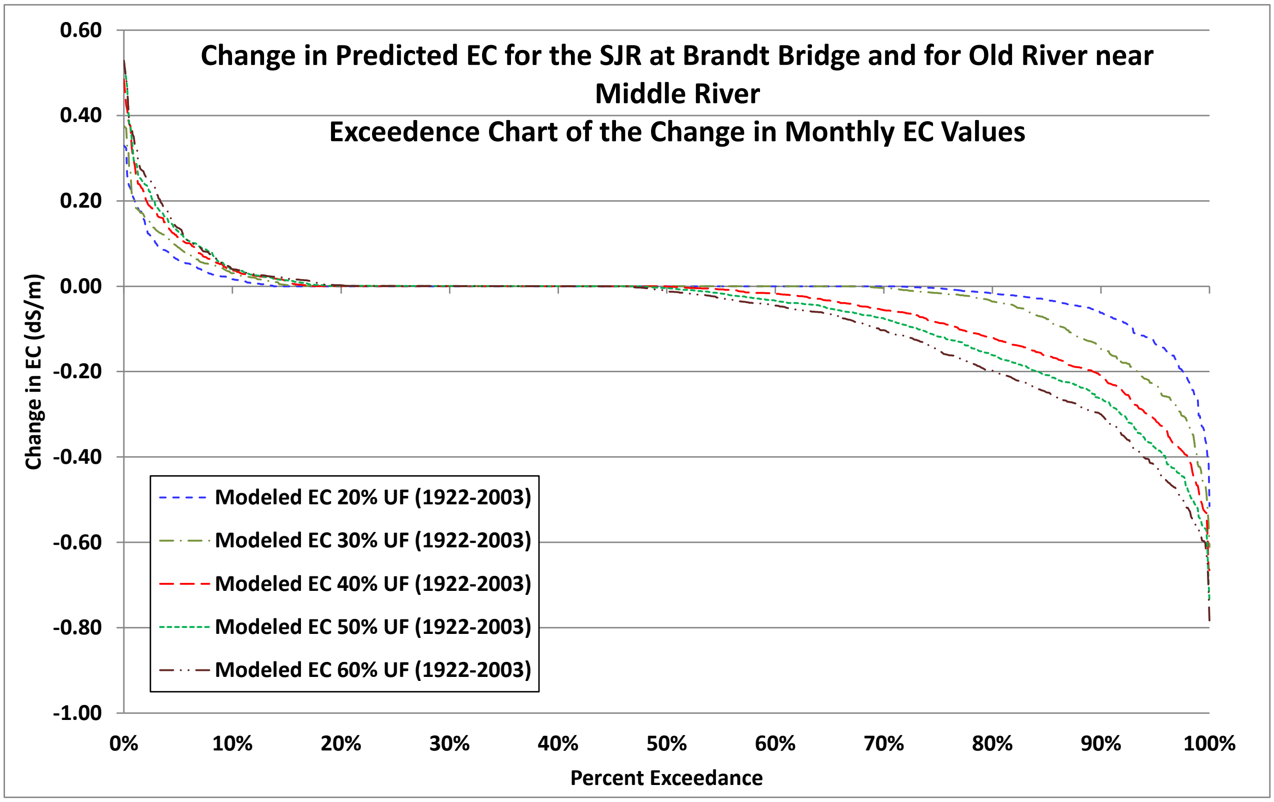

Figure 23-6. Exceedance Chart of the Change in Monthly EC Values, for the SJR at Brandt Bridge and for Old River near Middle River Based on Percent of Unimpaired Flow, Relative to Modeled Baseline

