Chapter 1
Introduction

This chapter provides a brief description of the project and plan area, as well as contextual background for this recirculated substitute environmental document (SED). It also describes the State Water Quality Control Board's (State Water Board's) authorities and provides a timeline of State Water Board past and proposed actions related to the plan amendments.

1.1 Project Description

The State Water Board is considering amendments to the 2006 *Water Quality Control Plan for the San Francisco Bay/Sacramento–San Joaquin Delta Estuary* (2006 Bay-Delta Plan). The 2006 Bay-Delta Plan designates beneficial uses of water within the Bay-Delta, water quality objectives for the reasonable protection of those beneficial uses, and a program of implementation for achieving the water quality objectives.

The project (plan amendments) would establish the following updates to the 2006 Bay-Delta Plan.

- New flow objectives on the Lower San Joaquin River (LSJR)[1] and its three eastside tributaries[2] for the protection of fish and wildlife beneficial uses.
- Revised water quality objectives for the protection of agricultural beneficial uses in the southern Delta.
- A program of implementation to achieve these objectives.
- Monitoring and special studies necessary to fill information needs and determine the effectiveness of, and compliance with, the new objectives.

The new LSJR flow objectives and revised southern Delta water quality (SDWQ) objective and associated program of implementation would replace the existing San Joaquin River (SJR) flow and southern Delta salinity objectives and associated program of implementation in the 2006 Bay-Delta Plan.

1.2 Plan Area

The plan amendments involve changes in flow requirements in the SJR Basin and changes in water quality objectives for the southern Delta (Figure ES-1). The plan area encompasses the areas where the plan amendments apply to protect beneficial uses of water. For example, the LSJR flow objectives would require flows below the rim dams on the Stanislaus, Tuolumne, and Merced Rivers, and the mainstem of the LSJR between the confluence of the Merced River to Vernalis to protect fish and wildlife beneficial uses in those reaches. Thus, these plan amendments could directly affect

---

[1] The LSJR is that portion of the San Joaquin River between its confluence with the Merced River and downstream to Vernalis, and its three eastside tributaries—the Stanislaus, Tuolumne, and Merced Rivers.

[2] In this document, the term *three eastside tributaries* refers to the Stanislaus, Tuolumne, and Merced Rivers.

portions of the SJR Basin and Delta that drain into, divert water from, or otherwise obtain beneficial use (e.g., surface water supplies) from the following water bodies. These portions of the SJR Basin and Delta are referred to as the *plan area* throughout this SED (Figure ES-2).

- Stanislaus River Watershed, from and including New Melones Reservoir to the confluence of the LSJR.
- Tuolumne River Watershed, from and including New Don Pedro Reservoir to the confluence of the LSJR.
- Merced River Watershed, from and including Lake McClure to the confluence with the LSJR.
- Mainstem of the LSJR, between its confluence with the Merced River downstream to Vernalis.
- Areas that receive a portion of their water supply from, and that are contiguous with, the above areas.
- The southern Delta, including the SJR from Vernalis to Brandt Bridge, Middle River from Old River to Victoria Canal, and Old River/Grant Line Canal from the Head of Old River to West Canal.

In addition to implementing the plan amendments in the plan area, the State Water Board will evaluate, in a subsequent water rights proceeding, whether to impose responsibility on surface water users who divert surface water from the Stanislaus, Tuolumne, and Merced River Watersheds above the major dams. The plan amendments also have the potential to affect areas within the watersheds that receive a portion of their water supply from these areas. These areas are referred to as the *extended plan area* throughout this SED and are listed below (Figure ES-2).

- Stanislaus River Watershed upstream of New Melones Reservoir.
- Tuolumne River Watershed upstream of New Don Pedro Reservoir.
- Merced River Watershed upstream of Lake McClure.

Finally, the plan amendments also have the potential to affect areas outside of the plan area or extended plan area that obtain beneficial use of water from the Stanislaus, Tuolumne, and Merced Rivers, and the LSJR downstream of the Merced River, but are not contiguous with the plan area or extended plan area. These areas are included in the areas of potential effects for some of the resources evaluated throughout this SED and are listed below.

- City and County of San Francisco (CCSF).
- Any other area served by water delivered from the plan area or extended plan area not otherwise listed above.

1.3 Background

This document is a recirculated SED. On December 31, 2012, the State Water Board released a draft SED (2012 Draft SED) for the review and update of the SJR flow and southern Delta salinity objectives and associated program of implementation. After holding a public workshop and receiving public comments on the 2012 Draft SED in 2013, the State Water Board decided to recirculate the document. This SED considers comments received on the 2012 Draft SED, as summarized in Appendix M, *Summary of Public Comment on the 2012 Draft SED,* and provides updated information and additional analyses on certain subjects, as described in the *Executive Summary* and Chapter 4, *Introduction to the Analysis*.

The State Water Board is currently conducting a phased evaluation of the 2006 Bay-Delta Plan. Phase I consists of a review and update of the current SJR flow and southern Delta salinity objectives and associated program of implementation. Phase II consists of review and potential modification to other parts of the 2006 Bay-Delta Plan, including Delta outflows, State Water Project (SWP) and Central Valley Project (CVP) export restrictions, and other requirements in the Bay-Delta to protect fish and wildlife beneficial uses. Phases I and II are independent of each other, addressing different water quality objectives and associated programs of implementation. In Phase III, the State Water Board will conduct proceedings to assign responsibility for actions to implement the water quality objectives established in Phase I and Phase II, including changes to water rights or other implementation actions.

When proposing to undertake or approve a discretionary project, state agencies must comply with the procedural and substantive requirements of the California Environmental Quality Act (CEQA).[3] (Pub. Resources Code, § 21000 et seq.) CEQA applies to discretionary projects that may cause a direct or indirect physical change in the environment. The State Water Board is the lead agency under CEQA. This SED was prepared in compliance with CEQA and other laws to analyze the potential environmental impacts of adopting and implementing the proposed amendments to the Bay-Delta Plan associated with Phase I. Environmental impacts associated with Phase II will be evaluated in a separate environmental document. Adoption of the Bay-Delta Plan itself will not result in physical changes in the environment. Rather, it is through the implementation of the objectives in the Bay-Delta Plan that physical changes in the environment potentially may occur. Because the Bay-Delta Plan does not approve any particular projects, the assessment of the potential environmental impacts associated with amendments to the Bay-Delta Plan are necessarily conducted at a programmatic level. Specific actions to implement the water quality objectives in the Bay-Delta Plan will be assessed at a project-level basis in compliance with CEQA. The State Water Board anticipates preparing an environmental impact report (EIR) to evaluate environmental effects of assigning responsibility to implement the water quality objectives, such as in a water rights proceeding to implement the amendments to the 2006 Bay-Delta Plan (Phase I and Phase II).

In addition to other legal requirements, the State Water Board must comply with the requirements of CEQA when adopting water quality control plans (WQCP). The purpose of this SED, in part, is to provide an environmental analysis of the proposed amendments to the Bay-Delta Plan and the reasonably foreseeable methods of compliance with the amendments, as well as consideration of other factors. CEQA authorizes the Secretary of the Resources Agency to certify a regulatory program of a State agency as exempt from the requirements for preparing EIRs, negative declarations, and initial studies if certain conditions are met. (Pub. Resources Code, § 21080.5.) The State Water Board's water quality control planning program is a certified regulatory program and thus, a SED may be prepared in lieu of an EIR. (*Ibid*.; Cal. Code Regs., tit. 14, § 15251, subd. (g).)

---

[3] CEQA's basic purposes are to: (1) inform the decision makers and public about the potential significant environmental effects of a proposed project; (2) identify ways that environmental damage may be avoided or reduced; (3) prevent significant, avoidable damage to the environment by requiring changes in projects through the use of alternative or mitigation measures when feasible; and (4) disclose to the public why an agency approved a project in the manner the agency chose if significant effects are involved. (Cal. Code Regs., tit. 14, § 15002, subd. (a).) To fulfill these functions, a CEQA review need not be exhaustive, and CEQA documents need not be perfect. The CEQA documents should be adequate, complete, and represent a good faith effort at full disclosure. (*Id*., § 15151.)

This SED fulfills the requirements of CEQA and the State Water Board's CEQA regulations (Cal. Code Regs., tit. 23, § 3775 et seq.) to analyze the environmental effects of the proposed regulatory activity, as well as requirements of the Porter-Cologne Water Quality Control Act (Porter-Cologne Act) and other applicable requirements as described in Section 1.4, *State Water Board Authorities*. This SED will inform the State Water Board's consideration of the potential amendments to the 2006 Bay-Delta Plan described above.[4]

1.4 State Water Board Authorities

The State Water Board was formed in 1967 when the State Water Rights Board and the State Water Quality Control Board were merged by the legislature, based on the principle that water rights and water quality are interrelated and should be regulated in an integrated manner. The State Water Board is composed of five full-time appointees of the governor. The State Water Board allocates rights to the use of surface water, protects water quality by setting statewide policy, regulates public drinking water systems and, in coordination with the nine regional water quality control boards (Regional Water Boards), takes actions to ensure the highest reasonable quality for waters of the state through administration of the Porter-Cologne Act and portions of the federal Clean Water Act (CWA).

1.4.1 Porter-Cologne Act

The Porter-Cologne Act is the principal water quality control law for California. It establishes a comprehensive program to protect surface and groundwater quality and the beneficial uses of water in the state. Under the Porter-Cologne Act, the state is divided into nine regions, and a Regional Water Board has primary responsibility for protecting water quality within each region. The State Water Board oversees the Regional Water Boards' implementation of the Porter-Cologne Act. Together with the Regional Water Boards, the State Water Board implements the federal Clean Water Act in California. Section 303 of the Clean Water Act (33 U.S.C., § 1313) provides for the adoption of water quality standards by the states.

The Regional Water Boards have primary responsibility for the formulation and adoption of water quality control plans for their respective regions, subject to the State Water Board's and United States Environmental Protection Agency (USEPA) approval, as appropriate. (Wat. Code, § 13240 et seq.) The State Water Board may also adopt water quality control plans, which will supersede regional water quality control plans for the same waters to the extent of any conflict. (*Id*., § 13170.) For a specified area, the water quality control plans designate the beneficial uses of waters that are to be protected, water quality objectives for the reasonable protection of the beneficial uses or the prevention of nuisance, and a program of implementation to achieve the water quality objectives. (*Id*., §§ 13241, 13050, subds. (h), (j).) The beneficial uses together with the water quality objectives that are contained in the water quality control plans, and applicable federal anti-degradation requirements, constitute California's water quality standards for purposes of the federal CWA. Water quality objectives usually are implemented through water quality actions, such as waste discharge requirements, or in the case of flow-related objectives, as conditions of water right permits or licenses or water quality certifications.

---

[4] These plan amendments are the *project* as defined in State CEQA Guidelines, Section 15378.

WQCPs are periodically reviewed and amended to protect water quality. After a WQCP is adopted, the Water Code and the CWA require, respectively, a periodic and a triennial review of water quality control plans or water quality standards under Water Code Section 13240 and under Section 303 subdivision (c)(1) of the CWA. (33 U.S.C., § 1313, subd. (c)(1).) As explained herein, compliance with CEQA and the preparation of environmental documentation is required as part of the WQCP amendment process.

1.4.2 Water Rights

The State Water Board exercises adjudicatory and regulatory water quality and water rights functions in California. All water in California belongs to the people of the State. Although water cannot be privately owned, the right to use water can be acquired pursuant to statutory and common law. The State Water Board's water rights authority has been the principal authority used to implement the Bay-Delta Plan in the past because the flow and salinity objectives have been implemented through flow measures that have required changes in water rights. The State Water Board has authority to amend an existing water right permit or license under various authorities, including by invoking: (1) its reserved jurisdiction over permits under Water Code Section 1394; (2) its continuing authority to prevent the waste, unreasonable use, or unreasonable method of use of water under the California Constitution, Article X, Section 2; or (3) its continuing authority to protect public trust uses of water.

California law recognizes several types of rights to surface water, of which riparian and appropriative rights are the most common. A riparian right exists by reason of ownership of land abutting a stream or other body of water. The right allows a water user to divert from the natural flow of a stream for use on land within the watershed of the source. Seasonal storage of water is not allowed under a riparian right. In general, riparian water users have first priority to the use of the natural flow in a river. Water remaining after riparian users have taken their share is available to appropriators.

An appropriative water right consists of the right to divert a specified quantity of water for a reasonable, beneficial use. Appropriative rights carry a priority relative to other appropriative rights. The water user who is first in time is entitled to the full quantity of water specified under the right before junior appropriators may exercise their rights. Since December 19, 1914, the effective date of the Water Commission Act of 1913, the acquisition of an appropriative right requires a person to obtain a permit or license from the State Water Board or its predecessor agencies. Appropriative water rights fall into two general categories: pre-1914 appropriative water rights and post-1914 appropriative water rights. No permit or license is necessary to divert water under claim of pre-1914 appropriative right.

To obtain a new appropriative water right, a person must file a water rights application with the State Water Board to appropriate water, obtain a water right permit, and use the water in accordance with the permit for a reasonable and beneficial purpose. In acting on an application, the State Water Board considers a number of factors, including whether water is available for appropriation, whether the water will be put to beneficial use, and whether it is necessary to impose conditions to protect the environment, the public trust, and prior rights, including conditions to carry out water quality control plans. If the water is diverted and used in accordance with the terms of the permit, a license eventually will be issued confirming the extent of the appropriative right.

1.5 State Water Board Actions

The State Water Board is considering amendments to the 2006 Bay-Delta Plan, which was adopted by the State Water Board by Resolution No. 2006-0098 on December 13, 2006. The 2006 Bay-Delta Plan identified a number of emerging issues that required additional evaluation and water quality control planning. Two of the emerging issues identified for further evaluation and prioritization were SJR flows and southern Delta salinity (State Water Board 2006), which are the focus of the State Water Board's current planning efforts and this SED. In July 2008, the State Water Board adopted the *Strategic Workplan for Activities in the San Francisco Bay/Sacramento–San Joaquin Delta Estuary* and expressed its intent to review and potentially modify the SJR flow and southern Delta salinity objectives. The State Water Board again identified these issues for further review in the *2009 Staff Report on the Periodic Review of the 2006 Bay-Delta Plan*, adopted by Resolution No. 2009-0065 on August 4, 2009.

This is a recirculated SED. On February 13, 2009, the State Water Board initiated the review and potential amendment of the Bay-Delta Plan. It issued two notices: (1) a notice of preparation (NOP) and a scoping meeting notice for environmental documentation for the update and implementation of the Bay-Delta Plan relating to the southern Delta salinity and LSJR flow objectives; and (2) a notice of public staff workshop to receive information regarding potential amendments to the objectives. On April 1, 2011, the State Water Board issued a revised NOP and notice of an additional scoping meeting for June of 2011. The State Water Board also held several other public meetings and workshops to receive information and conduct discussions regarding issues related to the potential plan amendments.

1.5.1 Lower San Joaquin River Flows

This section describes the State Water Board's past actions and proposed plan amendments related to LSJR flows.

Flow Objectives Background

Storage reservoirs were constructed in the SJR Basin beginning in the 1940s through the 1970s. These storage reservoirs were constructed by local irrigation districts and as part of the larger federal CVP. The SJR flows at Vernalis and in the three eastside tributaries are generally much lower than the natural peaks in flow that would have occurred in spring and early summer because of reservoir storage and diversions. At the same time, the natural low flow periods of the late summer and early fall have been elevated at times due to agricultural return flows and power generation releases of previously stored water. The flow changes and physical habitat modification activities (e.g., gravel mining) have resulted in poor habitat conditions for native fishes and native LSJR fish populations (e.g., Chinook salmon and Central Valley steelhead) have declined.

The State Water Board first established flow objectives for the SJR at Vernalis in the 1995 Bay-Delta Plan to protect fish and wildlife beneficial uses. These SJR flow objectives were primarily intended to protect anadromous species (ocean-going fish that migrate upstream to spawn), such as fall-run Chinook salmon, which use the three eastside tributaries.[5] They were also intended to provide incidental benefits to Central Valley steelhead. The State Water Board set different numeric

---

[5] The State Water Board established a narrative objective for salmon protection that is consistent with the anadromous fish doubling goals of the Central Valley Project Improvement Act (CVPIA).

objectives based on water year type for three time periods: February–June, excluding April 15–May 15 (spring flows); April 15–May 15 (pulse flows); and October (fall flows). The spring flows were intended to provide minimum net downstream freshwater flows in the SJR to address habitat concerns from reduced flows and water quality degradation. The pulse flows were developed to increase the success of Chinook salmon smolt outmigration from the SJR through the Bay-Delta. The fall flows were developed to provide attraction flows for adult salmon returning to the SJR Watershed to spawn. The spring flow and pulse flow objectives include two levels for each time period. The trigger for the higher flow is linked to the February–June Delta outflow objectives (X2),[6] which are based on hydrologic conditions in the Sacramento River Basin and the SJR Basin.

In Water Right Decision 1641 (revised March 15, 2000), the State Water Board allocated responsibility for meeting the SJR flow objectives in the 1995 Bay-Delta Plan to the U.S. Bureau of Reclamation (USBR). In order to obtain additional scientific information on which to base future objectives, in the State Water Board's Water Right Decision 1641 (D-1641), the State Water Board also approved the Vernalis Adaptive Management Plan (VAMP) experiment proposed by parties to the San Joaquin River Agreement in lieu of meeting the pulse flow objectives included in the 1995 Bay-Delta Plan. VAMP, which was initiated in 2000 and expired in 2011, was a large-scale, experimental management program that was designed to determine how juvenile fall-run Chinook salmon survival rates change in response to alterations in SJR flows and CVP and SWP exports, and with the installation of a permanent barrier at the head of Old River (HORB) (which was never permanently installed). The VAMP experiment, which was implemented for a 31-day period each year during April and May, was designed to assess a combination of SJR flows, varying between 3,200 cubic feet per second (cfs) and 7,000 cfs, and exports varying between 1,500 and 3,000 cfs. Information from the VAMP experiment was intended to inform potential changes to the SJR flow objectives. For various reasons, however, VAMP was not implemented as originally designed. In the 2006 Bay-Delta Plan, the flow objectives were not modified, but the program of implementation was changed to allow for the ongoing staged implementation of the pulse flow objectives through VAMP. In addition, as discussed above, SJR flows were identified as an emerging issue requiring additional consideration to address ongoing population declines of salmonids and the effect of SJR flows on pelagic organisms.

Other flow requirements for the SJR, including Endangered Species Act (ESA) biological opinion requirements and Federal Energy Regulatory Commission (FERC) licensing requirements are described in Chapter 2, *Water Resources*, and Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*.

---

[6] X2 is the location of the 2 parts per thousand salinity contour (isohaline), 1 meter off the bottom of the estuary measured in kilometers upstream from the Golden Gate Bridge. The abundance of several estuarine species has been correlated with X2. In the 2006 Bay-Delta Plan, a salinity value--or electrical conductivity (EC) value--of 2.64 millimhos/centimeter (mmhos/cm) is used to represent the X2 location. Note, in this SED, EC is generally expressed in deciSiemens per meter (dS/m). The conversion is 1 mmhos/cm = 1 dS/cm.

Proposed Amendments

The State Water Board is considering amending the Bay-Delta Plan to establish new flow objectives on the LSJR and its three eastside tributaries to protect fish and wildlife beneficial uses. These objectives would establish flows sufficient to support and maintain the natural production of fish populations in the plan area. The flows are intended to mimic the natural hydrograph with respect to relative magnitude, duration, timing, and spatial extent of flows. The objectives also require a percentage of unimpaired flows to be maintained. The alternatives evaluated in this SED include implementation of the flow objectives by a range of percentages of unimpaired flow during the February–June period. Unimpaired flow represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization. The program of implementation of the flow objectives also provides flexibility to adaptively manage flows outside of the February–June time period. The LSJR alternatives are listed below, including the No Project Alternative, which must be evaluated under CEQA.

- LSJR Alternative 1, the No Project Alternative, would continue the flow requirements as established in the 2006 Bay-Delta Plan and implemented through D-1641; this also includes continuation of, and full compliance with, the southern Delta salinity objectives as described in SDWQ Alternative 1.
- LSJR Alternative 2 would establish a range between 20 and 30 percent, with 20 percent as the starting percentage of unimpaired flow in the program of implementation.
- LSJR Alternative 3 would establish a range between 30 and 50 percent, with 40 percent as the starting percentage of unimpaired flow in the program of implementation.
- LSJR Alternative 4 would establish a range between 50 and 60 percent, with 60 percent as the starting percentage of unimpaired flow in the program of implementation.

The program of implementation for LSJR alternatives 2, 3, and 4 also describes the potential State Water Board actions listed below.

- How the State Water Board could use adaptive implementation to implement the flow objectives.
- The water rights actions that will be taken by the State Water Board to implement the flow objectives.
- Other State Water Board implementation actions to implement the flow objectives, including modification of hydropower project FERC license requirements through the FERC hydropower relicensing process.
- Non-flow measures that could be used to support and maintain the natural production of fish populations in the plan area.
- Special studies, reporting, and monitoring.

As noted at the beginning of this document, the State Water Board's Phase III would specifically identify the water rights that could be modified as a result of adopting and applying the program of implementation for the LSJR flow objectives analyzed in this SED as part of Phase I. Details of the

LSJR alternatives are provided in Chapter 3, *Alternatives Description*, and the language of the amended WQCP is included in Appendix K, *Revised Water Quality Control Plan.*

1.5.2 Southern Delta Water Quality

This section describes the State Water Board's past actions and proposed plan amendments related to southern Delta water quality.

Water Quality Objectives Background

Elevated salinity in the southern Delta is caused by various factors, including low flows; salts imported to the SJR Basin in irrigation and wetland supply water; municipal discharges; subsurface accretions from groundwater; tidal actions; diversions of water by the CVP, SWP, and local water users; channel capacity; and agricultural drainage discharges to the SJR upstream of the Delta and in the Delta. Poor flow or circulation patterns in the southern Delta waterways also cause localized increases in salinity concentrations.

The State Water Board established the current southern Delta salinity objectives for the protection of agricultural beneficial uses in the 1978 Delta Plan. The 1978 Delta Plan includes salinity objectives, in the form of electrical conductivity (EC),[7] for the protection of agriculture in the southern Delta at four compliance locations including: the SJR at Vernalis, the SJR at Brandt Bridge, Old River near Middle River, and Old River at Tracy Road Bridge. The approach used in developing the objectives involved an initial determination of the water quality needs of significant crops grown in the area, the predominant soil type, and local irrigation practices. In addition, the extent to which these water quality needs would be satisfied under "without project" (without the CVP and SWP) conditions was also considered. The State Water Board based the southern Delta EC objectives on the calculated maximum salinity of applied water (assuming no precipitation) that sustains 100 percent yields of two important salt-sensitive crops grown in the southern Delta (beans and alfalfa) in conditions typical of the southern Delta (surface irrigation of mineral soils) per the *University of California Guidelines and Irrigation and Drainage Paper 29: Water Quality for Agriculture of the Food and Agriculture Organization of the United Nations* (State Water Board 1978, page VI-16 – VI-19). The State Water Board set an objective of 0.7 deciSiemens per meter (dS/m) during the summer irrigation season (April 1–August 31) based on the salt sensitivity and growing season of beans and an objective of 1.0 dS/m during the winter irrigation season (September 1–March 31) based on the growing season and salt sensitivity of alfalfa during the seedling stage. In the 1978 Delta Plan, the State Water Board found that the most practical solution for long-term protection of southern Delta agriculture was construction of physical facilities to provide adequate circulation and substitute supplies.

The State Water Board delayed implementation of the southern Delta salinity objectives pending negotiations by the California Department of Water Resources (DWR), USBR, and the South Delta Water Agency (SDWA) concerning construction of physical facilities to protect agriculture in the southern Delta (permanent barriers or other devices). Because the negotiations were never completed, the 1991 Bay-Delta Plan provided for a staged implementation of the objectives.

---

[7] In this document, EC is *electrical conductivity*, which is generally expressed in deciSiemens per meter (dS/m). Measurement of EC is a widely accepted indirect method to determine the salinity of water, which is the concentration of dissolved salts (often expressed in parts per thousand or parts per million). EC and salinity are therefore used interchangeably in this document.

The 1991 Bay-Delta Plan called for implementation of the objectives at Vernalis and Brandt Bridge by 1994 and implementation of the objectives at the two Old River sites by 1996 unless a three-party agreement was reached between DWR, USBR, and SDWA. In the 1995 Bay-Delta Plan, the State Water Board further delayed implementation of the EC objectives for the two Old River sites until December 31, 1997.

In D-1641, the State Water Board authorized a staged implementation of the southern Delta EC objectives. Pursuant to D-1641, USBR was required to meet the Vernalis EC objectives using any measures available. DWR and USBR also were required to meet an EC objective of 1.0 dS/m at Brandt Bridge on the SJR, Old River near Middle River, and Old River at Tracy Road Bridge (collectively, the interior southern Delta stations) September–March, and April–August, until April 1, 2005. As of April 1, 2005, D-1641 required that DWR and USBR, through their water right permits and license, meet an EC objective of 0.7 dS/m April–August at the interior southern Delta stations unless permanent barriers were constructed or equivalent measures were implemented to protect southern Delta agriculture along with an operations plan. As discussed below in Section 1.5.3, *Related Litigation*, the appellate court reviewing D-1641 struck down the provision allowing 1.0 dS/m at the interior salinity stations for April–August if such measures were taken. Accordingly, the objectives in the 2006 Bay-Delta Plan are in effect: 0.7 dS/m for April–August, and 0.7 dS/m for September–March.

Since 1991, DWR has installed temporary rock barriers in the southern Delta at three locations to improve water levels, circulation patterns, and water quality in the southern Delta for local agricultural diversion.[8] DWR and USBR were planning to construct permanent physical facilities in the form of permanent operable gates (known as the South Delta Improvements Program) that would have provided better compliance with the objectives. However, the permanent facilities have not been constructed to date, and their construction is unlikely to occur due to endangered species concerns. The National Marine Fisheries Service (NMFS) biological opinion (BO) Stanislaus River reasonable and prudent alternative, including Action 3.1.3 (NMFS BO) was issued in June 2009 and specifically directs DWR to halt implementation of the South Delta Improvements Program. NMFS has indicated that consultation for the program cannot be reinitiated until after 3 years of fish predation studies at the southern Delta temporary barriers are completed. The studies were completed in 2011, and DWR is currently working with NMFS. After all permits have been acquired DWR can proceed with construction; however, there is not a schedule available for project completion at this time.

In 2006 the State Water Board issued a cease and desist order (CDO) against USBR and DWR for threatened violation of the interior southern Delta salinity objectives that imposed a time schedule for compliance with the objectives (State Water Board Order WR 2006-0006). In 2010, the State Water Board issued Order WR 2010-0002 modifying Order WR 2006-0006. The modified order amends the compliance schedule in Order WR 2006-0006 and imposes other interim measures. As an example, pursuant to Condition 5 of Order WR 2010-0002, DWR, in cooperation with USBR, is required to continue implementing temporary barriers in the southern Delta and is required to pursue and implement feasible improvements to the temporary barriers. Pursuant to Condition 7 of Order WR 2010-0002, DWR and USBR are also required to study the feasibility of controlling salinity by implementing measures other than the temporary barriers project, such as the feasibility of installing low lift pumps. Order WR 2010-0002 also delegates to the State Water Board Executive

---

[8] DWR is the lead agency pursuant to CEQA and has prepared several environmental documents for construction and operations of the barriers.

Director the authority to require DWR and USBR to implement, on an interim basis, any alternative salinity control measures that the Executive Director determines are reasonable and feasible, based on the feasibility study.

Under the current objectives and methods for determining compliance, there have been many instances of exceedance of the EC objective in the southern Delta, in particular at the Old River near Tracy Road Bridge, Station P-12. Typically exceedance occurs due to dry hydrologic conditions in the Sacramento River and SJR Basins and degradation occurring downstream of Vernalis. The proposed interior southern Delta salinity compliance locations are comprised of three river segments rather than the current three specific point locations so that compliance measurements can be determined that will best represent and protect the beneficial uses in a an environment subject to alternating tidal flows. To facilitate this effort, DWR and USBR will work with State Water Board staff and solicit stakeholder input to develop and implement a special study to characterize the spatial and temporal distribution and associated dynamics of water level, flow, and salinity conditions in the southern Delta waterways. The study will identify the extent of low or null flow conditions and associated concentrations of local salt discharges. DWR and USBR's water rights will then be conditioned to require gathering of information to determine the appropriate locations and methods to assess attainment of the salinity objectives in the interior southern Delta.

Proposed Amendments

The existing SDWQ objectives for salinity identified in the 2006 Bay-Delta Plan would be amended to continue to protect agricultural beneficial uses in the southern Delta. The alternatives evaluated in this SED are listed below, including the No Project Alternative, which must be evaluated under CEQA.

- SDWQ Alternative 1, the No Project Alternative, would continue the 2006 Bay-Delta Plan southern Delta salinity objectives and require full compliance with1.0 dS/m September–March and 0.7 dS/m April–August in the southern Delta and Vernalis; and continued conditioning of the DWR's and USBR's water rights to meet the interior southern Delta objectives and the USBR's water rights to meet the Vernalis objective. This also includes continuation of, and full compliance with, the SJR flow requirements as established in the 2006 Bay-Delta Plan as described in LSJR Alternative 1.
- SDWQ Alternative 2 would establish an annual 1.0 dS/m salinity objective for the southern Delta and Vernalis and would require continued conditioning of the DWR's and USBR's water rights to meet the interior southern Delta objectives. This alternative would also change the three interior southern Delta compliance locations. Instead of compliance being determined at the current compliance monitoring points (stations), the objective would be applicable in specified segments of the SJR, Middle River, and Old River/Grant Line Canal affecting agricultural beneficial uses. USBR's water rights would continue to be conditioned to meet EC levels of 0.7 dS/m August and 1.0 dS/m from September–March in the SJR at Airport Way Bridge near Vernalis to provide assimilative capacity for salinity inputs downstream of Vernalis. Various study, planning and monitoring requirements would also be imposed.
- SDWQ Alternative 3 would establish an annual 1.4 dS/m salinity objective for the southern Delta and Vernalis and would require continued conditioning of the DWR's and USBR's water rights to meet the interior southern Delta objectives. This alternative would also change the three interior southern Delta compliance locations. Instead of compliance being determined at the current compliance monitoring point stations, the objective would be applicable in specified

segments of the SJR, Middle River, and Old River/Grant Line Canal affecting agricultural beneficial uses. USBR's water rights would continue to be conditioned to meet EC levels of 0.7 dS/m from April–August and 1.0 dS/m from September–March in the SJR at Airport Way Bridge near Vernalis to provide assimilative capacity for salinity inputs downstream of Vernalis. Various study, planning and monitoring requirements would also be imposed

Details of the SDWQ alternatives are provided in Chapter 3, *Alternatives Description*, and the language of the amended WQCP is included in Appendix K, *Revised Water Quality Control Plan*.

1.5.3 Related Litigation

This section discusses litigation related to the establishment and implementation of water quality objectives in the 2006 Bay-Delta Plan and D-1641.

In 2006, the Third District Court of Appeal in *State Water Resources Control Board Cases* 136 Cal. App.4th 674 issued a decision addressing challenges to the State Water Board's adoption of D-1641and CEQA compliance. The court rejected the CEQA challenges and, in large part, upheld D-1641 but concluded that when a WQCP calls for an objective to be achieved by allocating responsibility to meet that objective in a water rights proceeding, the water right decision must fully implement that objective. Accordingly, the court determined that the State Water Board failed to fully implement the Vernalis pulse flow objective in the 1995 Bay-Delta Plan by instead allowing the immediate implementation of an alternate experimental flow regime under VAMP, thus accomplishing a de facto amendment of the Bay-Delta Plan without complying with the procedural requirements for amending such a plan. The court also found that the State Water Board failed to adequately implement the southern Delta salinity objectives at the three interior Delta locations by delaying implementation of the 0.7 dS/m objective at those locations. The court required a writ of mandate be issued commanding the State Water Board to commence proceedings to either assign responsibility for meeting the Vernalis pulse flow objective and the southern Delta salinity objectives in the 1995 Bay-Delta Plan or to modify those objectives. The State Water Board complied with the writ by amending the 2006 Bay-Delta Plan to allow staged implementation of the Vernalis pulse flow objective (through the target flows in VAMP) and by commencing the current project to evaluate the southern Delta salinity objectives and program of implementation.

Implementation of the southern Delta salinity objectives is at issue in *City of Tracy v. California State Water Resources Control Board* (Sacramento Superior Court Case No. 34-2009-80000392). In this case, the City of Tracy (Tracy) challenged the State Water Board's 2009 decision to remand the National Pollutant Discharge Elimination System permit issued by the Central Valley Regional Water Quality Control Board (Central Valley Water Board) for Tracy's wastewater treatment plant. The State Water Board had partially remanded the permit to the Central Valley Water Board to include more rigorous requirements (including final water quality-based effluent limitations) to implement the southern Delta salinity objectives. In part, Tracy challenged the applicability of the salinity objectives in the underlying Bay-Delta Plan, arguing that they were never properly adopted and that the 2006 amendments did not provide an adequate program of implementation for municipal dischargers. The Central Valley Clean Water Association intervened in the litigation, representing municipal dischargers in the Central Valley. In 2011, the trial court ruled against the State Water Board, concluding that the State Water Board failed to comply with Water Code Section 13241 when it established the water quality objectives for EC in 1978 and that the Bay-Delta Plan's program of implementation was inadequate in relation to municipal dischargers. The trial court issued a writ ordering the State Water Board to vacate the portions of the Tracy order relating to the effluent limitations for EC and to revise the order consistent with the court's decision, and requiring the Board to consider Water Code Section 13241's factors in establishing the salinity objective and to adopt a program of implementation describing the nature of actions for municipal dischargers to achieve the salinity objective. The State Water Board did not appeal.

Chapter 2
Water Resources

This chapter discusses existing surface and groundwater resources and the management of those resources within the plan area and extended plan area, as described in Chapter 1, *Introductio*n, as well as resources upstream that drain to the plan area and extended plan area. The information in this chapter provides context for the description of the Lower San Joaquin River (LSJR) alternatives and southern Delta water quality (SDWQ) alternatives in Chapter 3, *Alternatives Description*. As needed, this recirculated substitute environmental document (SED) present additional existing setting and modeling information for each relevant resource area and impact analysis.

This chapter is generally organized by large geographic areas within the plan area: the San Joaquin River (SJR) Basin, Delta, and San Joaquin Groundwater Basin. Section 2.1, *Overview*, provides a general overview of the existing surface, delta, and groundwater resources within the SJR Basin, Delta, and San Joaquin Groundwater Basin and the water supply and uses those resources provide. Sections 2.2 through 2.6 further discuss surface water resources by tributary from south to north (upstream to downstream) in the SJR Basin, including the operation of rim dams[1] for hydropower and water storage, existing water diversions, current flow requirements for fish protection, and hydrology (unimpaired and historical flow). Section 2.7, *Southern Delta*, describes existing salinity and water quality conditions and water management in the southern Delta that influence water quality. Management, in this context, includes operations of the Central Valley Project (CVP) and State Water Project (SWP), existing water diversions, and existing municipal and agricultural drainage discharges. Finally, Section 2.8, *San Joaquin Valley Groundwater Basin*, describes general characteristics of existing groundwater resources within the San Joaquin Groundwater Basin geographically from north to south.

2.1 Overview

This section generally describes the surface and groundwater resources located within the SJR Basin, the Delta, and the San Joaquin Valley Groundwater Basin that occur primarily within in the plan area and the extended plan area and that could be affected by the LSJR alternatives. Major water supplies and uses are summarized.

2.1.1 San Joaquin River Basin

The Central Valley Basin of California is surrounded by mountains except for a narrow gap on its western edge at the Carquinez Strait. Streamflow in the Central Valley is chiefly derived from runoff from the Cascade and Sierra Nevada ranges, with minor amounts from the Coast Ranges. Precipitation varies, with approximately four-fifths of the total occurring between the end of October and the beginning of April. Snowpack in the high Sierra delays runoff until the snow melts,

---

[1] In this document, the term *rim dams* is used when referencing the three major dams and reservoirs on each of the eastside tributaries: New Melones Dam and Reservoir on the Stanislaus River; New Don Pedro Dam and Reservoir on the Tuolumne River; and New Exchequer Dam and Lake McClure on the Merced River.

typically in April, May, and June. Normally, approximately half of the annual runoff occurs in these months. The 450-mile-long Central Valley Basin of California is divided into the Sacramento Valley in the north and the San Joaquin Valley in the south. The San Joaquin Valley spans two basins: the SJR Basin and the Tulare Lake Basin (DWR 2009). These two basins are distinct drainage areas separated by a low divide formed by coalescing alluvial fans. The divide lies between the SJR to the north, part of which is in the plan area and extended plan area, and Kings River to the south, which is not in the plan area or extended plan area (Figure 2-1a shows the SJR Basin).

The SJR Basin drains approximately 15,550 square miles of the Sierra Nevada and the southern portion of the Central Valley of California. The headwaters of the SJR are on the western slope of the Sierra Nevada at elevations in excess of 10,000 feet (ft). The Upper SJR and the LSJR tributaries drain large areas of high-elevation watersheds that supply snowmelt runoff during the late spring and early summer. Other SJR tributaries on the east side of the SJR Basin include the Chowchilla and Fresno Rivers, which drain the Sierra Nevada foothills. Most of the runoff in these smaller SJR tributaries results from rainfall, which is stored in reservoirs for irrigation purposes. A few small tributaries to the west, with headwaters in the rain shadow of the Coast Ranges, contribute little flow to the LSJR.

At the foot of the mountains (in the foothills), the SJR is impounded by Friant Dam, which forms Millerton Lake. The SJR reaches the valley floor near Fresno. Infrequent floodwaters from the Kings River flow into the SJR at Mendota Pool reservoir via the Fresno Slough. The river then flows north-northwest, and three eastside tributaries[2] enter it before it flows into the southern Delta at Vernalis (Vernalis is a unincorporated community in San Joaquin County downstream of the Stanislaus River and upstream of tidal effects from the Delta, where the LSJR enters the southern Delta).

In the Upper SJR, Friant Dam diverts water into the Friant-Kern and Madera canals. Until the SJR Restoration Program[3] began in 2009, only a small seasonal flow (125 cubic feet per second [cfs] maximum) was released from Friant Dam for downstream riparian water uses. Flood control releases have frequently been necessary in above-normal and wet years.[4] Downstream of Friant Dam, the primary sources of surface water to the SJR are its three eastside tributaries that drain the western slope of the Sierra Nevada. Table 2-1 summarizes the SJR Basin characteristics and existing reservoirs the tributaries.

In this document, the LSJR is defined as the portion of the SJR between its confluence with the Merced River and downstream to Vernalis. It receives flow from the three eastside tributaries. These tributaries provide the primary sources of surface water to the LSJR together with flow from the Upper SJR. The LSJR extends through San Joaquin, Stanislaus, and Merced Counties. The three eastside tributaries and rim dams, New Melones, New Don Pedro, and New Exchequer, are located in several different counties. Table 2-2 and Figure 2-1b identify the tributaries, rim dams, and localities within the plan area and extended plan area.

---

[2] In this document, the term *three eastside tributaries* refers to the Stanislaus, Tuolumne, and Merced Rivers.

[3] Implementation of the settlement and the Friant Dam release flows required by the San Joaquin River Restoration Program are expected to increase the existing SJR flows at Stevinson in the near future.

[4] Flows released from Friant Dam for fish protection or for flood control would contribute to the SJR flow at Vernalis, but they are not part of the plan amendments or alternatives evaluated in this document as described in Chapter 3, *Alternatives Description*.

Table 2-2. Location of LSJR Tributaries and Rim Dams

River	Rim Dam/ Reservoir	Downstream Dam(s)	Plan Area Counties	Extended Plan Area Counties	Communities within General Proximity of the Rim Dams
Stanislaus	New Melones/ New Melones	Tulloch Goodwin	Calaveras Tuolumne San Joaquin	Alpine Calaveras Tuolumne	Angels Camp, Copperopolis, Columbia, Sonora, Jamestown, Copper Cove
Tuolumne	New Don Pedro/ New Don Pedro	La Grange	Tuolumne Stanislaus	Tuolumne	Blanchard, Granit Springs
Merced	New Exchequer/ Lake McClure	Crocker Huffman	Mariposa Merced	Mariposa Madera	Granite Springs

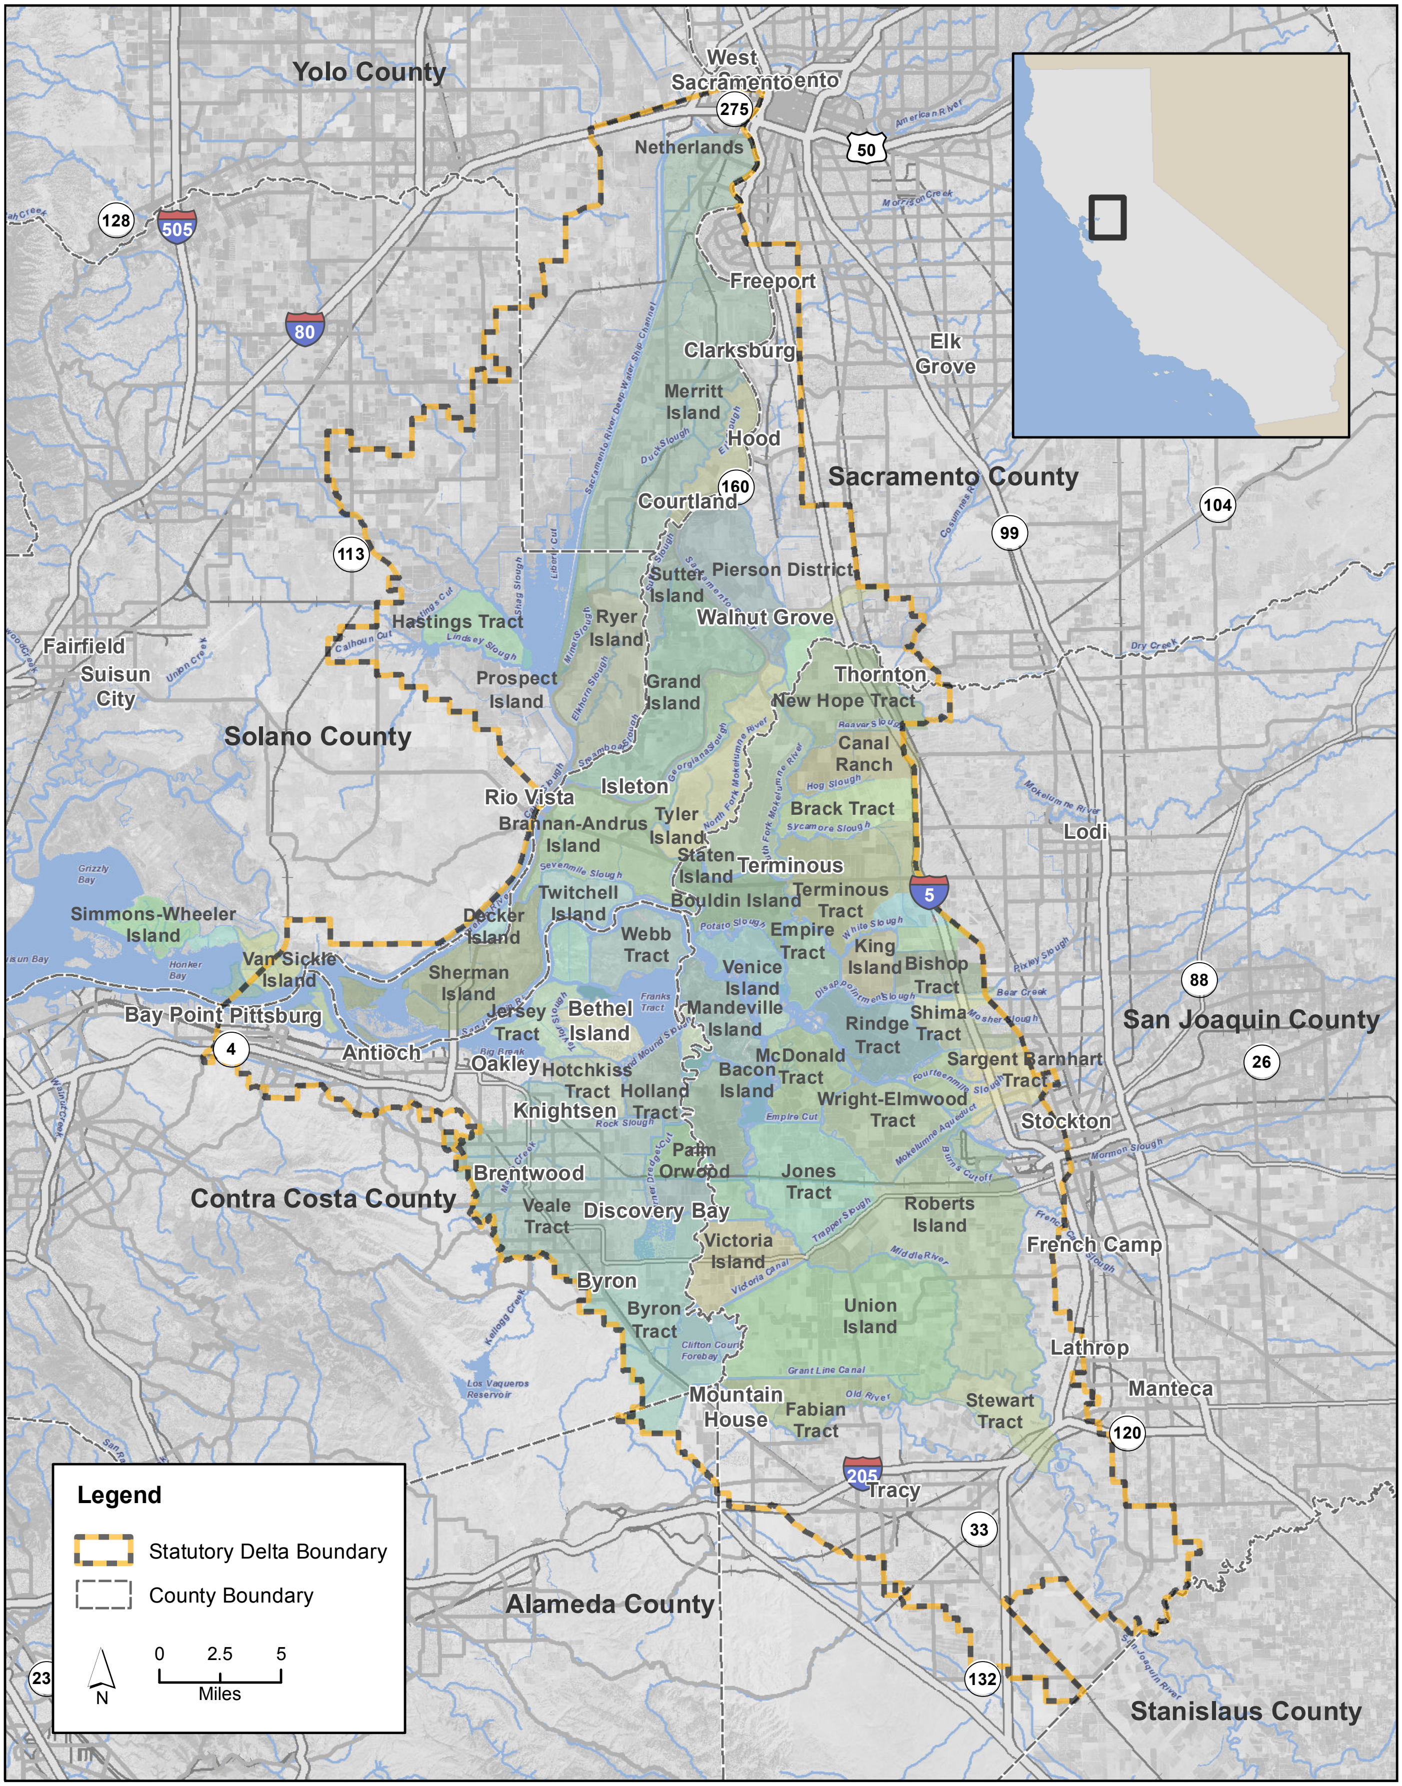
The hydrology of the LSJR tributaries and the SJR at Vernalis is dominated by precipitation in winter and early spring and snowmelt runoff in late spring and early summer (McBain and Trush 2002). The components of the unimpaired flow[5] regime in the Sierra Nevada are fall and winter storms (rainfall-runoff), spring snowmelt, and summer declining base flow (McBain and Trush 1999; Cain et al. 2003). In recent years, only a small fraction of the estimated unimpaired flow reaches Vernalis, except in high runoff years (e.g., 1986). During these high runoff years, flood control releases are made and a majority of the unimpaired runoff reaches Vernalis. In most years, a large fraction of the unimpaired flow is diverted directly for beneficial uses, such as irrigation or diverted to storage reservoirs for later use. Construction of storage reservoirs with hydropower diversions in the Sierra Nevada and the major tributary reservoirs with irrigation diversions in the Central Valley have greatly altered the natural flow regime of the LSJR and the three eastside tributaries (McBain and Trush 1999; Kondolf et al. 2001; Cain et al. 2003; Brown and Bauer 2009).

2.1.2 Delta

The Delta, with legal boundaries established by California Water Code Section 12220, encompasses a 738,000-acre area generally bordered by the cities of Sacramento, West Sacramento, Stockton, Tracy, Antioch, and Pittsburg (Figure 2-2). This former wetland area has been reclaimed into more than 60 islands and tracts, 700 miles of waterways, and roughly 520,000 acres devoted primarily to farming (CALFED 2005). The largest source of fresh water for the Delta is the Sacramento River, which transports an average of approximately 18.3 million acre-feet (MAF) per year into the Delta (DWR 2012). Additional flows from the Yolo Bypass, the LSJR, the Mokelumne River, and the Cosumnes River contribute an average of 5.8 MAF, with Delta precipitation adding approximately another 1.0 MAF (DWR 2009, 2012). Of the 5.8 MAF contributed from sources to the south of the Delta, an average of 1.9 MAF comes from the three LSJR tributaries. During low-flow periods, the hydrodynamics of the channels within the Delta are influenced primarily by the tides, with secondary effects from inflows and CVP and SWP exports (Burau et al. 1999; Kimmerer 2004).

---

[5] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.



K:\Projects_2\SWRCB\00427_11_SJ_River\mapdoc\Fig_2_2_Legal_Delta_20150729.mxd Date: 7/29/20

Figure 2-2
The Sacramento–San Joaquin Delta

Tidal rise and fall varies with location, from less than 1 foot in the eastern Delta to more than 5 ft in the western Delta (DWR 2009). Approximately half of the tidal flows follow the Sacramento River channel and about half follow the SJR channel into the southern Delta. The magnitude and movement of tidal flows diminish at locations farther into the Delta, and one-directional riverine movement begins to become more prominent. The twice-daily tides and varying inputs from rivers and streams result in highly dynamic Delta conditions that change continuously (Deltares 2009).

Major diversions in the southern Delta include the SWP (Banks Pumping Plant), CVP (Jones Pumping Plant), and Contra Costa Water District (CCWD). Both the CVP and the SWP use Delta channels to convey water released from the upstream Sacramento River Basin reservoirs to pumping stations in the southern Delta. The use of the Delta channels to convey water from the northern Delta to the southern Delta export facilities modifies the natural net flow patterns (i.e., direction) in some of the southern Delta channels (i.e., Old and Middle Rivers).

The southern portion of the Delta overlies the Tracy Groundwater Subbasin. The Tracy Subbasin is defined by the areal extent of unconsolidated to semiconsolidated sedimentary deposits that are bounded by the Diablo Range on the west, the Mokelumne River and SJR on the north, the SJR on the east, and the San Joaquin–Stanislaus County line on the south. The Eastern San Joaquin Subbasin is adjacent to the east of the Tracy Subbasin and the Delta-Mendota Subbasin is adjacent to the south. These subbasins are all within the San Joaquin Valley Groundwater Basin. The Tracy Subbasin lies south of the Sacramento Valley Groundwater Basin and Solano Subbasin. The Tracy Subbasin is drained by the SJR and one of its major westside tributaries, Corral Hollow Creek (DWR 2003f).

2.1.3 San Joaquin Valley Groundwater Basin

The plan area lies within the northern portion of the San Joaquin Valley Groundwater Basin. This portion of the San Joaquin Valley Groundwater Basin, as defined in the California Department of Water Resources (DWR) Bulletin 118,[6] approximately coincides with the western portion of the River (SJR) Hydrologic Region. The SJR Hydrologic Region covers approximately 3.73 million acres of the larger San Joaquin Valley Groundwater Basin, with the remaining 5 million acres in the Tulare Lake Hydrologic Region.

The San Joaquin Valley Groundwater Basin is comprised of 17 subbasins, of which 9 subbasins underlie within the SJR Hydrologic Region. Two additional groundwater basins, the Los Banos Creek Valley Basin and Yosemite Valley Basin, are not part of the San Joaquin Valley Groundwater Basin, but also underlie the SJR Hydrologic Region. The plan area lies almost entirely within the boundaries of four subbasins on the east side of the San Joaquin Valley Groundwater Basin: Eastern San Joaquin, Modesto, Turlock, and Merced (Figure 2-3). Portions of the plan area also lie within small parts of three additional subbasins: Tracy, Chowchilla, and Delta-Mendota (Figure 2-3). Groundwater extracted from these subbasins provides water for agricultural and municipal uses. Many San Joaquin Valley cities rely either wholly or partially on groundwater to meet municipal needs. Groundwater levels in the San Joaquin Valley Groundwater Basin have generally declined as a result of extensive agricultural pumping—by as much as 100 ft in some areas, primarily in the southern and western-most portions of the basin (USGS 1999). Groundwater pumping in the region continues to increase in response to growing urban and reduced surface water deliveries from north of the Delta.

---

[6] DWR's Bulletin 118 series of reports summarize and evaluate California groundwater resources.

Groundwater quality varies throughout the San Joaquin Valley Groundwater Basin and its subbasins. Variation in groundwater quality is attributed to the composition of the subsurface and the quality of the surface water infiltrating into the aquifer. Adverse water quality conditions—caused by naturally occurring constituents, as well as by agricultural and industrial contaminants—can affect the beneficial uses of groundwater. Salinity is one of the primary water quality issues, particularly in the western portion of the basin.

The Eastern San Joaquin, Modesto, Turlock, and Merced[7] Subbasins are further described, along with a summary of agricultural and municipal uses, in Sections 2.8.1 through 2.8.4, respectively. Additional information and the evaluation of groundwater impacts are provided in Chapter 9, *Groundwater Resources*.

2.1.4 Water Supply and Use

Surface Water

Several irrigation and water districts hold pre-1914 and/or appropriative water rights or contracts to divert surface waters from each of the three LSJR tributaries. These districts provide primarily agricultural supply and, in some limited cases through existing agreements, local municipal supply. Some of these districts also provide power to their service areas from hydropower generated by the rim dams. These dams also provide flood control, recreation, and other uses. Property owners with riparian water rights also divert surface water from the LSJR tributaries, primarily for agricultural uses. A summary of the irrigation district and riparian diversions from the LSJR tributaries is presented in Table 2-3, and Figure 2-4 shows the service areas of the irrigation and water districts. The information in Table 2-3 is from the irrigation districts' most recent agricultural water management plans (AWMPs) or water management plans. This information is provided to illustrate surface water diversions based on published irrigation district data. It is possible that surface water diversions may have been higher in the past, at levels not reflected by the numbers in the table, depending on the time frames and available data reported in the agricultural water management plans. The general description of various water rights in this chapter, and other chapters of this SED, are for informational purposes only, and do not constitute any confirmation by the State Water Board of the validity of any given water right claim. A more detailed description of the major irrigation districts is presented in Sections 2.3.2, 2.4.2, and 2.5.2 for diversions from the Merced, Tuolumne, and Stanislaus Rivers, respectively.

---

[7] As described in Chapter 9, *Groundwater Resources*, the Merced Subbasin was extended for the analysis to include a part of the Chowchilla Subbasin.

ICF INTERNATIONAL

Figure 2-4
Vicinity Map of Irrigation Districts

A representation of the water balance associated with the surface water diversions is shown in Figure 2-5. Diverted water is delivered separately to riparian diverters and irrigation districts. Riparian diverters directly deliver water for crop irrigation. Irrigation districts deliver water to a distribution system that may deliver water to a municipal water system that is separate from the delivery system for crop irrigation. Water delivery to crops is defined as applied surface water. Consumptive Use of Applied Water (CUAW) accounts for water losses due to crop irrigation. CUAW is generally defined in this analysis as irrigation water consumed by crops (not returned to the system), and it includes evaporation. Water losses separate from CUAW include deep percolation from agricultural fields, recharge and system seepage, and surface water returns. To promote water use efficiency, irrigation districts engage in conjunctive use of groundwater to supplement surface water deliveries and in-lieu recharge practices in years of adequate surface water supplies. These practices are intended to provide a net input to the groundwater over the long term.

Table 2-3. Summary of Major LSJR Surface Water Diverters and Surface Water Diversions as Reported by Irrigation District Agricultural Water Management Plans

River	Rim Dam	Surface Water Diverters	Surface Diversion Water (AF/y)[a]	Surface Water Users [b]
Stanislaus	New Melones	South San Joaquin Irrigation District (SSJID)	259,165 [c]	SSJID City of Lathrop City of Manteca City of Tracy City of Ripon SEWD
		Oakdale Irrigation District (OID)	261,896 [d]	OID SEWD
		Stockton East Water District (SEWD)	118,216 [e]	City of Stockton CalWater San Joaquin County
		Central San Joaquin Water Conservation District (CSJWCD)	32,000 [f]	CSJWCD
Tuolumne	New Don Pedro	Turlock Irrigation District (TID)	537,685 [g]	TID
		Modesto Irrigation District (MID)	315,912 [h]	MID City of Modesto
Merced	New Exchequer	Merced Irrigation District (Merced ID)	484,759 [i]	Merced ID City of Merced Stevinson Water District

River	Rim Dam	Surface Water Diverters	Surface Diversion Water (AF/y)[a]	Surface Water Users [b]

[a] These are assumed maximum diversions based on a review of published data by irrigation districts. The recent documents contain diversion values for multiple years; the year with the maximum value was selected for this table. Because the published data do not necessarily represent a lengthy time series (i.e., many years over the past 82 years), surface water diversions could be greater for these various surface water diverters than are reported in this table.

[b] Surface water users include those entities with rights to divert surface water released from the rim dams as well as those entities that have contracts to receive surface water. In some cases the diverters and the users are the same; in other cases, the diverters provide surface water to additional users.

[c] SSJID 2012. (maximum diversions from Joint Supply Canal [Table 5-13 value for 2004] and maximum direct diversions from Main Canal [Table 5-15 value for 2008]).

[i] Merced ID 2013. (Table C-3, diverted water for 2006).

Groundwater

Figure 2-6 illustrates a conceptual representation of municipal and agricultural groundwater usage. Many San Joaquin Valley cities rely either wholly or partially on groundwater to meet municipal needs (DWR 2003a). Some agricultural and municipal uses are supplied only by groundwater pumping within the plan area. Additionally, applied groundwater is pumped by private users—those outside of irrigation district jurisdiction yet within the same groundwater basin. Generally, little information is available regarding irrigated acres and crop types for areas outside the irrigation districts irrigated primarily by groundwater.

2.2 Upper San Joaquin River

2.2.1 Basin Overview

The Upper SJR is the river south (upstream) of the confluence of the Merced River and the LSJR and includes the north, middle, and south forks.[8] The forks converge upstream of Mammoth Pool Reservoir and are impounded at the uppermost region of the valley floor by Friant Dam, approximately 25 miles northeast of Fresno—the location for measuring the unimpaired flow from the Upper SJR Watershed.[9] As identified in Table 2-1, the Upper SJR above Friant Dam drains an area of approximately 1,676 square miles with an annual average unimpaired runoff of 1.7 MAF. While the Upper SJR Watershed is outside the plan area, it is

---

[8] The SJR Restoration Program defines the Middle SJR as the region between Friant Dam and the Merced River. There is very little runoff from the middle SJR as the Fresno and Chowchilla Rivers are the only two tributaries in this part of the river.

[9] Most of the information in Sections 2.2 through 2.6 is based on several reports including USBR 2008, EA EST 1999, and State Water Board 1999. Throughout this chapter, if no citation is given, the information was taken from one or a combination of these reports.

Figure 2-6
Schematic Representation of Groundwater Pumping with Associated Consumptive Use and Returns

drained by the SJR and abuts the plan area at the Merced River confluence; accordingly, it is included in the description below.

Several dams and reservoirs on the Upper SJR are primarily used for seasonal storage for hydroelectric power generation. These dams and reservoirs—Edison, Florence, Huntington, Mammoth Pool, and Shaver Lakes—are upstream of Friant Dam. Friant Dam, completed in 1942 and placed into full operation (with canal diversions) in 1951, has a capacity of 520 thousand acre-feet (TAF) and provides flood control, releases for senior water rights diversions, and diversions into the Madera and Friant-Kern Canals (discussed below). Friant Dam forms Millerton Lake; upstream reservoir operations affect inflows to Millerton Lake. Flood control storage space in Millerton Lake is limited, and additional flood control is provided by the upstream reservoirs.

2.2.2 Water Diversion and Use

The Friant Water Authority delivers water to more than a million acres of agricultural land in Fresno, Kern, Madera, and Tulare Counties in the San Joaquin Valley. Two major canal systems divert water from Friant Dam and deliver it via the 152-mile Friant-Kern Canal south into the Tulare Lake Basin and via the 36-mile Madera Canal north to the Madera and Chowchilla Irrigation Districts. The average annual water diversion at Friant Dam is approximately 1.1 MAF. Under their water contracts, irrigation districts receive Class I (reliable) and Class II (less dependable) deliveries, as well as surplus water during flood control operations.

2.2.3 Flow Requirements

Two requirements for flow are in effect below Friant Dam, primarily to convey irrigation water to downstream diversion points: (1) a minimum of 5 cfs to bypass the last water right diversion about 40 miles downstream near Gravelly Ford, and (2) a maximum river release of approximately 125 cfs in the summer months to supply downstream riparian and water rights users. These flows generally do not make it past the Mendota Pool on the Upper SJR; consequently, water released from Friant Dam often does not reach the LSJR and Merced River confluence. The U.S. Bureau of Reclamation (USBR) is undertaking an SJR Restoration Program[10] that would provide water throughout the year to reconnect the river upstream of Friant Dam to the Upper SJR at the mouth of the Merced River. In 2006, parties to federal lawsuit *NRDC v. Rodgers* executed a stipulation of settlement that calls for, among other things, restoration of flows on the Upper SJR from Friant Dam to the confluence of the LSJR with the Merced River. Required release flows from Friant Dam for each water year type have been identified, but the amount of this Upper SJR water observed at the mouth of the Merced River is uncertain.[11]

---

[10] Implementation of the settlement and the Friant Dam release flows required by the SJR Restoration Program are not part of the alternatives described in Chapter 3, *Alternatives Description*. The State Water Board expects the SJR Restoration Program would increase the existing SJR flows at Stevinson (the existing flows are currently simulated in CALSIM).

[11] In 2006, a settlement was reached in *Natural Resources Defense Council et al. v. Rodgers et al.*, and the San Joaquin River Restoration Settlement Act (Settlement Act), Public Law No. 111-11, Section 1001 et seq., 123 Stat. 991, 1349 was established. The settlement addressed restoration of fish habitat in the SJR below Friant Dam and ended an 18-year legal dispute over the operation of Friant Dam. The San Joaquin River Restoration Program was established to implement the settlement.

2.2.4 Hydrology

The average annual unimpaired flow for the Upper SJR at Friant Dam from 1984 through 2009 was 1,702 TAF. This represents approximately 28 percent of the unimpaired flow on the SJR at Vernalis. Most of this water is seasonally stored in upstream reservoirs and in Millerton Lake and diverted to the Friant-Kern and Madera Canals for irrigation. Historically, during high flow years, there are considerable flood control releases from Friant Dam. The historical monthly flows on the Upper SJR at Friant Dam were less than 125 cfs in all months, except when releases were made for flood control purposes. From 1984 through 2009, Friant Dam releases averaged 420 TAF per year (TAF/y), or approximately 25 percent of the unimpaired flow.

As an example of these historical releases, Figure 2-7 shows the monthly unimpaired flow and the historical flow below Friant Dam for the recent 10-year period of water years 2000 through 2009.[12] The average Friant Dam release for this period was approximately 20 percent of the unimpaired flow. Often, however, releases were less than 20 percent of the unimpaired flow, with flood control releases providing the majority of the flow below Friant Dam.

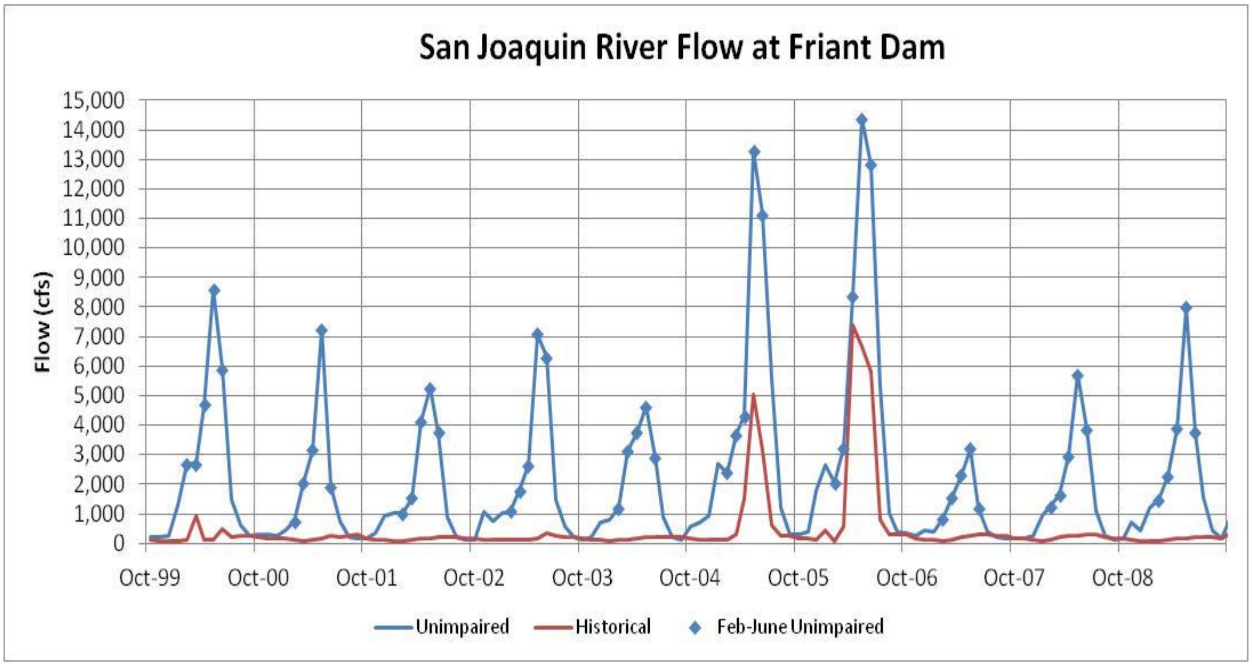

Figure 2-7. Monthly Unimpaired and Historical San Joaquin River Flows at Friant Dam for Water Years 2000–2009 (cfs = cubic feet per second)

---

[12] A water year begins in October of the previous year. For example, water year 2000 begins in October, 1999.

2.3 Merced River

2.3.1 Basin Overview

As shown in Table 2-1, the Merced River is 135 miles long and drains a 1,270-square-mile watershed. The Merced River originates high in the Sierra Nevada and flows into the LSJR approximately 35 miles upstream of the Tuolumne River confluence. Approximately 52 miles of the Merced River are downstream of Crocker Huffman Dam, the most downstream barrier to fish migration. Like the Stanislaus and Tuolumne Rivers, reservoir operations have increased average monthly flows during late summer and early fall and reduced the average monthly flows during the remainder of the year (Stillwater Sciences 2001a).

Four mainstem dams and eight Division of Safety of Dams (DSOD) dams on the Merced River regulate flow conditions. The four mainstem dams, which are known collectively as the Merced River Development Project, are owned by Merced ID and licensed by the Federal Energy Regulatory Commission (FERC). New Exchequer Dam and McSwain Dam, a regulating dam downstream of New Exchequer, are the largest of the four mainstem dams; Merced Falls Dam and Crocker-Huffman Dam are the smallest. Tributaries of the Merced River upstream of New Exchequer Dam are regulated by three small dams MacMahon, Green Valley, and Metzger (Stillwater Sciences 2001b). New Exchequer Dam is the largest dam on the Merced River. It creates Lake McClure, which has a capacity of approximately 1 MAF and regulates releases to the Merced River. The New Exchequer powerhouse has a capacity of approximately 95 megawatts (MW) with a maximum flow of approximately 3,200 cfs. Water released for peaking power is regulated at the approximately 10 TAF McSwain Reservoir.

2.3.2 Water Diversion and Use

Water is withdrawn from the Merced River and used at numerous locations and by many users, including the Cowell Agreement Diverters and Merced ID, both discussed below. In the entire Merced River Watershed there are 105 post-1914 appropriative water rights, with a combined face value of approximately 5.5 MAF. Of these 105 rights, 101 are non-power water rights with a face value of approximately 1.04 MAF. Of the 101 rights, three are non-power water rights held by the Merced ID. The face value[13] of these three water rights totals approximately 1.01 MAF, accounting for approximately 98 percent of the water authorized for diversion (based on face value) under non-power water rights in the Merced River Watershed.

Cowell Agreement Diverters

The downstream Merced River diverters of water released from storage from Lake McClure are known as the Cowell Agreement Diverters (CAD). The Cowell Agreement was established on January 17, 1926, in an effort to supply riparian diverters and pre-1914 claims of water rights with releases from Lake McClure. The Merced Superior Court Order stipulates a scheduled quantity of

---

[13] The *face value* of a water right refers to the maximum amount of water the right authorizes for diversion. Typically the amount diverted is less.

flow rates in the Merced River to be maintained by the Merced ID and measured at Crocker-Huffman Dam (State Water Board 2007).

The Agreement requires the Merced ID to bypass and release water in the summer so that the riparian and pre-1914 downstream users experience the same hydrologic conditions that were in place prior to the construction of the New Exchequer Dam (State Water Board 2007).

The water diverted under the Cowell Agreement is used on acreage outside the Merced ID service area. The ID has at times been required to supplement downstream flows in the Merced River with releases from storage when inflow to Lake McClure has been insufficient to satisfy the flow requirements downstream of the Crocker-Huffman Dam (State Water Board 2007).

Merced Irrigation District

Merced ID provides water and electric service to approximately 164,000 acres in the Central Valley in portions of Merced County (Merced ID 2008a), using primarily surface water diversions from the Merced River to supply irrigation water to its service area. The ID diverts approximately 100 cfs from the Merced Falls reservoir via the Northside Canal, serving roughly 10,000 acres of farmland. Merced ID diverts up to another 2,000 cfs of water from the Merced River via the Main Canal at the Crocker-Huffman Dam primarily for agricultural purposes (Merced ID 2008b). These diversions are approximately 500,000 AF/y (MAGPI 2008). In conjunction with the surface water diversions from the Merced River, Merced ID owns, operates, and maintains 239 deep irrigation wells, of which 170 wells are currently active (Merced ID 2008b). These deep irrigation wells have historically produced a maximum of 182,900 AF/y. The amount of water diverted from the Merced River and pumped from groundwater varies from year to year, so not all estimates of these volumes are the same.

Table 2-4 presents a summary of Merced ID water supply and use values from the most recent AWMP. This plan was prepared by the ID as required by Senate Bill X7-7, which was adopted by California in 2009. The AWMP does not provide one summary table for all the values incorporated in Table 2-4; rather it presents a wide array of values over multiple years or different time frames. Because the values represent different time frames there may be inherent inconsistencies between the reported values in Table 2-4. This information is presented to illustrate estimated water supply and use of surface water diversions based on published irrigation district data.

Table 2-4. Merced Irrigation District—Water Supply and Use

Water Supply/Use	Amount (thousand acre-feet)
Surface water diversions[a]	445.6
Irrigated acres[a]	100,237
Applied water[b]	279.3
CUAW (surface water & groundwater)[b]	237.8
Pumped groundwater—district[c]	7.6
Pumped groundwater—private[c]	44.1
Deep percolation of applied water[b]	60.1
Groundwater recharge from precipitation[b]	42.8
Canal system seepage[c]	103.0

Source: Merced ID 2013.

CUAW = Consumptive Use of Applied Water

[a] Reported as 2000–2008 average.

[b] Reported as 2000–2003 average.

[c] Reported as 1995–2008 average.

Merced ID generates electricity at New Exchequer Dam and McSwain Dam and sells it to utility companies (Merced ID 2008c). It also provides electric services to customers in eastern Merced County, including the Cities of Livingston, Atwater, and Merced, and to the Castle Airport and Aviation Development Center (Merced ID 2008c).

2.3.3 Flow Requirements

Flows released from the Crocker-Huffman Dam to the Merced River must satisfy FERC requirements, a Davis-Grunsky Contract between the State of California and Merced ID, and the Cowell Agreement. Flood control release limits are established by the U.S. Army Corps of Engineers (USACE) such that the combination of Dry Creek and Merced River flows must not exceed 6,000 cfs.

Merced ID holds the initial FERC license (Project Number 2179) for the Merced River Hydroelectric Project, issued on April 18, 1964. As shown in Table 2-5, FERC Project Number 2179 requires the licensee to provide minimum streamflows in the Merced River downstream from the project reservoirs.

Table 2-5. FERC Project Number 2179 Streamflow Requirements for the Merced River (cfs)

Period	Normal Year	Dry Year
June 1–October 15	25	15
October 16–October 31	75	60
November 1–December 31	100–200	75–150
January 1–May 31	75	60

FERC Project Number 2179 also requires that during the period November 1–December 31, the Merced River streamflow downstream from McSwain Dam be regulated between 100 and 200 cfs, except during dry years when the streamflow should be maintained between 75 and 150 cfs. Streamflows are measured at Shaffer Bridge on the Merced River downstream of McSwain Dam. These flows are required during the fall-run Chinook salmon egg incubation period to prevent redd scouring or dewatering. The Project is currently undergoing relicensing with the Commission, and a Section 401 water quality certification issued by the State Water Board is required. (33 U.S.C. § 1341.)

In 1967, Merced ID executed a Davis-Grunsky Contract with the California Department of Fish and Wildlife (CDFW, formerly the California Department of Fish and Game). The contract provides minimum flow standards that require flows no less than 180–220 cfs to be maintained between November and March from Crocker-Huffman Dam to Shaffer Bridge.

The Cowell Agreement, between Merced ID and the Cowell Agreement Diverters, calls for flows downstream of the Crocker-Huffman Dam to meet the water rights of other diverters. The Cowell Agreement Diverters are downstream riparian and pre-1914 water users. This water can then be diverted from the river at a number of private ditches between Crocker-Huffman Dam and Shaffer Bridge. The minimum flow requirements are provided in Table 2-6.

Table 2-6. Cowell Agreement Streamflow Requirements for the Merced River (cubic feet per second)

Month	Flow
October 1–15	50
October 16–31	50
November–February	50
March	100
April	175
May	225
June	250
July	225
August	175
September	150

2.3.4 Hydrology

The unimpaired flow of the Merced River is the flow that would occur without existing diversions. The historical flow of the Merced River is influenced by the operation of the existing dams and diversions. The hydrographs in Figure 2-8 depict both types of flows and show the monthly unimpaired historical flow below Crocker-Huffman Dam for the recent 10-year period of water years 2000 through 2009. During this period, the unimpaired flow at New Exchequer Dam averaged 884 TAF/y and the historical releases (including flood flows in 2000, 2005, and 2006) averaged 403 TAF/y.

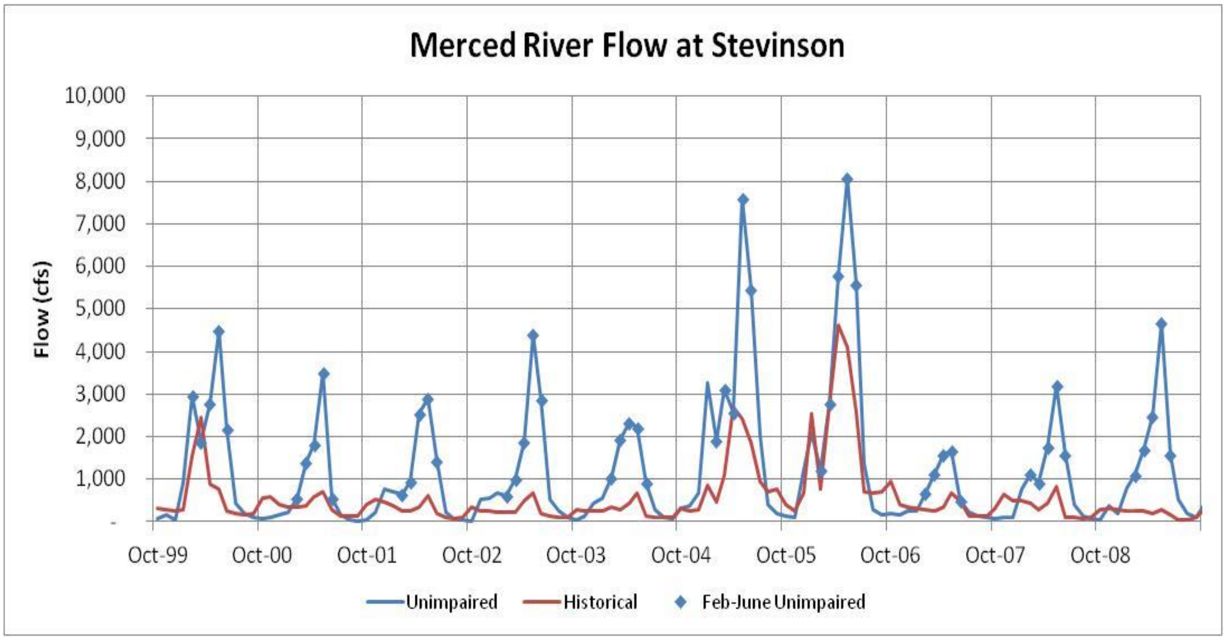

Figure 2-8. Monthly Unimpaired and Historical Merced River Flows February–June for Water Years 2000–2009 (cfs = cubic feet per second)

The Crocker-Huffman Dam releases averaged approximately 45 percent of the unimpaired flow, but the releases were usually less than 40 percent of the unimpaired flow, with flood control releases providing the majority of the flow below Crocker-Huffman Dam. The historical monthly flows at Stevinson (near the mouth of the Merced) are generally lower than the unimpaired flows in the winter and spring months, and often slightly higher than the unimpaired flows in the fall months. Table 2-7 summarizes the range of historical and unimpaired flows on the Merced River February–June. The peak historical flows were in April and May 2006 because Lake McClure was nearly full, and the relatively high flow of 4,500 cfs was for flood control purposes.