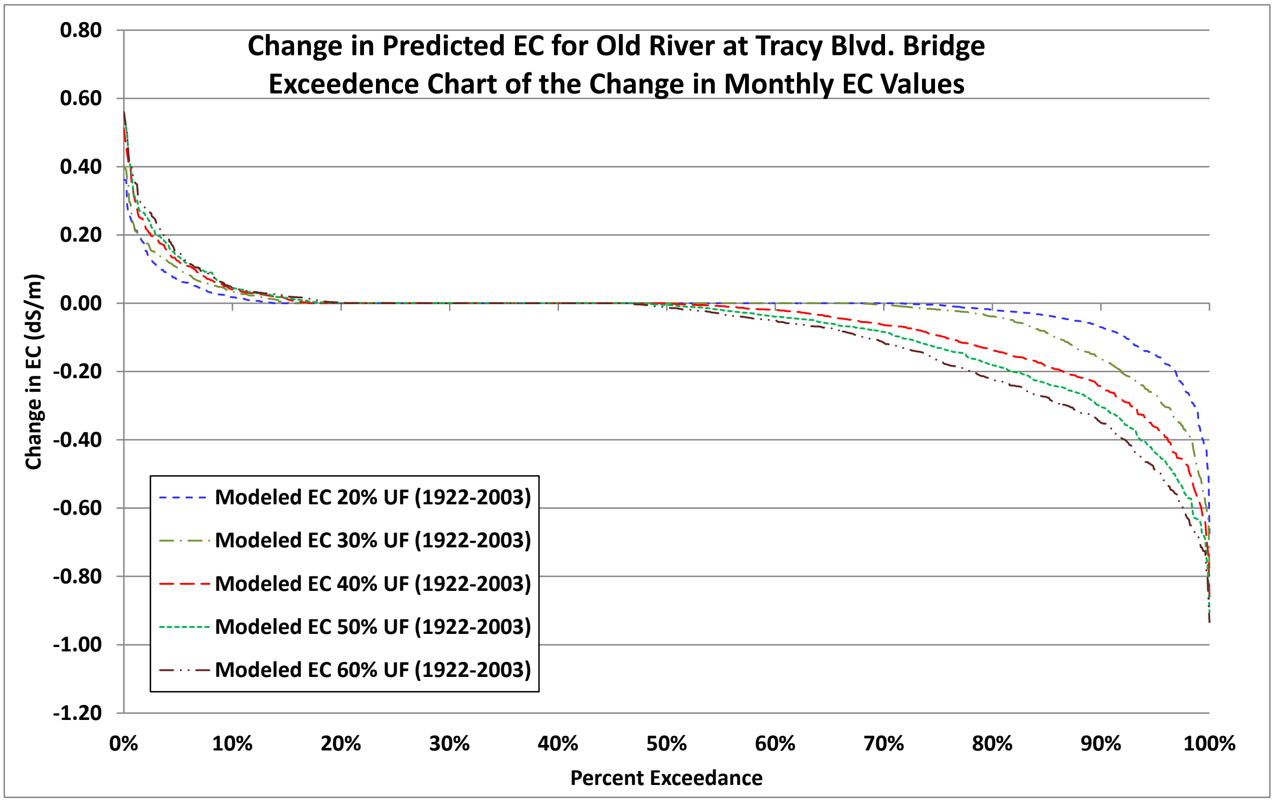

Figure 23-7. Exceedance Chart of the Change in Monthly EC Values for Old River at Tracy Boulevard Bridge Based on Percent of Unimpaired Flow, Relative to Modeled Baseline

Seasonal exceedance distributions are also analyzed to see if EC values might impair beneficial uses, particularly during the irrigation season. Figures 23-8 through 23-10 below compare the predicted average monthly EC results during the April – August irrigation season for each of the southern Delta compliance locations under the modeled baseline conditions and LSJR flow objectives ranging from 20 to 60 percent unimpaired flow. The LSJR alternatives would lead to lower EC values compared to baseline at all locations during the April – August period, with each subsequently higher unimpaired flow objective lowering the EC further.

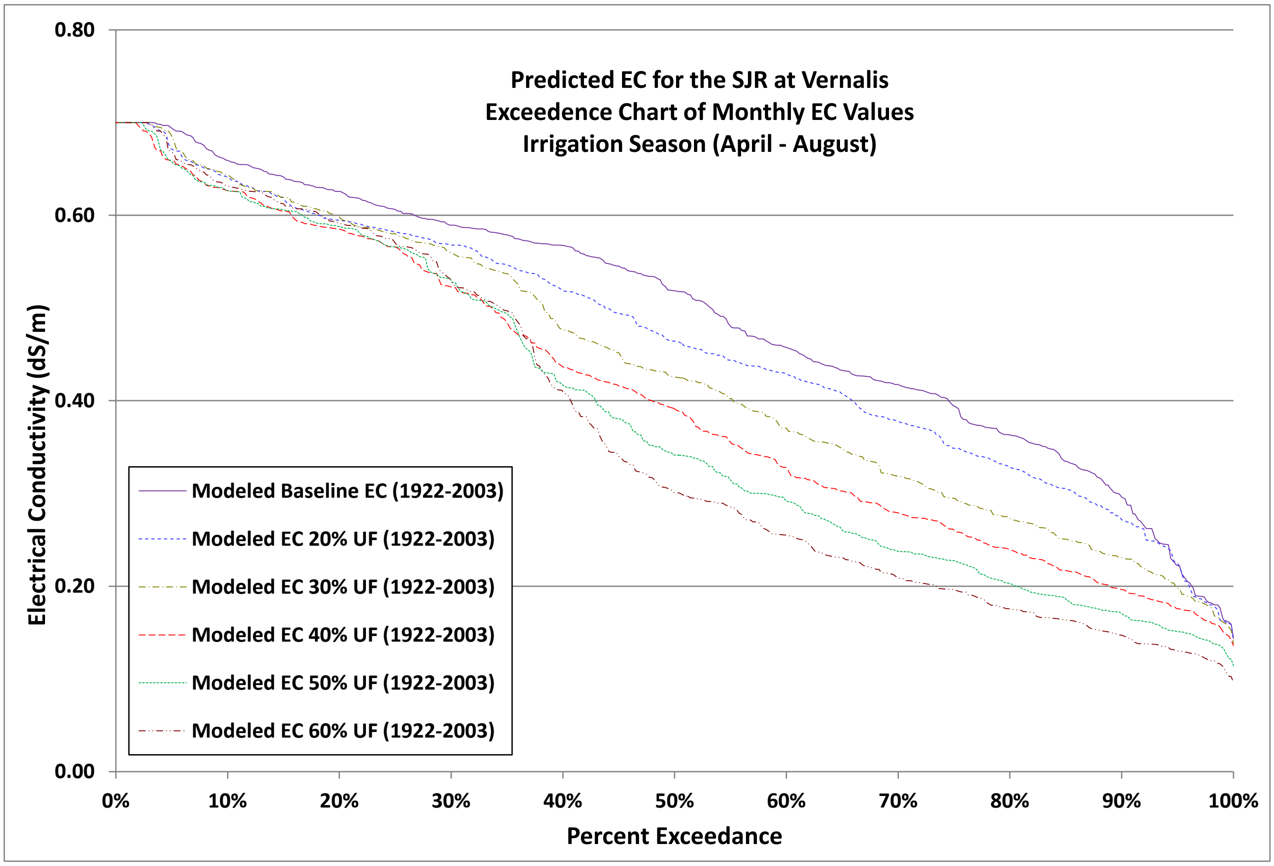

Figure 23-8. Exceedance Chart of Monthly EC Values at Vernalis during April–August under Modeled Baseline and Percent of Unimpaired Flow