Table 2-7. Historical and Unimpaired Flow February–June on the Merced River (cubic feet per second)

Water Year	Historical (observed) Range	Unimpaired Range
2000	250–2,500	2,000–4,500
2001	250–750	500–3,500
2002	250–500	750–3,000
2003	250–750	500–4,500
2004	250–750	1,000–2,250
2005[a]	750–2,500	2,000–7,500
2006[a]	1,000–4,500	1,000–8,000
2007	250–750	750–1,750
2008	250–750	1,000–3,000
2009	250	1,000–5,000

[a] The high historical flows in 2005 and 2006 were because Lake McClure was nearly full, and releases for flood control purposes were made in each of these years.

The Merced River monthly unimpaired flows (at New Exchequer Dam) are summarized in Table 2-8, with the cumulative distributions of unimpaired flow (in 10 percent increments) for each month from 1984 to 2009. Each month has a range of runoff depending on the rainfall and accumulated snowpack. The median flows (50 percent cumulative) can be used to characterize generally the seasonal runoff pattern. The peak runoff for the Merced River is observed in May and highest runoff (median monthly runoff greater than 90 TAF, or 1,500 cfs) is observed March–June. The minimum flows are observed in August, September, October, and November. The distribution of annual unimpaired flow ranged from 410 TAF (10th percentile) to 1,746 TAF (90th percentile), with a median runoff of 721 TAF. The average unimpaired flow was 884 TAF/y, 23 percent more than the median runoff, representing approximately 15 percent of the unimpaired flow at Vernalis.

Table 2-9 provides a monthly summary of the historical flows observed at Stevinson. The Merced River flows are subject to minimum flow requirements, as described above. The majority of the historical monthly flows were between 5 TAF and 30 TAF (75 cfs and 500 cfs). The annual river flow volume ranged from 102 TAF (10th percentile) to 1,167 TAF (90th percentile). The median historical annual river flow was 398 TAF. The average historical flow was 452 TAF/y for these years, 14 percent higher than the median. The average historical flow was approximately 48 percent of the average unimpaired flow, but the majority of the flow occurred in the wet years due to flood control releases. Lake McClure is the smallest of the three eastside tributary reservoirs and is generally filled and drawn down each year. Nevertheless, flood control releases are not necessary each year; consequently, it is difficult to anticipate when reservoir releases for flood control storage will be required.

Table 2-8. Monthly and Annual Unimpaired Flow in the Merced River 1984–2009 (thousand acre-feet)

Percentile	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Annual
10	2	5	6	11	22	50	93	104	32	11	4	1	410
20	2	6	8	13	28	56	104	117	48	13	5	2	450
30	3	7	10	18	34	61	113	153	56	18	6	3	548
40	4	9	13	35	37	69	129	184	85	25	7	4	608

80	13	22	34	103	105	161	181	316	228	51	15	7	1,559
90	16	30	61	195	181	181	199	386	328	110	23	10	1,746

Note: The cumulative distribution indicates the probability of occurrence for the variable. For example, a 10th value of 2 indicates that 10 percent of the time, the value would be expected to be less than 2. This term is not referring to, and should not be confused with, the term cumulative impacts, which is a specific CEQA term. A discussion of cumulative impacts for CEQA purposes is provided in Chapter 4, *Introduction to Analysis*, and Chapter 17, *Cumulative Impacts, Growth-Inducting Effects, and Irreversible Commitment of Resources*.

2.4 Tuolumne River

2.4.1 Basin Overview

As shown in Table 2-1, the Tuolumne River is approximately 155 miles long and drains an area of approximately 1,900 square miles. The Tuolumne River originates in the high elevations of the Sierra Nevada and flows into the LSJR approximately 8 miles upstream of the Stanislaus River confluence. Like the other two eastside tributaries of the LSJR, the Tuolumne River receives most of its flow from late spring and early summer snowmelt; however, peak flows generally occur during winter rain events.

Existing dams, water diversions, and downstream minimum flow agreements influence the hydrology of the Tuolumne River. New Don Pedro Dam, the major dam on the Tuolumne River, provides water to the Turlock Irrigation District (TID) and Modesto Irrigation District (MID). The dams constructed on tributaries in the upper Tuolumne River Watershed provide hydropower and water supply for the City and County of San Francisco (CCSF). CCSF operates several water supply and hydroelectric facilities in the upper reaches of the Tuolumne above New Don Pedro Dam. O’Shaughnessy Dam on the mainstem Tuolumne River impounds approximately 360 TAF in the Hetch Hetchy Reservoir to address CCSF’s water needs of and to provide instream flows in the Tuolumne River below O’Shaughnessy Dam. Two other storage facilities upstream of New Don Pedro Reservoir, Lake Eleanor and Cherry Lake, are also operated by CCSF for hydropower and water supply purposes. The combined capacity of these two reservoirs is approximately 300 TAF. Water from Lake Eleanor is diverted through the Lake Eleanor Diversion Tunnel and into Cherry Lake where it is released to supplement flows of the upper Tuolumne River. The Hetch-Hetchy aqueduct conveys water from the Tuolumne River to the CCSF service area; the physical capacity of approximately 500 cfs is limited by the Coastal Tunnel.

New Don Pedro Dam, the major dam on the Tuolumne River, was constructed in 1971 to replace the original Don Pedro Dam. The hydroelectric power plant with four units has a combined capacity of 203 MW, with a maximum flow of 5,500 cfs. Flows in the lower portion of the Tuolumne River are controlled primarily by operation of New Don Pedro Dam. The 2 MAF reservoir stores water for irrigation, hydroelectric generation, fish and wildlife enhancement, recreation, and flood control purposes (340,000 AF for flood control). Water released from the New Don Pedro Dam is regulated at LaGrange Dam and Reservoir. La Grange Dam, 2.5 miles downstream of New Don Pedro Dam, is the diversion point for the TID and Merced ID canals.

2.4.2 Water Diversion and Use

Water is withdrawn from the Tuolumne River and used at numerous locations and by many users, including TID, MID, and CCSF, discussed below. In the Tuolumne River Watershed there are 165 post-1914 appropriative water rights with a combined face value of approximately 7.2 MAF. Of these 165 rights, 160 are non-power water rights with a face value of approximately 2.65 MAF. Of the 160 rights, 5 are non-power water rights held by TID and MID. The face value of these five water rights totals approximately 2.62 MAF, accounting for approximately 99 percent of the water authorized for diversion (based on face value) under non-power water rights in the Tuolumne River Watershed (State Water Board 2015).

The amount and uses of water actually diverted vary. On average, more than 60 percent of the annual flow of the Tuolumne River is diverted for agricultural or municipal and industrial use by TID and MID. Each year, approximately 575 TAF of water is diverted to TID's canal into Turlock Lake and 310 TAF is diverted to MID's canal into the Modesto Reservoir for use in the service districts. Nearly all the diverted surface water irrigates crops in the two districts. Many of the TID and MID diversions from the Tuolumne River occur at New Don Pedro and La Grange reservoirs.

City and County of San Francisco

The current CCSF demand for water is approximately 290 TAF/y, or about 15 percent of the annual average unimpaired flow of the Tuolumne River. The water rights and operating agreement for New Don Pedro Reservoir includes seasonal storage in the CCSF upstream reservoirs and water banking (accounting) between TID, MID, and CCSF. CCSF has the right to store up to 740,000 AF/y in New Don Pedro Reservoir (CCSF, TID, and MID 1966).

Turlock Irrigation District

TID has an irrigation service area of approximately 307 square miles (196,000 acres) (TID 2013). It provides water and electric services to areas in Stanislaus and Merced Counties, as well as portions of Tuolumne and Mariposa Counties (TID 2010a, 2010b). TID uses primarily surface water diversions from the Tuolumne River and supplements them with groundwater to supply irrigation water (TID 2010c) (Table 2-10).

Table 2-10 presents a summary of TID water supply and use values from the most recent AWMP. This plan was prepared by the irrigation district as required by Senate Bill X7-7, which was adopted by California in 2009. The AWMP does not provide one summary table for all of the values incorporated in Table 2-10. Rather it presents a wide array of values over multiple years or different time frames. Because the values represent different time frames there may be inherent inconsistencies between the reported values in Table 2-10. This information is provided to illustrate estimated water supply and use of surface water diversions based on published irrigation district data.

Table 2-10. Turlock Irrigation District - Water Supply and Use

Water Supply/Use	Amount (thousand acre-feet)
Surface water supply [a]	503.6
Ground water supply [a]	100.0
Irrigated acres [b]	157,800
Agricultural water delivered [c]	499.0
Pumped groundwater— district [a]	99.8
Pumped groundwater— private [c]	19.0
Total Recharge [a]	243.2

Source: TID 2012.

[a] Reported as 1991–2011 average.

[b] Reported in 2012.

[c] Reported as 2007–2011 average.

TID provides electrical service to an area encompassing approximately 660 square miles and includes more than 98,000 accounts. TID is the majority owner and operating partner of the Don Pedro Hydroelectric Project. TID owns approximately 68 percent of the total capacity, which is approximately 139 MW of power (TID 2010b, 2010d).

Modesto Irrigation District

MID is an independent, publicly owned utility that provides water and electric services to parts of Stanislaus County, San Joaquin County and a small portion located in Calaveras County around the New Don Pedro Dam. The water service area encompasses approximately 113,000 acres (MID 2012a) (Table 2-11). MID has pre-1914 water rights to obtain surface water supply at diversion points below New Don Pedro Reservoir and La Grange Dam as described above and pumps groundwater to supplement surface water supplies for irrigation. It provides approximately 173,750 AF (20-year average) of irrigation water to approximately 58,000 irrigated acres within its service area (MID 2012b). It also provides up to 42 million gallons of drinking water to the City of Modesto per day and is expanding the Modesto Regional Water Treatment Plant to increase delivery to an average of 60 million gallons of water per day (MID 2012b, 2015).

Table 2-11 presents a summary of MID water supply and use values from the most recent AWMP. This plan was prepared by the irrigation district as required by Senate Bill X7-7, which was adopted by California in 2009. The AWMP does not provide one summary table for all the values incorporated in Table 2-11; rather it presents a wide array of values over multiple years or different time frames. Because the values represent different time frames, there may be inherent inconsistencies between the reported values in Table 2-11. This information is provided to illustrate estimated water supply and use of surface water diversions based on published irrigation district data.

Table 2-11. Modesto Irrigation District—Water Supply and Use

Water Supply/Use	Amount (thousand acre-feet)
Surface water supplies [a]	284.3
Applied surface water [a]	153.0
Irrigated acres [b]	66,517
Crop CUAW [a]	173.2
Pumped groundwater— district[a]	20.1
Municipal deliveries [a]	30.0
On farm recharge from irrigation[a]	58.1
Canal seepage [a]	8.0

Source: MID 2012a.
CUAW = Consumptive Use of Applied Water.
[a] Reported as year 2009.
[b] Reported as year 2012.

MID provides electrical service to approximately 560 square miles and more than 110,000 accounts in the following areas: the Greater Modesto Area (north of the Tuolumne River, Waterford, Salida, Mountain House [Northwest of Tracy], and parts of Ripon, Escalon, Oakdale and Riverbank). Pacific Gas and Electric Company (PG&E) also provides electric service in Riverbank, Oakdale, Ripon and Escalon in conjunction with MID. MID produces approximately 25 percent of its own electricity and purchases the remaining 75 percent (MID 2012b). MID owns approximately 64 MW of the power generated by New Don Pedro Reservoir, comprising approximately 9 percent of the power MID generates (TID 2010d; MID 2012b).

2.4.3 Flow Requirements

Flow requirements on the Tuolumne River include the original FERC license (1966) for the operation of New Don Pedro Reservoir and a 1995 settlement agreement that amended the FERC license. TID and MID jointly hold the initial FERC license (Project Number 2299) for the New Don Pedro Project. USACE also established flood control release limits. These requirements are summarized in Table 2-12.

Table 2-12. Tuolumne River Flow Requirement Summary

Requirement	Description	Parties	Releases
FERC License Project No. 2299	Provides specified releases from New Don Pedro to protect fall-run Chinook salmon spawning below La Grange Dam	TID, MID, and FERC	Annual volume for normal water years is 120 TAF; annual volume for dry water years is 65 TAF; specific flows identified during different months
Article 37 of FERC License Project No. 2299	Provides additional flows from original FERC License	CDFW, FERC, MID, and TID	Annual volume of water was increased to 95 TAF in dry water years and 300 TAF in normal water years
USACE	Establishes flood control release limits	USACE, MID, and TID	Releases are established by USACE for 12 months such that releases cannot exceed 9,000 cfs per month on Tuolumne River below Dry Creek

USBR = U.S. Bureau of Reclamation
CDFW = California Department of Fish and Wildlife
USACE = U.S. Army Corps of Engineers
FERC = Federal Energy Regulatory Commission
MID = Modesto Irrigation District
TID = Turlock Irrigation District

The original FERC license was issued on March 10, 1964; became effective on May 1, 1966; and has a term that expired April 30, 2016. The Project is currently undergoing relicensing with the Commission, and a Section 401 water quality certification issued by the State Water Board is required. (33 U.S.C. § 1341.) The FERC license is conditioned to require specified releases of water from New Don Pedro Reservoir for the protection of fall-run Chinook salmon, which spawn in the Tuolumne River below La Grange Dam. These required flows in most years (normal) were 200–400 cfs from October through March, with 100 cfs in April and 3 cfs from May through September. As shown in Table 2-13, the annual volume of required streamflows was almost 120 TAF. The dry year flows were approximately half of the normal year flows, with an annual volume of almost 65 TAF.

Table 2-13. FERC Project Number 2299 Streamflow Requirements for the Tuolumne River

Period	Normal Year (cfs)	Dry Year (cfs)
October 1–15	200	50
October 16–October 31	250	200
November	385	200
December 1–15	385	200
December 16–31	280	135
January	280	135
February	280	135
March	350	200
April	100	85
May–September	3	3
Annual (TAF)	118	64

cfs = cubic feet per second
TAF = thousand acre-feet

The settlement agreement with CDFW established in 1995 proposed that Article 37 of the FERC license be amended to increase flows released from the New Don Pedro Dam. Several different runoff conditions were associated with higher required streamflows, and the annual volume of water required for stream flows was increased from approximately 95 TAF in the driest years to a maximum of approximately 300 TAF in years with greater-than-average runoff. Pulse flows are specified for salmonid attraction in October and outmigration in April and May.

2.4.4 Hydrology

The unimpaired flow of the Tuolumne River is the flow that would occur without existing diversions. The historical flow of the Tuolumne River is influenced by the operation of the existing dams and diversions as described above. The hydrograph in Figure 2-9 depicts both types of flow over time. It shows the monthly unimpaired and historical flow below LaGrange Dam for the recent 10-year period of water years 2000 through 2009, reflects that the unimpaired flow at New Don Pedro Dam averaged 1,738 TAF/y, and that the historical releases (including flood flows in 2000, 2005, and 2006) averaged 695 TAF/y.

LaGrange Dam released an average of approximately 40 percent of the unimpaired flow, but the releases were usually much less than 40 percent of the unimpaired, with flood control releases providing most of the flow below LaGrange Dam. The historical monthly flows at Modesto (near the mouth of the Tuolumne River) were generally less than the unimpaired flows in the winter and spring months, and were often slightly higher than the unimpaired flows in the late summer and fall months.

Table 2-14 summarizes the range of historical and unimpaired flows on the Tuolumne River February–June. The peak historical flows were in April and May 2006 because New Don Pedro Reservoir was nearly full, and 8,000 cfs was released for flood control purposes.

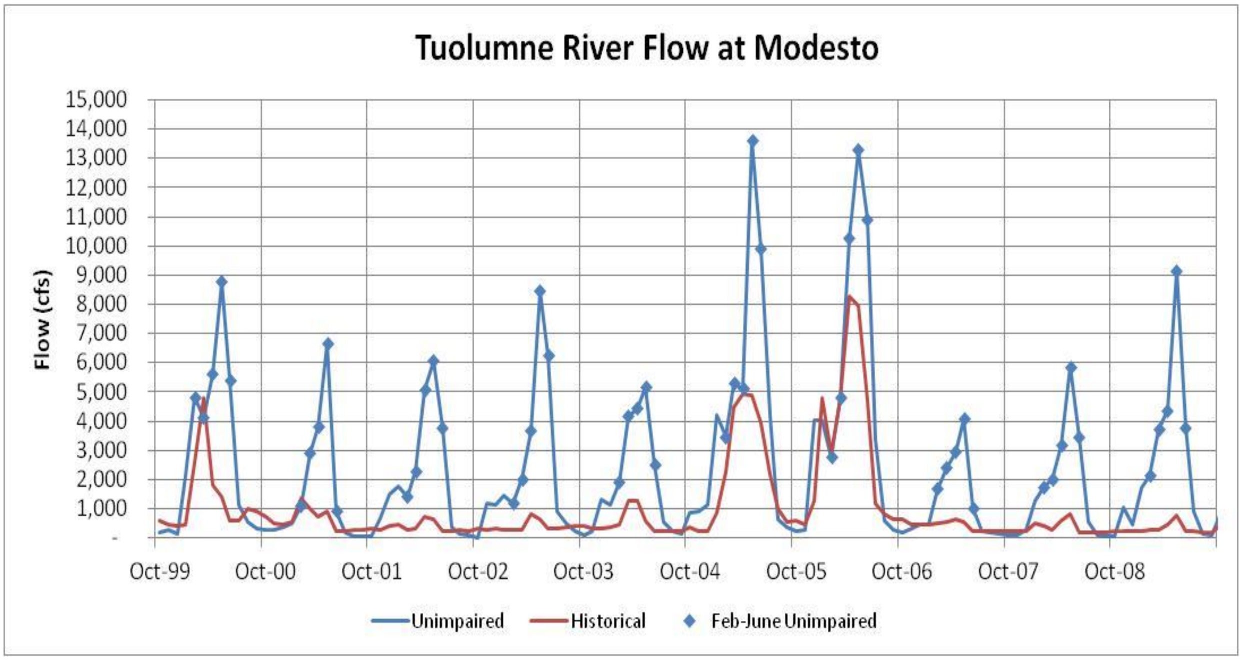

Figure 2-9. Monthly Unimpaired and Historical Tuolumne River Flows February–June for Water Years 2000–2009 (cfs = cubic feet per second)

Table 2-14. Historical and Unimpaired Flow February–June on the Tuolumne River (cubic feet per second)

Water Year	Historical Range	Unimpaired Range
2000	500–5,000	2,000–9,000
2001	250–1,000	1,000–7,000
2002	250–500	1,500–6,000
2003	250–750	1,000– 8,500
2004	250–1,250	2,000–5,000
2005[a]	2,000–5,000	3,500–13,500
2006[a]	3,000–8,000	3,000–13,000
2007	250–500	1,000–4,000
2008	250–750	2,000–6,000
2009	250–750	2,000–9,000

[a] In 2005 and 2006, the high historical flows occurred because New Don Pedro Reservoir was nearly full, and releases for flood control purposes were made in each month February–June.

The Tuolumne River monthly unimpaired flows (at New Don Pedro Dam) are summarized in Table 2-15 with the cumulative distributions of unimpaired flow (in 10 percent increments) for each month 1984–2009. Each month has a range of runoff depending on the rainfall and accumulated snowpack. The median flows (50 percent cumulative) can be used to generally characterize the seasonal runoff pattern. The peak runoff for the Tuolumne River is in May, and highest runoff (median monthly runoff greater than 180 TAF, or 3,000 cfs) is observed March–June. The minimum flows are observed in August, September, October, and November. The distribution of annual unimpaired flow ranges from 839 TAF (10th percentile) to 3,268 TAF (90th percentile), with a median runoff of 1,514 TAF. The average unimpaired flow was 1,851 TAF/y, 22 percent more than the median runoff. This represents approximately 30 percent of the unimpaired flow at Vernalis. Since 300 TAF/y are diverted upstream of New Don Pedro Reservoir, the average inflow to New Don Pedro Reservoir is approximately 85 percent of the Tuolumne River unimpaired flow.[14]

Table 2-15. Monthly and Annual Unimpaired Flow in the Tuolumne River 1984–2009 (thousand acre-feet)

Percentile	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Annual
10	4	8	16	24	53	112	184	208	63	17	4	3	839
20	5	13	18	32	60	124	195	275	100	24	8	4	884
30	9	17	25	40	67	136	219	329	141	30	9	7	1,114
40	10	18	29	70	93	168	230	360	207	33	14	7	1,312
50	11	23	47	97	105	190	263	443	260	57	20	10	1,514
60	15	26	58	129	151	232	301	536	330	67	26	15	2,018
70	18	49	70	134	161	271	307	541	381	101	33	18	2,394
80	21	62	82	202	192	296	323	569	507	144	37	20	2,971
90	38	77	171	269	313	340	343	645	619	242	52	23	3,268

The Tuolumne River flows are subject to minimum flow requirements as described above. Table 2-16 provides a monthly summary of the historical flows in the Tuolumne River at Modesto. The majority of the historical monthly flows were between 10 TAF and 30 TAF (150 cfs and 500 cfs). The annual river flow volume ranged from 155 TAF (10th percentile) to 2,249 TAF (90th percentile). The median historical annual river flow was 398 TAF. The average historical flow was 845 TAF/y, considerably greater (112 percent) than the median. The average historical flow was approximately 46 percent of the average unimpaired flow, but most of this historical flow was observed in the wet years with flood control releases. New Don Pedro Reservoir is the second largest reservoir on the LSJR tributaries and allows considerable carryover storage from one year to the next. Therefore, flood control releases are not necessary each year; consequently, it is difficult to anticipate when reservoir releases for flood control storage will be required.

---

[14] Approximately 300 TAF of the unimpaired Tuolumne River flows are diverted each year to the San Francisco Hetch Hetchy aqueduct for municipal water supply purposes.

2.5 Stanislaus River

2.5.1 Basin Overview

As shown in Table 2-1, the Stanislaus River is approximately 161 miles long and covers an area of approximately 1,195 square miles. The Stanislaus River originates in the high elevations of the Sierra Nevada and flows into the LSJR approximately 3 miles upstream of Vernalis at Ripon. The Stanislaus River receives most of its flow from late spring and early summer snowmelt; however, peak flows generally occur during winter rain events.

The New Melones Dam, the major CVP dam on the Stanislaus River, is located just downstream of the confluence of the river's three forks. There are two smaller dams downstream of New Melones: Tulloch Dam and Goodwin Dam. Two irrigation districts, South San Joaquin Irrigation District (SSJID) and Oakdale Irrigation District (OID) divert water from the Stanislaus River and generate hydropower, which they sell to the California Independent System Operator (CalISO). One municipal water conservation district—Stockton East Water District (SEWD)—and the Central San Joaquin Water Conservation District (CSJWCD) also divert water.

The Stanislaus River has 28 dams under DSOD jurisdiction storing an approximate 2.8 MAF of water; these include the New Melones, Tulloch, and Goodwin Dams and several small dams both upstream and downstream of New Melones. The New Melones Reservoir was completed by USACE in 1979 and first filled in 1982. New Melones Reservoir is approximately 60 miles upstream of the confluence of the Stanislaus River and the LSJR and is operated by USBR. With a storage capacity of approximately 2.4 MAF, the dam has two hydroelectric generators with a combined capacity of 300 MW (USBR 2010) and a maximum flow of 8,000 cfs. Existing flow requirements in the 1987 Agreement, Decision 1422, U.S. Fish and Wildlife Service (USFWS) Anadromous Fish Restoration Program (AFRP), and National Marine Fisheries Service (NMFS) Biological Opinion and Conference Opinion on the Long-Term Operations of the Central Valley Project (CVP) and State Water Project (SWP) (NMFS BO), specify flow releases on the Stanislaus River.

New Melones Reservoir is a component of the CVP, but it is authorized to provide water supply benefits within the defined Stanislaus River Basin per the 1980 Record of Decision (ROD) before additional water supplies can be used outside of the defined basin. New Melones Reservoir is operated for the following purposes: water supply, maximum storage for flood control and maximum releases conducted in accordance with USACE's operational guidelines, power generation, fishery enhancement, improvement of SJR water quality at Vernalis, and dissolved oxygen requirements at Ripon. The reservoir and river corridor also provide recreational benefits.

Tulloch Dam and power plant are located approximately 6 miles downstream of New Melones Dam. Tulloch dam is part of the Tri-Dam Project, which is a power generation project that consists of two additional dams, Donnells and Beardsley Dams, located upstream of New Melones Reservoir. The water released from New Melones Dam (for peaking power) is regulated by Tulloch Reservoir, which has a capacity of 67 TAF. Goodwin Dam, approximately 2 miles downstream of Tulloch Dam, was constructed by OID and SSJID in 1912. Water released from Tulloch Dam flows into Goodwin Dam, which impounds water for diversion into the irrigation canals for OID and SSJID or release to the lower Stanislaus River. Goodwin Dam also creates a reregulating reservoir for peaking power releases from Tulloch power plant. Water may also be gravity fed into the Goodwin Tunnel for deliveries to the CSJWCD and SEWD.

2.5.2 Water Diversion and Use

The Stanislaus River has many diverters that apply the water to beneficial use, including SEWD/CCSJID, SSJID, and OID, discussed below. These districts also receive water diverted and released by USBR at New Melones Reservoir. These water diverters include appropriative water rights holders, pre-1914 users, and riparian claim users. In the Stanislaus River Watershed there are 160 post-1914 appropriative water rights with a combined face value of approximately 19.7 MAF. Of these 160 water rights, 139 are non-power water rights with a face value of approximately 4.2 MAF. Of the 139 water rights, 16 are non-power water rights held by OID, SSJID, USBR, McMullin Reclamation District #2075, and River Junction Reclamation District #2064. The face value of these 16 rights totals approximately 3.9 MAF, accounting for approximately 94 percent of the water authorized for diversion (based on face value) under non-power water rights in the Stanislaus River Watershed.

SSJID and OID hold pre-1914 water rights to divert water from the Stanislaus River for use within their service districts. These districts also generate hydropower, which they sell to CalISO. Delivery of water from New Melones Reservoir to SSJID and OID is described by the 1988 agreement and stipulation with USBR, which specifies that the districts receive 600,000 AF of water when the projected flow in the Stanislaus River is greater than 600,000 AF (OID 1988). OID and SSJID generally divide the water available to them under the 1988 agreement equally, each receiving approximately 300,000 AF. OID has an adjudicated pre-1914 water right held jointly with SSJID to directly divert 1,816.6 cfs of flow from the Stanislaus River (OID 2012). The location and general characteristics of the four districts that receive water from the Stanislaus River are provided below.

South San Joaquin Irrigation District

The SSJID service area covers approximately 70,000 acres in San Joaquin County. The predominant land use in SSJID is agricultural (approximately 60,000 acres, Table 2-17); however, SSJID currently provides some surface water to cities, including Lathrop, Manteca, Tracy, and Ripon. Stanislaus River surface water is diverted into the SSJID and OID Joint Main Canal at the Goodwin Dam and is channeled into Woodward Reservoir. SSJID releases water from Woodward Reservoir into a conveyance system of canals to provide irrigation water for agricultural customers. Unused surface water drains north to the French Camp Outlet Canal. A small portion of irrigation runoff drains south as surface water return flows to the Stanislaus River. Return flows to the Stanislaus River are estimated to be approximately 3,000 AF/y based on monitored 1996 and 1997 data (EA EST 1999).

Table 2-17. South San Joaquin Irrigation District—Water Supply and Use

Water Supply/Use	Amount (thousand acre-feet)
Total applied water [a]	222.5
Recharge activities [a]	97.0
Canal & reservoir seepage[a]	50.5
Irrigated acreage [a]	58,551
Pumped groundwater—district [a]	5.8
Pumped groundwater—private [a]	33.8
Crop CUAW [b]	142.6

CUAW = Consumptive Use of Applied Water.

[a] Reported as 1994-2008 average.

[b] Reported as year 2008.

Table 2-17 presents a summary of SSJID water supply and use values from the most recent AWMP. This plan was prepared by the irrigation district as required by Senate Bill X7-7, which was adopted by California in 2009. The AWMP does not provide one summary table for all of the values incorporated in Table 2-17; rather, it presents a wide array of values over multiple years or different time frames. Because the values represent different time frames, there may be inherent inconsistencies between the reported values in Table 2-17. This information is provided to illustrate estimated water supply and use of surface water diversions based on published irrigation district data.

Oakdale Irrigation District

The OID service area covers approximately 70,000 acres in San Joaquin and Stanislaus Counties. The predominant land use in OID is agricultural (approximately 60,000 acres, Table 2-18). More than 95 percent of the water served by OID is surface water diverted from the Stanislaus River at Goodwin Dam into the Joint Supply Canal and the South Main Canal.

Surface water is supplemented by groundwater pumping from 22 groundwater wells located throughout the district on both sides of the Stanislaus River, especially during dry periods when surface water supplies are limited. Approximately 8,000 AF/y is pumped from these wells in dry years. OID also pumps approximately 1,500 AF/y from four shallow wells to control water table levels. Over the last 10 years, these domestic wells have produced approximately 1,000 AF/y (EA EST 1999).

Table 2-18 presents a summary of OID water supply and use values from the most recent AWMP. This plan was prepared by the irrigation district as required by Senate Bill X7-7, which was adopted by California in 2009. The AWMP does not provide one summary table for all of the values incorporated in Table 2-18; rather, it presents a wide array of values over multiple years or different time frames. Because the values represent different time frames, there may be inherent inconsistencies between the reported values in Table 2-18. This information is provided to illustrate estimated water supply and use of surface water diversions based on published irrigation district data.

Table 2-18. Oakdale Irrigation District—Water Supply and Use

Water Supply/Use	Amount (thousand acre-feet)
Surface water supply [a]	232.0
Irrigated acres [b]	55,746
Farm deliveries [a]	186.7
Crop CUAW [a]	128.9
Pumped groundwater—district [a]	7.1
Pumped groundwater—private [a]	19.3
Recharge activities [c]	71.7
Canal seepage [a]	35.6
Deep percolation [a]	24.5

Source: OID 2012.

CUAW = Consumptive Use of Applied Water

[a] Reported as 2005-2011 average.

[b] Reported acreage for year 2010.

[c] Recharge activities include canal seepage, drain seepage, and deep percolation of applied water.

Stockton East Water District

SEWD is a water conservation district that provides surface water for both agricultural and urban uses and groundwater recharge. SEWD covers approximately 116,300 acres, of which approximately 47,600 acres are within the city of Stockton. SEWD supplies wholesale treated surface water, which is retailed to Stockton area customers, several different water districts, and retail suppliers. SEWD delivers a minimum of 20,000 AF/y to these water districts and retail suppliers. Currently, raw water sent to the SEWD Treatment Plant originates from either New Hogan Reservoir on the Calaveras River or New Melones Reservoir on the Stanislaus River.

The estimated average amount of water that SEWD receives from the Calaveras River during a wet year is 67 TAF/y (Northeastern San Joaquin County Groundwater Banking Authority 2004). On the Stanislaus River, SEWD partially owns Goodwin Dam and uses it for diverting water into Goodwin Tunnel, which is at the upstream end of the New Melones Conveyance System. SEWD has a contract with USBR to receive 75,000 AF/y from the New Melones Reservoir through the CVP (SEWD 2011). However, during dry years, water delivery amounts may vary depending upon USBR water allocations. In the past, SEWD contracted with SSJID and OID to receive up to 30,000 AF/y through the New Melones Conveyance System, specifically for municipal use. This agreement ended in 2009, but was extended beyond 2010 and may be renewed pending further studies (SEWD 2014).

Table 2-19 presents a summary of SEWD's water supply and use values from the most recent water management plan. The water management plan does not provide one summary table for all of the values incorporated in Table 2-19; rather it presents a wide array of values over multiple years or different time frames. Because the values represent different time frames, there may be inherent inconsistencies between the reported values in Table 2-19. This information is provided to illustrate estimated water supply and use of surface water diversions based on published data.

Table 2-19. Stockton East Water District—Water Supply and Use

Water Supply/Use	Amount (thousand acre-feet)
Total surface water supply [a]	118.2
Irrigated acres [b]	50,981
CUAW [b]	127.6
Municipal deliveries [b]	52.4
Deep percolation of applied water	13.0
Conveyance system evaporation [b]	4.7
Pumped groundwater—district [b]	0
Pumped groundwater—private [b]	117.4
Recharge activities [c]	53.2
System seepage [b]	29.4

CUAW = Consumptive Use of Applied Water

[a] Total water supply from the Calaveras and Stanislaus Rivers, year 2010, includes Federal Ag. Water, Federal non-Ag. Water, and water transfers.

[b] Reported total for year 2010.

[c] Recharge activities include Farmington GW Recharge Program ponds as well as natural creeks/rivers and canals.

Central San Joaquin Water Conservation District

The CSJWCD service area is approximately 65,000 acres. CSJWCD has contracted with USBR to receive a total of 80,000 AF/y of surface water from the Stanislaus River. Of this total, 49,000 AF/y is a firm supply and 31,000 AF/y is an interim supply subject to other users' requirements. CSJWCD water is diverted through the Goodwin Tunnel at Goodwin Dam. The total contracted amount has never been fully delivered. On occasion, SSJID and OID have also made water available to CSJWCD for irrigation (Northeastern San Joaquin County Groundwater Banking Authority 2004).

Approximately 48,000 acres of CSJWCD land is irrigated. Because the CSJWCD surface water supply has generally been relatively small (in 2009 it was 32 TAF), groundwater has been the primary source of water for meeting irrigation needs. CSJWCD does not pump and sell groundwater, but it charges irrigators for groundwater pumping volumes that are estimated on the basis of an assumed water application rate of 2.8 acre-feet/acre (CSJWCD 2013).

Tri-Dams Project

The Tri-Dam project is a partnership between OID and SSJID. Together they developed, operate, and maintain the Beardsley, Donnells, and Tulloch projects, including the dams, tunnels, penstocks, power houses, communications systems, and general offices. The Tri-Dam facilities are located on the Middle Fork of the Stanislaus River in Tuolumne County.

The project is responsible for providing irrigation water to 117,500 acres of land on farms in San Joaquin and Stanislaus Counties. The Beardsley, Donnells, and Tulloch facilities provide OID and SSJID with storage reservoirs necessary to meet this water obligation. Storage and power are carried out pursuant to the districts' water rights and the districts' license issued by FERC. The Tri-Dam project has 660,000 acre-feet of water rights on the Stanislaus River (Richardson & Company 2010). In 2005, the State Water Board issued a water quality certification for the Tri-Dam Project (Beardsley/Donnels Hydroelectric Project) and in 2006 for the Tulloch Hydroelectric Project. Both certifications contain a reopener provision "to implement any new or revised water quality standards and implementation plans adopted or approved pursuant to [Porter-Cologne] or section 303 of the Clean Water Act" (State Water Board 2005, 2006).

2.5.3 Flow Requirements

Various flow requirements on USBR established through agreements, BOs, and water rights decisions govern the flow released from the dams on the Stanislaus River. Four of these are discussed below: the 1987 Agreement, Decision 1422, USFWS AFRP, and 2009 NMFS BO. In recent drought years, low storage levels in New Melones Reservoir, limited projected inflows and the junior nature of USBR's water rights for New Melones Reservoir, limited supplies are available to USBR to meet its flow and other water quality requirements and maintain water in storage. USBR does not appear to have adequate water in New Melones Reservoir under its water right permits to meet the State Water Board's Water Right Decision D-1641 (D-1641) spring base flow and spring pulse flow requirements in 2016 as well as other requirements without depleting storage in New Melones Reservoir to unreasonably low levels. OID's and SSJID's water rights and other SJR Basin water rights are not conditioned on meeting any of these requirements.

1987 Agreement and Interim Operations Plan

USBR and CDFW executed an agreement titled *Interim Instream Flows and Fishery Studies in the Stanislaus River Below New Melones Reservoir* on June 5, 1987 (1987 Agreement). The interim plan of operations (IPO) increased the fisheries release by changing 98,300 AF from the maximum to the minimum required release and allowed for releases as high as 302,100 AF in wetter years. The exact quantity to be released each year is determined based on a formulation involving storage, projected inflows, projected water demands, and target carryover storage.

State Water Board Water Right Decision 1422

State Water Board Water Right Decision 1422 to USBR specifies flow releases from New Melones Reservoir up to 70,000 AF in any 1 year for water quality control purposes in the LSJR. The flows must maintain a maximum mean monthly total dissolved solids (TDS) concentration below the mouth of the Stanislaus River at 500 parts per million (ppm). They must also maintain at least 5 ppm of dissolved oxygen in the river.

State Water Board Water Right Decision 1641

The State Water Board established flow objectives for the SJR at Vernalis for the period from February through June and the month of October. With the exception of a 31-day pulse flow period from approximately April 15 through May 15, the February through June flows are referred to as the spring base flow objectives. The objectives require a specified minimum monthly average flow rate based on the San Joaquin Valley Water Year Hydrologic Classification (at the 75 percent exceedance level) and include two levels. The higher flow level applies when the 2 parts per thousand (ppt) isohaline (X2[15]) is required to be at or west of Chipps Island pursuant to Table 4 of D-1641. The fall pulse objective in all years except a critical year following a critical year is required to be 1,000 cfs plus up to an additional 28 TAF limited to the amount necessary to provide a monthly average flow of 2,000 cfs. The additional 28 TAF is not required in a critical year following a critical year.

In D-1641, the State Water Board assigned responsibility to USBR for ensuring that all of the SJR flow objectives are met. As part of the San Joaquin River Agreement (SJRA), a voluntary agreement between parties in the SJR Watershed to implement provisions of the 1995 Bay-Delta Plan from 2000 through 2011, USBR and DWR purchased water from other water users in the SJR Watershed to meet some of the SJR flow requirements. Instead of meeting the 1995 Bay-Delta Plan pulse flow objectives (the current D-1641 requirements), the SJRA parties proposed and the State Water Board approved the conduct of the Vernalis Adaptive Management Plan (VAMP). The VAMP provided for generally lower flows and offramps in very dry conditions. The SJRA also provided for the purchase of flows to meet the D-1641 fall flow requirements. After the expiration of the SJRA in 2011, USBR purchased some water to help to meet the SJR flow requirements in 2012 and 2013, but did not fully achieve the requirements. Due to inadequate water supplies in New Melones Reservoir to meet all of USBR's various obligations and the lack of water releases from elsewhere in the SJR Watershed, USBR has repeatedly failed to comply with the SJR flow objectives since the SJRA expired.

U.S. Fish and Wildlife Service AFRP

USFWS requires USBR to provide water for fish flows below CVP reservoirs on the Stanislaus River. This program generally released pulse flows in the April–May period that were coordinated with the VAMP). The AFRP is continuing, although the VAMP ended in 2011. The annual allocation and scheduling of release flows are made annually but are supplemental to the basic IPO flows, described above.

2009 National Marine Fisheries Service BO

Reasonable and Prudent Alternative (RPA) Action 3.1.3 of the June 2009 NMFS BO to USBR for the long-term operation of the CVP and SWP (Operational Criteria and Plan [OCAP])imposes minimum Stanislaus River flows according to a flow schedule as measured at Goodwin Dam. These daily flows are dictated by the lifecycles of species: the fall flow for attraction, spring pulse flow for outmigration cues in wet years, and sustained late-spring flows for outmigration. The flows range from approximately 500 to 1,500 cfs in the fall and approximately 800 to 4,800 cfs in the spring. The daily flow schedule (with several pulse flows) is equivalent to the monthly average RPA flow requirement simulated by the Water Supply Effects (WSE) model. Section 2.6.3 provides additional information regarding the 2009 NMFS BO as it relates to the flows measured on the SJR at Vernalis.

2.5.4 Hydrology

The unimpaired flow of the Stanislaus River is the flow that would occur without existing diversions. The historical flow of the Stanislaus River is influenced by the operation of the existing dams and

---

[15] X2 is the location of the 2 parts per thousand salinity contour (isohaline), 1 meter off the bottom of the estuary measured in kilometers upstream from the Golden Gate Bridge. The abundance of several estuarine species has been correlated with X2. In the 2006 Bay-Delta Plan, a salinity value—or electrical conductivity (EC) value—of 2.64 millimhos/centimeter (mmhos/cm) is used to represent the X2 location. Note, in this SED, EC is generally expressed in deciSiemens per meter (dS/m). The conversion is 1 mmhos/cm = 1 dS/cm.

diversions described above. The hydrograph in Figure 2-10 depicts both types of flow over time. It shows that the unimpaired flow at New Melones Dam averaged 1,100 TAF/y and the historical bypasses or releases averaged 611 TAF/y below the Goodwin Dam for the recent 10-year period of water years 2000–2009.[16]

The Goodwin Dam bypasses or releases averaged approximately 55 percent of the unimpaired flow, but the historical flows were usually much less than 50 percent of the unimpaired flow, with flood control releases providing most of the flow below Goodwin Dam. The historical monthly flows at Ripon are generally less than the unimpaired flows in the winter and spring months, and are often slightly higher than the unimpaired flows in the summer and fall months.

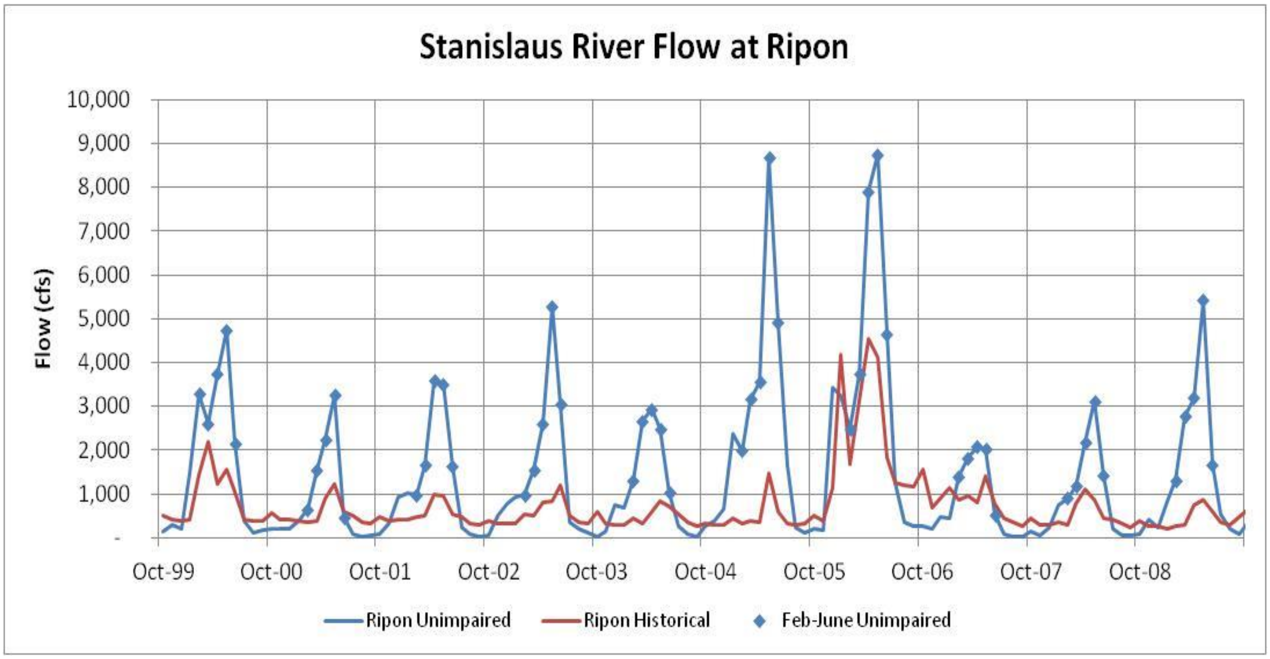

Figure 2-10. Monthly Unimpaired and Historical Stanislaus River Flows February–June for Water Years 2000–2009 (cfs = cubic feet per second)

Table 2-20 summarizes the range of historical and unimpaired flows on the Stanislaus River to demonstrate the baseline hydrology of the river in February–June. The peak historical flows during this period were in 2006 because New Melones Reservoir was nearly full, and relatively high flows ranging from 2,000 to 4,500 cfs were released for flood control purposes.

The Stanislaus River monthly unimpaired flows at New Melones Dam are summarized in Table 2-21, with the cumulative distributions of unimpaired flow (in 10 percent increments) for each month from 1984 through 2009. Each month has a range of runoff depending on the rainfall and accumulated snowpack. The median flows (50 percent cumulative) can be used to generally characterize the seasonal runoff pattern. The peak runoff for the Stanislaus River is observed in May, and highest runoff (median monthly runoff greater than 90 TAF, or 1,500 cfs) is observed March–June. The minimum flows are observed in August, September, and October. The distribution of

---

[16] These releases include flood flows in 2000 and 2006.

annual unimpaired flow ranged from 463 TAF (10th percentile) to 2,015 TAF (90th percentile), with a median runoff of 922 TAF. The average unimpaired flow was 1,100 TAF/y, 19 percent more than the median runoff. This represents approximately 18 percent of the estimated unimpaired flow at Vernalis.

Table 2-20. New Melones Reservoir Historical and Unimpaired Flow (cubic feet per second) February–June

Water Year	Historical Range	Unimpaired Range
2000	1,000–2,000	2,000–5,000
2001	250–1,000	500–3,000
2002	500–1,000	1,000–3,500
2003	500–1,000	1,000–5,000
2004	500–750	1,000–3,000
2005	250–1,250	2,000–9,000
2006[a]	2,000–4,500	2,500–9,000
2007	750–1,250	500–2,000
2008	250–1,000	1,000–3,000
2009	250–750	1,000–5,500

[a] New Melones Reservoir was nearly full, and flood control releases were made in each month February–June.

Table 2-21. Monthly and Annual Unimpaired Flow in the Stanislaus River 1984–2009 (thousand acre-feet)

Percentile	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Annual
10	3	5	12	17	29	67	105	95	30	5	2	1	463
20	5	8	13	23	35	79	130	153	41	12	4	1	510
30	6	10	14	27	50	90	135	167	57	14	5	2	595
40	9	13	15	42	55	102	157	192	94	19	6	3	752
50	10	16	27	55	75	127	178	224	103	22	7	4	922
60	11	18	31	86	90	160	206	297	128	24	10	6	1,162
70	12	24	42	100	104	176	218	329	178	40	13	6	1,463
80	13	31	47	146	138	215	245	370	215	57	16	10	1,692
90	17	44	105	191	224	233	254	446	285	89	21	18	2,015

Compared to the other two eastside tributaries, the Tuolumne and Merced Rivers, the Stanislaus River historical flows are relatively high because of the minimum flow requirements for fish; additional releases for salinity control; AFRP flow releases for anadromous fish in April, May, and June; and the VAMP flow releases in April and May. The New Melones Reservoir is the largest reservoir on the SJR tributaries and has considerable carryover storage from one year to the next. Therefore, flood control releases are not necessary each year; consequently, it is difficult to anticipate when reservoir releases for flood control storage will be required. The monthly historical flows are summarized in Table 2-22 with the cumulative distributions (in 10 percent increments) from 1984 through 2009. The majority of the historical monthly flows were between 10 TAF and 40 TAF (150 cfs and 600 cfs). The annual river flow volume ranged from 310 TAF (10th percentile) to 1,249 TAF (90th percentile). The median historical annual river flow was 429 TAF. The average historical flow was 611 TAF/y, which is 42 percent more than the median. The average historical flow of 611 TAF was approximately 55 percent of the average unimpaired flow, but most of this flow was observed in the wet years with flood control releases.

Table 2-22. Monthly and Annual Historical (Observed) Flow in the Stanislaus River 1984–2009 (thousand acre-feet)

2.6 Lower San Joaquin River

2.6.1 Basin Overview

The drainage area of the SJR above Vernalis encompasses approximately 12,250 square miles. All of the SJR flow from upstream of the Merced River (including the Friant Dam flood control releases) as well as the tributary flows from the three eastside tributaries are combined and measured at the Vernalis Bridge. On the west side of the LSJR, tributary streams include Hospital, Del Puerto, Orestimba, San Luis, and Los Banos Creeks. These intermittent streams are commonly referred to as the westside tributaries to the SJR. However, at times of high rainfall, these streams contribute significant runoff to the LSJR. Vernalis, an unincorporated community in San Joaquin County downstream of the Stanislaus River and upstream of tidal effects from the Delta, is where the LSJR enters the southern Delta.

The water for irrigated agriculture in the San Joaquin Valley is supplied by the LSJR and its tributaries and the Delta-Mendota Canal (DMC), which conveys water from the southern Delta to the Mendota Pool. The CVP Jones Pumping Plant (with seasonal storage in San Luis Reservoir) exports water from the southern Delta through the DMC, supplying the SJR exchange contractors and several water districts along the DMC that have contracts for CVP water supplies.

2.6.2 Water Diversion and Use

The LSJR within the plan area includes the confluences of the Stanislaus, Tuolumne, and Merced Rivers. The stretch of river from the Merced River confluence north to Vernalis has approximately 40 diversions. Of these diversions, approximately 15 are covered under appropriative water rights, and approximately 25 diversions are claimed under Statements of Water Use and Diversion.
The major use of diverted water is for agricultural and domestic uses (State Water Board 2015).

2.6.3 Flow Requirements

Various flow requirements established through basin plans and agreements have governed the flow at Vernalis, including objectives in the 1995 and 2006 Bay-Delta Plans, SJRA, VAMP, D-1641, and 2009 NMFS BO.

The State Water Board first established LSJR flow objectives in the 1995 Bay-Delta Plan. The flow objectives were primarily intended to protect fall-run Chinook salmon and provide incidental benefits to Central Valley steelhead. The objectives were unaltered in the 2006 Bay-Delta Plan, but as authorized in D-1641, the 2006 Bay-Delta Plan allowed for the VAMP (discussed below) to be conducted instead of the plan's April 15–May 15 pulse flow requirements.

The SJRA signatory parties, including the California Resources Agency, U.S. Department of the Interior, San Joaquin River Group, CVP/SWP Export Interests, and two environmental groups, agreed that the San Joaquin River Group Authority (SJRGA) members would meet the experimental flows specified in the VAMP program in lieu of meeting the spring pulse flow objectives adopted in the 2006 Bay-Delta Plan. The VAMP, which ended in 2011, was a 12-year program designed to protect juvenile Chinook salmon migration from the LSJR through the Delta. It was also a scientific experiment with monitoring to determine how juvenile fall-run Chinook salmon survival rates change in response to alterations in LSJR flows and CVP and SWP exports as a result of the installation of the Head of Old River Barrier (HORB). The VAMP was designed to assess a combination of flows, varying between 3,200 cfs and 7,000 cfs, and exports varying between 1,500 cfs and 3,000 cfs.

The SJRA included flows for the October pulse flow objective. Supplemental water up to 28,000 AF was also released in October during all water year types. The amount of additional water was limited to that amount necessary to provide a monthly average flow of 2,000 cfs at Vernalis.

As discussed above in the Stanislaus River section, under D-1641, USBR is assigned responsibility for ensuring that all of the SJR flow objectives are met. Due to inadequate water supplies in New Melones Reservoir to meet all of USBR's various obligations and the lack of water releases from elsewhere in the SJR Watershed, USBR has repeatedly failed to comply with the SJR flow objectives since the SJRA expired.

The 2009 NMFS BO for the long-term OCAP included several RPAs related to New Melones Reservoir operations and the Stanislaus River that affect the flows at Vernalis. RPA action IV 2.1 requires a minimum LSJR inflow-to-export ratio and minimum flows at Vernalis based on SJR water year type during the 2-month pulse flow period of April and May. (USBR and DWR are required to seek a supplemental agreement with SJRGA to achieve these minimum long-term flows at Vernalis.) The LSJR inflow-to-export ratio is the inverse of the already established Delta Export/Inflow (E/I) ratio, which is calculated using the total Delta inflow. The LSJR inflow-to-export ratios are more restrictive and allow the exports to be 100 percent of the LSJR inflow in critical years, 50 percent of the LSJR inflow in dry years, 33 percent of the LSJR inflow in below normal years, and 25 percent of the LSJR inflow in above normal or wet years. As indicated in Table 2-23, these criteria effectively limit exports to 1,500 cfs during April and May unless the LSJR is higher than the minimum flow required in these months.

Table 2-23. Minimum April and May Vernalis Flows (cubic feet per second)

San Joaquin River (60-20-20) Index Year Types	Minimum Flow at Vernalis	Corresponding Exports
Critical	1,500	1,500
Dry	3,000	1,500
Below Normal	4,500	1,500
Above Normal	6,000	1,500

2.6.4 Hydrology

Construction and operation of the numerous water supply, hydroelectric, and flood control reservoirs during the twentieth century upstream of Vernalis have significantly modified the flows at Vernalis in comparison to the historical (observed) flows. Peak flows currently occur earlier in the year—during February, March, April, and May, rather than in May and June as occurred under the unimpaired flow regime. Figure 2-11 shows the monthly unimpaired and historical flows at Vernalis for the recent 10-year period of water years 2000 through 2009. The unimpaired flows at Vernalis average 6,056 TAF/y and the historical flows (including flood flows in 2000, 2005, and 2006) average 2,915 TAF/y.

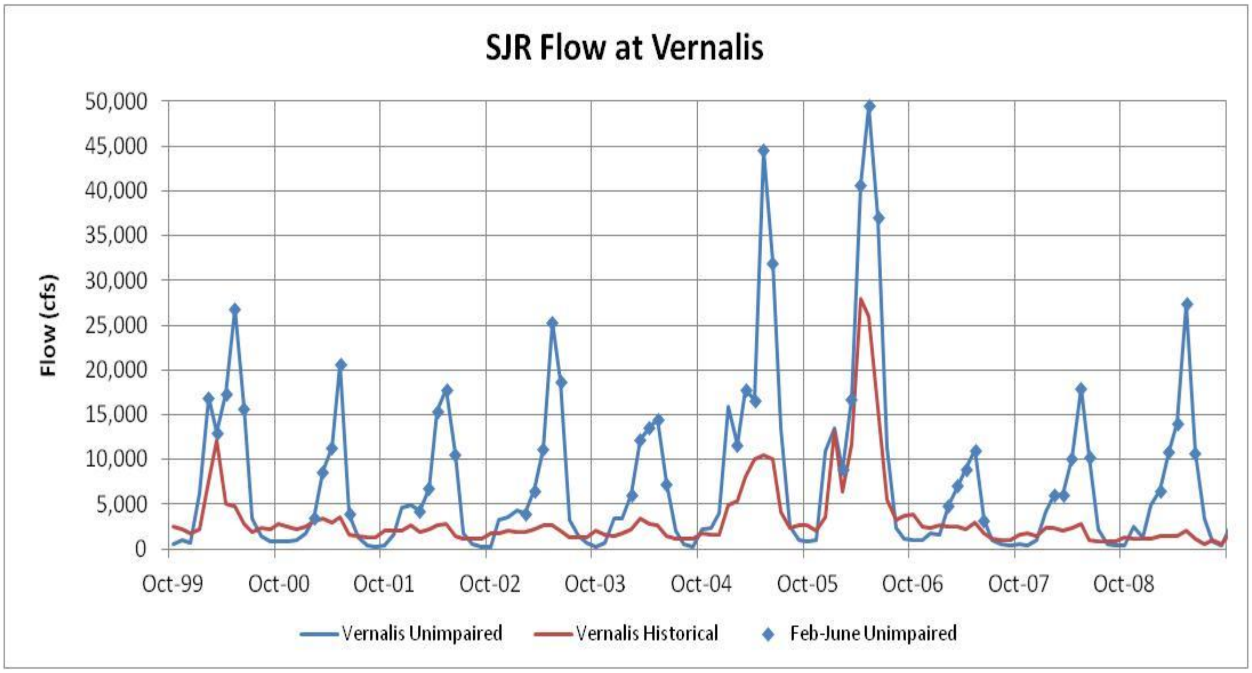

Figure 2-11. Monthly Unimpaired and Historical LSJR Flows at Vernalis February–June for Water Years 2000–2009 (cfs = cubic feet per second)

The historical (1930–2009) Vernalis flows average approximately 48 percent of the unimpaired flow, but the releases were usually much less than 40 percent of the unimpaired flow, with flood control releases providing the majority of the flow. The historical monthly flows at Vernalis were generally lower than the unimpaired flows in the winter and spring months, and were often slightly higher than the unimpaired flows in the fall months.

Observed flow at Vernalis after 1984 reflects conditions that existed following completion and filling of New Melones Reservoir in 1983. Tables 2-24 and 2-25 show the monthly unimpaired and historical flows, respectively, for the SJR at Vernalis from 1984 through 2009. The hydrologic variability in the SJR Basin after 1983 has been substantially altered, with greatly reduced monthly flows and annual runoff volumes. The median annual unimpaired flow in the SJR at Vernalis was 4,578 TAF, while the median annual historical runoff was 1,718 TAF, or approximately 38 percent of unimpaired flow.

Increased storage and water supply diversions have resulted in flow conditions that are more static with less seasonally variable flows throughout the year. There are now reduced flows in the winter and spring months, with increased flow in the fall, both of which combine to create managed flows that diverge significantly from what would occur under unimpaired conditions.

2.7 Southern Delta

The LSJR enters the southern Delta at Vernalis. When the Head of Old River Barrier is not in place, about half of the LSJR volume flows west into Old River (which diverges from the LSJR downstream of Mossdale and connects with Middle River and the Grant Line Canal) and is typically diverted by the CVP and SWP export pumps, and about half continues north toward Stockton. Most of the lands in the southern Delta are within the South Delta Water Agency (SDWA) in San Joaquin County. Figure 2-12 shows the outline of the SDWA relative to the San Joaquin County line and the legal boundary of the Delta. Of the nearly 150,000 acres within the southern Delta, irrigated lands comprise approximately 100,000 acres. The non-irrigated area includes urban lands, watercourses, levees, farm homesteads, islands within channels, and levees. Just west of the plan area in the southern Delta are the CVP and SWP pumping plant intakes. Just outside the plan area to the north and west are two CCWD intakes. Figure 2-12 shows the location of these intakes and of wastewater treatment plant (WWTP) facilities that discharge treated effluent into the southern Delta.

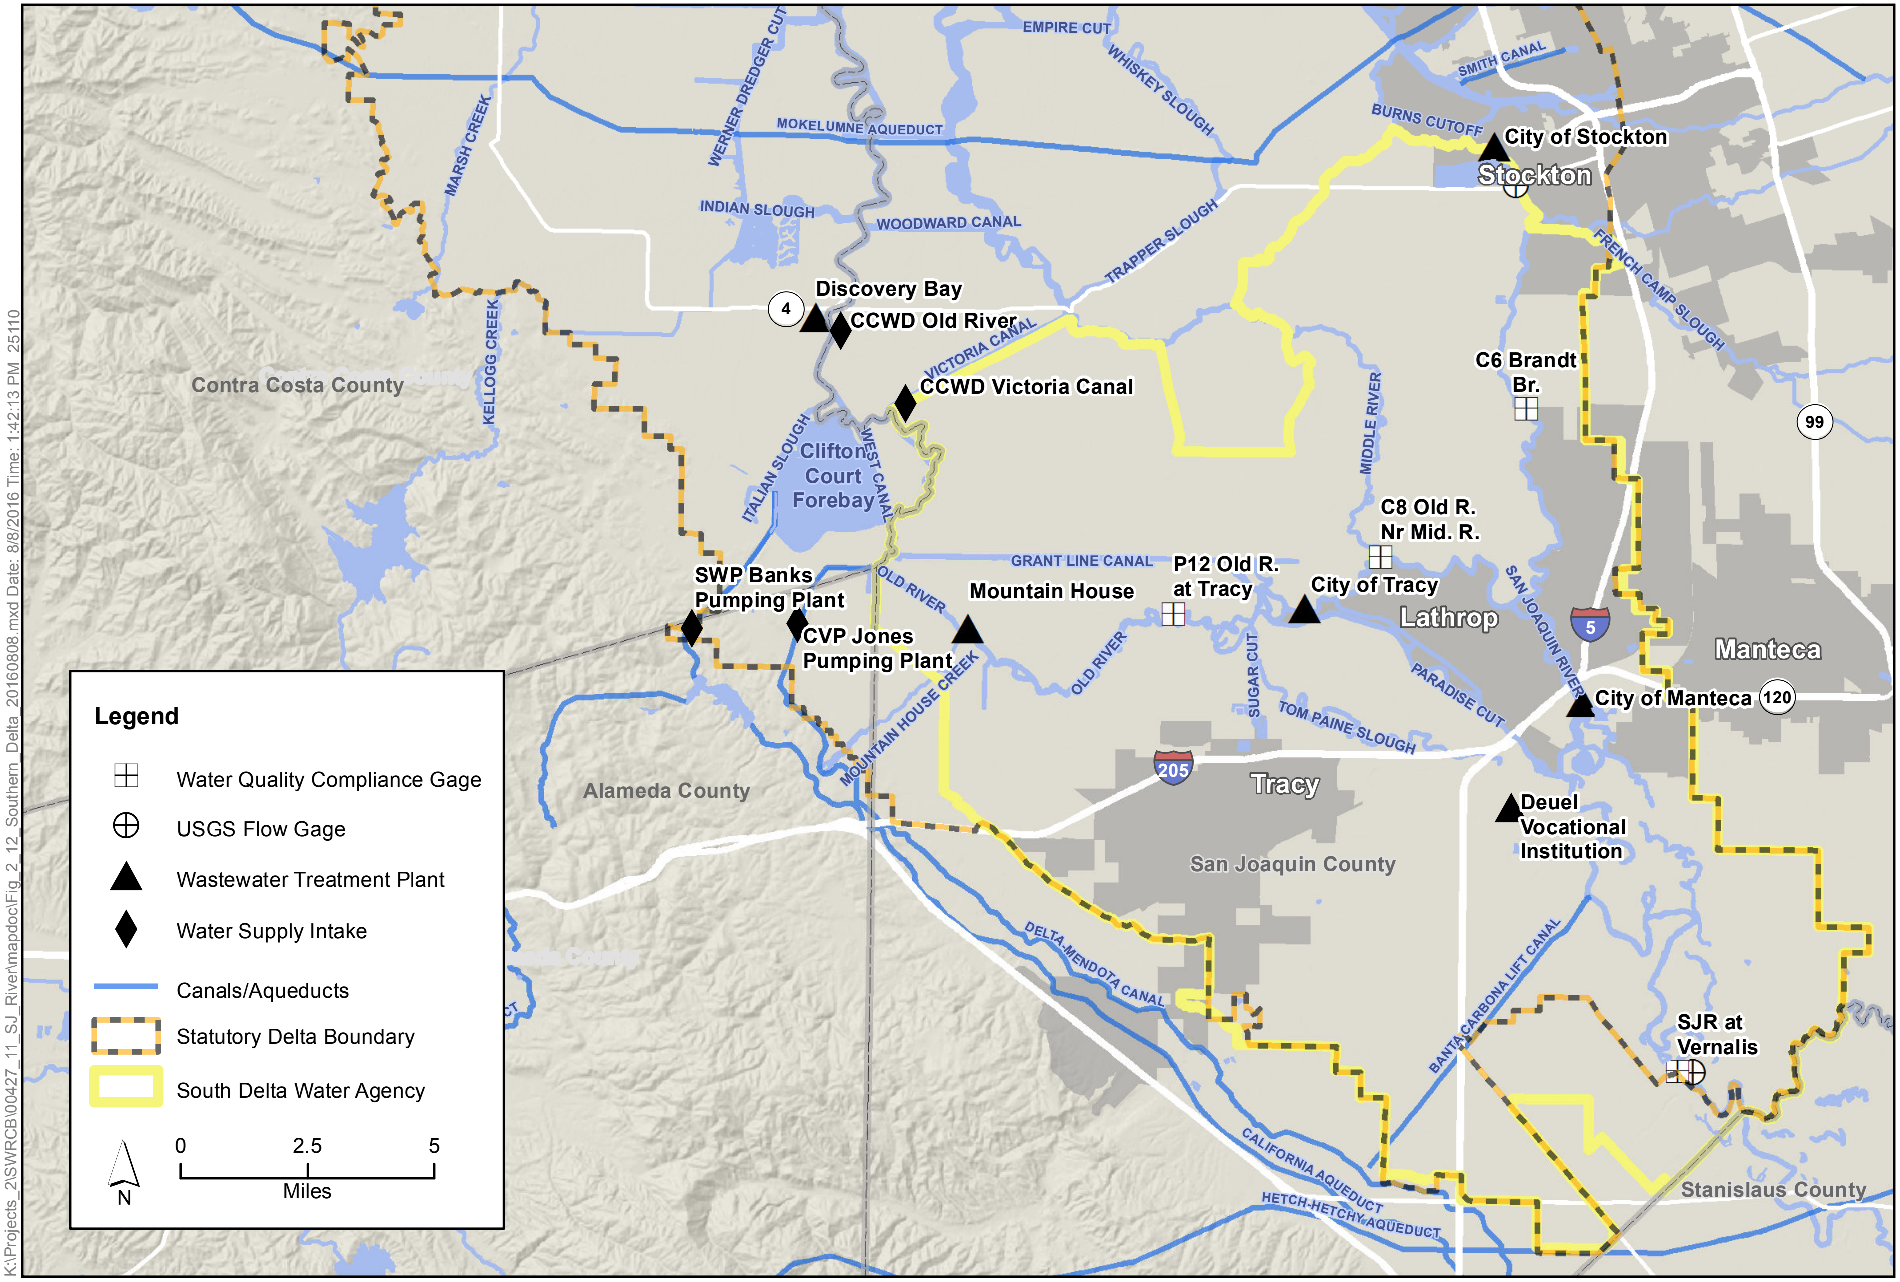
Southern Delta salinity concentrations are affected by numerous factors, including the amount and salinity concentration of SJR flow entering the southern Delta at Vernalis, daily tidal action, CVP and SWP pumping operations, agricultural return flows, municipal wastewater discharges, and other influences. These are discussed in more detail below.

2.7.1 Lower San Joaquin River and Tidal Conditions

Water enters the southern Delta channels along three major pathways: from the LSJR west through Old River and Grant Line Canal toward the CVP Jones and SWP Banks pumping facilities; from the central Delta through Middle River and Victoria Canal; and from the central Delta through Old River and West Canal to the Clifton Court Forebay (CCF) and the DMC. Approximately 50 percent of the LSJR flow splits into the Old River channel, and the other 50 percent continues down the LSJR channel toward Stockton. During storm flows of greater than approximately 15,000 cfs at Vernalis, the Paradise Cut weir (elevation 12.5 ft) diverts some of the flow at LSJR mile 60 into Paradise Cut toward Grant Line Canal, reducing the LSJR flow at Mossdale and the Head of Old River.

There are three major southern Delta channels: Old River channel, Middle River channel, and Grant Line Canal. The Old River channel flows west about 4 miles to the upstream end of Middle River and continues past Doughty Cut (which connects with the upstream end of Grant Line Canal) toward Tracy. The Old River channel in the vicinity of Tracy is the southernmost Delta channel. The Old River channel length between the Head of Old River and the CVP Tracy Facility (DMC and fish facility) is about 24 miles, with a surface area of about 550 acres and a volume of 3,500 AF at an elevation of 0 ft mean sea level (MSL). Most of the Old River flow moves through Doughty Cut to Grant Line Canal.

Middle River is a relatively narrow and shallow channel that extends 12 miles from its head to Victoria Canal. The surface area of Middle River is approximately 175 acres, with a volume of 750 AF at an elevation of 0 ft MSL. Export conditions (described further below) pull water from the Sacramento River and create cross-Delta water conditions. This cross-Delta water flows south (upstream) in the portions of Old and Middle Rivers that are north of the exports. Approximately 60 percent of this Old and Middle River (OMR) flow is in the Old River channel and approximately 40 percent is in the Middle River and Victoria Canal, because Victoria Canal is shallow and Old River is a larger conveyance channel.



K:\Projects_2\SWRCB\00427_11_SJ_River\mapdoc\Fig_2_12_Southern_Delta_20160808.mxd Date: 8/8/2016 Time: 1:42:13 PM 25110

Figure 2-12
Vicinity Map of Southern Delta

The third major channel is the Grant Line Canal, which is about 7.5 miles long and extends from near Doughty Cut to the Old River channel just north of the Tracy fish facility. The surface area of the Grant Line Canal is approximately 400 acres, with a volume of approximately 3,250 AF at an elevation of 0 ft MSL. The Fabian and Bell Canal, which runs parallel to and is interconnected with Grant Line Canal for much of its length, is included in these measurements.

The total surface area of these three major southern Delta channels is approximately 1,125 acres with a volume of 7,500 AF at a water surface elevation of 0 ft MSL. As the tidal elevation fluctuates, the surface area and volume change. The average southern Delta tidal fluctuation is approximately 3 ft (i.e., from -1 to 2 ft), and the surface area increases from 1,000 acres at low tide to 1,250 acres at high tide (Delta Simulation Model 2 [DSM2]). The southern Delta channel volume increases from approximately 6,000 AF at low tide to approximately 9,500 AF at high tide, a change of approximately 3,500 AF. This tidal volume, also known as the tidal prism, moves into and out of the southern Delta channels twice each day, constituting an average tidal flow of approximately 3,500 cfs flowing into these channels during the flood tides (for about 12 hours each day) and approximately 3,500 cfs flowing out during the ebb tides.

The longitudinal movement of water between low tide and high tide depends on the cross-section of the channels but averages several miles in the southern Delta channels. This tidal movement provides considerable mixing and diluting of the agricultural drainage and wastewater discharges in the southern Delta channels. The CCF gates are usually operated to remain closed during flood tide periods to preserve as much upstream flow into the southern Delta channels as possible and to maintain the high tide elevations. Sacramento River water moving toward the export pumps from the central Delta through Old and Middle Rivers is tidally mixed with LSJR water in the vicinity of CCF and the DMC intake, with some Sacramento River water moving upstream in Old River and Grant Line Canal during flood tide, and some LSJR water moving downstream past CCF in West Canal, Old River, and Victoria Canal during ebb tide.

The HORB is a temporary rock barrier that has often been installed by DWR in the fall (late September through November). The barrier reduces the normal diversion of SJR flow into Old River. When the rock barrier is installed, the majority of the LSJR flows north to the Stockton Deep Water Ship Channel. However, some of the LSJR flow is drawn through Turner Cut and Middle River and Victoria Canal toward the CVP and SWP pumping facilities. The barrier is meant to increase flow in the Stockton DWSC and improve the migration of adult SJR Chinook salmon. The HORB was also installed in the spring during the VAMP pulse flow period to reduce the number of juvenile SJR Chinook salmon diverted into Old River and subsequently entrained (or salvaged) at the CVP and SWP fish collection facilities. The increased flow past Stockton was intended to improve the survival of SJR fish migrating through the Delta to Chipps Island.

2.7.2 Water Diversions

The two major water export facilities in the Delta are the CVP and SWP, which are both located west of Tracy just outside the western boarder of the SDWA boundary. The CCWD also diverts water from the southern Delta at Old River and Victoria Canal. These facilities and their influence on southern Delta circulation and salinity are described below.

Export Facilities

CVP Jones Pumping Plant

The CVP Jones Pumping Plant, formerly known as the Tracy Pumping Plant, is located about 5 miles northwest of Tracy. The Jones Pumping Plant consists of six pumps with a permitted diversion capacity of 4,600 cfs. It is located at the end of an earth-lined intake channel approximately 2.5 miles long. The Tracy Fish Collection Facility is located at the entrance to the intake channel on Old River. Water is pumped approximately 200 ft into the DMC, which, as mentioned earlier, delivers water to LSJR water rights holders at Mendota Pool (exchange contractors) and CVP contractors along the DMC and conveys water to San Luis Reservoir for seasonal storage.

The southern Delta CVP contractors are composed of three separate water demand types: CVP water service contractors, exchange contractors, and wildlife refuge contractors. Exchange contractors "exchanged" their senior rights to water in the LSJR for a CVP water supply from the Delta. USBR guaranteed the exchange contractors a firm water supply of 840 TAF/y, with a maximum reduction to 650 TAF/y. The exchange allowed USBR to build Friant Dam and to divert the LSJR water supply to the Friant-Kern and Madera Canals. Additional CVP contactors and wildlife refuge water supply contracts total almost 3,500 TAF/y of water supply demand for the Jones Pumping Plant.

SWP Banks Pumping Plant

The Harvey O. Banks Pumping Plant has a physical pumping capacity of 10,300 cfs. However, flow diverted from the Delta into CCF is limited by a USACE permit under Section 10 of the Rivers and Harbor Act to a maximum of 6,680 cfs during much of the year. SWP exports are diverted into CCF and then pumped at the Banks Pumping Plant into the California Aqueduct (State Water Board 1999). This exported water is pumped into the South Bay aqueduct, pumped into San Luis Reservoir for seasonal storage, pumped farther south in the California Aqueduct to Kern County Water Agency, pumped over the Coast Range in the Coastal Aqueduct, or pumped over Tehachapi Pass to southern California contractors. The total water supply demand for the Banks Pumping plant is approximately 4,000 TAF/y.

CVP and SWP Exports

CVP and SWP export pumping are subject to 2006 Bay-Delta Plan objectives, which are implemented through D-1641. Both the CVP and the SWP have maximum permitted pumping rates. Delta outflow requirements may limit export pumping if the combined Delta inflow is not enough to satisfy both the in-Delta agricultural diversions described earlier in this chapter and the CVP and SWP pumping. The coordinated operations agreement (COA) governs the CVP and SWP share in reservoir releases and Delta pumping.

Export rates are also limited by the 2008 USFWS and the 2009 NMFS BOs for the long-term OCAP of the CVP and SWP. These two BOs added limits on the reverse (negative) OMR flows December–June. The BOs allow a range of reverse OMR limits to be imposed for delta smelt and salmonid protection, but the largest monthly average reverse OMR flows for December–June are negative 5,000 cfs. This effectively limits the CVP and SWP exports to approximately 5,000 cfs plus one-half of the LSJR flow at Vernalis.

The 1995 Bay-Delta Plan introduced the E/I ratio, which limits the combined export to a specified monthly fraction of the combined Delta inflow. The E/I ratio is 35 percent February–June and

65 percent June–January. The February E/I can be increased to 45 percent under low-flow conditions. This E/I objective allows a maximum pumping that is often similar to the allowable exports under the Delta outflow objectives, but sometimes the E/I ratio is more limiting than the required outflow. At other times, the exports must be further reduced to increase the Delta outflow to satisfy the salinity requirements at Emmaton and Jersey Point or at CCWD's Rock Slough diversion.

The monthly cumulative distribution of CVP and SWP pumping for water years 1984 through 2009, which corresponds to the LSJR historical and unimpaired flows, suggests that the CVP pumping is uniform throughout most of the year. The largest reductions in pumping occur during April–June for fish protection. The median CVP pumping was greater than 3,500 cfs in all months except April, May, and June. The SWP pumping shows a greater range from year to year in most months. The median SWP pumping is 3,000–4,000 cfs from October to March, and approximately 2,000 cfs in April, 1,000 cfs in May, and 2,000 cfs in June. SWP pumping has been greatest in July–September with a median pumping of approximately 5,000 cfs because of the peak irrigation demand and because reduced pumping for fish protection is not usually required in these months.

CCWD Intakes

CCWD has four surface water intakes: Mallard Slough Intake, Rock Slough Pumping Plant #1, Old River Intake near State Route 4, and Victoria Canal Intake. The Old River and Victoria Canal Intakes are immediately north/northwest of the SDWA boundary (Figure 2-12). The Mallard Slough and Rock Slough Intakes are located farther west and closer to the ocean. The Old River Intake is the largest intake, accounting for the majority of surface water diverted by CCWD (CCWD and USBR 2006).

Generally, CCWD intakes are located where the effects of seawater intrusion are very pronounced. Therefore, salinity at CCWD intakes can vary substantially over the course of a year. CCWD's intakes typically experience relatively fresh conditions in the late winter and early spring, and salinity increases in summer and fall as conditions become drier and regulatory standards governing Delta operations shift. For example, in dry years, salinity begins to increase in July, while in wet years, an increase in salinity may not occur until September. Additionally, periods with high agricultural drainage contributions in the summer may increase salinity loads that CCWD diverts, as agricultural return flows tend to carry higher salt concentrations (CCWD and USBR 2006).

Use of the Mallard Slough Intake is generally restricted due to salinity concentrations because it experiences more tidal fluctuations as a result of its location. Water quality conditions have restricted diversions from Mallard Slough (an average of 3,100 AF/y) with no diversions available in dry years. When Mallard Slough supplies are used, CVP diversions at Rock Slough are reduced by an equivalent amount. The Victoria Canal Intake allows CCWD the flexibility to divert water with lower salinity and allows seasonal operations shifts between diversions. The seasonal variation in salinity between Old River/Rock Slough and Victoria Canal allows CCWD to divert predominantly in winter and spring from Old River and in the summer and fall from Victoria Canal (CCWD and USBR 2006).

2.7.3 Return Flows

Return flows in the southern Delta are those flows generated by different uses and then discharged (or returned) to the receiving waters of the southern Delta. There are two primary sources of return flows in the southern Delta: discharges from the existing WWTPs and agricultural discharges from irrigators in the southern Delta. These two sources are discussed below.

Wastewater Treatment Plants

Existing WWTPs are considered point sources and discharge salt into the southern Delta, thereby influencing southern Delta salinity. There are six WWTPs that discharge into the southern Delta, all of which are required to comply with effluent limitations established by National Pollution Discharge Elimination System (NPDES) permits. Effluent limitations that regulate the quality of the effluent discharged from the WWTPs are set for a wide variety of constituents, including salt. Chapter 13, *Service Providers*, provides additional information and specific characteristics for each WWTP. Table 2-26 lists these six WWTPs with discharges into the southern Delta, their receiving water bodies, and their total permitted discharge rate.

Table 2-26. Wastewater Treatment Plants with Discharges into the Southern Delta

Facility Name	Receiving Water	Current Permitted Discharge (million gallons per day)
City of Tracy WWTP	Old River	16
Deuel Vocational Institution	Paradise Cut and Old River	0.62
City of Manteca Wastewater Quality Control Facility	San Joaquin River	17.5
Stockton Regional Wastewater Control Facility	San Joaquin River	55
Mountain House Community Service District WWTP	Old River	5.4
Discovery Bay WWTP	San Joaquin River	2.1

WWTP = wastewater treatment plant

The City of Tracy WWTP discharge has limited effects on the salinity in the southern Delta compared to other sources of salinity, including drainage and runoff from agricultural activities and groundwater accretions. Salinity loads from the City of Tracy, Deuel Vocational Facility, and Mountain House CSD WWTPs are a small percentage of the salt load entering from upstream (Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*).