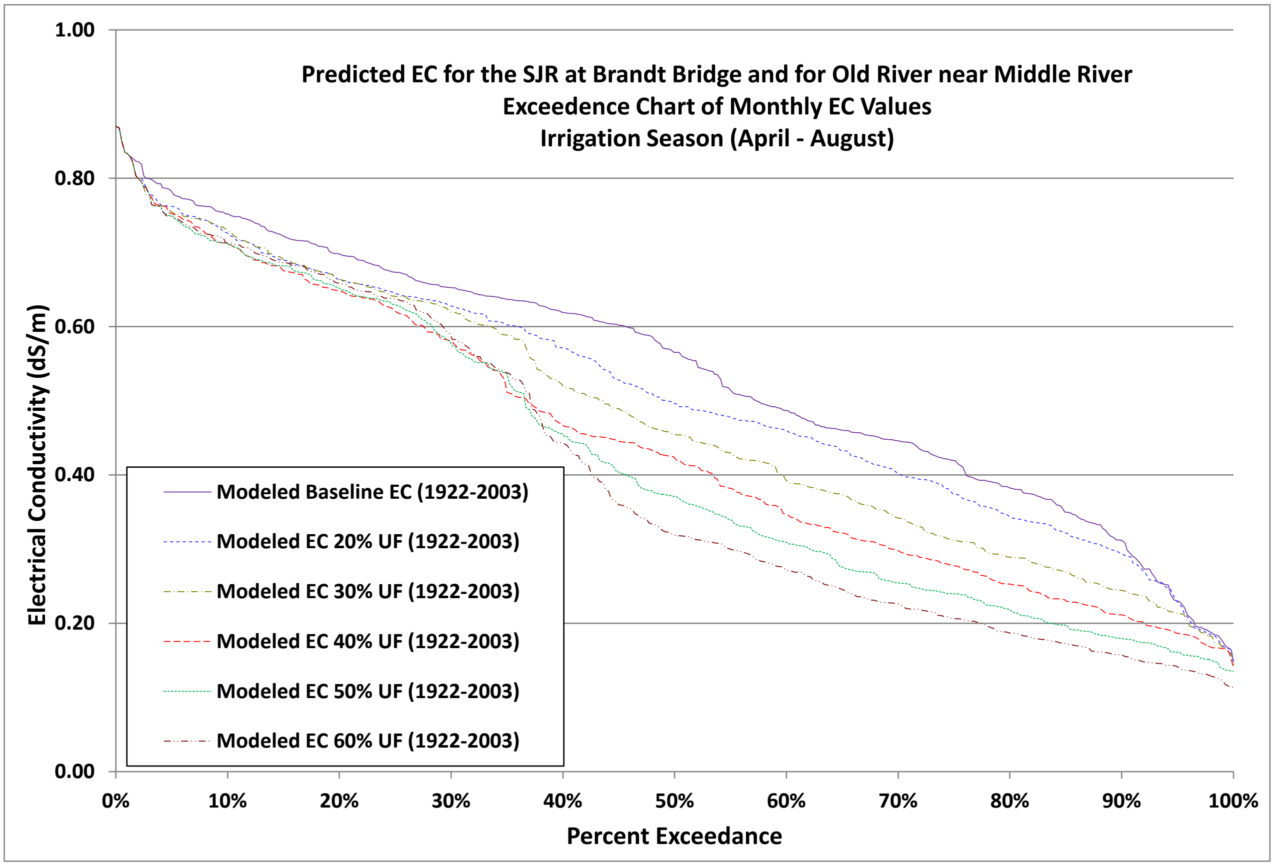

Figure 23-9. Exceedance Chart of Monthly EC Values for the SJR at Brandt Bridge and for Old River near Middle River during April–August under Modeled Baseline and Percent of Unimpaired Flow