Agricultural Discharges

Various crops in the southern Delta are irrigated primarily with surface water through numerous local agricultural diversions of existing surface waters. Many small agricultural diversions (siphons and pumps) move water throughout the Delta during the spring and summer irrigation season. All of the Delta islands and tracts use these drainage pumping stations to pump off stormwater runoff as well as seepage during the winter and discharge it into the Delta channels. Once the land has been irrigated, water not evapotranspired by the crops returns to the surface waters through either groundwater recharge (as a result of the high water table) or through runoff over the lands. As irrigation water is continually applied, salt infiltrates and builds up in the soil. Salt-leaching from the fields occurs naturally during the rainy season or may be managed by applying water in the fall or winter to maintain the soil salinity within acceptable bounds. Chapter 11, *Agricultural Resources*, and Appendix E, *Salt Tolerance of Crops in the Southern Sacramento–San Joaquin Delta*, provide specific information about the current crop mix and salinity tolerances of each crop.

2.7.4 Water Quality and Water Quality Objectives

The LSJR delivers water of relatively poor quality to the Delta, with agricultural drainage to the river being a major source of salts and pollutants (i.e., boron, selenium, pesticides). During periods of high flow, water quality generally improves. Because the southern Delta receives a substantial portion of its water from the LSJR, the influence of this relatively poor LSJR water quality is greatest in the southern Delta channels. Vernalis, upstream of the southern Delta Channels, is a focal point on the LSJR as the three eastside tributaries contribute to the combined flow of the SJR at Vernalis. Flow at Vernalis represents the positive inflow that the LSJR contributes to the southern Delta. The LSJR flow at Vernalis has a large effect on the salinity at Vernalis and the southern Delta. Higher flows generated by reservoir releases or decreased diversions generally reduce the salinity by diluting the LSJR, which tends to be higher in salt from agricultural return flows. Higher CVP and SWP pumping also results in reduced southern Delta salinity as higher pumping brings more Sacramento River water across the Delta to the export pumps. The State Water Board has conditioned the water right permits held by DWR and USBR on meeting salinity standards at compliance locations. DWR and USBR meet the salinity standards by changing water project operations, particularly releases from New Melones on the Stanislaus River. Historically, southern Delta water quality has generally ranged from 0.2 deciSiemens per meter (dS/m) to 1.2 dS/m. Salinity generally remains below 1.0 dS/m when salinity at Vernalis is less than approximately 0.9 dS/m (see Chapter 5, *Surface Hydrology and Water Quality*, and Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta*).

The four D-1641 water quality compliance stations in the southern Delta are at the following locations (shown in Figure 2-12): SJR at Airport Way Bridge near Vernalis (C-10), Old River at Tracy Road Bridge (C-6), Old River near Middle River (C-8), and SJR at Brandt Bridge (P-12). Currently, the salinity objective set for the southern Delta and measured at these four salinity (electrical conductivity [EC][17]) compliance stations is a maximum 30-day running average of mean daily EC of 0.7 dS/m from April 1 through August 30 and 1.0 dS/m from September 1 through March 31 for all types of water year. Since D-1641 was implemented in 2000, the objective at Vernalis have generally been met. However, compliance with the southern Delta salinity objective at the three interior stations (C-6, C-8, and P-12) has not always been achieved (see Chapter 5 and Appendix F.1, *Hydrologic and Water Quality Modeling*, for a description of exceedances). There is a strong relationship of increasing salinity from Vernalis to the interior stations under most conditions.

2.8 San Joaquin Valley Groundwater Basin

The plan area lies almost entirely within the boundaries of four subbasins on the east side of the San Joaquin Valley Groundwater Basin: Eastern San Joaquin, Modesto, Turlock, and Merced (Figure 2-3). Small portions of the plan area also lie within small parts of three additional subbasins: Tracy,

---

[17] In this document, EC is *electrical conductivity*, which is generally expressed in deciSiemens per meter (dS/m). Measurement of EC is a widely accepted indirect method to determine the salinity of water, which is the concentration of dissolved salts (often expressed in parts per thousand or parts per million). EC and salinity are therefore used interchangeably in this document.

Chowchilla, and Delta-Mendota (Figure 2-3). A summary of the subbasins and their associated irrigation districts is described in Sections 2.8.1 through 2.8.4 geographically from north to south. Further information regarding groundwater, and the subbasins, is in Chapter 9, *Groundwater Resources*.

Groundwater accounts for approximately 30 percent of the annual agricultural and municipal water supply within the SJR Hydrologic Region, and many cities in this area rely either wholly or partially on groundwater to meet municipal and community non-agricultural needs (DWR 2003a). More than half of all land within the subbasins is irrigated agriculture, and thus the largest use of groundwater is for agricultural purposes.

Although agricultural application of surface water provides significant contribution to groundwater recharge, groundwater levels in the San Joaquin Valley Groundwater Basin have generally declined as a result of extensive pumping. A USGS study of Central Valley groundwater shows that groundwater storage in the San Joaquin Valley Groundwater Basin has varied by plus or minus 5 million AF between 1962 and 2002, but the total storage of the San Joaquin Valley Groundwater Basin was about the same in 2002 as in 1962 (USGS 2009). DWR conducted a recent groundwater evaluation of all groundwater subbasins in California with potential water shortages and prioritized all of the subbasins to assess and rank them throughout the state (DWR 2014). The subbasin prioritization process is based on an evaluation of eight required data components specified by the California Water Code. All the subbasins within the plan area were identified as high priority by DWR and are considered to be at high risk of overdraft (DWR 2014). The Merced, Modesto, and Turlock subbasins experienced varying degrees of overdraft and recharge conditions between 1970 and 2000; however, each subbasin experienced a net overdraft condition during this period as indicated by average declines in groundwater elevation of approximately 30, 15, and 7.5 ft, respectively, with the eastern portion of the subbasins experiencing more severe overdraft (DWR 2003c, 2003d, 2003e). The Eastern San Joaquin subbasin has been in a consistent overdraft condition (approximately 1.7 ft/year) for the same time period. It is estimated that the overdraft has reduced storage in the basin by 2 million acre-feet over a 40-year period (DWR 2003e). Additional pumping in any of the subbasins would increase the drawdown, with a noticeable effect on groundwater levels over a number of years. Additional pumping and overdraft can also cause land subsidence. In the southern portion of the study area, increased dependence on groundwater during the recent drought resulted in groundwater levels approaching or surpassing historic lows, which caused aquifer-system compaction and land subsidence that most likely is permanent (Sneed and Brandt 2015). Further information regarding groundwater, and the subbasins, is in Chapter 9.

2.8.1 Eastern San Joaquin Groundwater Subbasin

The Eastern San Joaquin Subbasin is drained by the SJR and several of its major tributaries, mainly the Stanislaus, Calaveras, and Mokelumne Rivers. The subbasin is located under the urban centers of Manteca, Lathrop, Ripon, and Stockton, which use groundwater for a large portion of their drinking water supply.

The subbasin spans approximately 707,000 acres and includes several water and irrigation districts. SEWD, CSJWCD, SSJID, and a portion of OID fall within the subbasin boundaries. Water use within these districts is primarily for irrigation of approximately 200,000 acres. There are approximately 200,000 acres of irrigated land outside these irrigation districts but within the subbasin boundary (Table 9-5). These districts rely on surface water and groundwater to fulfill customer demand throughout the irrigation season. The agricultural areas outside these irrigation district lands are more dependent on groundwater, although some of these lands receive surface water from the Mokelumne River and SJR.

Historically, pumping from urban, rural, and agricultural wells has been above the safe yield of the subbasin (SSJID 2012). Groundwater levels have continuously declined over the past 40 years at an average rate of 1.7 ft/year and have dropped as much as 100 ft in some areas (USACE 2001 in DWR 2003b). Significant groundwater depressions are present under the city of Stockton, east of Stockton, and east of Lodi (SJCFC 1999 in DWR 2003b). However this cone of depression is not as severe as it once was; between 2005 and 2010, groundwater elevations within some portions of this area showed some signs of improvement.

Groundwater recharge is primarily from deep percolation of applied irrigation water, conveyance losses, and precipitation. Additional recharge also occurs as a result of lateral inflows from other subbasins and seepage from rivers, creeks, and reservoirs (Northeastern San Joaquin County Groundwater Banking Authority 2004). In recent years, multiple methods have been used to increase groundwater recharge in this subbasin. These methods include installation of check dams on waterways, increased use of surface water, creation of surface ponds, and flooding of fields (CSJWCD 2013; SEWD 2014). These recharge efforts have likely improved groundwater conditions in the subbasin. Between 2005 and 2010, some of the areas with the lowest groundwater levels in this subbasin experienced increases in groundwater levels at the same time that levels dropped in other subbasins (DWR 2015).

2.8.2 Modesto Groundwater Subbasin

The Modesto Subbasin is bordered by the Stanislaus River to the north and the Tuolumne River to the south. The subbasin is located under the urban centers of Modesto, Oakdale, and Riverbank, and under small areas of the southern boundary of Ripon. These cities use groundwater for a large portion of their drinking water supply.

The subbasin encompasses approximately 247,000 acres and includes MID and a portion of OID. These irrigation districts rely on surface water and groundwater to fulfill customer demand throughout the irrigation season. Approximately 116,000 acres are irrigated (Table 9-5), with approximately 77 percent of these acres being supplied with surface water from OID or MID.

Groundwater levels in this subbasin decreased at an estimated 0.5 foot/year during 1970–2000 (DWR 2003c), with groundwater declines coinciding with dry periods and stabilization and recovery coinciding with wet periods. Water level declines have been more severe in the eastern portion of the subbasin (DWR 2015).

Groundwater recharge is primarily from deep percolation of applied irrigation water and canal seepage from MID and OID facilities. Seepage from Modesto Reservoir is also significant (STRGBA 1995 in DWR 2003c). Lesser recharge occurs as a result of subsurface flows originating in the mountains and foothills along the east side of the subbasin, losses from minor streams and from percolation of direct precipitation.

2.8.3 Turlock Groundwater Subbasin

The Turlock Subbasin is bordered by the Tuolumne River to the north, the SJR to the west, and the Merced River to the south. The subbasin is located under the urban centers of Ceres, south Modesto, Turlock, and several smaller communities, which use groundwater for a large portion of their drinking water supply.

The subbasin encompasses approximately 349,000 acres. There are approximately 269,000 acres of irrigated land in the subbasin, with approximately 56 percent of these acres potentially being supplied with surface water from TID and a small portion from Merced ID (Table 9-5).

Groundwater levels in this subbasin decreased at approximately 0.25 foot/year during 1970–2000, with groundwater declines coinciding with dry periods and stabilization and recovery coinciding with wet periods. Since 1982, water level declines have been more severe in the eastern portion of the subbasin; however, from 1970 to 1982, water level declines were more severe in the western portion of the subbasin (DWR 2003d).

Groundwater recharge primarily comes from deep percolation of surface water used for irrigation. Additional recharge also occurs as a result of precipitation, seepage from Turlock Lake, lateral groundwater inflow from the east, and upward inflow from deep geologic fractures. The net effect of the groundwater interaction with the Tuolumne and Merced Rivers and the SJR was estimated to be negative, with more groundwater discharging to the rivers in the western portion of the subbasin than seeping from the upstream portions of the Tuolumne and Merced Rivers in the eastern portion of the subbasin (Turlock Groundwater Basin Association 2008).

2.8.4 Merced Groundwater Subbasin

The Merced Subbasin is bordered by the Merced River to the north, the SJR to the west, and partially by the Chowchilla River to the south. The subbasin is located under the urban centers of Atwater, Livingston, Merced, and several smaller communities, which use groundwater for a large portion of their drinking water supply.

The subbasin encompasses approximately 491,000 acres, and approximately 55 percent (approximately 269,000 acres) is irrigated. Approximately 32 percent of these acres (86,000 acres) are potentially supplied with surface water from Merced ID (Table 9-5). Merced ID relies primarily on surface water, but also on groundwater, to fulfill customer demand throughout the irrigation season. Agricultural land outside the Merced ID is more dependent on groundwater than the agricultural land within Merced ID service boundaries.

Groundwater levels in this subbasin decreased at approximately 1 foot/year during 1970–2000 (DWR 2003e), although some other estimates show different rates of decline. Determination of the rate is dependent on the span of years evaluated because groundwater levels rise and fall in response to hydrologic conditions. Water level declines have been more severe in the eastern part of the subbasin (DWR 2015).

Recharge from rivers and creeks tends to occur more in the eastern part of the subbasin where the Merced and Chowchilla Rivers are well above the water table. In contrast, groundwater tends to be discharged to the Merced River and the SJR at the western edge of the subbasin where the rivers are close to the water table. Merced ID has been increasing groundwater recharge by taking several actions to replace groundwater use with surface water use. These actions include providing surface water to land previously inaccessible to the Merced ID conveyance system, responding more quickly to requests for surface water delivery, and starting a direct recharge project at Cressey Basin (MAGPI 2008).

Chapter 3
Alternatives Description

3.1 Introduction

The State Water Resources Control Board (State Water Board) is considering amendments to the 2006 *Water Quality Control Plan for the San Francisco Bay/Sacramento–San Joaquin Delta Estuary* (2006 Bay-Delta Plan). The Porter-Cologne Water Quality Control Act requires water quality control plans (WQCP) to designate or establish the beneficial uses of water to be protected, water quality objectives that will ensure the reasonable protection of the beneficial uses, and a program of implementation designed to achieve the objectives. (Wat. Code, §§ 13050(j), 13241.)

The plan amendments[1] would include new February–June Lower San Joaquin River (LSJR) flow objectives for the protection of fish and wildlife beneficial uses and an associated program of implementation. The plan amendments would also modify the existing southern Delta water quality (SDWQ) objectives for the protection of agricultural beneficial uses and the associated program of implementation for those objectives.[2] Potential changes to the program of implementation (Appendix K, *Revised Water Quality Control Plan*) that would not result in significant or potentially significant adverse environmental effects are not discussed in detail in this recirculated substitute environmental document (SED).

The California Environmental Quality Act (CEQA) requires an environmental document such as an SED to describe a range of reasonable alternatives to a project that "would feasibly attain most of the basic objectives of the project but would avoid or substantially lessen any of the significant effects of the project, and evaluate the comparative merits of the alternatives." (State CEQA Guidelines § 15126.6, subd. (a); Cal. Code Regs., tit. 23, § 3777, subd. (b).) An SED need not consider every conceivable alternative to a project, but instead, it "must consider a reasonable range of potentially feasible alternatives that will foster informed decision making and public participation." (State CEQA Guidelines § 15126.6, subd. (a).) An SED is not required to consider alternatives that are infeasible. (*Ibid.*)

This chapter describes: the purposes and goals[3] of the plan amendments; the LSJR and SDWQ alternatives evaluated in this SED; the No Project Alternative; and the alternatives considered but eliminated from consideration in this SED.

---

[1] These plan amendments are the *project* as defined in State CEQA Guidelines, Section 15378.

[2] This SED may refer to the proposed amendments to the southern Delta salinity objectives in the singular or plural. The use of singular or plural is immaterial to the description of the southern Delta salinity alternatives.

[3] State CEQA Guidelines Section 15124, subdivision (b), requires the lead agency to include a statement of the objectives sought by the proposed project. To avoid confusion with the term "objective" as it is used in reference to flow and water quality objectives, this document will refer to the "objectives" mentioned in Section 15124 instead as "goals."

3.2 Purposes and Goals

The 2006 Bay-Delta Plan designates beneficial uses of water, establishes water quality objectives for the reasonable protection of those beneficial uses, outlines a program of implementation for achieving the water quality objectives, and includes monitoring and special studies. It also provides recommended actions for other entities to take that will contribute to achieving the objectives. The underlying fundamental purpose and goal of the plan amendments is twofold.

- To establish flow water quality objectives during the February–June period and a program of implementation for the reasonable protection of fish and wildlife beneficial uses in the LSJR Watershed, including the three eastside, salmon-bearing tributaries.[4]
- To establish SDWQ objectives for the reasonable protection of southern Delta agricultural beneficial uses and a program of implementation to achieve the objectives.

As described in Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*, scientific information indicates that higher flows of a more natural pattern are needed from the three eastside, salmon-bearing tributaries to the LSJR during the spring (February–June) to protect fish and wildlife beneficial uses (including San Joaquin River [SJR] Basin fall-run Chinook salmon). Therefore, in addition to the fundamental purpose and goal of the plan amendments, the purposes and goals related to the LSJR flow objectives and associated program of implementation are as follows.

1. Maintain inflow conditions from the SJR Watershed sufficient to support and maintain the natural production of viable native fish populations migrating through the Delta.
2. Provide flows that more closely mimic the natural hydrographic conditions (including frequency, timing, magnitude, and duration of natural flows) in the LSJR and three eastside, salmon-bearing tributaries—the Stanislaus, Tuolumne, and Merced Rivers—to which these migratory native fish species are adapted.
3. Provide flows in a quantity necessary to achieve functions essential to native fishes such as increased floodplain inundation, improved temperature conditions, improved migratory conditions, and promote other conditions that favor native fishes over nonnative fishes.
4. Allow adaptive implementation of flows that will afford maximum flexibility in establishing beneficial habitat conditions for native fishes, addressing scientific uncertainty and changing conditions, developing scientific information that will inform future management of flows, and meeting biological goals, while still reasonably protecting the fish and wildlife beneficial uses.
5. Promote transparency in decision-making and provide certainty to the regulated community by expressing flow requirements for the protection of fish and wildlife as a share of the total quantity of water available for all beneficial uses.
6. In establishing flow water quality objectives to reasonably protect fish and wildlife, take into consideration all of the demands being made and to be made on waters in the LSJR and the three eastside, salmon-bearing tributaries and the factors to be considered for establishing water quality objectives in Water Code Section 13241, including, but not limited to, past, present and probable future beneficial uses and economic considerations.

---

[4] In this document, the term *three eastside tributaries* refers to the Stanislaus, Tuolumne, and Merced Rivers.

7. Provide for the development and implementation of an appropriate monitoring and evaluation program to inform adaptive implementation of LSJR flows and future changes to the Bay-Delta Plan.
8. Provide for, and encourage, collaboration, coordination, and integration of regulatory, scientific, and management processes related to LSJR flows.

As described in Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*, salt stress can damage crops in several different ways, including stunting growth, diminishing seedling success, and causing foliar damage, thus reducing yield of crops. Salinity levels in the southern Delta are affected primarily by the salinity of water flowing into the southern Delta from the SJR near Vernalis and evapoconcentration of salt in water that is diverted from and discharged back into southern Delta channels for agricultural purposes. Point sources of salt in the southern Delta have a small overall salinity effect. Salinity conditions are also affected by the capacity of the southern Delta water bodies to assimilate these salinity inputs. This assimilative capacity is potentially affected by hydrodynamic conditions, such as water levels and the direction and magnitude of flow in the various channels of the southern Delta. The purposes and goals related to the SDWQ objective and associated program of implementation are as follows.

1. Provide salinity conditions that reasonably protect agricultural beneficial uses of surface waters in the southern Delta.
2. In establishing salinity water quality objectives to reasonably protect agricultural beneficial uses, take into consideration all of the demands being made and to be made on waters in the southern Delta, the LSJR and the three eastside, salmon-bearing tributaries and the factors to be considered for establishing water quality objectives in Water Code Section 13241, including, but not limited to, past, present and probable future beneficial uses and economic considerations.
3. Establish a salinity objective, supported by existing scientific information, that is not lower than necessary to reasonably protect the most salt sensitive crops currently grown or suitable to be grown on saline- and drainage-impaired soils in the southern Delta.
4. Maintain or improve salinity conditions in the southern Delta to comply with state and federal antidegradation policies.
5. Provide for development and implementation of monitoring and modeling studies needed to better understand the characteristics of salinity conditions in the southern Delta and the dynamics of factors controlling or contributing to those conditions.

3.3 Lower San Joaquin River (LSJR) Alternatives

The development of alternatives requires an understanding of the attributes of alternatives that could feasibly attain most of the basic objectives of the plan amendments but would avoid or substantially lessen any of the significant environmental effects. Attributes of flow objective alternatives may be described or constrained by geography, method, season and averaging period, magnitude, and other aspects of a flow regime. A regulatory program may also consider non-flow measures and adaptive management. Attributes of salinity objective alternatives may be described or constrained by geographic scope, season and averaging period, and the level of protection. The attributes of flow and salinity objectives can then be used to assess the potential for alternatives to achieve the plan amendment goals and to have potential effects, in order to determine which alternatives are feasible, and should be evaluated, and which are infeasible, and may eliminated from further consideration.

In evaluating potential amendments to the 2006 Bay-Delta Plan, the State Water Board identified key elements that would reasonably protect fish and wildlife beneficial uses in the LSJR Watershed. These key elements form the foundation of the fundamental purpose of the plan amendments:

> "To establish flow water quality objectives during the February–June period and a program of implementation for the reasonable protection of fish and wildlife beneficial uses in the LSJR watershed, including the three eastside, salmon-bearing tributaries (the Stanislaus, Tuolumne, and Merced Rivers)."

First, the State Water Board, which is the State agency responsible for protecting the State's water resources, focused on establishing flow water quality objectives because the best available science identifies flow as a major factor affecting fisheries and other instream uses of water in the Delta. The State Water Board, which is the State agency responsible for protecting the State's water resources, is best suited to using its regulatory authority to address the flow regime. Second, the State Water Board focused on SJR basin fall-run Chinook salmon (*Oncorhynchus tshawytscha*) and Central Valley steelhead (*Oncorhynchus mykiss*), because these anadromous species are among the most sensitive to inflows from the SJR basin to the Bay-Delta. Flows that benefit these species will also generally benefit other species in the SJR Watershed. Third, the State Water Board identified the geographic scope of the plan amendments to protect the existing fishery in the LSJR Watershed—the three eastside salmon-bearing tributaries—because that portion of the watershed supports an existing fishery that can be maintained and improved. The State Water Board will consider additional measures in future Bay-Delta Plan updates to protect beneficial uses in other areas, such as the Upper SJR, when those areas are restored and can support a fishery. Finally, the State Water Board identified the February-June period as the period in which flows are most critical to support ecosystem functions such as migration.

3.3.1 Attributes of LSJR Flow Objectives

Attributes of flow objective that inform the feasibility of the LSJR alternatives and the ability of the alternatives to avoid or substantially lessen any of the significant environmental effects are: geography; method; season and averaging period; and magnitude. In addition, other considerations, such as non-flow measures and adaptive management, inform the selection of the LSJR alternatives.

Geography

The current flow objective applies only to the SJR at Vernalis. In developing the alternatives, the State Water Board considered whether alternative flow objectives would apply only to Vernalis, just as the current objective, or be extended upstream to some other location. Goals 1 and 2 of the of the plan amendments are as follows.

1. Maintain inflow conditions from the SJR Watershed sufficient to support and maintain the natural production of viable native fish populations migrating through the Delta.
2. Provide flows that more closely mimic the natural hydrographic conditions (including frequency, timing, magnitude, and duration of natural flows) in the LSJR and three eastside, salmon-bearing tributaries —the Stanislaus, Tuolumne, and Merced Rivers—to which these migratory native fish species are adapted.

These goals support the selection of a flow alternative that includes the Stanislaus, Tuolumne, and Merced Rivers, not just Vernalis, because the expanded geographic area supports a variety of critical life history stages. For example, flows that support juvenile rearing in the tributary streams and migration through the Delta are needed to maintain the natural production of SJR fall-run Chinook salmon. Though these goals do not explicitly preclude consideration of alternative flow objectives upstream of the Merced River confluence, that area does not currently support viable native fish populations, and such alternatives would not reduce or avoid impacts. For example, such an alternative would not reduce the quantity of water needed from the Stanislaus, Tuolumne, and Merced Rivers to achieve the goals. Inclusion of the flow alternatives for the SJR upstream of the Merced River confluence would increase the adverse environmental effects of the LSJR alternatives in a larger geographic area by reducing the quantity of water available for other uses in areas that rely upon water supplies in the SJR upstream of Merced River confluence. For this reason, alternatives that considered establishing flow objectives in geographic areas other than the LSJR Watershed and the Stanislaus, Tuolumne, and Merced Rivers, were eliminated from further consideration.

Method

There are two principal methods that can be used to develop a flow objective, and that could be considered as an alternative: (1) fixed monthly flows or blocks of water that vary by water year type or other variables, or (2) a percent of unimpaired flow. Unimpaired flow is the flow that would accumulate in surface waters in response to rainfall and snowmelt, and flow downstream if there were no reservoirs or diversions to change the quantity, timing, and magnitude of flows.

The current flow objective at Vernalis is comprised of fixed monthly flows that vary by water year type--higher fixed flows in wet years, and lower fixed flows in dry years. There are five water year types. The relative quantities of water required vary by month and year, and are intended to provide more flow when needed to achieve certain functions such as the outmigration of salmon during an April/May pulse flow. Fixed monthly flows could, alternatively, be established that are not linked to hydrology. These would be purely functional flows that are needed to benefit fish and wildlife but are not tied to the available water supply that is determined by precipitation. LSJR alternatives that are not tied to hydrology were eliminated from any further consideration because they do not mimic natural hydrographic conditions or consider other beneficial uses of water and would, therefore, be in conflict with goals 2, 5, and 6.

2. Provide flows that more closely mimic the natural hydrographic conditions (including frequency, timing, magnitude, and duration of natural flows) in the LSJR and three eastside, salmon-bearing tributaries—the Stanislaus, Tuolumne, and Merced Rivers—to which these migratory native fish species are adapted.
5. Promote transparency in decision-making and provide certainty to the regulated community by expressing flow requirements for the protection of fish and wildlife as a share of the total quantity of water available for all beneficial uses.
6. In establishing flow water quality objectives to reasonably protect fish and wildlife, take into consideration all of the demands being made and to be made on waters in the LSJR and the three eastside, salmon-bearing tributaries and the factors to be considered for establishing water quality objectives in Water Code Section 13241, including, but not limited to, past, present and probable future beneficial uses and economic considerations.

Alternatively, flows can be tied directly to unimpaired flow by establishing a flow objective based on a percentage of unimpaired flow. LSJR alternatives tied directly to unimpaired flow achieve goals 2 and 3, among others.

2. Provide flows that more closely mimic the natural hydrographic conditions (including frequency, timing, magnitude, and duration of natural flows) in the LSJR and three eastside, salmon-bearing tributaries—the Stanislaus, Tuolumne, and Merced Rivers—to which these migratory native fish species are adapted.
3. Provide flows in a quantity necessary to achieve functions essential to native fishes such as increased floodplain inundation, improved temperature conditions, improved migratory conditions, and promote other conditions that favor native fishes over nonnative fishes.

Fixed monthly flows that vary by month and water year type (similar in method to current flow objectives), or blocks of water that vary by year type, could also be used to achieve these goals instead of flows tied directly to unimpaired flow. Many of the LSJR alternatives suggested by commenters are monthly flows that vary by month and water year type. All of these other LSJR alternatives, however, can be represented by a percent of unimpaired flow quantity, so long as the quantity of water represented by a percent of unimpaired flow is large enough to apportion and shape as needed to achieve fish and wildlife protection goals. These other fixed monthly flow alternatives are discussed in Section 3.3.9, *LSJR Alternatives Considered but Eliminated from Further Evaluation*, and the total volumes of water are compared with the alternatives considered in this SED. In general, however, varying the methodology does not reduce or avoid potentially significant environmental effects, which is the relevant consideration in evaluating the LSJR alternatives.

Season and Averaging Period

The current flow objective is applicable only at Vernalis, and varies by month and year type for the February–June period. There is also an October flow objective. The flow objectives are established as monthly average flows, meaning that flows can vary within the month so long as the average monthly flow rate achieves the flow objective. New flow objectives could be established for specific months, seasons, or every month of the year. Averaging periods could be monthly, or longer or shorter duration. Goal 2 informs both the seasonality and averaging period for LSJR alternatives.

2. Provide flows that more closely mimic the natural hydrographic conditions (including frequency, timing, magnitude, and duration of natural flows) in the LSJR and three eastside, salmon-bearing tributaries—the Stanislaus, Tuolumne, and Merced Rivers—to which these migratory native fish species are adapted

Although the State Water Board identified the February-June period as the period in which flows are most critical to support ecosystem functions such as migration, other time periods are also important for other life stages. These other time periods include the fall, which is important for providing a migration cue for returning salmon, and summer, which is important for steelhead.

Magnitude

Goal 2 also directly informs the development of alternatives with regard to the magnitude of flows. Magnitude and total quantity of flow are the principal considerations in the development and selection of alternatives because the total quantity of water provided for the protection of fish and wildlife must be considered in relation to goals 5 and 6, in addition to the other goals.

5. Promote transparency in decision-making and provide certainty to the regulated community by expressing flow requirements for the protection of fish and wildlife as a share of the total quantity of water available for all beneficial uses.
6. In establishing flow water quality objectives to reasonably protect fish and wildlife, take into consideration all of the demands being made and to be made on waters in the LSJR and the three eastside, salmon-bearing tributaries and the factors to be considered for establishing water quality objectives in Water Code Section 13241, including, but not limited to, past, present and probable future beneficial uses and economic considerations.

Alternatives should therefore include quantities of water that are big enough to achieve the fish and wildlife protection goal, but are not so big such that they would have an unreasonable effect on other beneficial uses of water. These constraints allow for the determination of: (1) a lower bound (representing a relatively small quantity of water), below which there could be no reasonable expectation that fish and wildlife protection goals will be achieved; and (2) an upper bound (representing a relatively large quantity of water) beyond which an alternative would have an unreasonable effect on other beneficial uses of water.

Other Considerations

Flow objectives are intended to provide the conditions needed to reasonably protect the fish and wildlife beneficial uses. Goals 1, 2, and 3, explicitly identify flows as a necessary element of alternatives.

1. Maintain inflow conditions from the SJR Watershed sufficient to support and maintain the natural production of viable native fish populations migrating through the Delta.
2. Provide flows that more closely mimic the natural hydrographic conditions (including frequency, timing, magnitude, and duration of natural flows) in the LSJR and three eastside, salmon-bearing tributaries—the Stanislaus, Tuolumne, and Merced Rivers—to which these migratory native fish species are adapted.
3. Provide flows in a quantity necessary to achieve functions essential to native fishes such as increased floodplain inundation, improved temperature conditions, improved migratory conditions, and promote other conditions that favor native fishes over nonnative fishes.

It may be possible to achieve the ecosystem functions identified in goal 3, in part, through the application of non-flow measures such as temperature control and increased floodplain habitat. Temperature and floodplain improvements could occur without the need for as much water, and could directly improve conditions for fish and wildlife without relying entirely on flow. Nonetheless, flow is an essential element for protecting fish and wildlife beneficial uses.

Another consideration in developing alternatives is whether or not to allow adaptive implementation. A flow objective with no adaptive implementation would have to be met exactly as prescribed, without adjustment. Adaptive implementation, in contrast, allows a flow objective to be adjusted based on other information, thus allowing flexibility. LSJR alternatives with adaptive implementation achieve goal 4.

4. Allow adaptive implementation of flows that will afford maximum flexibility in establishing beneficial habitat conditions for native fishes, addressing scientific uncertainty and changing

conditions, developing scientific information that will inform future management of flows, and meeting biological goals, while still reasonably protecting the fish and wildlife beneficial uses.

Alternatives that do not include adaptive implementation were not considered because they would require rigid adherence with flows that may not be optimal based on new information or changed conditions. Alternatives with no adaptive implementation would therefore also conflict with goal 6 because more water than is needed to reasonably protect fish and wildlife would have to be provided even in light of new information or changed conditions.

3.3.2 LSJR Alternatives Considered

The State Water Board considered a range of reasonable alternatives that would feasibly attain most of the basic goals of the plan amendments, discussed in Section 3.2, *Purposes and Goals*, but would avoid or substantially lessen any of the significant environmental effects of the plan amendments. Because the indirect effects of the plan amendment are primarily associated with increased instream flows or reductions in water supply available for diversion, this SED focuses on alternatives that evaluate a range of flows, based on unimpaired flow, with a lower and upper bound. The lower bound represents the minimum quantity of water at which there is a reasonable expectation that fish and wildlife protection goals will be achieved, although at this level, it may require other actions, such as non-flow measures. The upper bound represents the maximum quantity of water beyond which an alternative would have an unreasonable effect on other beneficial uses of water, and would therefore not be feasible. Each LSJR alternative also includes an adaptive range that has the effect of lessening the impact of the alternatives.

This SED evaluates four alternatives for LSJR flow requirements during the February–June time frame, including the LSJR Alternative 1 (No Project Alternative) and three other LSJR alternatives (LSJR Alternatives 2, 3, and 4).

LSJR Alternatives 2, 3, and 4 are comprised of narrative and numeric flow objectives and an associated program of implementation. The objectives will require flows below the rim dams[5] on the Stanislaus, Tuolumne, and Merced Rivers, and the mainstem of the LSJR between its confluence with the Merced River and downstream to Vernalis. The narrative objective calls for the following:

> "Maintain inflow conditions from the San Joaquin River Watershed to the Delta at Vernalis, sufficient to support and maintain the natural production of viable native San Joaquin River Watershed fish populations migrating through the Delta. Inflow conditions that reasonably contribute toward maintaining viable native migratory San Joaquin River fish populations include, but may not be limited to, flows that more closely mimic the natural hydrographic conditions to which native fish species are adapted, including the relative magnitude, duration, timing, and spatial extent of flows as they would naturally occur. Indicators of viability include population abundance, spatial extent, distribution, structure, genetic and life history diversity, and productivity."

In addition to the narrative objective, there are numeric flow objectives from February–June. This is the element of the flow objective where LSJR Alternatives 2, 3, and 4 have different lower and upper bounds of the adaptive range:

> "A percent of unimpaired flow between a lower and upper limit from each of the Merced, Tuolumne, and Stanislaus Rivers shall be maintained from February through June."

---

[5] In this document, the term *rim dams* is used when referencing the three major dams and reservoirs on each of the eastside tributaries: New Melones Dam and Reservoir on the Stanislaus River; New Don Pedro Dam and Reservoir on the Tuolumne River; and New Exchequer Dam and Lake McClure on the Merced River.

The final element of the flow objective requires, the same for all alternatives, requires a base flow at Vernalis:

> "Notwithstanding the above unimpaired flow requirement, a minimum base flow value between 800-1,200 cfs [cubic feet per second], inclusive, at Vernalis, shall be maintained at all times."

Each LSJR alternative evaluates a different range of flows.

- LSJR Alternative 2 evaluates a range between 20 and 30 percent, with 20 percent as the starting percentage of unimpaired flow in the program of implementation.
- LSJR Alternative 3 evaluates a range between 30 and 50 percent, with 40 percent as the starting percentage of unimpaired flow in the program of implementation.
- LSJR Alternative 4 evaluates a range between 50 and 60 percent, with 60 percent as the starting percentage of unimpaired flow in the program of implementation.

Ultimately, however, the State Water Board, in exercising its authority and responsibilities, may select a range within the LSJR alternatives analyzed that is consistent with the requirements of applicable law, including CEQA and the Porter-Cologne Water Quality Control Act. In other words, the Board may select a percent of unimpaired flow anywhere between the 20 and 60 percent range evaluated in this SED. Likewise, the Board may implement the range with a different starting percentage of unimpaired flow in the program of implementation.

The program of implementation includes specific flow requirements and other measures to implement the objectives. Specifically, LSJR Alternatives 2, 3, and 4 implement the numeric flow objective by requiring 20 percent, 40 percent, and 60 percent, respectively, of unimpaired flow, based on a minimum 7-day average, from each of the Stanislaus, Tuolumne and Merced Rivers and allow for adaptive adjustments within the numeric water quality objective range for each alternative. The program of implementation provides that the State Water Board will fully implement the February–June LSJR flow objectives by 2022 through water right actions and water quality actions, including Federal Energy Regulatory Commission (FERC) hydropower licensing processes. These actions are necessary because the amendments to the 2006 Bay-Delta Plan are not self-implementing.

These unimpaired flow percentages, 20, 40, and 60 percent, were selected as alternatives to capture a range of potential flow alternatives that the State Water Board may implement, thus allowing an examination of alternatives that would feasibly obtain most of the goals of the plan amendments while avoiding or substantially lessening any significant impacts. The alternative with the lowest flow, LSJR Alternative 2 is 20 to 30 percent unimpaired flow, and was selected to bracket the low end of flows under current conditions because it potentially could have fewer impacts on the environment than higher flows.[6] LSJR Alternative 3 is 30 to 50 percent of unimpaired flow, which represents a mid-point for the analysis, and would be more likely to both meet most of the goals of the plan amendments while potentially having fewer impacts on the environment. LSJR Alternative 4 has the highest level of flow, with 50 to 60 percent of unimpaired flow. The State Water Board's 2010 report, *Development of Flow Criteria for the Sacramento–San Joaquin Delta Ecosystem*, determined that approximately 60 percent of unimpaired flow at Vernalis from February–June would be fully protective of fish and wildlife beneficial uses in the three eastside tributaries and LSJR when considering flow alone. This level of unimpaired flow, however, also represents the

---

[6] Flows in the Stanislaus, Tuolumne, and Merced Rivers and the SJR at Vernalis had median values of 40, 21, 26, and 29 percent of February–June unimpaired flow, respectively, for water years 1986–2009.

upper bound above which there would be unacceptably high adverse effects on water supply and temperature control.

3.3.3 Adaptive Implementation

The unimpaired flow objective does not have to be implemented in a way that requires rigid adherence with a fixed percent of unimpaired flow. LSJR Alternatives 2, 3, and 4 include an adaptive implementation element. This adaptive implementation element allows for flows under each alternative to be "shaped" or shifted in time to provide more functionally useful flows and to respond to changing information and conditions. Functionally useful flows achieve a specific function such as increased habitat, more optimal temperatures, or a migration cue. The unimpaired flow requirement also does not need to remain at one fixed percent, but may be adaptively implemented within a range of unimpaired flow in response to changing information, and changing conditions. Each of the three LSJR alternatives is intended to provide the flexibility to be achieved through adaptive implementation. Each of the three tributaries may be managed differently, with respect to the percent of unimpaired flow and the specific adaptive implementation, so long as the adaptive implementation in the three rivers is coordinated.

The adaptive implementation element of the flow proposal consists of a defined adaptive implementation process that allows the magnitude and timing of flows to be adjusted in a number of ways, within a prescribed range of flows, if scientific information supports that such changes would continue to support and maintain the natural production of the viable native fish LSJR fish populations migrating through the Delta. Adaptive implementation achieves one of the principal goals for flow objectives.

4. Allow adaptive implementation of flows that will afford maximum flexibility in establishing beneficial habitat conditions for native fishes, addressing scientific uncertainty and changing conditions, developing scientific information that will inform future management of flows, and meeting biological goals, while still reasonably protecting the fish and wildlife beneficial uses.

Adaptive Implementation also achieves these related goals.

- Quickly respond to changing information and changing conditions, including changes in flow patterns as a result of climate change.
- Minimize adverse water temperature effects.
- Allow for adaptive management and conducting of scientific experiments.

Adaptive implementation could also be used to optimize flows to achieve the objectives while allowing for consideration of other beneficial uses, such as agricultural, municipal, and recreational uses, provided that these other considerations do not reduce intended benefits to fish and wildlife and that requirements are met. Adaptive implementation allows for flows to be reduced to the low end of the range as long as these reductions do not reduce benefits to fish and wildlife and, thus, could have the effect of lessening the environmental impacts associated with higher flow alternatives. The State Water Board may approve adaptive adjustments to the flow requirements as forth in (1)–(4) below if information produced through the monitoring and review processes in the program of implementation, or other best available scientific information, indicates that the change for the period at issue will: (a) be sufficient to support and maintain the natural production of viable native SJR Watershed fish populations migrating through the Delta, and (b) meet any existing biological goals approved by the State Water Board. The Stanislaus, Tuolumne, and Merced Working

Group (STM Working Group) will assist with implementation, monitoring, and assessment activities for the flow objectives and with developing biological goals to help evaluate the effectiveness of the flow requirements and adaptive implementation actions. The STM Working Group may recommend adjusting the flow requirements through adaptive implementation if scientific information supports such changes to reasonably protect fish and wildlife beneficial uses. Scientific research may also be conducted within the adaptive range to improve scientific understanding of measures needed to protect fish and wildlife and reduce scientific uncertainty through monitoring and evaluation. Further details describing the methods, the STM Working Group, and the approval process are included in Appendix K, *Revised Water Quality Control Plan*.