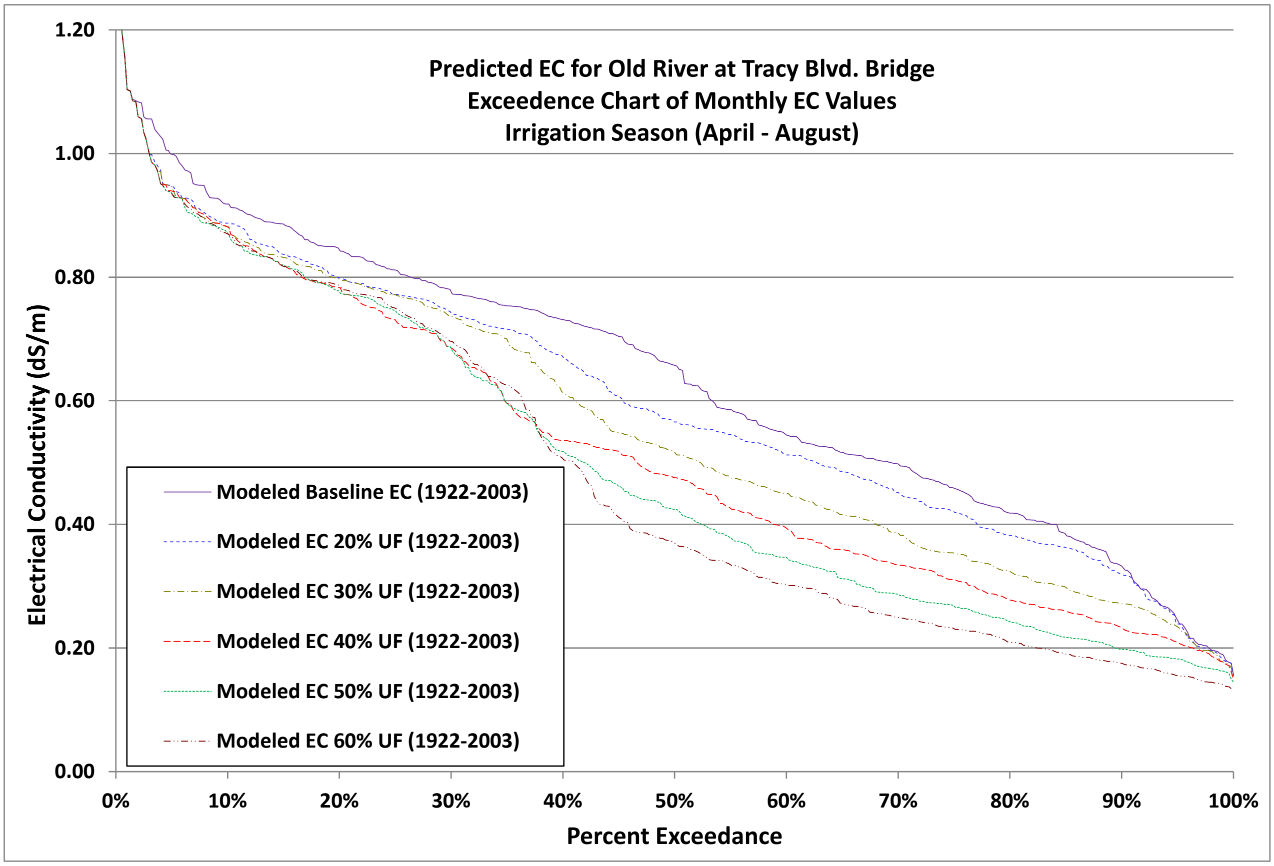

Figure 23-10. Exceedance Chart of Monthly EC Values for Old River at Tracy Boulevard Bridge during April–August under Modeled Baseline and Percent of Unimpaired Flow

Figures 23-11 through 23-13 compare the predicted average monthly EC results during the September–March non-irrigation season for each of the south Delta compliance locations under the modeled baseline conditions and LSJR flow objectives ranging from 20 to 60 percent unimpaired flow. The exceedance distribution of EC values does increase slightly over baseline conditions for some of the LSJR alternatives. These increases usually occur in the months of January and December when agricultural beneficial uses are not likely to be impacted. As described above, these occasional increases do not indicate a degradation of water quality, but rather only a shift in variable salinity as the timing and magnitude of flood control releases change.

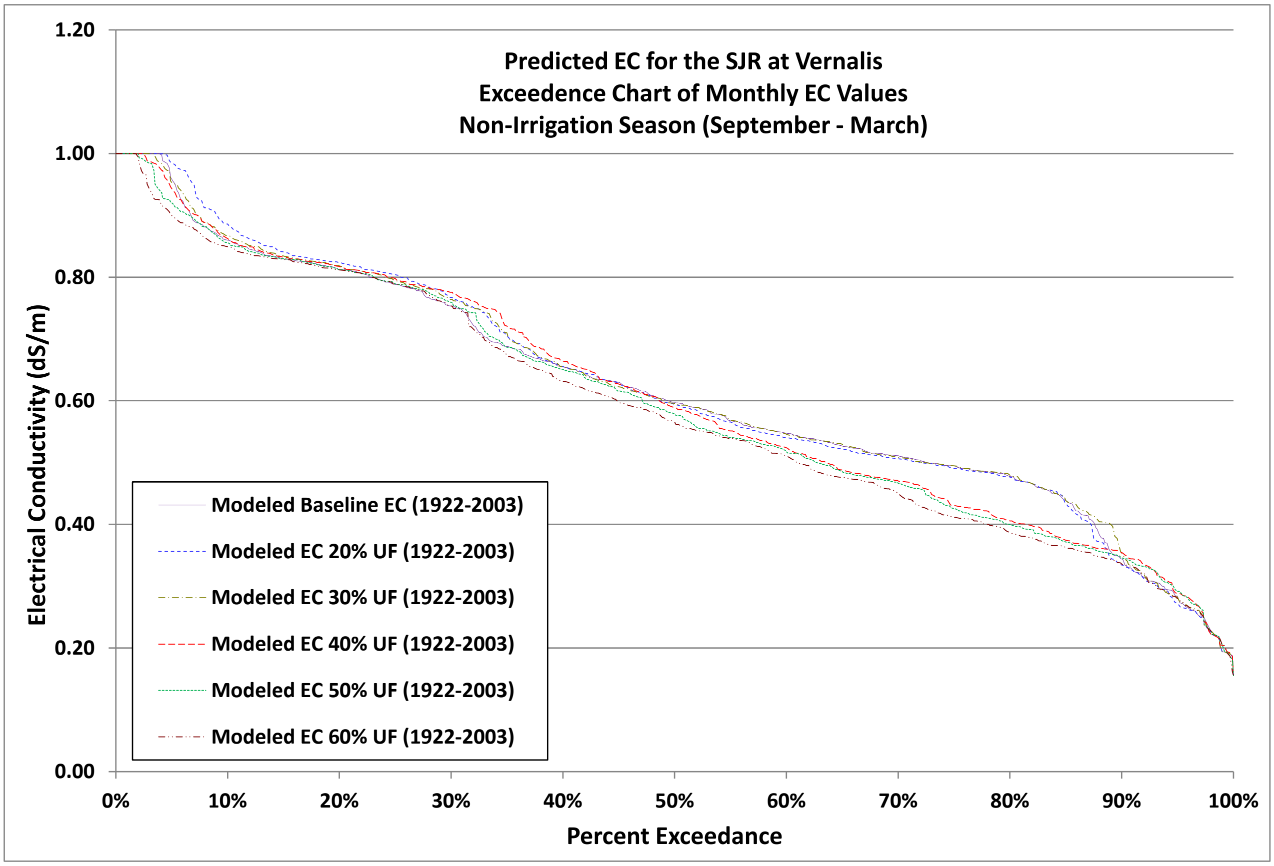

Figure 23-11. Exceedance Chart of Monthly EC Values at Vernalis during September–March under Modeled Baseline and Percent of Unimpaired Flow

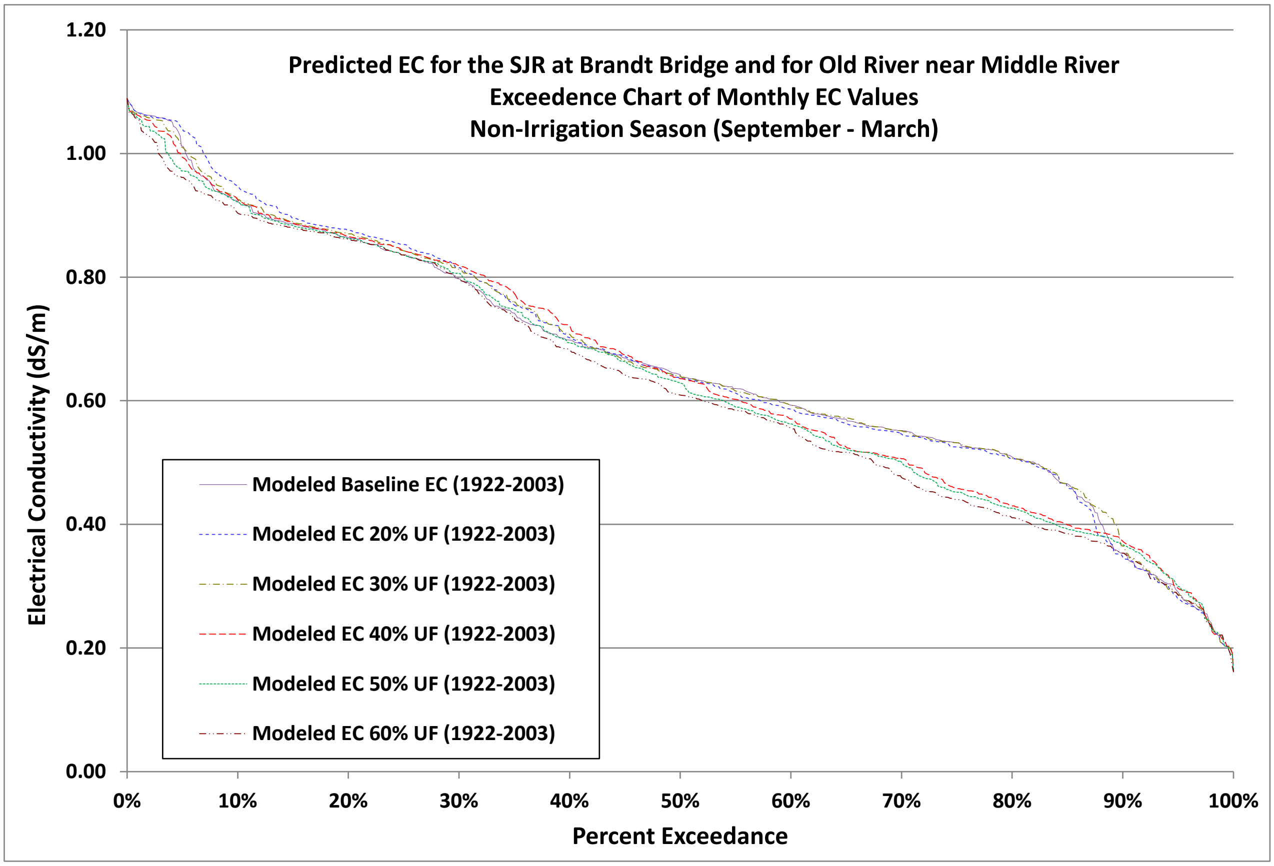

Figure 23-12. Exceedance Chart of Monthly EC Values for the SJR at Brandt Bridge and for Old River near Middle River during September–March under Modeled Baseline and Percent of Unimpaired Flow