Without adaptive implementation, flow must be managed such that it tracks the daily unimpaired flow percentage based on a running average of no more than 7 days. The four methods of adaptive implementation are generally described below; they are described in Sections 3.3.5 through 3.3.7 as they relate to each LSJR alternatives.

1. Based on best available scientific information indicating that more flow is needed or less flow is adequate to reasonably protect fish and wildlife beneficial uses, the specified annual February–June minimum unimpaired flow requirement may be increased or decreased to a percentage within the ranges listed below. For LSJR Alternative 2 (20 percent unimpaired flow), the percent of unimpaired flow may be increased to a maximum of 30 percent. For LSJR Alternative 3 (40 percent unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 30 percent or increased to a maximum of 50 percent. For LSJR Alternative 4 (60 percent unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 50 percent.

2. Based on best available scientific information indicating a flow pattern different from that which would occur by tracking the unimpaired flow percentage would better protect fish and wildlife beneficial uses, water may be released at varying rates during February–June. The total volume of water released under this adaptive method must be at least equal to the volume of water that would be released by tracking the unimpaired flow percentage from February–June.

3. Based on best available scientific information, release of a portion of the February–June unimpaired flow may be delayed until after June to prevent adverse effects to fisheries, including temperature, that would otherwise result from implementation of the February–June flow requirements. The ability to delay release of flow until after June is only allowed when the unimpaired flow requirement is greater than 30 percent. If the requirement is greater than 30 percent but less than 40 percent, the amount of flow that may be released after June is limited to the portion of the unimpaired flow requirement over 30 percent. For example, if the flow requirement is 35 percent, 5 percent may be released after June. If the requirement is 40 percent or greater, then 25 percent of the total volume of the flow requirement may be released after June. As an example, if the requirement is 50 percent, at least 37.5 percent unimpaired flow must be released in February–June and up to 12.5 percent unimpaired flow may be released after June. If after June the STM Working Group determines that conditions have changed such that water held for release after June should not be released by the fall of that year, the water may be held until the following year. See Appendix K, for further details.

4. Based on best available scientific information indicating that more flow is needed or less flow is adequate to reasonably protect fish and wildlife beneficial uses, the February–June Vernalis base flow requirement of 1,000 cfs may be modified to a rate between 800 and 1,200 cfs.

Any of the adjustments in (1)–(4) above may be made independently of each other or combined. The adjustments in (1), (2), and (3) may also be made independently on each of the Stanislaus, Tuolumne, and Merced Rivers, so long as the flows are coordinated to achieve beneficial results in the LSJR related to the protection of fish and wildlife beneficial uses. Experiments may also be conducted within the adaptive adjustments in (1)–(4), subject to the approvals provided therein, in order to improve scientific understanding of needed measures for the protection of fish and wildlife beneficial uses, such as the optimal timing of required flows. Any experiment shall be coordinated with the San Joaquin River Monitoring and Evaluation Program (SJRMEP), described below, and identify the scientific uncertainties to be addressed and the actions that will be taken to reduce those uncertainties, including monitoring and evaluation.

Although framed as February– June flow objectives, the range of alternatives captures the entire feasible quantity of water that could be used to reasonably protect fish and wildlife in the LSJR year round. As shown in Table 3-1, approximately 80 percent of the annual volume of unimpaired flow occurs in February–June (based on 1984–2009 unimpaired flow data from Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*). This means that LSJR Alternative 4 evaluates the effects of directing approximately 48 percent of mean annual flows towards the protection of fish and wildlife (60 percent multiplied by 80 percent). The impacts assessment of LSJR Alternative 4 shows that redirecting this quantity of water at the current level of water development would cause large adverse effects on water supply and temperature control. The adaptive element of the LSJR alternatives means that up to 25 percent of the February–June flows can be shifted to time periods after June, thus assuring that there will be no adverse effects on fisheries, including temperature, that would otherwise result from implementation of the February–June flow requirements. The combination of an alternative that requires 60 percent of February –June unimpaired flows, in combination with adaptive implementation, which allows shifting of up to 25 percent of this flow volume means that this SED has evaluated all feasible alternatives with regard to the quantity of water consistent with the goal to "take into consideration all of the demands being made and to be made on waters in the LSJR" (goal 6).

Table 3-1. February–June Unimpaired Flow as a Percent of Annual Unimpaired Flow on the Three Eastside Tributaries

	Feb–June Unimpaired Flow as a % of the Annual Unimpaired Flow		
Averaged for:	Stanislaus	Tuolumne	Merced
All Years	80	79	80
Wet	73	71	72
Above Normal	83	82	85
Below Normal	82	80	80
Dry	84	84	85
Critical	85	85	85

The specific constraints on the use of adaptive implementation vary between LSJR Alternatives 2, 3, and 4 because the alternatives have different starting percentages and ranges. These differences are identified in the description of alternatives below. Also, see Figure 3-1 which provides conceptual illustrations of the adaptive implementation methods for each of the LSJR alternatives.

Applicability of Methods for Each LSJR Alternative

Conceptual Illustrations of Adaptive Implementation Methods for each LSJR Alternative

3.3.4 LSJR Alternative 1: No Project Alternative

California Code of Regulations, Title 14, Section 15126.6, Subdivision (e), requires evaluation of a no project alternative and its impacts. The purpose of a no project alternative is to compare the impacts of approving a project with the impacts of not approving a project. When a project is the amendment of a regulatory plan, such as the 2006 Bay-Delta Plan, the no project alternative will be the continuation of the existing plan into the future. In evaluating the impacts of a no project alternative, a lead agency should consider what is reasonably expected to occur in the foreseeable future.

LSJR Alternative 1 is the No Project Alternative (see Section 3.4.3, *SDWQ Alternative 1: No Project Alternative*). The No Project Alternative assumes continued implementation of, and full compliance with, the 2006 Bay-Delta Plan, as implemented through State Water Board's Water Right Decision 1641 (D-1641). The No Project Alternative focuses on efforts related to the implementation of Vernalis flow objectives and a southern Delta salinity objective because these objectives are the ones proposed to be amended. The Vernalis flow objectives were first established in the 1995 Bay-Delta Plan to protect fish and wildlife beneficial uses. These objectives include the minimum monthly flow rates for fish and wildlife beneficial uses during specific times of the year, as presented in Table 3 of the 2006 Bay-Delta Plan and implemented through D-1641. In D-1641, the State Water Board assigned compliance with these minimum flows on the SJR at Vernalis to the U.S. Bureau of Reclamation (USBR). When the State Water Board subsequently amended the Bay-Delta Plan in 2006, it approved an interim flow regime through the Vernalis Adaptive Management Program (VAMP) experiment, as proposed in the San Joaquin River Agreement (SJRA), in lieu of meeting the April–May pulse flow objective (as presented in Table 3 of the 2006 Bay Delta Plan).

No Project Alternative conditions differ from the baseline because the Vernalis flow objectives in Table 3 of the 2006 Bay-Delta Plan have not been fully implemented and are not part of the baseline because of implementation of the SJRA and VAMP. The VAMP flows, which are generally lower than the Table 3 flows in the 2006 Bay-Delta Plan, are thus included in the baseline. During VAMP, a portion of the flows needed to comply with VAMP came from the three eastside tributaries (Stanislaus, Tuolumne, and Merced Rivers), even though the 2006 Bay-Delta Plan and D 1641 do not contain numeric or narrative flow requirements specific to these rivers. However, the No Project Alternative does not include VAMP flows because that experimental flow regime concluded in 2011. The No Project Alternative and the baseline both include the 2009 National Marine Fisheries Service (NMFS) Biological Opinion (BO) flow requirements on the Stanislaus River, FERC requirements on the Tuolumne and Merced Rivers, and the Davis Grunsky requirements on the Merced River.

The No Project Alternative assumes that the flows would continue to be the responsibility of USBR and that the objectives would be met with additional releases from New Melones Reservoir on the Stanislaus River. There are other possible ways that compliance with the objectives could be achieved, but it is speculative to identify which other measures, or combination of measures, would be used. For example, the flow objective could be achieved by a combination of releases from New Melones Reservoir and other actions (e.g., water purchases and transfers among different water users and other upstream SJR actions [such as SJR Restoration Program[7] flows]). However, these other actions are difficult to predict or quantify. The analytical approach used here evaluates increased releases from New Melones Reservoir to meet the objectives because such releases could be the primary method by which the Vernalis flow objectives and southern Delta salinity objective

---

[7] Implementation of the settlement and the Friant Dam release flows required by the San Joaquin River Restoration Program are expected to increase the existing SJR flows at Stevinson in the near future.

would be achieved. Focusing the evaluation on New Melones Reservoir releases affords an evaluation of maximum potential water supply impacts compared to assuming that increases in Vernalis flow would be distributed among the tributaries.

The No Project Alternative also assumes the continuation of the southern Delta salinity objective for agricultural beneficial uses, as identified in Table 2 of the 2006 Bay-Delta Plan, and full compliance with these objectives as implemented through D-1641 (see Section 3.4.3, *SDWQ Alternative 1: No Project Alternative*). Under D-1641, compliance with the numeric salinity objective on the SJR at Vernalis (station C-10) is the obligation of USBR. Compliance with the numeric salinity objective at the three interior southern Delta compliance stations—SJR at Brandt Bridge (station C-6), Old River near Middle River (station C-8), and Old River at Tracy Road Bridge (station P-12)—is the combined obligation of USBR and the California Department of Water Resources (DWR).

Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*, evaluate the potential impacts of the No Project Alternative. Appendix D provides the modeling assumptions and technical analysis considered in Chapter 15. LSJR Alternative 1 and SDWQ Alternative 1 are evaluated together as the No Project Alternative because continuation of the 2006 Bay-Delta Plan would require compliance with the Vernalis flow objectives and southern Delta salinity objective. Appendix D quantifies the amount of water needed to meet both objectives in the 2006 Bay-Delta Plan.

3.3.5 LSJR Alternative 2

LSJR Alternative 2 implements the 20–30 percent numeric flow water quality objective range by initially requiring maintenance of 20 percent of unimpaired flows at the confluences of each of the Stanislaus, Tuolumne, and Merced Rivers with the SJR from February–June based on a minimum 7-day running average. As described above in Section 3.3.3, *Adaptive Implementation*, the flow requirements could be adaptively adjusted in the same manner for LSJR Alternatives 2, 3, and 4. The following discussion describes aspects of adaptive implementation as specifically applied to LSJR Alternative 2.

1. Adjust the unimpaired flow objective within a range of 20 percent to 30 percent, inclusive.
2. Manage the February–June percent of unimpaired flow as a total volume of water and release the water on an adaptive schedule during that period where scientific information indicates a flow pattern different from that which would occur by tracking the unimpaired flow percentage, would better protect fish and wildlife beneficial uses. Applying this method, the total volume of water released would be the same as LSJR Alternative 2 without adaptive implementation; however the rate could vary from the actual (7-day running average) unimpaired flow rate and the volume for each month could vary.
3. Unlike LSJR Alternatives 3 and 4, a portion of the total February–June unimpaired flow volume may not be held and released after June in order to prevent adverse effects to fisheries, including temperature, that would otherwise result from implementation of the February–June flow requirements.
4. The minimum required LSJR base flow objective for February–June of 1,000 cfs, based on a minimum 7-day running average, at Vernalis may be adjusted to a value between 800 and 1,200 cfs.

3.3.6 LSJR Alternative 3

LSJR Alternative 3 implements the 30–50 percent numeric flow water quality objective range by initially requiring maintenance of 40 percent of unimpaired flows at the confluences of each of the Stanislaus, Tuolumne, and Merced Rivers with the SJR from February–June based on a 7-day minimum running average. As described above in Section 3.3.3, *Adaptive Implementation*, the flow requirements could be adaptively adjusted in the same manner for LSJR Alternatives 2, 3, and 4. The following discussion describes aspects of adaptive implementation as specifically applied to LSJR Alternative 3.

1. Adjust the minimum unimpaired flow objective within a range of 30 percent to 50 percent.
2. Implementing this method would allow an increase or decrease of up to 10 percent in the February–June 40 percent minimum unimpaired flow requirement (with a minimum of 30 percent and maximum of 50 percent).
3. Manage the February–June percent of unimpaired flow as a total volume of water and release the water on an adaptive schedule during that period where scientific information indicates a flow pattern different from that which would occur by tracking the unimpaired flow percentage, would better protect fish and wildlife beneficial uses. Applying this method, the total volume of water released would be the same as LSJR Alternative 3 without adaptive implementation; however the rate could vary from the actual (7-day running average) unimpaired flow rate and the volume for each month could vary.
4. Allow a portion of the total February–June unimpaired flow volume to be held and released after June in order to prevent adverse effects to fisheries, including temperature, that would otherwise result from implementation of the February–June flow requirements. If the requirement is greater than 30 percent but less than 40 percent, the amount of flow that may be released after June is limited to the portion of the unimpaired flow requirement over 30 percent. If the requirement is 40 percent or greater, then 25 percent of the total volume of the flow requirement may be released after June.
5. The minimum required LSJR base flow objective for February–June of 1,000 cfs, based on a minimum 7-day running average, at Vernalis may be adjusted to a value between 800 and 1,200 cfs.

3.3.7 LSJR Alternative 4

LSJR Alternative 4 implements the 50–60 percent numeric flow water quality objective range by initially requiring maintenance of 60 percent of unimpaired flows at the confluences of each of the Stanislaus, Tuolumne, and Merced Rivers with the SJR from February–June based on minimum a 7-day running average. As described above in Section 3.3.3, *Adaptive Implementation*, the flow requirements could be adaptively adjusted in the same manner for LSJR Alternatives 2, 3, and 4. The following discussion describes aspects of adaptive implementation as specifically applied to LSJR Alternative 4.

1. Adjust the minimum unimpaired flow objective within a range of 50 percent to 60 percent.
2. Manage the February–June percent of unimpaired flow as a total volume of water and release the water on an adaptive schedule during that period where scientific information indicates a flow pattern different from that which would occur by tracking the unimpaired flow percentage, would better protect fish and wildlife beneficial uses. Applying this method, the total volume of

water released would be the same as LSJR Alternative 4 without adaptive implementation; however the rate could vary from the actual (7-day running average) unimpaired flow rate and the volume for each month could vary.

3. Allowing a portion of the total February–June unimpaired flow volume to be held and released after June in order to prevent adverse effects to fisheries, including temperature, that would otherwise result from implementation of the February–June flow requirements. If the requirement is 50 percent or greater, then 25 percent of the total volume of the flow requirement may be released after June.
4. The minimum required LSJR base flow objective for February–June of 1,000 cfs, based on a minimum 7-day running average, at Vernalis may be adjusted to a value between 800 and 1,200 cfs.

3.3.8 Common Elements of LSJR Alternatives

The following elements of the LSJR alternatives are the same for LSJR Alternatives 2, 3, and 4.

- Implementing entity and biological goals.
- Planning, monitoring, and reporting.
- State of emergency provisions.
- Non-flow measures.

Implementing Entity and Biological Goals

The State Water Board will establish the STM Working Group to assist with implementation, monitoring and assessment activities for the LSJR flow objectives. The STM Working Group will be comprised of representatives from the State Water Board; California Department of Fish and Wildlife (CDFW); NMFS; United States Fish and Wildlife Service (USFWS); water users on the Stanislaus, Tuolumne, and Merced Rivers; and any other representatives deemed appropriate by the Executive Director. The STM Working Group or State Water Board staff as necessary, will, in consultation with the Delta Science Program, develop specific measures necessary to implement the February–June LSJR flow requirements and assess their effectiveness. The STM Working Group, or State Water Board staff as necessary, will also, in consultation with the Delta Science Program, develop proposed procedures for allowing the adaptive adjustments to the February–June flow requirements.

The program of implementation requires the development of biological goals that can be used to demonstrate the reasonable protection of LSJR fish and wildlife beneficial uses, evaluate the effectiveness of the program of implementation, and to inform adaptive implementation. These biological goals will be developed by the STM Working Group or State Water Board staff, as necessary. Based on the STM's recommendations and input from other interested persons, the State Water Board will make a final determination regarding the biological goals that will be used to evaluate the effectiveness of the program of implementation. Once developed, those biological goals may be modified by the State Water Board based on new information developed through the monitoring and evaluation activities described below or other new sources of scientific information. Biological goals will be developed specifically for LSJR salmonids for abundance; productivity as measured by population growth rate; genetic and life history diversity; and population spatial extent, distribution, and structure. It is expected that the biological goals for the LSJR will be incorporated into the water rights implementation of the flow objectives. In this way, the biological goals will be one of the tools that will guide the specific flow percent that is required within the adaptive range.

Planning, Monitoring, and Reporting

A comprehensive monitoring, special studies, evaluation, and reporting program is necessary to determine compliance with the LSJR flow objectives, inform adaptive implementation, investigate the technical factors involved in water quality control, and identify potential needed future changes to the LSJR flow objectives, including flows for other times of the year. The State Water Board will require annual and comprehensive monitoring, evaluation, and reporting, as part of the SJRMEP, including:

1. Monitoring, special studies, and evaluations of the effects of flow and other factors on the viability of native LSJR Watershed fish populations throughout the year, including assessment of abundance, spatial extent (or distribution), diversity (both genetic and life history), and productivity.
2. Consideration of recommendations from entities with relevant Central Valley monitoring plans to improve standardization of methods, including the quantification of bias and precision of population estimates.
3. Regular external scientific review of monitoring, evaluation, and reporting.

Monitoring under this program would be integrated and coordinated with new and ongoing monitoring and special studies programs in the LSJR, including federal BO requirements, FERC licensing proceedings for the Merced and Tuolumne Rivers, Central Valley Regional Water Board requirements, and the Delta Science Program. The SJRMEP consists of annual and comprehensive monitoring and reporting.

To inform the next year's operations and other activities, the State Water Board will require preparation and submittal of an annual report to the State Water Board by December 31 of each year. The annual report shall describe implementation of flows, including any flow shifting done pursuant to the annual adaptive operations plan, monitoring and special studies activities, and implementation of other measures to protect fish and wildlife during the previous water year, including the actions by other entities identified in this program of implementation. The annual report shall also identify any deviations from the annual adaptive operations plan and describe future special studies. The State Water Board may hold public meetings to receive and discuss the annual report.

Additionally, every 3 to 5 years following implementation of this update to the Bay-Delta Plan, the State Water Board will require preparation and submittal of a comprehensive report that, in addition to the requirements of annual reporting, reviews the progress toward meeting the biological goals and identifies any recommended changes to the implementation of the flow objectives. The comprehensive report and any recommendations shall be peer-reviewed by an appropriate independent science panel, which will make its own conclusions and recommendations. The State Water Board will hold public meetings to consider the comprehensive report, technical information, and conclusions or recommendations developed through the peer review process. This information will be used to inform potential adaptive changes to the implementation of the flow objectives and, as appropriate, future potential changes to the Bay-Delta Plan.

In summary, the program of implementation for LSJR flow objectives identifies the following information, plans, and reports that must prepared and submitted to the State Water Board or its Executive Director for approval.

- Biological goals—one time preparation, but can be modified thereafter; to be considered for approval within 180 days after Office of Administrative Law (OAL) approval of the amendments to Bay-Delta Plan.
- Measures to achieve, monitor, and evaluate compliance with the flow objectives—one time preparation and submittal; to be considered for approval within 180 days after OAL approval of the amendments to the Bay-Delta Plan.
- Adaptive Methods Procedures—one time preparation and submittal, to be considered for approval within 1 year after OAL approval of the amendments to the Bay-Delta Plan.
- Annual Adaptive Operations Plan—due January 10 each year.
- Annual Report on Implementation Activities—due December 31 each year.
- Comprehensive Review of Implementation Actions—due every 3 to 5 years.

State of Emergency Change Provision

The current drought has highlighted the need to adjust requirements in water rights that implement the current Bay-Delta standards during emergencies. The flow proposal therefore includes a provision to adjust flows for a state of emergency, such as the current drought emergency. Under this emergency element of the flow proposal, the State Water Board, at its discretion or at the request of any affected responsible agency or person, may authorize a temporary change to the implementation of the LSJR flow objectives if the State Water Board determines that either: (1) there is an emergency as defined by CEQA (Pub. Resources Code, § 21060.3), or (2) the Governor of the State of California or a local governing body has declared a state or local emergency pursuant to the California Emergency Services Act. (Gov. Code, § 8550 et seq.) Before authorizing any temporary change, the State Water Board must find that measures will be taken to reasonably protect the beneficial use in light of the circumstances of the emergency.

Non-Flow Measures

The program of implementation for the flow proposal recommends and encourages the development of non-flow measures to assist in further improving protections for fish and wildlife beneficial uses. This is intended to provide guidance to the entities that will be responsible for attainment of flow objectives, and other entities, as regarding non-flow that are complementary to the LSJR flow objectives and that may help to achieve the overarching goal of supporting and maintaining the natural production of viable native LSJR Watershed fish populations. Increased flows, however, remain the principal means of compliance with the LSJR flow objectives. As discussed above, adaptive adjustments to the range of flows may be made if certain requirements are met, which allows for consideration of benefits associated with the non-flow measures, but the lower number of the adaptive range still represents the minimum required flow. In other words, some level of flow is always required.

The following actions are non-flow measures that can be used to improve conditions for fish and wildlife in a manner that may support a change in the flows within the adaptive range, thus lessening the significant effects of the alternatives that occur as a result of reduced water availability for diversions. These recommended actions, together with the coordinated monitoring and adaptive implementation described above, are expected to improve habitat conditions that benefit native fish and wildlife, or are expected to improve related science and management within the LSJR Watershed. The following actions are recommended for evaluation and subsequent implementation.

- Restore, enhance, and protect floodplain and riparian habitat.
- Reduce vegetation disturbing activities in floodplains and floodways, where safe and appropriate.
- Provide and maintain coarse sediment for salmonid spawning and rearing.
- Enhance in-channel complexity.
- Improve reservoir operations and/or physical structures to maintain adequate water temperature conditions.
- Expand fish screening.
- Improve fish passage above dams.
- Improve fish and water barrier programs.
- Reduce predation and competition by nonnative fish.
- Reduce invasive species.

Allowance for and implementation of these non-flow measures achieve the goal of taking “into consideration all of the demands being made and to be made on waters in the LSJR and the three eastside, salmon-bearing tributaries” (goal 6) by allowing measures other than flow to help achieve the overarching goal of supporting and maintaining the natural production of viable native LSJR Watershed fish populations.

3.3.9 LSJR Alternatives Considered but Eliminated from Further Evaluation

CEQA requires identification of any alternatives that were considered by the lead agency but were rejected as infeasible during the scoping process with a brief explanation of the reasons underlying the lead agency’s determination. (State CEQA Guidelines, § 15126.6, subd. (c).) Among the factors that may be used to eliminate alternatives from detailed consideration are: “(i) failure to meet most of the basic project objectives, (ii) infeasibility, or (iii) inability to avoid significant environmental impacts.” (*Ibid.*)

This section summarizes alternatives that were considered by the State Water Board and eliminated from detailed consideration. It includes a discussion of suggestions that were received from the public during the comment periods associated with the February 13, 2009 notice of preparation and the April 1, 2011 revised notice of preparation. This section also includes discussion of flow recommendations received during the process of preparing the August 2010 State Water Board staff report entitled *Development of Flow Criteria for the Sacramento–San Joaquin Delta Ecosystem* (State Water Board 2010). These potential alternatives were evaluated for their ability to meet most of the underlying fundamental purposes and goals of the plan amendments, feasibility, and ability to avoid significant effects on the environment.

3.3.10 LSJR Flow Objectives and Program of Implementation

Fixed Monthly Flow-Based Programs of Implementation

Several commenters suggested the State Water Board consider fixed monthly flow objectives similar to the current flow objectives, that vary by water year type and month instead of using an unimpaired flow approach.

As detailed in Appendix C, *Technical Report on the Scientific Basis Alternative for San Joaquin River Flow and Southern Delta Salinity Objectives*, retaining the spatial and temporal attributes of the natural flow regime is important in protecting a wide variety of ecosystem processes. The historical practice of developing fixed monthly flow objectives to be met from limited sources has been shown to be less than optimal in protecting fish and wildlife beneficial uses in the SJR Basin. Accordingly, to preserve the attributes of the flow regime to which native SJR Basin fish and wildlife have adapted and that are believed to be generally protective of the current beneficial uses, the flow requirements in the program of implementation are expressed as a percentage of unimpaired flow (e.g., 40 percent of unimpaired flow). However, if specific information indicates that more fixed flows would be more protective of fish and wildlife, the adaptive management provisions of LSJR Alternatives 2, 3, and 4 could allow for such an approach to be implemented, provided that the required amount of flow is less than or equal to that of the LSJR alternatives. To assess whether this would be possible for the specific flow recommendations that the State Water Board received, an analysis was conducted to compare the flow exceedance curves for LSJR Alternatives 2, 3, and 4 with the different recommended flow schedules. If flow exceedance curves for the recommended flows are less than or equal to the flow exceedance curves for the LSJR alternatives, and if it is determined that the recommended flow schedule is more protective than the percent of unimpaired flow pursuant to the LSJR alternatives, then adequate water would generally be available to meet the recommended flows. Accordingly, this category of recommendation is effectively included within the LSJR alternatives analyzed in this SED. Moreover, there is no information to support a conclusion that a fixed monthly flow objective would reduce or avoid potentially significant effects on the environment any more than the current alternatives.

Contra Costa County Department of Conservation and Development

The Contra Costa County Department of Conservation and Development (CCCDCD) submitted scoping comments on the *Southern Delta Agriculture and San Joaquin River Flows Revised Notice of Preparation* (CCCDCD 2011). The CCCDCD scoping comments included recommendations on setting quantitative LSJR flow objectives that would have percentages of unimpaired flow that vary by month yet ensure additional reduced-flow impacts are not created outside of the February–June period. Presented in Table 3-2 are the flow schedule-based recommendations submitted by CCCDCD.

Table 3-2. Contra Costa County Department of Conservation and Development Flow Schedule-Based Recommendations

	Minimum Monthly Average Flow as a Percentage of Monthly Unimpaired Flow				
Month	Vernalis	Stanislaus River upstream of the confluence with the SJR	Tuolumne River upstream of the confluence with the SJR	Merced River upstream of the confluence with the SJR	Upper SJR upstream of the confluence with the Merced
Jan[a]	20	20 with an upper cap[b]	20 with an upper cap	20 with an upper cap	20 with an upper cap
Feb	50	30	30	30	30
Mar	50	30	30	30	30
Apr	40	20	20	20	20
May	30	20	20	20	20
Jun	30	20	20	20	20
Jul–Dec[a]	20	20 with an upper cap	20 with an upper cap	20 with an upper cap	20 with an upper cap

[a] Minimum flows are also needed outside the February–June period of greatest concern for fish and wildlife to ensure flow impacts are not redirected to the July–January period.

[b] The upper cap should be based on the 70th percentile of the unimpaired flows for each tributary and month. In other words, the minimum flow requirement of 20% of unimpaired flow would generally apply in critical, dry, and normal years but would be capped at 20% of the 70th-percentile unimpaired flow in wet years. This cap would only apply from July–January (i.e., outside of the period of greatest concern for fish).

Comparison of the exceedance plots for flow at Vernalis in Figure 3-2 indicates that LSJR Alternatives 2, 3, and 4 encompass the CCCDCD flow recommendations for all water year types. The CCCDCD flow recommendations are less than LSJR Alternative 4 in all years. The CCCDCD flow recommendations are generally greater than LSJR Alternative 2 in all years and would not avoid or substantially lessen potentially significant effects.

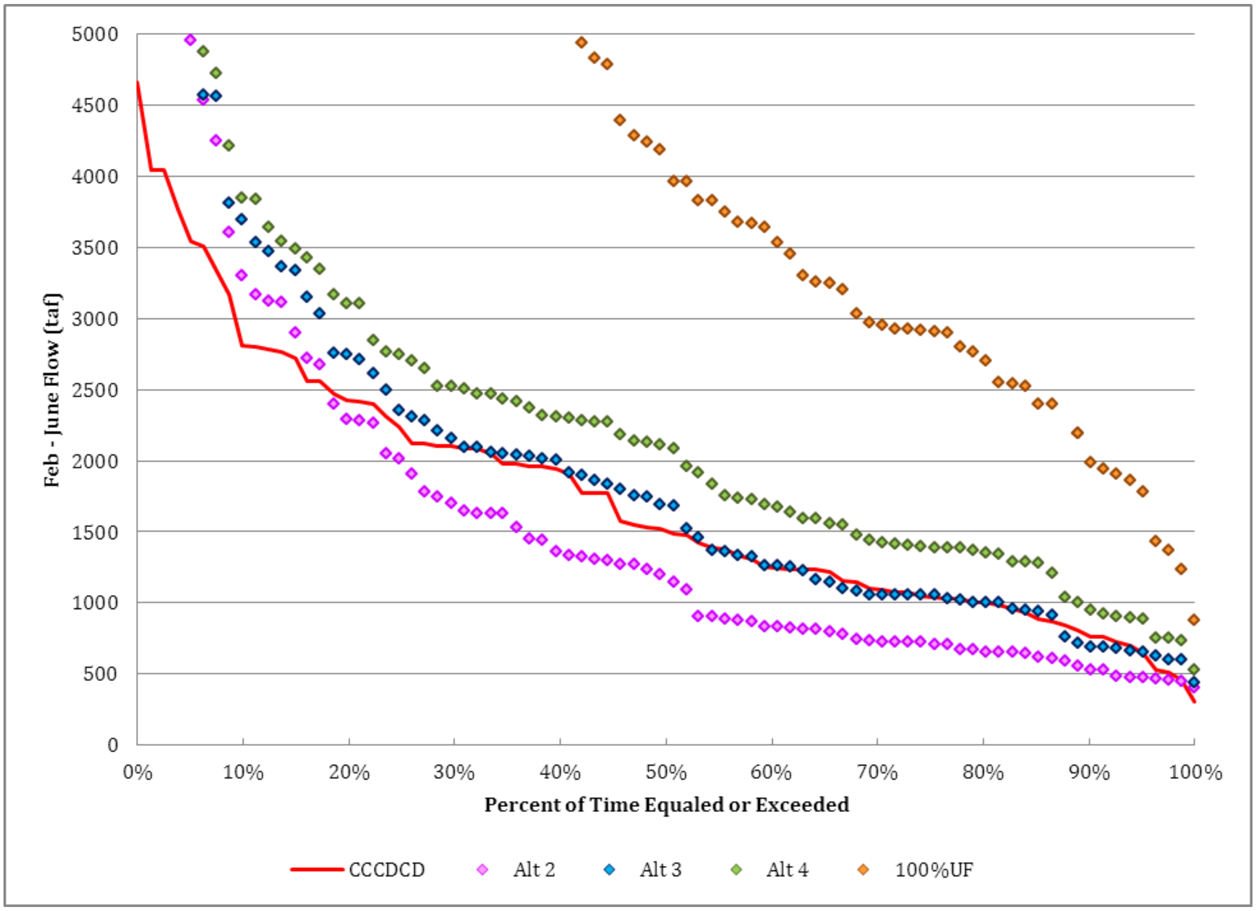

Figure 3-2. Flow Exceedance Plot of Contra Costa County Department of Conservation and Development's (CCCDCD's) Flow Recommendations and State Water Board's LSJR Alternatives (TAF = thousand acre-feet; UF = unimpaired flow)

California Department of Fish and Wildlife

CDFW (formerly the California Department of Fish and Game) provided written testimony and closing comments as part of the State Water Board Proceeding to Develop Flow Criteria for the Delta (CDFG 2010a, 2010b). CDFG testimony and comments included flow recommendations for the SJR at Vernalis that would double Chipps Island SJR fall-run Chinook salmon smolt production from 78,210 to more than 156,420 (derived from SJR Salmon Model V.1.6 output). Table 3-3 presents the flow schedule-based recommendations from CDFG.

Table 3-3. California Department of Fish and Game Flow Schedule-Based Recommendations, 2010 (cubic feet per second)

Water Year	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sept	Oct	Nov	Dec
C				1500 (Base) 5500 (Pulse) (4/15-5/15) (Total 7000)								
D				2125 (Base) 4875 (Pulse) (4/11-5/20) (Total 7000)								
BN				2258 (Base) 6242 (Pulse) (4/6-5/25) (Total 8500)								
AN				4339 (Base) 5661 (Pulse) (4/1-5/30) (Total 10000)								
W				6315 (Base) 8685 (Pulse) (3/27-6/4) (Total 15000)								

C = critical
D = dry
BN = below normal
AN = above normal
W = wet

A comparison of the exceedance plots for flow at Vernalis in Figure 3-3 indicates that LSJR Alternatives 2, 3, and 4 generally encompass the CDFG flow recommendations. The CDFG flow recommendations are generally greater than LSJR Alternative 2 in all years, and would not avoid or substantially lessen potentially significant effects.

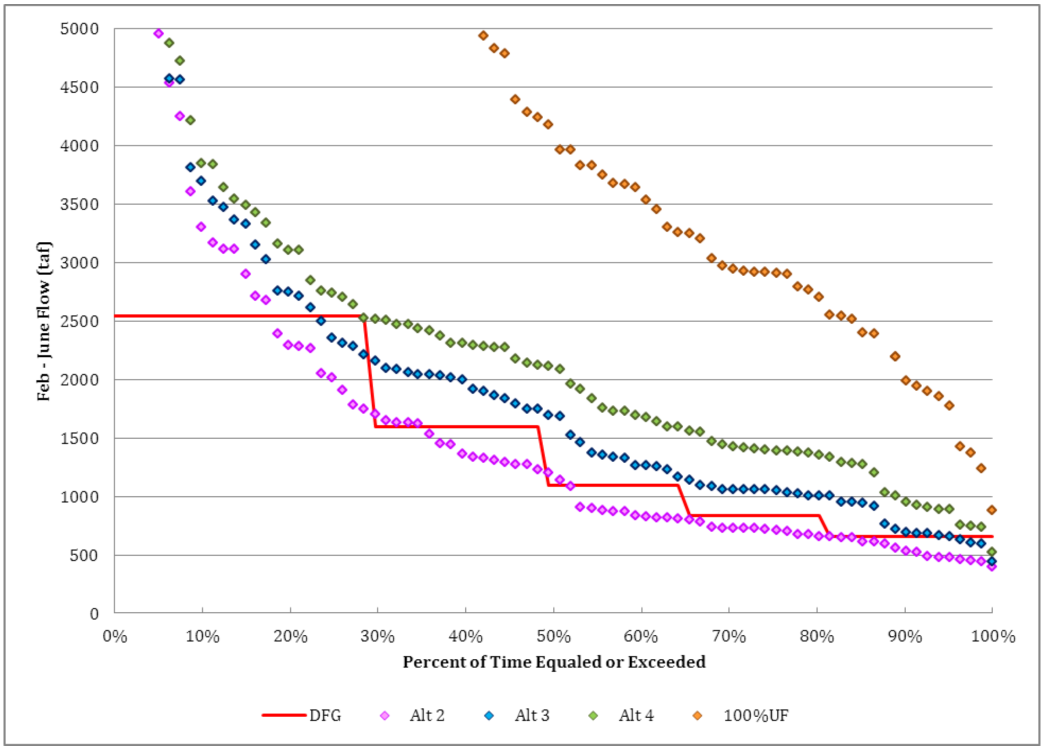

Figure 3-3. Flow Exceedance Plot of California Department of Fish and Game's (CDFG's) Flow Recommendations and State Water Board's LSJR Alternatives (TAF = thousand acre-feet; UF = unimpaired flow)

California Water Impact Network and California Sportfishing Protection Alliance

California Water Impact Network and California Sportfishing Protection Alliance (C-WIN/CSPA) provided closing comments as part of the State Water Board Proceeding to Develop Flow Criteria for the Delta (C-WIN 2010; CSPA 2010). The C-WIN/CSPA comments included flow recommendations based on pulse flows considered to match and facilitate the early life stages of salmonid larvae, juvenile rearing, and smoltification. Table 3-4 presents the flow schedule-based recommendations by C-WIN/CSPA.

Table 3-4. California Water Impact Network and California Sportfishing Protection Alliance Flow Schedule-Based Recommendations (cubic feet per second)

Comparison of the exceedance plots for flow at Vernalis in Figure 3-4 indicates that LSJR Alternatives 2, 3, and 4 largely encompass the C-WIN/CSPA flow recommendations and entirely encompasses them for above-normal and dry water year types. The C-WIN/CSPA flow recommendations are generally greater than LSJR Alternative 2 in all years, and would not avoid or substantially lessen potentially significant effects.

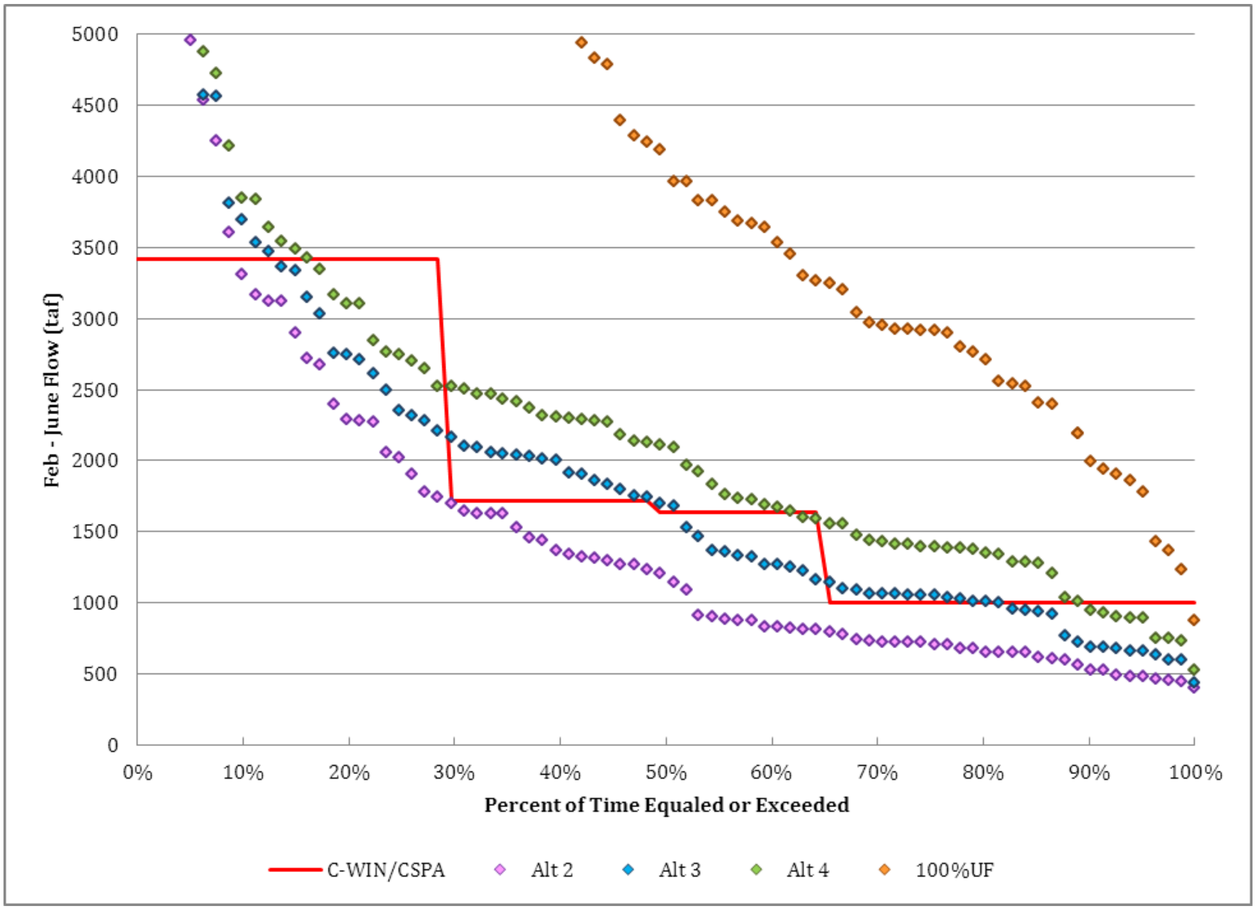

Figure 3-4. Flow Exceedance Plot of California Water Impact Network and California Sportfishing Protection Alliance's (C-WIN/CSPA) Flow Recommendations and State Water Board's LSJR Alternatives (TAF = thousand acre-feet; UF = unimpaired flow)

The Bay Institute and Natural Resources Defense Council

The Bay Institute and Natural Resources Defense Council (TBI/NRDC) provided testimony and closing comments as part of the State Water Board Proceeding to Develop Flow Criteria for the Delta (TBI/NRDC 2010a, 2010b, 2010c). The TBI/NRDC testimony and comments included flow recommendations developed by analyzing the relationship between LSJR flows with abundance, productivity, and life history diversity of SJR fall-run Chinook salmon. Table 3-5 presents the TBI/NRDC flow schedule-based recommendations.