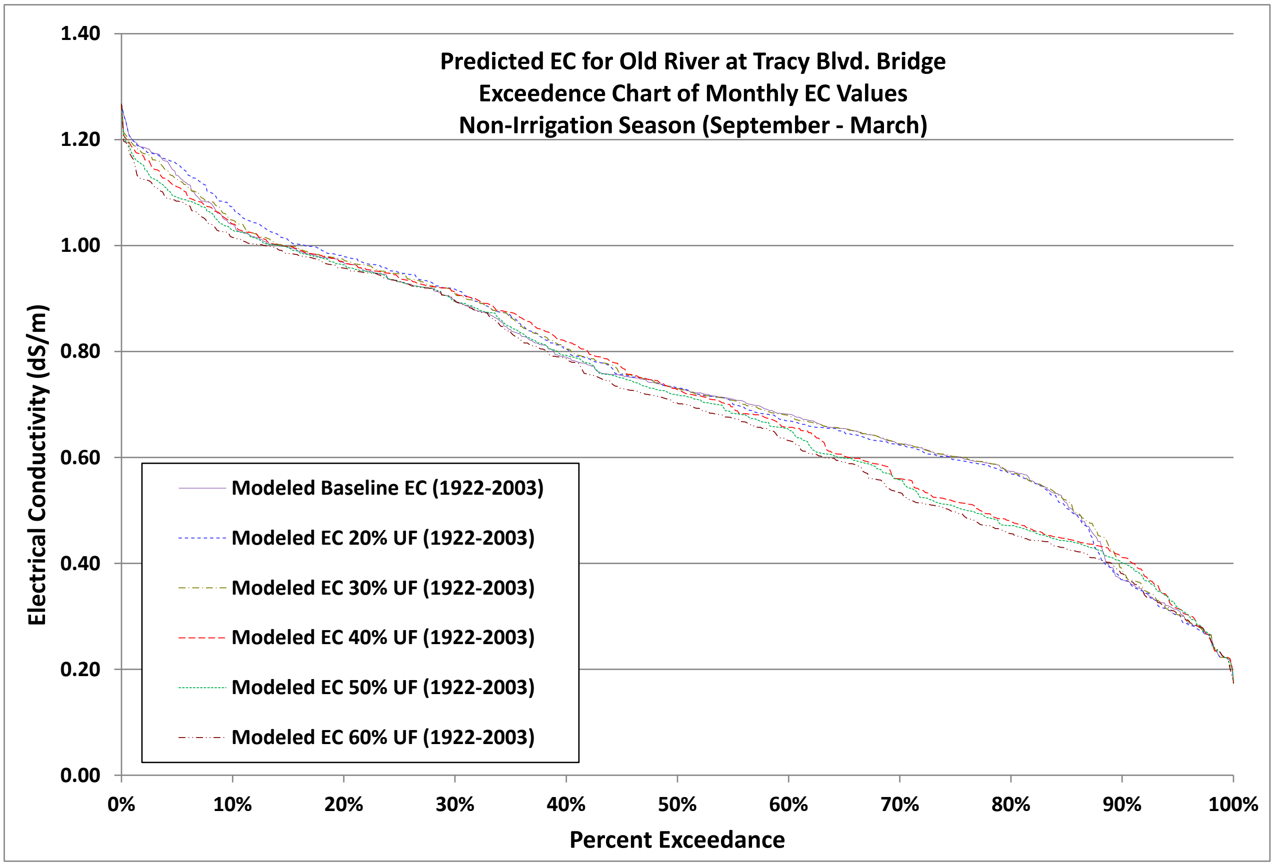

Figure 23-13. Exceedance Chart of Monthly EC Values for Old River at Tracy Boulevard Bridge during September–March under Modeled Baseline and Percent of Unimpaired Flow

Qualitative Discussion

WSE model runs for 1922 to 2003 show that changed flow patterns under the LSJR alternatives would also change salinity conditions, resulting in an overall decrease in salinity, and thus improving water quality with regard to salinity. This 82-year WSE model time period does not fully overlay the 1995 to 2015 period used to represent the baseline period of highest water quality for the purpose of the antidegradation analysis. The 82-year record, however, does include a range of hydrologic conditions that adequately characterizes the shorter, 20-year, 1995–2015 period. As described in Chapter 21, *Drought Evaluation*, WSE model simulations were used to compare drought impacts on water supply over the 1922–2003 analysis period with drought impacts during the more recent period of 2004–2015. The drought analysis showed, among other things, that runoff and water supply effects from 2004–2015 are not more extreme than drought conditions during the 1922–2003 period. Delta EC estimates are likely to be elevated during droughts because there is less water available to dilute salinity concentrations. The drought analysis, therefore, confirms that the modeled hydrologic conditions from 1922–2003 can be used to determine the overall and worst case salinity effects, with regard to antidegradation, for the 1995–2015 period.

The potential effect of the LSJR alternatives during the 1995–2015 period, with regard to antidegradation, would be to change the timing and magnitude of flows in the Stanislaus, Tuolumne, and Merced Rivers, and in the LSJR downstream of the Merced River confluence. Most of the SJR salt load originates upstream of the Merced River where high salinity agricultural discharges enter the Upper SJR and since the eastside tributaries have relatively low salinity the salt loads on the SJR would not change considerably. With increased flows, and unchanged salt loading, salt concentration would be diluted and EC would decrease. Conversely, with decreased flows and unchanged salt loading, salt concentrations would increase. From February–June, implementation of the proposed LSJR alternatives would generally increase flows, and would, therefore, decrease salinity concentrations. At other times of year, from July–January, EC would be the same as historical conditions during most years, except when flood control releases changed. Overall, salinity conditions would improve or be maintained in most years and annual average EC values would decrease, similar to the results presented in Table 23-2.