Table 3-5. The Bay Institute and Natural Defense Council Flow Schedule-Based Recommendations (cubic feet per second)

Comparison of the exceedance curves shown in Figure 3-5 indicates that the State Water Board's flow resulting at Vernalis from the range of LSJR alternatives generally encompasses the TBI/NRDC flow recommendations and entirely encompasses them for above-normal and dry water year types. The TBI/NRDC flow recommendations are generally greater than LSJR Alternative 2 in all years, and would not avoid or substantially lessen potentially significant effects.

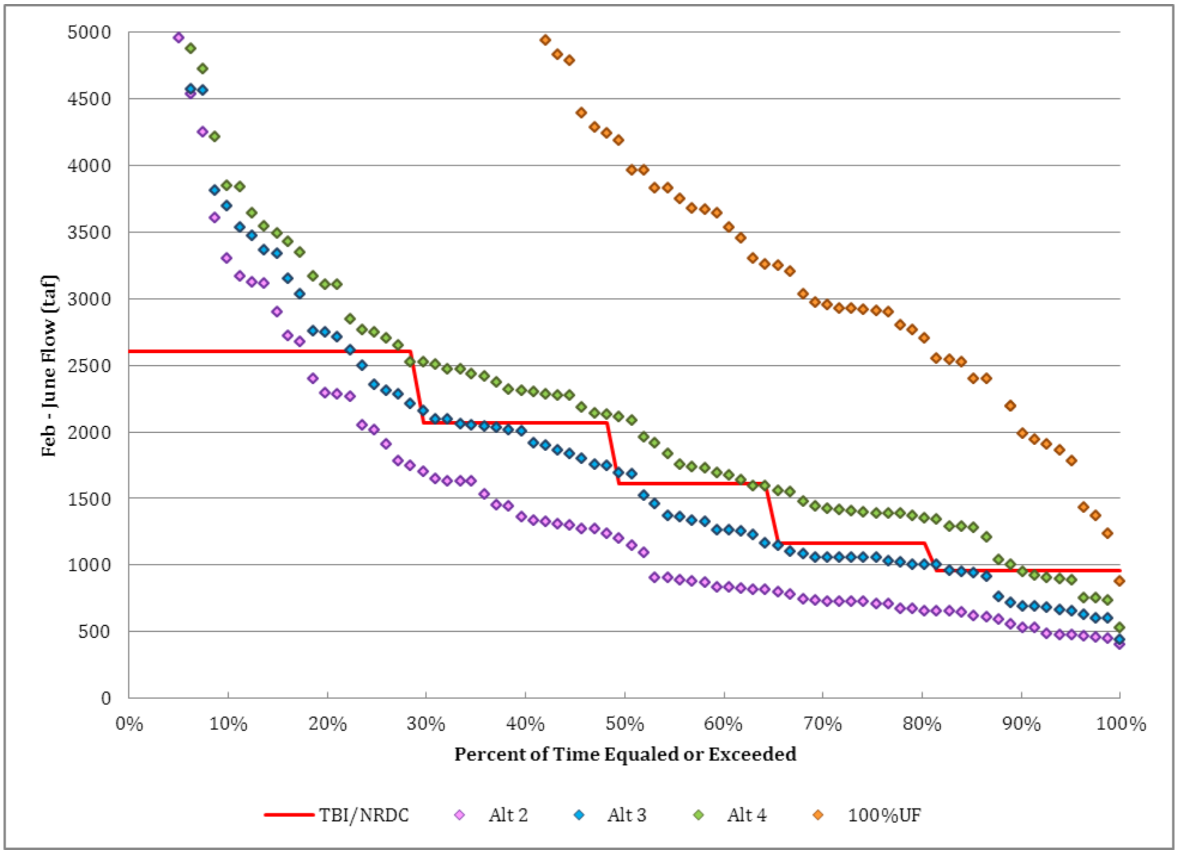

Figure 3-5. Flow Exceedance Plot of The Bay Institute and Natural Defense Council's (TBI/NRDC) Flow Recommendations and State Water Board's LSJR Alternatives (TAF = thousand acre-feet; UF = unimpaired flow)

American Rivers and Natural Heritage Institute

The American Rivers and Natural Heritage Institute (AR/NHI) provided testimony and closing comments as part of the State Water Board Proceeding to Develop Flow Criteria for the Delta (AR/NHI 2010a, 2010b). Included in the testimony and closing comments were recommendations for LSJR flows that would benefit salmon rearing habitat and smolt outmigration (i.e., increased flow velocities and turbidity), with focus on temperature (i.e., maintaining temperature at or below 65°F). These flow recommendations are to be in addition to those stipulated in D-1641. Table 3-6 presents the flow schedule-based recommendations provided in the AR/NHI testimony and closing comments.

Table 3-6. American Rivers and Natural Heritage Institute Flow Schedule-Based Recommendations

Comparison of the exceedance plots for flow at Vernalis in Figure 3-6 indicates that LSJR Alternatives 2, 3, and 4 generally encompass the AR/NHI flow recommendations and entirely encompass them for above-normal and dry water year types. The AR/NHI flow recommendations are generally greater than LSJR Alternative 2 in all years, and would not avoid or substantially lessen potentially significant effects.

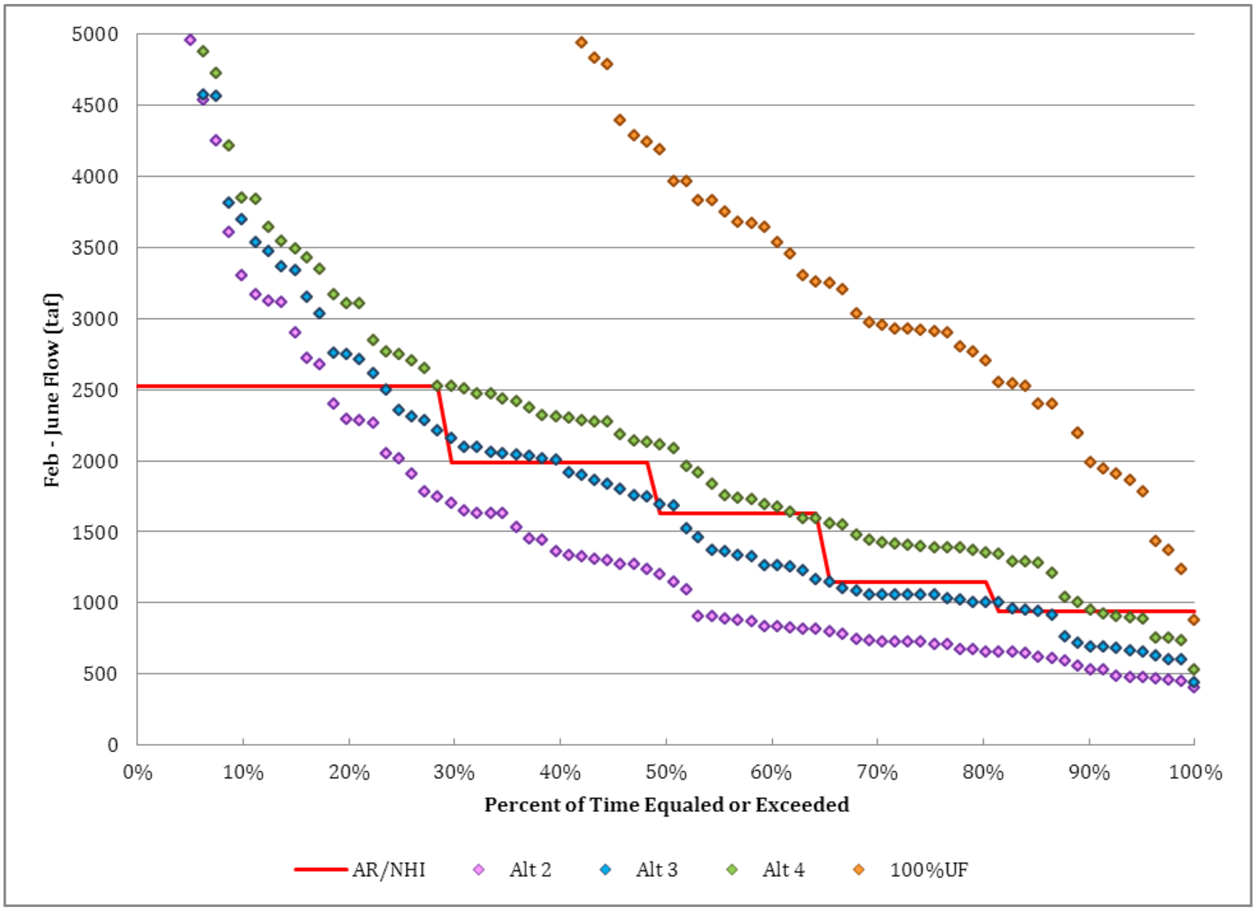

Figure 3-6. Flow Exceedance Plot of American Rivers and Natural Heritage Institute's (AR/NHI) Flow Recommendations and State Water Board's LSJR Alternatives (TAF = thousand acre-feet; UF = unimpaired flow)

U.S. Department of the Interior

Pursuant to the Central Valley Project Improvement Act (CVPIA), the U.S. Department of the Interior (DOI) is required to develop and implement measures to at least double the natural production of anadromous fish in Central Valley streams; the program to achieve this is known as the Anadromous Fish Restoration Program (AFRP). DOI submitted a written summary and witness testimony on behalf of both USFWS and USBR as part of the State Water Board Proceeding to Develop Flow Criteria for the Delta (DOI 2010). DOI recommended evaluation of the flow recommendations contained within the CVPIA's 2005 AFRP Report (USFWS 2005) for salmon population doubling and increasing salmon population by 53 percent. Table 3-7 presents USFWS/USBR flow recommendations, as stated in the CVPIA's 2005 AFRP Report, for salmon population doubling and increasing salmon population by 53 percent.

Table 3-7. Central Valley Project Improvement Act's 2005 Anadromous Fish Restoration Program Report Flow Schedule-Based Recommendations (cubic feet per second)

	Water Year Type	Flow			
		Feb	Mar	Apr	May
Doubling Salmon Population	C	1744	2832	4912	5665
	D	1784	3146	5883	7787
	BN	1809	3481	6721	9912
	AN	2581	5162	8151	13732
	W	4433	8866	10487	17369
53% Increase in Salmon Population	C	1250	1665	2888	3331
	D	1350	1850	3459	4579
	BN	1450	1933	3733	5505
	AN	1638	2703	4266	7194
	W	2333	4667	5520	9142

C = critical
D = dry
BN = below normal
AN = above normal
W = wet

Comparison of the exceedance plots for flow at Vernalis in Figure 3-7 indicates that LSJR Alternatives 2, 3, and 4 encompass the USFWS/USBR salmon population doubling flow recommendations for above-normal, below-normal, and dry water year types. The USFWS/USBR salmon population doubling flow recommendations are generally greater than LSJR Alternative 2 in all years.

Comparison of the exceedance plots for flow at Vernalis in Figure 3-7 indicates that LSJR Alternatives 2, 3, and 4 generally encompass the USFWS/USBR flows. With the exception of critical years, the LSJR alternatives entirely encompass both sets of flows. The USFWS/USBR salmon population 53 percent increase flow recommendations are generally lower than LSJR Alternative 2 in most years. These recommendations would not avoid or substantially lessen potentially significant effects, and in years with lower flows, would not meet the plan amendment purpose and goals of protecting the fish and wildlife beneficial uses, including by maintaining inflow conditions sufficient to support and maintain the natural production of viable migratory fish populations.

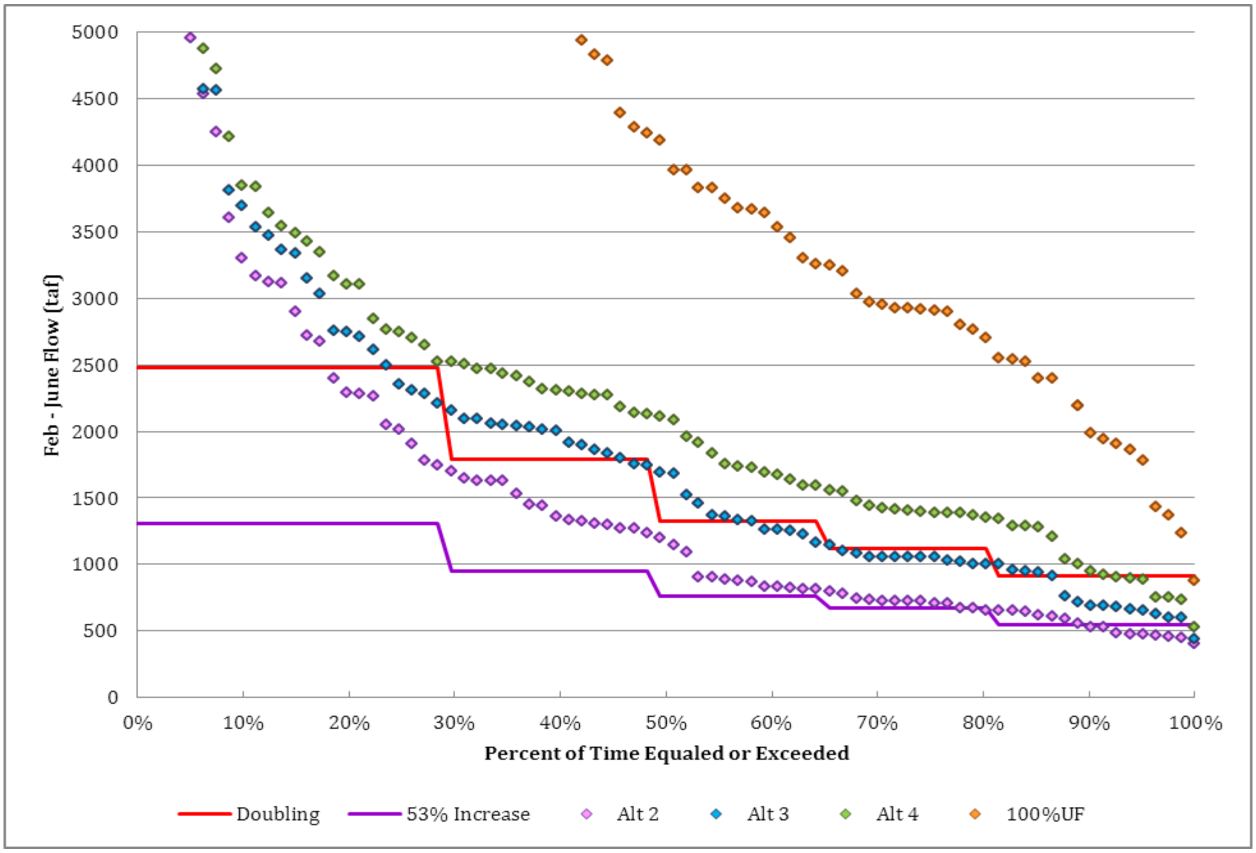

Figure 3-7. Flow Exceedance Plot of Central Valley Project Improvement Act's 2005 Anadromous Fish Restoration Program's Flow Recommendations and State Water Board's LSJR Alternatives (TAF = thousand acre-feet; UF = unimpaired flow)

Delta Solution Group

During the development of flow criteria for the Sacramento–San Joaquin Delta, the State Water Board invited a group of experts to participate in and provide scientific information relevant to the Delta Flow Criteria Informational Proceeding. This led to the formation of the Delta Environmental Flows Group. A subset of this group was the U.C. Davis Delta Solutions Group (DSG), who prepared three papers to inform the Delta Flow Criteria Informational Proceeding. Of the three papers, Fleenor et al. (2010) explored several approaches for establishing freshwater flow prescriptions. Detailed in the Fleenor et al. (2010) paper are functional flow prescriptions to support and promote habitat conditions for desirable estuarine fishes. In Table 3-8 are the LSJR flow schedule-based recommendations presented in the Fleenor et al. (2010) paper by the DSG.

Table 3-8. Delta Solution Group LSJR Flow Schedule-Based Recommendations (cubic feet per second)

Water Year Type	Flow											
	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sept	Oct	Nov	Dec
C	2000	2000	2000	5000	2000	2000	2000	2000	2000	2000	2000	2000
D	2000	2000	2000	7000[a]	2000[b]	2000	2000	2000	2000	2000	2000	2000
BN	2000	2000	2000	10000	2000	200	2000	2000	2000	2000	2000	2000
AN	2000	2000	2000	15000	15000[c]	2000[d]	2000	2000	2000	2000	2000	2000
W	2000	2000	2000	20000	20000	20000	2000	2000	2000	2000	2000	2000

C = critical
D = dry
BN = below normal
AN = above normal
W = wet

[a] 7000 cubic feet per second (cfs) from April 1–May 15.

[b] 2000 cfs from May 16–December 31.

[c] 15000 cfs from May 1–June 15th.

[d] 2000 cfs from June 16–December 31.

Comparison of the exceedance plots for flow at Vernalis in Figure 3-8 indicates that LSJR Alternatives 2, 3, and 4 generally encompass the DSG flow recommendations with the exception of wetter years when flows are often uncontrolled and may incidentally meet the proposed levels. The DSG flow recommendations are generally greater than LSJR Alternative 2 in all years and would not avoid or substantially lessen potentially significant effects.

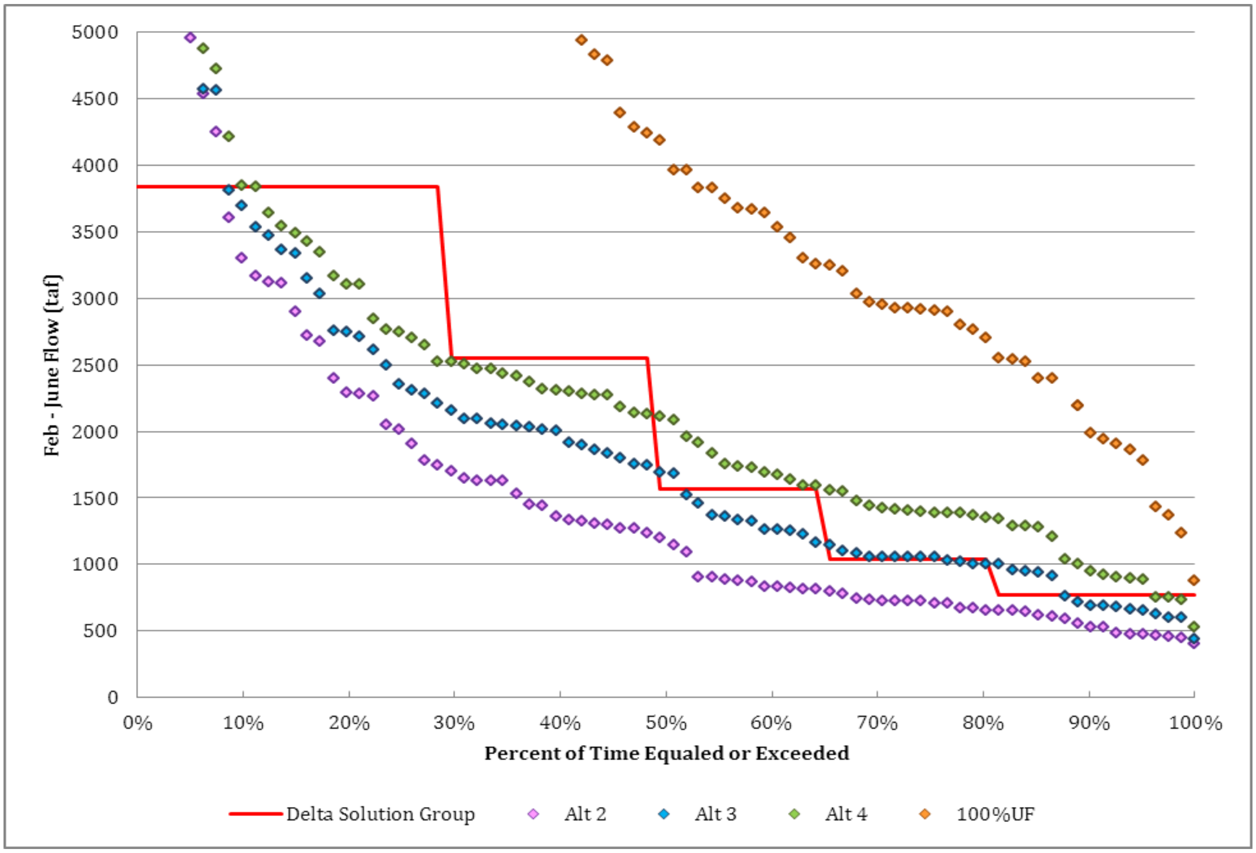

Figure 3-8. Flow Exceedance Plot of Delta Solution Group's Flow Recommendations and State Water Board's LSJR Alternatives (TAF = thousand acre-feet; UF = unimpaired flow)

The LSJR alternatives considerably bracket the flow schedule-based recommendations submitted by commenters. There are, however, periods of time when the flow recommendations are outside of this bracket, and the LSJR alternatives provide more or less flow than the recommendations. Table 3-9 presents the number of years out of 82 that the February–June flow schedule-based recommendations exceed LSJR Alternative 4 flows.

Table 3-9. Number of Years February– June Flow Schedule-Based Recommendations Exceed LSJR Alternative 4 at Vernalis by Water Year Type

Water Year Type	Total Number of Years (1922–2003) per Water Year Type	Recommendation							
							USFWS/USBR		
		CCCDCD	CDFG	C-WIN/CSPA	TBI/NRDC	AR/NHI	Doubling	53% Incr.	DSG

AN	16	0	0	0	0	0	0	0	13
BN	13	0	0	2	2	2	0	0	1
D	13	0	0	0	0	0	0	0	0
C	16	0	1	9	9	8	7	1	4
Total	82	0	5	21	15	14	11	1	33

USFWS = U.S. Fish and Wildlife Service
USBR = U.S. Bureau of Reclamation
CCCDCD = Contra Costa County Department of Conservation and Development
CDFG = Department of Fish and Game
C-WIN/CSPA = California Water Impact Network and California Sportfishing Protection Alliance
TBI/NRDC = The Bay Institute and Natural Resources Defense Council
AR/NHI = The American Rivers and Natural Heritage Institute
DSG = Delta Solutions Group
W = wet
AN = above normal
BN = below normal
D = dry
C = critical

With the exception of the C-WIN/CSPA and DSG, LSJR Alternative 4 provides more flow than the recommendations for 80–100 percent of the 24 wet water years evaluated. For critically-dry years, LSJR Alternative 4 provides more flow than CCCDCD (all critically-dry years), CDFG/USBR 53 percent salmon increase recommendations (15 out of 16 critically-dry years), and DSG (12 out of 16 years), but less flow than C-WIN/CSPA, TBI/NRDC, AR/NHI, and USBR Doubling recommendations in 9, 9, 8, and 7 years out of 16 critically-dry years, respectively.

For the time periods when the aforementioned flow recommendations are within the LSJR alternatives' brackets, the LSJR alternatives exceed the recommendations. The result is a balance in which the time the LSJR alternatives are not satisfying the recommendations is offset by the time the alternatives exceed the recommendations. The LSJR alternatives may not satisfy each of the flow recommendations all the time, but the flow schedule-based recommendations are satisfied the majority of the time. Further, adaptive management of flows would increase the amount of time that the flow recommendations are achieved if information indicates that achieving these schedules is more protective of fish and wildlife. In general, these recommendations would not avoid or substantially lessen potentially significant effects. To the extent lower flows are proposed, they would not meet the plan amendment purpose and goals of protecting the fish and wildlife beneficial uses, To the extent that higher flows are proposed, they would not meet the plan amendment purpose and goal to consider all of the demands being made and to be made on waters in the LSJR and the three eastside, salmon-bearing tributaries.

Other Suggested Program of Implementation Elements

Additional program of implementation suggestions for the LSJR flow objectives involve water rights. These suggestions are described below.

Commenters suggested that this SED should evaluate a "No Action Implementation Alternative," with a program of implementation under which the 2006 Bay-Delta Plan narrative objective for LSJR flows would not be amended, D-1641 would remain in place, and USBR would be responsible for meeting D-1641. The No Project Alternative evaluated in this SED consists of these elements.

One commenter suggested an "Upstream Inclusion Alternative" that was to include flow contributions and implementation measures from throughout the entire historical SJR Watershed, including flow contributions upstream of the Merced River. The purpose of the plan amendments is to establish flow objectives and a program of implementation for the LSJR, including the three eastside salmon-bearing tributaries. This flow proposal applies to the entire migration pathway of salmon from the rim dams on the three salmon bearing tributaries of the SJR to the SJR near Vernalis. Currently, the SJR does not support salmon runs upstream of the Merced River confluence (Upper SJR). However, pursuant to the San Joaquin River Restoration Program (SJRRP), spring-run Chinook salmon are planned to be reintroduced to the Upper SJR no later than December 31, 2012. Flows needed to support this reintroduction are being determined and provided through the SJRRP. During the next review of the Bay-Delta Plan, the State Water Board will consider information made available through the SJRRP process, and any other pertinent sources of information, in evaluating the need for any additional flows from the Upper SJR Basin to contribute to the narrative LSJR flow objective. At this time, however, an alternative that would require flow contributions upstream of the Merced River would not meet the plan amendment goals of providing more flows on the three east-side salmon-bearing tributaries, unless it were in addition to flows on the Merced, Tuolumne, and Stanislaus Rivers. Additional flows from upstream of the Merced would increase, rather than reduce or substantially lessen, potentially significant environmental effects.

A "South Delta and Lower San Joaquin Alternative" was a commenter suggestion that would restrict water diverters in the southern Delta and LSJR from diverting water that was released upstream to meet the narrative objective. The alternative would include a mechanism to assure flows released pursuant to the narrative objective are not rediverted downstream for purposes other than meeting the narrative objective. The program of implementation in Appendix K, *Revised Water Quality Control Plan*, addresses this alternative with the following language:

> "The State Water Board will exercise its water right and water quality authority to help ensure that the flows required to meet the LSJR flow objectives are used for their intended purpose and are not diverted for other purposes."

This alternative would not reduce or substantially lessen potentially significant environmental effects.

3.4 Southern Delta Water Quality (SDWQ) Alternatives

The development of alternatives requires an understanding of the attributes of alternatives that could feasibly attain most of the basic objectives of the plan amendments but would avoid or substantially lessen any of the significant environmental effects. Attributes of salinity objective alternatives may be described or constrained by geographic scope, season and averaging period, and the level of protection. These attributes of salinity objectives can then be used to assess the potential for alternatives to achieve plan amendment goals and to have potential effects, in order to determine which alternatives are feasible, and should be evaluated, and which are infeasible, and may eliminated from further consideration.

In evaluating potential amendments to the Bay-Delta Plan, the State Water Board identified the fundamental purpose of the plan amendments:

> "To establish southern Delta water quality objectives for the reasonable protection of southern Delta agricultural beneficial uses and a program of implementation to achieve the objectives."

As discussed in Section 3.2, *Purposes and Goals*, the purpose of the plan amendments is to establish southern Delta water quality objectives for the reasonable protection of southern Delta agricultural beneficial uses. Salinity levels in the southern Delta are affected primarily by the salinity of water flowing into the southern Delta from the SJR near Vernalis and the evapoconcentration of salts in water diverted and discharged back into the channels. Point sources of salt in the southern Delta have a small overall salinity effect (Appendix C, *Technical Report on the Scientific Basis for Alternatives*, and Appendix E, *Salt Tolerance of Crops in the Southern Sacramento–San Joaquin Delta*). Accordingly, the State Water Board identified a numeric range of alternatives that would be met through flow as the means of protecting agricultural beneficial uses. Additional information related to southern Delta salinity is provided in Appendix C.

3.4.1 Attributes of the SDWQ Objectives

Attributes of salinity alternatives that inform the feasibility of alternatives and the ability of alternatives to avoid or substantially lessen any of the significant effects of the project are: magnitude/level of protection, seasonality and averaging period, geographic scope, and other measure, such as improved circulation.

Magnitude/Level of Protection

The magnitude of salinity alternatives could vary over a wide range because different crops have a wide range of sensitivities to salinity. Salt sensitivity is affected by a number of variables including soil characteristics, irrigation and management techniques, and rainfall. Salt sensitive crops of significance in the southern Delta include almond, apricot, dry bean, and walnut, with dry bean being the most sensitive. Analyses and modeling summarized in Appendix C, *Technical Report on the Scientific Basis for Alternatives*, show that water quality objectives could be 0.9–1.1 deciSiemens per meter (dS/m) and be protective of all crops normally grown in the southern Delta under current irrigation practices, although during low rainfall years, this might lead to yield loss of approximately 5 percent under certain conditions. Additional information summarized in Appendix E, *Salt Tolerance of Crops in the Southern Sacramento-San Joaquin Delta*, shows that crops such as alfalfa, although somewhat more salt tolerant, is frequently grown on low permeability soils with low leaching fractions. The report shows that alfalfa grown on low permeability soils (with a very low leaching fraction of 0.10) with irrigation water of 1.4 dS/m might lead to yield loss of approximately 5 percent under certain conditions (Appendix E, Figure 5.13).

Revision of other salinity objectives in the Bay-Delta Plan are not being considered at this time, including the salinity objectives for the protection of agricultural beneficial uses at the intakes of the Central Valley Project (Delta Mendota Canal at Tracy Pumping Plant) and State Water Project (West

Canal at Clifton Court Forebay). The objectives at these locations, which are west, and generally downstream of, the southern Delta salinity stations, are 1.0 dS/m on a monthly average, year-round. The federal Central Valley Project (CVP) and State Water Project (SWP) both also deliver water to cities for drinking water supply.

Drinking water has a Recommended Secondary MCL of 0.9 dS/m, with an Upper MCL of 1.6 dS/m and a Short Term MCL of 2.2 dS/m. Salinities lower than the Secondary MCL are more desirable to a higher degree of consumers, however, it can be exceeded and is deemed acceptable to approach the Upper MCL if it is neither reasonable nor feasible to provide more suitable waters.

For these reasons, water salinity of 1.4 dS/m was selected as the upper limit for SDWQ alternatives, even though this level is higher than other objectives in the immediate area and above the Recommended Secondary MCL. Salinity of 1.4 dS/m is the level at which crops in the southern Delta would have no more than a 5 percent yield loss, and still complies with the 1.6 dS/m drinking water Upper MCl.

This limit achieves goals 1 and 3.

1. Provide salinity conditions that reasonably protect agricultural beneficial uses of surface waters in the southern Delta."

3. Establish a salinity objective, supported by existing scientific information, that is not lower than necessary to reasonably protect the most salt sensitive crops currently grown or suitable to be grown on saline- and drainage-impaired soils in the southern Delta.

Salinity levels in the southern Delta are now maintained at levels generally no higher than approximately 1.0 dS/m because USBR is required, under terms of its water rights, to maintain EC levels of 0.7 dS/m at Vernalis for April– August and 1.0 dS/m for September–March, as a maximum 30-day running average. Salinity generally increases downstream of Vernalis, in the southern Delta, principally as a result of evapoconcentration of salt when the water is used and returned, in smaller quanities, by agriculture in the southern Delta. This evapoconcentation of salts is greatest during peak periods of irrigation and consumptive use of water, which corresponds to the April–August time period. The USBR maintains salinity at Vernalis through the release of low salinity water from New Melones Reservoir. Currently this requires the release of approximately 3 TAF per year (TAF/y) on average to meet the Vernalis salinity requirement. Although there are number of projects that have been developed and are currently under development to reduce salt loading in the SJR, release of stored water by USBR will continue to be the principal means to comply with the salinity objective at Vernalis.

Lowering the objective below the current seasonal requirements of 0.7 and 1.0 dS/m at Vernalis would require the release of even more water for the sole purpose of meeting the lower objective. This means that salinity objectives lower than 0.7 and 1.0 dS/m in the interior southern Delta locations could not be achieved without the release of stored water because salinity generally increases in the southern Delta downstream from Vernalis. Objectives lower than 1.0 were eliminated from consideration because if such low salinities were required in the interior southern Delta this would require much lower salinity at Vernalis to account for the degradation of water quality that occurs downstream, and thus the release of more stored water. Modeling of the No Project Alternative, which includes full compliance with current interior southern Delta salinity objectives, shows that approximately 60 TAF/y, on average, would have to be released from New Melones Reservoir to meet the 0.7 dS/m April–August and 1.0 ds/cm September–March objectives in the interior southern Delta (see Table D.3 in Appendix D, *Evaluation of No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)* for estimated New Melones water quality releases for baseline and the No Project Alternative). Water released from storage would not be available for other uses of water. Salinity objectives lower than 0.7 dS/m at Vernalis were eliminated from consideration because of the unreasonably high water costs.

In addition to achieving goals 1 and 3, evaluation of a southern Delta salinity objective no lower than 1.0 dS/m also achieves goals 2 and 4.

2. In establishing salinity water quality objectives to reasonably protect agricultural beneficial uses, take into consideration all of the demands being made and to be made on waters in the southern Delta, the LSJR and the three eastside, salmon-bearing tributaries and the factors to be considered for establishing water quality objectives in Water Code Section 13241, including, but not limited to, past, present and probable future beneficial uses and economic considerations.
4. Maintain or improve salinity conditions in the southern Delta to comply with state and federal antidegradation policies.

Seasonality and Averaging Period

Steady-state modeling presented in Appendix E, *Salt Tolerance of Crops in the Southern Sacramento-San Joaquin Delta*, and the results from other transient model studies suggest that the water quality objective could be increased up to 0.9 to 1.1 dS/m and be protective of all crops normally grown in the southern Delta under current irrigation practices. These models calculate the effect of irrigation water quality on soil water salinity, but it is soil water salinity that ultimately affects crop yield, not the salinity of the irrigation water itself. That is why it is possible, in general, to irrigate with higher salinity water on high permeability soils. With the adequate leaching provided by high permeability soils, salts are flushed from the root zone, thus keeping soil water salinities relatively low. The steady state and transient state modeling analysis all assume constant salinity, rather than variable mean annual or variable mean seasonal salinity. The models do, however, consider the effects of additional leaching of salts from the soil profile that occurs as a result of precipitation. Precipitation, unlike most irrigation water, contains no added salt, so has the effect of leaching salts from the soil.

This means that long averaging periods, longer than a 30-day average, have the potential to cause more significant local and seasonal negative effects. Short duration high salinity water supply has the potential to coincide with irrigation of crops, and could therefore have large negative effects because the irrigated crop does not "see" the average salinity. This is particularly the case if high salinity water coincides with irrigation of a salt sensitive crop during emergence and early seedling development, when crops can be most susceptible to damage from high salinity.

Shorter duration averaging periods were deemed infeasible because a short duration average would effectively lower the required salinity objective by reducing the ability to even out high and low salinities. As discussed under magnitude/level of protection above, this would have unreasonable water costs.

Geographic Scope

Different objectives could be considered at different locations to account for different soil types, circulation patterns in back channels of the Delta, and the ability to achieve certain threshold salinity. Variability in soils, including the variable leaching requirement of soils in the southern delta are discussed in Appendix E, *Salt Tolerance of Crops in the Southern Sacramento-San Joaquin Delta.* The irrigation water salinity requirements can vary depending on these and other such characteristics. Although more site-specific irrigation requirements, could be developed based on more detailed soil surveys and models, Appendix E has already taken into account the variability, and the most limiting characteristics of soils and crops grown in the southern delta, to determine, a range in irrigation water salinity that would result in no more than a 5 percent yield reduction for the most sensitive crops. This also means that most crops would not suffer yield reductions at all. Site specific salinity requirements would allow the salinity objective to be higher in some areas, but implementing such a set of variable objectives would be infeasible because of the mixed nature of the water supply.

Different salinity objectives could also be considered based on circulation patterns. Back water areas in the southern Delta, with poor circulation, are currently susceptible to locally higher salinity levels. As for varying soils, implementing a set of variable objectives would be infeasible to account for backwater areas because of the mixed nature of the water supply.

Finally, different salinity objectives could be considered to account for the need to provide assimilative capacity for downstream locations. This would be feasible for the Vernalis location because it is upstream of the interior southern Delta. Although feasible, a different objective in close proximity to other similar locations with the same beneficial use may suggest a different level of protection for the same use, which is not the case. As described below, the SDWQ alternatives rely upon the program of implementation to provide geographic variability by including an implementation provision for the needed assimilative capacity, instead of a different objective. As stated above, a salinity objective at Vernalis lower than 0.7 dS/m is infeasible. An implementation provision lower than 0.7 dS/m would therefore also be infeasible, and was not considered.

Other Measures

Measures other than salinity objectives could be employed to protect agricultural beneficial use. Such measures include improved (raised) water levels and improved flow patterns (circulation) that would have the effect of improving salinity conditions by evening out areas of high and low salinity and moving salts discharged into the southern Delta out of the area. Such measures could be used instead of, or in addition to, salinity objectives. There is a risk, however, that use of such measures without any numeric salinity objective may not protect agricultural beneficial uses. Improved circulation of high salinity water may help to move salts, but the agricultural use would still not be protected if background salinity is still high. Other measures are, therefore, most useful if combined with numeric objectives, unless specific physical measures can be identified and fully relied upon to protect the use.

3.4.2 SDWQ Alternatives Considered

This SED evaluates SDWQ Alternative 1 (No Project Alternative) and two other SDWQ alternatives (SDWQ Alternatives 2 and 3). SDWQ Alternatives 2 and 3 are comprised of a numeric objective and an associated program of implementation. SDWQ Alternatives 2 and 3 have different numeric objectives, which are described in detail below, and the same program of implementation. The different numeric objectives provide a basis for analyzing a range of alternatives that are not lower than necessary to reasonably protect the agricultural beneficial uses. The range of alternatives analyzed in this SED is based on the water quality needs of the most salt-sensitive crops grown in the southern Delta, the predominant soil type, and irrigation practices in the area. The range of alternatives analyzed help to inform which alternatives meet the purposes and goals of the plan amendments as discussed in Section 3.2, *Purposes and Goals*, while minimizing any potentially significant effects.