In addition, the proposed southern Delta salinity objectives would have no effect on salinity because USBR would still be required to meet a 0.7 dS/m EC objective at Vernalis from April–August as part of its water rights permits under the program of implementation. The September–March 1.0 dS/m EC objective would not change. Therefore, the responsibilities of USBR would not have changed from those in the period of 1995–2015, and New Melones would have been operated in the same way to protect EC conditions at Vernalis. This will assure that assimilative capacity is maintained downstream of Vernalis to meet the 1.0 dS/m EC water quality objective at the three remaining compliance locations in the southern Delta. Based on the crops grown in the southern Delta, an EC value of 1.0 dS/m would protect agricultural beneficial uses in the southern Delta (Appendix E, *Salt Tolerance of Crops in the Southern Sacramento–San Joaquin Delta*).

23.5.2 Flow

Antidegradation policies focus on water quality to protect beneficial uses. As part of the LSJR alternatives, flows from the eastside tributaries to the LSJR would increase during the February–June time period compared to the modeled baseline conditions. To the extent that antidegradation policies apply to water volume, increasing the flows is not expected to cause degradation in water quality. On the contrary, increasing the volume of flow would likely improve conditions for fish and wildlife beneficial uses throughout the LSJR Watershed. Annual flow contributions from the tributaries to the SJR are expected to increase by 3 percent under LSJR Alternative 2, 15 percent under LSJR Alternative 3, and 37 percent under LSJR Alternative 4. Adaptive implementation allows some shifting of flows both within and outside the February–June time frame to improve conditions for the protection of fish and wildlife beneficial uses and to preserve coldwater pool resources in the reservoirs. Though there may be instances when flows are lower than under modeled baseline, this would generally occur in wetter years during already high flows due to reduced need for flood control releases.

23.5.3 Other Parameters

This section evaluates whether changes in the LSJR flow objectives, together with the adaptive implementation measures described in Appendix K, *Revised Water Quality Control Plan*, would lower water quality for other parameters, like temperature and Clean Water Act (CWA) Section 303(d)[12] listed pollutants. This section serves as a simplified antidegradation analysis; based on best

---

[12] Clean Water Act section 303(d) requires states, territories, and authorized tribes to develop a ranked list of water quality limited segments of rivers that do not meet water quality standards.

professional judgment, the proposed alternatives would not be adverse to the intent and purpose of the antidegradation policies (State Water Board 1990). This section employs the analyses and conclusions from elsewhere in this SED to explain why there will not be a lowering of water quality with respect to these other parameters. Chapter 5, *Surface Hydrology and Water Quality*, of this SED examines how the LSJR alternatives could impact water quality, including a discussion of impacts on water temperature and CWA Section 303(d) pollutants. Chapter 5 also investigates the potential water quality impacts of adaptive implementation for the LSJR alternatives by analyzing 30 and 50 percent of unimpaired flow.

Effects of the LSJR alternatives for pollutant concentrations are examined qualitatively based on flow changes in the LSJR and eastside tributaries predicted by the WSE model. Table 5-4 of Chapter 5 provides a list of current CWA Section 303(d) water quality impairments identified in the vicinity of the plan area. As described in more detail below, flow objectives ranging from 20 to 60 percent unimpaired flow on the eastside tributaries are not expected to lower water quality with respect to temperature or CWA Section 303(d) listed pollutants and they are expected to maintain or improve water quality for protection of beneficial uses.

The eastside tributaries are generally considered to be high quality waters. However, the tributaries still face impairment from several different pollutants. Agricultural activity in the lower segments of the Stanislaus, Tuolumne, and Merced Rivers is likely responsible for impairments due to pesticides (303[d] listed since 1998, 2002 and 1996, respectively), while mining activity has likely caused impairments due to mercury (listed since 2002, 2010 and 2006, respectively). All three tributaries were identified as impaired due to water temperature in 2010. The Merced River was identified as impaired due to E. coli in 2010 as well. Additionally, all three tributaries were listed as impaired due to unknown toxicity in 1998 for the Stanislaus River, 2006 for the Tuolumne River, and 2010 for the Merced River. The mainstem of the LSJR between Vernalis and the Merced River is also identified as impaired for a variety of water quality constituents. Segments of the LSJR are listed as impaired for mercury (beginning in 2006), unknown toxicity (beginning in 1994), and for various pesticides (beginning in 1994). The LSJR was first identified as impaired due to water temperature in the 2010 303(d) list. In addition, the small section of the LSJR between the Stanislaus River and Vernalis was also listed as impaired for E.coli in 2010.

In general, adding more streamflow can help dilute many of the above constituents that impair water quality in the LSJR and the tributaries. Inflows to the LSJR from the Stanislaus, Tuolumne, and Merced Rivers, which are characterized by low EC values, help dilute the salt loads entering the SJR from upstream, improving EC values between the Merced River and Vernalis. Elevated water temperature in the LSJR and in the tributaries is also influenced by streamflow, as a larger volume of water will take longer to warm.

In addition to concerns related to salinity, portions of the southern Delta are listed as impaired on the current CWA Section 303(d) list for a variety of constituents, including pesticides (first listed in 1992), and mercury (first listed in 1992). Old River and Middle River were both identified as impaired due to low dissolved oxygen in 2002. As noted in Chapter 5, Table 5-4 of the SED, the entire Delta is identified as impaired due to unknown toxicity. Aquatic toxicity causes mortality or severe negative sublethal effects (e.g., significant impacts on growth, reproductive success) for aquatic organisms. In the case of unknown toxicity, one or more constituents are causing the toxic effects, but they have not been identified.

Water Temperature

Chapter 5, *Surface Hydrology and Water Quality*, and Appendix F.1, *Hydrologic and Water Quality Modeling*, describe the analysis of water temperature impacts resulting from the LSJR alternatives. For this analysis, monthly streamflow results from the WSE model are entered into the HEC-5Q water quality model, developed for the SJR Watershed, to produce daily temperature results for the eastside tributaries and the LSJR. For the impact analysis, the water temperature modeling covers the time period from 197–2003. The average monthly streamflow temperatures for the modeled baseline conditions are compared with the same results for the LSJR alternatives.

As described in Chapter 5 and shown in Tables 5-23a, 5-23b, and 5-23c, the biggest reduction in water temperature is expected to occur during the April–June time period when higher flows are required under the LSJR alternatives. Generally, greater water temperature improvements are expected on the Tuolumne and Merced Rivers than on the Stanislaus River. For the SJR at Vernalis, modeling results indicate either slight improvement or no change in water temperature compared to the modeled baseline conditions. The program of implementation contained in Appendix K, *Revised Water Quality Control Plan*, allows for some flexibility in managing flows outside of the February–June time period. This flow shifting approach was incorporated into the WSE and water temperature modeling, which is why the water temperature model results (shown in Chapter 5, Tables 5-23a-c) show changes outside of the February–June period. Flow shifting may occur under any of the LSJR alternatives above 30 percent unimpaired flow. Water temperatures can also be affected by changes in reservoir storage, which could occur during any month. For a more detailed description of flow shifting and how it is implemented in the WSE model, see Appendix F.1.

Additionally, Chapter 7, *Aquatic Biological Resources*, includes analysis and discussion of how the water temperature modeling results under the LSJR alternatives might affect fisheries resources and why colder streamflow temperatures are more beneficial for them. In general, implementation of the LSJR alternatives would improve streamflow temperatures for developing Chinook salmon and steelhead in the three eastside tributaries. Higher flows and cooler water temperatures in the tributaries are also expected to reduce predation impacts, improve growth opportunities, and reduce temperature-related stress in juvenile Chinook salmon and steelhead.

Clean Water Act Section 303(d) Listed Pollutants

The concentrations of CWA Section 303(d) listed pollutants in the LSJR and the eastside tributaries are more likely to approach or exceed water quality criteria levels when streamflow is low. An increase in flows, which is expected to occur under the proposed LSJR alternatives, would likely dilute pollutant concentrations and, since water quality in the eastside tributaries is generally good, improve water quality overall. The impact assessment for CWA Section 303(d) contaminants in Chapter 5, *Surface Hydrology and Water Quality*, of this SED is more of a qualitative analysis that relates changes in pollutant concentrations to changes in streamflow. The analysis examines changes in the monthly cumulative distributions of flows between modeled baseline and the LSJR alternatives for each tributary and the LSJR.

As described in Chapter 5, water quality is generally poorest under low flow conditions; therefore, changes in the cumulative flow distribution at the low end of the distribution are most likely to affect water quality. The analysis in Chapter 5 concludes that pollutant concentrations are not expected to exceed water quality criteria levels as a result of implementation of the LSJR alternatives. Instead, pollutant concentrations would likely be reduced due to increased dilution from the higher flows associated with the LSJR alternatives. There is potential for flows to decrease compared to the model baseline in wetter periods, as implementation of the LSJR alternatives may result in lower reservoir storage levels and smaller flood control releases. However, higher pollutant concentrations due to lower flows are not likely to occur because adaptive implementation would minimize the frequency of reduced flows. Certain adaptive implementation measures in Appendix K, *Revised Water Quality Control Plan*, would allow some of the February–June flow objective to be retained in storage and released later in the year to maintain or improve current temperature conditions. Therefore, water quality, as indicated by pollutant concentrations in the LSJR and the tributaries, is expected to improve under all LSJR alternatives.

23.6 Conclusion

Water quality conditions in the LSJR Watershed and southern Delta vary both seasonally and annually and are strongly affected by streamflow levels, due to dilution of the salt loads and other constituents in the affected areas. The LSJR and SDWQ alternatives, as well as their implementation, are not expected to reduce water quality; rather, water quality will be maintained and generally improved. More specifically, the proposed southern Delta salinity objective and program of implementation would not lead to a degradation of water quality, with regard to salinity, and would reduce the frequency of exceedance for the EC water quality objective at the interior southern Delta compliance locations. Moreover, USBR's water rights would continue to be conditioned on meeting the 0.7 dS/m EC standard at Vernalis during the irrigation season (April–August); therefore, water quality, with regard to salinity, is not expected to be lowered due to implementation of the proposed amendments to the 2006 Bay-Delta Plan. Modeling results for streamflow used to assess changes in 303(d) contaminant concentrations indicate that they are not expected to increase as a result of the proposed LSJR alternatives either, since baseline flows will either increase or stay the same through adaptive implementation. Water temperatures are expected to improve in the tributaries as well, and to a lesser extent in the SJR at Vernalis, especially during the February–June time period, as higher flows will buffer streamflow temperatures against warmer air temperatures. Since water quality will not be lowered, findings for degradation are not required under state and federal antidegradation policies.