Appendix K, *Revised Water Quality Control Plan*, contains the proposed program of implementation for the southern Delta salinity objective. The program of implementation for SDWQ Alternatives 2 and 3 would require the USBR to continue complying with the terms of its water rights that require implementation of EC[8] levels of 0.7 dS/m at Vernalis for April–August and 1.0 dS/m for September–March as a maximum 30-day running average. This is in order to provide assimilative capacity so that the year-round salinity objective 1.0 dS/m can be met in the interior southern Delta after the consumptive use of water and evapoconcentration of salts that occur as a result of agricultural activities in the southern Delta downstream of Vernalis.

DWR and USBR are currently required, as a condition of their water rights, to meet EC levels of 0.7 dS/m from April–August and 1.0 dS/m from September–March at the three compliance stations in the interior southern Delta (Interagency Stations Nos. C-6, C-8, and P-12). As part of implementing the salinity objective for the interior southern Delta, DWR and USBR would be required to instead comply with the 1.0 dS/m objective year-round as a condition of their water rights.

DWR and USBR would also be required to develop a comprehensive operations plan to address the impacts of CVP and SWP export operations on interior southern Delta salinity levels. The operations plan must include detailed information, including describing actions that will address the impacts of SWP and CVP export operations on water levels and flow conditions that may affect salinity conditions in the southern Delta, containing information about the configuration and operations of any facilities relied upon in the plan, and identifying specific performance goals for the facilities.

USBR and DWR's water rights would also be conditioned to require continued operations of the agricultural barriers at specified locations, or other reasonable measures, to address the impacts their export operations. In addition, the program of implementation requires DWR and USBR to develop a long-term Monitoring and Reporting Plan to implement and determine compliance with the salinity objective and to inform the comprehensive operations plan. The agencies will be required to perform monitoring, modeling, special studies, and reporting activities, in coordination with other study and monitoring programs.

The program of implementation also includes recommendations to other agencies that would assist in meeting the SDWQ objective. SDWQ Alternatives 1, 2, and 3 are detailed below. As discussed earlier in this chapter, SDWQ Alternatives 2 and 3 have different numeric objectives but the same programs of implementation.

3.4.3 SDWQ Alternative 1: No Project Alternative

As discussed above in Section 3.3.4, *LSJR Alternative 1: No Project Alternative*, State CEQA Guidelines Section 15126.6, Subdivision (e) requires the evaluation of a no project alternative. When a project is the amendment of a regulatory plan, such as the 2006 Bay-Delta Plan, the no project alternative

---

[8] In this document, EC is *electrical conductivity*, which is generally expressed in deciSiemens per meter (dS/m). Measurement of EC is a widely accepted indirect method to determine the salinity of water, which is the concentration of dissolved salts (often expressed in parts per thousand or parts per million). EC and salinity are, therefore, used interchangeably in this chapter.

will be the continuation of the existing plan into the future. In evaluating the impacts of a no project alternative, a lead agency should consider what is reasonably expected to occur in the foreseeable future. SDWQ Alternative 1 (No Project Alternative) assumes full compliance with the water quality objectives in the 2006 Bay-Delta Plan. In addition, the No Project analysis includes flows required by other entities such as the NMFS 2009 BO flow requirements on the Stanislaus River, FERC requirements on the Tuolumne and Merced Rivers, and the Davis Grunsky requirements on the Merced River. SDWQ Alternative 1 is the continuation of the existing water quality objectives for agricultural beneficial uses for the southern Delta contained in the 2006 Bay-Delta Plan as currently implemented by DWR and USBR. The 2006 Bay-Delta Plan states that the maximum 30-day running average of mean daily EC is 0.7 millimhos per centimeter (mmhos/cm)[9] April 1–August 30 and 1.0 mmhos/cm September 1–March 31 for all water year types. This is applicable to the three interior compliance stations (C-6, C-8, and P-12) and the compliance station at Vernalis (C-10). Under baseline, these salinity levels are not always fully met.

Chapter 15, *LSJR No Project Alternative (Alternative 1 and SDWQ Alternative 1),* and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*, evaluate the potential impacts of the No Project Alternative. As described in Section 3.3.4, *LSJR Alternative 1: No Project Alternative*, LSJR Alternative 1 and SDWQ Alternative 1 are evaluated together as the No Project Alternative in Chapter 15 and Appendix D because continuation of the 2006 Bay-Delta Plan would require compliance with the Vernalis flow objectives and southern Delta salinity objective. Further, the proposed plan amendments consist of the revised flow and salinity water quality objectives and the LSJR flows are necessary to help achieve the salinity water quality objectives.

3.4.4 SDWQ Alternative 2

SDWQ Alternative 2 would establish a numeric salinity objective of 1.0 dS/m as a maximum 30-day running average of mean daily EC for all months in the SJR between Vernalis and Brandt Bridge, Middle River from Old River to Victoria Canal, and Old River/Grant Line Canal from the Head of Old River to West Canal.

3.4.5 SDWQ Alternative 3

SDWQ Alternative 3 is the same as SDWQ Alternative 2 except the maximum 30-day running average of mean daily EC is 1.4 dS/m for all months. The compliance locations are the same as for SDWQ Alternative 2. The program of implementation for SDWQ Alternatives 2 and 3 is the same. This alternative would lessen the impact on service providers because they would be able to reduce the level of treatment needed to comply with salinity requirements. This would, however, result in slightly higher salinity in some southern Delta channels, which would result in slightly lower yields of salt-sensitive crops.

3.4.6 SDWQ Alternatives Considered but Eliminated from Further Evaluation

The State Water Board is considering modifications to existing SDWQ salinity objectives to protect agricultural beneficial uses in the southern Delta. The range of alternatives examined in this SED

---

[9] In this SED, electrical conductivity (EC) is generally expressed in deciSiemens per meter (dS/m). The conversion is 1 mmhos/cm = 1 dS/cm).

considers the information and overall conclusions provided in Appendix E, *Salt Tolerance of Crops in the Southern Sacramento–San Joaquin Delta*, and public comments.

In developing the SDWQ alternatives, the State Water Board considered public comments regarding alternatives to the southern Delta salinity objective and its implementation. Several comment letters suggested the State Water Board analyze salinity objectives within the range of the State Water Board's SDWQ alternatives, and the Board did not analyze those specific recommendations separately because they were already considered in the range of alternative analyzed. There were a few commenters who suggested the State Water Board analyze salinity objectives below 0.7 dS/m, which does not meet the plan amendment goal of establishing a salinity objective that is not lower than necessary to reasonably protect the most salt sensitive crops currently grown or suitable to be grown on saline-and drainage-impaired soils in the southern Delta. It also would not lessen environmental impacts. Other commenters suggested that the State Water Board could further analyze southern Delta salinity issues and water circulation to identify specific actions that could be implemented to improve southern Delta salinity. The program of implementation includes monitoring, special studies, and reporting to identify actions that will fully address the impacts of the SWP and CVP export operations on water level and flow conditions that may affect salinity conditions in the southern Delta. Based on the information contained in Appendix E, the State Water Board believes there is adequate science at this time to refine the numeric salinity objective for the southern Delta. This SED analyzes the environmental impacts of a range of salinity objectives, expressed as a maximum 30-day running average of mean daily EC in dS/m. The State Water Board's SDWQ alternatives are presented in Table 3-10, and a more detailed description of these alternatives was presented earlier in this chapter (Section 3.4, *Southern Delta Water Quality [SDWQ] Alternatives)*.

Table 3-10. State Water Board's Southern Delta Water Quality (SDWQ) Alternatives

Southern Delta Water Quality Alternatives	Electrical Conductivity Values Analyzed in this SED
SDWQ Alternative 1, No Project Alternative	0.7 dS/m April–August 1.0 dS/m September–March
SDWQ Alternative 2	1.0 dS/m all year
SDWQ Alternative 3	1.4 dS/m all year

dS/m = deciSiemens per meter

Following is a description of the salinity objective recommendations submitted by commenters and a discussion of how they were considered in the development of the SDWQ alternatives.

South Delta Water Agency

In its letter dated May 15, 2009, the South Delta Water Agency (SDWA) submitted comments on the proposed SDWQ modeling alternatives (SDWA 2009) and suggested analyzing longer and more restrictive requirements. The SDWA comments include recommendations for the State Water Board to analyze salinity objectives at Vernalis (C-10) and three interior compliance locations (P-12, C-8, and C-6). These SDWA recommendations (Recommendations 1–3) are listed below.

1. 0.65 dS/m April–August.
2. 0.65 dS/m April–October.
3. 0.70 dS/m April–October.

In addition to these analyses, SDWA recommended the State Water Board analyze salinity objectives under dry conditions at Vernalis (C-10) and three interior compliance locations (P-12, C-8, and C-6). The dry condition SDWA recommendations (Recommendations 4–6) are listed below.

4. 0.65 dS/m March–August.
5. 0.65 dS/m March–October.
6. 0.70 dS/m March–October.

It was determined in Appendix E, *Salt Tolerance of Crops in the Southern Sacramento–San Joaquin Delta*, that existing water quality in the southern Delta was adequate for all agricultural crops. Based on steady-state soil water salinity analysis and published crop salt tolerance information, Appendix E concludes that salinity levels in the range of 0.9 dS/m–1.1 dS/m in irrigation water appear to be reasonably protective of the most salt-sensitive crops grown in the southern Delta. One of the State Water Board's goals for the plan amendments is to develop objectives that are not lower than necessary to reasonably protect the most salt sensitive crops currently grown or suitable to be grown on saline- and drainage-impaired soils in the southern Delta; therefore, this SED does not evaluate alternatives that provide more protection than is needed for the reasonable protection of the beneficial uses. Therefore, no SED alternative evaluates objectives less than the current objectives (i.e., those in the 2006 Bay-Delta Plan).

Contra Costa County Department of Conservation and Development

The CCCDCD submitted scoping comments on the *Southern Delta Agriculture and San Joaquin River Flows Revised Notice of Preparation* (CCCDCD 2011). The CCCDCD scoping comments included recommendations for the State Water Board to analyze two additional salinity objectives.

1. 0.6 dS/m April–August (as 30-day running average of mean daily) and 0.85 dS/m September–March (as 30-day running average of mean daily) at Vernalis (C-10). 0.7 dS/m April–August (as 30-day running average of mean daily) and 1. 0 dS/m September–March (as 30-day running average of mean daily) at interior compliance locations (P-12, C-8, and C-6).
2. 0.6 dS/m April–August (as 30-day running average of mean daily) and 0.85 dS/m September–March (as 30-day running average of mean daily) at Vernalis (C-10) and interior compliance locations (P-12, C-8, and C-6).

The CCCDCD recommendations are also equal to or less than existing objective levels. It was determined in Appendix E, *Salt Tolerance of Crops in the Southern Sacramento–San Joaquin Delta*, that existing water quality in the southern Delta was adequate for all agricultural crops. One of the State Water Board's goals for the plan amendments is to develop objectives that are not lower than necessary to reasonably protect the most salt sensitive crops currently grown or suitable to be grown on saline- and drainage-impaired soils in the southern Delta. Therefore, this SED does not evaluate alternatives that provide more protection than is needed for the beneficial uses, and no SED alternative evaluates objectives less than the current objectives in the 2006 Bay-Delta Plan.

San Joaquin River Group Authority

O'Laughlin and Paris LLP reviewed the *Peer Review Draft Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives* and prepared comments on behalf of the San Joaquin River Group Authority (SJRGA) (O'Laughlin and Paris LLP 2012). The

SJRGA comments included recommendations for the State Water Board to analyze five additional salinity objectives, which are as follows.

1. 0.7 dS/m March 15–October 31 at interior compliance locations (P-12, C-8, and C-6). Remove the Vernalis (C-10) compliance location.
2. 0.7 dS/m March 15–October 31 at Vernalis (C-10) and interior compliance locations (P-12, C-8, and C-6).
3. 1.0 dS/m March 15–October 31 at Vernalis (C-10). Remove interior compliance locations (P-12, C-8, and C-6).
4. For Recommendations 1–3, modify the salinity objective for April 1–June 31 to be 1.0 dS/cm maximum with a 10-year running average of 0.7 dS/cm at Vernalis (C-10) and interior compliance locations (P-12, C-8, and C-6).
5. For Recommendations 1–3, modify the salinity objective at Vernalis (C-10) for November 1–March 14 to be 1.4 dS/cm maximum with a 10-year running average of 1.2 dS/m. For the same time period, eliminate all salinity objectives at the interior compliance locations (P-12, C-8, and C-6), or set a 1.4 dS/m maximum.

Similar to the State Water Board's SDWQ Alternative 1, the recommendations provided by SJRGA are seasonal water quality objectives. However, unlike the SDWQ alternatives and the other recommendations received, the SJRGA recommendations are only effective for a portion of the year dependent on the recommendation (e.g., SJRGA Recommendations 1, 2, and 3 are only effective March 15–October 31).

SJRGA Recommendations 1, 2, and 3, contain salinity objectives that are encompassed in the SDWQ Alternative 1 objectives. SDWQ Alternatives 1 and 2 encompass the salinity objectives of SJRGA Recommendation 4. SDWQ Alternative 3 encompasses the salinity objectives of SJRGA Recommendation 5. These recommendations do not avoid or lessen any significant impacts and, to the extent they would provide more protection than is needed for the beneficial uses, they do not meet goal 3.

In addition to salinity objectives, SJRGA included specific recommendations pertaining to compliance locations and running averages that were not included in the salinity recommendations received. In SJRGA Recommendation 1, SJRGA recommends the removal of the Vernalis compliance location. Conversely, in SJRGA Recommendations 3 and 5, SJRGA recommends the removal of the interior compliance locations. The Vernalis and the interior compliance locations may not be eliminated because beneficial uses exist there and must be protected. In addition to the elimination of compliance locations, SJRGA Recommendations 4 and 5 included a maximum 10-year running average of 0.7 dS/m and 1.2 dS/m, respectively. The SJRGA recommendations do not provide a technical basis, nor is there one known, for the need to have a 10-year running average. Long averaging periods, longer than a 30-day average, have the potential to cause significant local and seasonal negative effects on crop yields, so does not achieve goal 1 to provide salinity conditions that reasonably protect agricultural beneficial uses of surface waters in the southern Delta.

City of Tracy

In a letter dated May 15, 2009, the City of Tracy recommended that sodium adsorption ratios should be used as the appropriate objective to protect irrigated agriculture instead of EC. The City of Tracy also recommended that experts should be polled as to the constituent(s) of EC that are of concern for irrigated agriculture, and the 2006 Bay-Delta Plan should be modified to remove EC objectives and include objectives only for those problematic constituents of EC (Downey Brand 2009).

Crop stress associated with salinity is caused by the increase in osmotic pressure across the root membranes, which makes it more difficult for plants to uptake water for evapotranspiration. This increase in osmotic pressure is due to the colligative properties of the soil water in the root zone and is not dependent on the type of solute particles, only their concentration. EC has been the standard way of quantifying this property in soil water as used in nearly all of the supporting literature and appears to be an appropriate measure of the relevant soil water properties. Alternatives based on sodium adsorption ratio, or other problematic constituents, do not address factors affecting crop stress (i.e., increased osmotic pressure). Such alternatives do not meet goal 1 of providing salinity conditions that reasonably protect agricultural beneficial uses of surface waters in the southern Delta, a goal that would include protecting against crop stresses such as increases in osmotic pressure.

U.S. Department of the Interior/U.S. Bureau of Reclamation

In its letter dated May 15, 2009, DOI/USBR suggested that the following recommendations be considered in the development and evaluation of the SED alternatives (USBR 2009).

- Add an alternative that includes no salinity objective at Vernalis, or downstream of Vernalis, during the nonirrigation season months.
- Use the modeling process to help identify carryover storage levels in all of the major SJR Basin reservoirs to meet the needs of all beneficial uses (possibly including dilution flows) in the short and long term.
- Include consideration of the Central Valley Water Board's total maximum daily load implementation program, which is based on the Vernalis salinity standard.
- Examine the system through a loading approach as well as a dilution flow approach. A loading approach could also examine the opportunities that other flow requirements provide for exporting salt loads from the basin and the potential for redirected impacts when salinity loads are sequestered in groundwater basins.
- Evaluate how changes to a southern Delta salinity objective may affect water control systems, which in turn could affect the control of coldwater resources and/or the value of fish habitat using a water temperature model for the SJR Basin.

The first recommendation is not an acceptable alternative for evaluation in the SED as it does not provide for protection of beneficial uses in the months of September–March. It, therefore, does not meet an underlying fundamental goal of the plan amendments to reasonably protect agricultural beneficial uses. The recommendations regarding the quantity of dilution flows needed to meet the salinity objective were considered under the No Project Alternative. Modeling of the No Project Alternative, which includes full compliance with current interior southern Delta salinity objectives, shows that approximately 60 TAF/y, on average, would have to be released from New Melones Reservoir to meet the 0.7 dS/m April–August and 1.0 ds/cm September–March objectives in the interior southern Delta (see Table D.3 in Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1).* The other recommendations described above could not be evaluated as alternatives in the SED, as they are recommendations about issues to consider in the cumulative impacts analysis or to consider during implementation of the SDWQ objective.

Stockton East Water District

In its comments received on May 15, 2009, the Stockton East Water District (SEWD) made the following specific recommendations (SEWD 2009).

- A monthly average salinity objective greater than 1.0 dS/m should be modeled to develop appropriate salinity limitations for evaluation.
- A monthly average EC at Vernalis of 1.5 mmhos/cm in all months and a monthly average EC at Brandt Bridge of 1.5 mmhos/cm and 1.8 mmhos/cm in all months should be modeled.
- Include the water year type in establishing the objectives. Modeling should be conducted to determine the effects that water year types have on the salinity objective. It may be appropriate to have differing salinity objectives based on water year type.

Because 1.4 dS/m was the level above which yield impacts became significant for salt sensitive crops, consideration of higher alternatives were not appropriate as the associated beneficial uses would not be adequately protected (Appendix E, *Salt Tolerance of Crops in the Southern Sacramento–San Joaquin Delta*). Also, crop salt tolerance is not a function of water year type; therefore, alternatives and modeling based on water year type are not technically appropriate.

Central Delta Water Agency

In its letter dated May 14, 2009, the Central Delta Water Agency (CDWA) provided four general recommendations regarding the SDWQ alternatives (CDWA 2009).

The first recommendation was that the sufficiency of the existing objectives to protect agricultural beneficial uses should be verified, and the existing objectives should be modeled and compared with all other alternatives. The existing objectives should be among the modeled alternatives to see how meeting the existing objectives compares with the other alternatives. This recommendation was incorporated into SDWQ Alternative 1.

The second recommendation was that an objective lower than the current 0.7/1.0 dS/m EC objective (e.g., 0.6/0.9 dS/m EC), should be modeled in the context of the current regime. Also, the existing objectives should be modeled with 0.7/1.0 dS/m EC substituted with 0.7 dS/m EC year-round. Appendix E, *Salt Tolerance of Crops in the Southern Sacramento–San Joaquin Delta*, describes that existing water quality in the southern Delta was adequate for all agricultural crops. The State Water Board determined that a goal would be to provide salinity conditions that reasonably protect agricultural uses, but it would not establish objectives that are lower than necessary to reasonably protect the most salt sensitive crops. Thus, alternatives that provided more protection than necessary did not meet the goals and were not considered.

The third recommendation was to include improvements to the southern Delta barrier program to better improve circulation, eliminate stagnant zones, etc., as well as recirculation of water exported from the Delta. USBR studies show limited benefits and significant environmental and economic impacts associated with recirculation so are not included in the SDWQ alternatives. The program of implementation includes requirements for the CVP and SWP projects to develop a coordinated operations plan to address their impact on assimilative capacity in the southern Delta. This coordination operations plan process can address the issues of improved circulation, elimination of stagnant zones, and recirculation.

Finally, CDWA recommended that alternatives should be designed to ensure that the full water supply needs of the New Melones Reservoir area of origin contractors are met. Placing water supply needs above protection of agricultural beneficial uses, however, is inconsistent with the fundamental purpose and goals of the plan amendments. Water supply effects, however, are inherently considered as part of goals 1, 2, and 3.

County of San Joaquin and the San Joaquin County Flood Control and Water Conservation District

In their letter dated May 15, 2009, the County of San Joaquin and the San Joaquin County Flood Control and Water Conservation District made two general comments (Neumiller & Beardslee 2009).

First, the two entities recommended that at least one of the model alternatives needs to include salinity monitoring objectives at locations within the southern Delta and that it is necessary to have Vernalis monitoring and compliance requirements. They recommended that both the interior Delta monitoring locations and the Vernalis monitoring location must remain. The Vernalis monitoring location will continue as a compliance location under the program of implementation for all alternatives. Specific monitoring locations for the interior Delta compliance locations will be determined under the program of implementation. The program of implementation, under all alternatives, provides flexibility on the specific locations and averaging periods. Second, it was recommended that an annual average could lead to "terrible" irrigation season flows being made up for with significantly better winter flows. The salinity objectives recommendation included meeting a minimum monthly compliance requirement and meeting the salinity objective at even more frequent intervals. It is agreed that an annual average objective could allow for unacceptably high concentrations during the growing season. But no information has been provided suggesting that an averaging period of less than a month is necessary. Soil water salinity levels are affected more by average conditions over the growing season than by short-term changes. The historical variability of daily salinity measurements and crop yields does not suggest that variability within a 30-day averaging period has negative effects on crop yields. Shorter averaging periods would require more water to be released to meet the shorter term requirement, so is inconsistent with the goal of considering other water supply demands.

Chapter 4
Introduction to Analysis

4.1 Introduction

The State Water Resources Control Board (State Water Board) is considering amendments to the 2006 *Water Quality Control Plan for the San Francisco Bay/Sacramento–San Joaquin Delta Estuary* (2006 Bay-Delta Plan) that would establish new Lower San Joaquin River (LSJR) flow objectives for the protection of fish and wildlife beneficial uses, revise the southern Delta water quality objectives (SDWQ) for salinity for the protection of agricultural beneficial uses, and establish a program of implementation to achieve those objectives.

This chapter provides an overview of the following topics: modifications made in this recirculated Substitute Environmental Document (SED) since the public draft 2012 SED (2012 Draft SED) was released on December 31, 2012; the framework for analysis; document and chapter organization; terminology used; baseline; and modeling and technical analyses.

4.2 Recirculated SED

The State Water Board has revised and recirculated the 2012 Draft SED released on December 31, 2012. This SED is a recirculated document that makes substantial changes from the 2012 Draft SED in consideration of the large number of oral and written public comments received concerning that document, and in light of additional information, including information stemming from the recent drought and in response to the state's adoption in 2014 of a state policy for sustainable groundwater management (Wat. Code, § 113) and passage of the Sustainable Groundwater Management Act (SGMA) (Wat. Code, §§ 10720 et seq.), which provide for sustainable local groundwater management. A summary of major changes made to address these concerns follows.

The State Water Board received approximately 4000 comments on the 2012 Draft SED during the public comment period (December 31, 2012 to March 29, 2013). The comments received on the 2012 Draft SED are in the administrative record and a summary of the comment letters is found in Appendix M, *Summary of Public Comments on the 2012 Draft SED*. Because the State Water Board is recirculating the entire document, it does not need to respond to the comments on the 2012 Draft SED. Instead, the State Water Board need only respond to comments submitted in response to this recirculated, revised SED. The State Water Board, however, has considered the major themes raised by the comments on the 2012 Draft SED in preparing this revised SED.

4.2.1 Hydrologic Modeling

Comments were received on the 2012 Draft SED regarding the assumptions used in developing the Water Supply Effects (WSE) model and the use of the WSE model to analyze impacts. In response, the WSE model was modified for use in this SED. Changes are summarized below. Appendix F.1, *Hydrologic and Water Quality Modeling*, provides additional details.

- The WSE model was modified to provide a representation of baseline conditions based on and calibrated to CALSIM[1] data but not using the CALSIM model results directly to represent the baseline scenario as was done in the 2012 Draft SED. The WSE model is used independently to simulate both the baseline and the LSJR alternatives for the purpose of analyzing impacts in this SED. The assumptions for the WSE modeled baseline and the LSJR Alternatives 2, 3, and 4 are listed below. All assumptions apply to both the modeled baseline and alternatives, except for the Vernalis Adaptive Management Plan (VAMP) minimum flow requirements (first bullet below, which were only included in the modeled baseline) and LSJR alternative minimum flow requirements, which are applied only in LSJR alternative scenarios.
    - VAMP minimum flow requirements on the Stanislaus and Merced Rivers per the San Joaquin River Agreement (SJRA) (USBR and SJRGA 1999). Water Right Decision D-1641 (D-1641) minimum flow requirements are in effect for February 1–June 30 for both baseline and the LSJR alternatives, although in baseline, D-1641 flows are replaced with the VAMP flow requirement volumes in April and May only.
    - Reasonable and Prudent Alternative (RPA) Action 3.1.3 of the June 2009 National Marine Fisheries Service (NMFS) Biological Opinion (BO) to the U.S. Bureau of Reclamation (USBR) for the long-term operation of the Central Valley Project (CVP) and the State Water Project (SWP) (Operational Criteria and Plan [OCAP]) minimum streamflows at Goodwin Dam required by BO Appendix 2E as a function of the New Melones Index (NMFS 2009).
    - Stanislaus River maximum CVP diversions based on a 155 thousand acre-feet (TAF) total maximum for Stockton East Water District (SEWD) and Central San Joaquin Water Conservation District (CSJWCD) (USBR 2013a, 2013b), and 600 TAF for South San Joaquin Irrigation District (SSJID) and Oakdale Irrigation District (OID) per the 1988 Stipulation Agreement with USBR (SJRGA 1999).
    - Implementation of LSJR alternative minimum flow requirements as a percent of unimpaired flow[2] February–June during high flow events.
    - Future San Joaquin River Restoration Program (SJRRP)[3] flows are not included.
- The WSE model calculates flow in each tributary as a continuous simulation for all months year-round, including July–January, as opposed to relying on CALSIM output for those months, as was done in the 2012 Draft SED. Streamflows are based on the minimum flow requirements applicable to each tributary and Vernalis, plus any reservoir releases needed to maintain compliance with flood storage curves. The model continues to use estimates of reservoir

---

[1] CALSIM is a generalized water resource simulation model for evaluating operational alternatives of the State Water Project (SWP)/Central Valley Project (CVP) system (USBR 2005). CALSIM II is the latest application of the generic CALSIM model to simulate SWP/CVP operations. CALSIM and CALSIM II are products of joint development between the California Department of Water Resources (DWR) and the U.S. Bureau of Reclamation (USBR). This document uses CALSIM and CALSIM II interchangeably.

[2] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.

[3] Implementation of the settlement and the Friant Dam release flows required by the San Joaquin River Restoration Program are expected to increase the existing SJR flows at Stevinson in the near future.

inflows, downstream accretions and depletions, and other inputs as developed by USBR for CALSIM.

- The previous WSE modeling in the 2012 Draft SED was configured to closely match the baseline distribution of end-of-September storage levels in the main reservoirs on each tributary. The modified WSE model calculates the amount of water available for diversion each year based on the sum of available end-of-February storage plus March–September inflows, less the sum of March–September river flow requirements and end-of-September minimum storage guidelines (the latter subject to annual drawdown limitations). Available water is then compared against estimates of surface water demand (primarily agricultural irrigation) for the year, with the lesser determining the amount diverted.
- The WSE model has multiple reservoir storage controls to both maintain empty storage capacity for flood control and to maintain carryover storage for coldwater reserves to ensure there are no temperature-related impacts on fisheries during the summer and fall. Reservoir releases for diversion are restricted based on minimum end-of-September storage guidelines in the model. Each year, only a certain percentage of the available water (i.e., the amount above what is required to meet end-of-September storage and in-stream flow requirements) can be released from storage for diversion. This protects storage prior to dry years. In addition, when reservoir levels are low (typically after a dry years) the model limits the amount of inflow that can be used in a subsequent wet year(s) for diversion. By reducing the amount of inflow that can be diverted in such years, reservoirs and associated coldwater pools recover more quickly after dry year(s).
- Diversion demands for major irrigation districts are derived from annually- and monthly-varying Consumptive Use of Applied Water (CUAW) demand estimates from CALSIM, with operational efficiency estimates derived from Agricultural Water Management Plans (AWMPs), and total diversion and use adjusted for best match to AWMP surface water use data. For smaller diversions, CALSIM values are used.
- The WSE model is calibrated to best match to CALSIM baseline diversions, streamflows, and reservoir levels. This exercise demonstrates the WSE model's effectiveness in representing system dynamics similarly to the CALSIM model.
- The water budget quantities in the WSE model are improved and based on published estimates of reservoir losses, municipal and industrial water use, and other factors described in Appendix F.1. The final WSE baseline used in LSJR alternatives analysis includes all of the above changes, but with additional revisions to improved parameters. This differs slightly from the original CALSIM baseline.
- In some water year types, a portion of LSJR alternative instream flow requirement has been "shifted" outside of the February–June period to summer or fall months to avoid temperature impacts caused by lower reservoir levels and to represent one of the methods of adaptive implementation as described in Chapter 3, *Alternatives Description*.
- Maximum streamflows ("flow caps") in downstream reaches have been removed.

4.2.2 Dry Year Evaluation

The 2012 Draft SED analyzed the effects of the flow proposal over an 82-year period of varied hydrology, which included dry years. It did not, however, specifically identify the water supply effects in dry years and consecutive dry years. This SED includes a new chapter Chapter 21, *Drought*

Evaluation, which provides analyses of dry years and multiple dry years. The drought years during the 1922–2003 time period that were modeled using the WSE model are compared with the more recent period of 2004–2015. This new analysis provides an examination and evaluation of the effects of LSJR Alternatives 2, 3, and 4 on reservoir operations and water supply for the more recent drought years from 2012–2015 to verify that water supply effects of drought conditions were accurately calculated and evaluated by the WSE model. It also includes a comparison of available water supply and other parameters during drought periods under baseline conditions and under LSJR Alternatives 2, 3, and 4.

4.2.3 Antidegradation Analysis

The 2012 Draft SED did not contain an antidegradation analysis. This SED contains an antidegradation analysis in Chapter 23, *Antidegradation Analysis*. The antidegradation analysis evaluates LSJR Alternative 3 and unimpaired flows ranging from 20 percent to 60 percent, and SDWQ Alternative 2 to assess the effect of the alternatives on water quality.

4.2.4 Fish Benefits Analyses

This recirculated SED includes Chapter 19, *Analyses of Benefits to Native Fish Populations from Increased Flow Between February 1 and June 30*, which is intended to assist the public with understanding the expected benefits of the LSJR alternatives to native fish. The chapter describes biologically important and measurable benefits of providing higher and more variable flow during the February 1–June 30 time period, with a focus on improved water temperature conditions and enhanced floodplain inundation. The chapter also presents results from a life-history population simulation model (SalSim) for fall-run Chinook salmon originating from the LSJR and the three eastside tributaries[4] to provide insight into population level changes that could be expected under a variety of flow conditions. These new analyses document the ecological linkages between flow, temperature, habitat, and other important criteria for evaluating the expected biological benefits over a range of percent of unimpaired flows encompassed by LSJR Alternatives 2, 3, and 4. The results of the temperature, floodplain, and SalSim evaluations indicate that as the percentage of unimpaired flow increases during the February–June time period, habitat conditions important to native fish can improve dramatically, and the number of adult salmon produced by the the three eastside tributaries would be expected to increase substantially compared to baseline conditions during the time period of 1994–2010.

The fish benefits analyses in Chapter 19 includes the following.

- Discussion of the importance of temperature for key fish species and their lifestages.
- A temperature analysis using San Joaquin River Basin-Wide Water Temperature Model for LSJR Alternatives 2, 3, and 4.
- Discussion of natural flow variation and floodplain inundation for key fish species and their lifestages and a floodplain analysis using the WSE model and floodplain area-versus-flow relationships to evaluate changes in frequency and magnitude of floodplain inundation events for LSJR Alternatives 2, 3, and 4.

---

[4] In this document, the term *three eastside tributaries* refers to the Stanislaus, Tuolumne, and Merced Rivers.

- SalSim analysis using WSE model results and temperature model results as input to explore and compare a variety of flow scenarios, including LSJR Alternatives 2, 3, and 4, in terms of modeled population-level responses of fall-run Chinook salmon from the Stanislaus, Tuolumne, and Merced Rivers.
- Discussion of the other expected benefits to native fish and wildlife.

4.2.5 Fish Impact Analyses

In response to comments on the 2012 Draft SED, Chapter 7, *Aquatic Biological Resources*, now analyzes flow impacts (e.g., cumulative distributions of weighted usable area values) based on changes in the magnitude and frequency of modeled flows over the 82-year modeling period instead of using median flows. It also includes a qualitative discussion regarding other fish species and incorporates Instream Flow Incremental Metholology and predation information where appropriate.

4.2.6 Groundwater Effects and Agricultural Resource Modeling

The analysis in the 2012 Draft SED did not attempt to quantify how much of the surface water supply deficit under the LSJR alternatives would be replaced by groundwater supplies. Instead, the 2012 Draft SED analyzed both full replacement by groundwater and no replacement, thereby accounting for the range of possible effects. As described in Appendix G, *Agricultural Economic Effects of Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*, this recirculated SED now evaluates the likely levels of groundwater replacement, surface water storage and reservoir reoperation, and quantity of surface water deficit not replaced by additional groundwater pumping. This updated analysis relies on new information provided by the water districts and is reflective of additional groundwater pumping capacity developed during recent drought years. Although this approach is intended to reasonably identify the most likely balance between water supply deficit and additional groundwater pumping, the precise balance is unknowable. The updated results from the groundwater pumping analysis are used in Chapter 9, *Groundwater Resources,* Chapter 13*, Service Providers,* and Chapter 22*, Integrated Discussion of Potential Municipal and Domestic Water Supply Management Options.*

This recirculated SED also uses the Statewide Agricultural Production (SWAP) model to perform an agricultural economic analysis. SWAP, an agricultural production model, is used to estimate the direct revenue and crop production effects associated with changes in applied water for agriculture, which is similar to how it was used in the 2012 Draft SED. However, as described in Appendix G, the results of the WSE model are post-processed differently, and the geographic boundaries for the SWAP analysis differ from the 2012 Draft SED. The geographic boundaries used in the SWAP modeling were refined from the 2012 Draft SED to include six geographic areas representing the different irrigation districts that could be most affected by the LSJR alternatives, rather than one aggregated region. Estimates of applied water are determined based on surface water diversions calculated in the WSE model and on groundwater pumping to replace surface water deficit calculated in the groundwater analysis. The applied water estimates are used, along with crop distributions from the California Department of Water Resources (DWR), as inputs for SWAP to estimate agricultural production and associated revenues under baseline conditions and LSJR Alternatives 2, 3, and 4. The changes to the agricultural economics analysis and the additional inputs to the SWAP model provide a more refined analysis, while taking into account potential groundwater pumping.

4.2.7 City and County of San Francisco Water Operations and Supply Analyses

The 2012 Draft SED contained a limited evaluation of the City and County of San Francisco (CCSF) water operations and supply. This SED includes additional analyses to address potential impacts on CCSF in Appendix L, *City and County of San Francisco Analyses,* Chapter 13, *Service Providers*, and Chapter 16, *Evaluation of Other Indirect and Additional Actions*. This appendix and these chapters generally describe how CCSF's water supply could be affected by the flow objectives; quantifies potential water supply effects on CCSF ; describes water transfers and other actions CCSF could take to meet water supply demand if water supplies are reduced; and summarizes the potential economic effects of water supply changes associated with a water transfer.

4.2.8 Effects of the Flow Proposal on Municipal Water Supplies

This SED includes a new chapter, Chapter 22, *Integrated Discussion of Potential Municipal and Domestic Water Supply Management Options*, summarizing the overall effect the project is expected to have on drinking water. This new chapter synthesizes information from other resource chapters, including Chapter 2, *Water Resources*, Chapter 9, *Groundwater Resources*, Chapter 13, *Service Providers*, and Chapter 21, *Drought Evaluation*, in order to provide an integrated discussion of how drinking water supplies would be affected by the plan amendments[5]. The chapter discusses both the initial effects and the potential long-term changes that could occur when SGMA is fully implemented.

4.2.9 Economic Analyses

Chapter 20, *Economic Analyses*, of this recirculated SED summarizes the economic effects associated with the LSJR Alternatives 2, 3, and 4 and SDWQ Alternatives 2 and 3. The information in Chapter 20 is derived from various locations in this SED, including: Chapter 10, *Recreational Resources and Aesthetics*; Chapter 13, *Service Providers*; Chapter 16, *Evaluation of Other Indirect and Additional Actions;* Chapter 19, *Analyses of Benefits to Native Fish Populations from Increased Flow Between February 1 and June 30*; Appendix G, *Agricultural Economic Effects of Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results;* and, Appendix L, *City and County of San Francisco Analyses*. Chapter 20 (as well as the other chapters and appendices that it relies on) contains the following new analyses that were not included in the 2012 Draft SED.

- Fiscal analysis associated with regional agricultural effects under the LSJR alternatives.
- Cost evaluation of municipal and industrial water supplies and affected regional economies under the LSJR alternatives.
- Cost evaluation of additional actions (e.g., non-flow measures[6]) under the LSJR alternatives.

---

[5] These plan amendments are the *project* as defined in State CEQA Guidelines, Section 15378.

[6] Depending on the context, the terms *non-flow measures* and *non-flow actions* may be used interchangeably in this document.

- Evaluation of potential use and non-use benefits associated with supporting and maintaining sustainable Chinook salmon populations in the three eastside tributaries under the LSJR alternatives.
- Regional economic analyses for CCSF under the LSJR alternatives using Impact Analysis for Planning (IMPLAN).

In addition, the agricultural economic analysis was refined using IMPLAN model multipliers to estimate total (direct, indirect, and induced) economic impacts on employment and regional economic output associated with changes in agricultural production. The discussion describes the effects on all inter-connected sectors of the regional economy.

4.2.10 Plan Area

The plan area and extended plan area are described in Chapter 1, *Introduction*. The plan area encompasses the areas where the proposed plan amendments apply to protect the beneficial uses. In addition to the implementation of the plan amendments in the plan area, implementation of the plan amendments also has the potential to affect the Stanislaus, Tuolumne, and Merced River Watersheds above the rim dams.[7] These areas are referred to as the extended plan area.

Impacts in the extended plan area are addressed in the SED as appropriate. As explained in Chapter 5, *Surface Hydrology and Water Quality*, given the small volume of water held in non-hydropower post-1914 rights for consumptive use in the extended plan area compared to the volume held in non-hydropower post-1914 water rights used below the rim dams, most of the effect of implementing LSJR alternatives would occur at, or downstream of, the major rim dams in the three tributaries. As such, the overall analysis of impacts in the SED focuses on the plan area, downstream of the rim dams, where the flow objectives would be implemented at the confluence of the Stanislaus, Tuolumne, and Merced Rivers. The primary means by which the extended plan area reservoirs and rivers might be affected is if water is bypassed by junior water rights holders, in accordance with the rules of priority and applicable law, to achieve the required flows in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR.

The impacts of reduced water diversions, reduced reservoir levels, and additional flow to rivers that could occur in the extended plan area under LSJR Alternatives 2, 3, and 4 are qualitatively evaluated. The analysis of the extended plan area generally identifies how the impacts may be similar or different to the impacts in the plan area (i.e., downstream of the rim dams) depending on the similarity of the impact mechanism (e.g., changes in reservoir levels, reduced water diversions, and additional flow in the rivers) or location of potential impacts in the extended plan area. The extended plan area impacts are primarily discussed in Chapters 5–14 and Appendix B, *State Water Board's Environmental Checklist*. Table 18-2 summarizes any differences between the impact determinations in the plan area and extended plan area.

---

[7] In this document, the term *rim dams* is used when referencing the three major dams and reservoirs on each of the eastside tributaries: New Melones Dam and Reservoir on the Stanislaus River; New Don Pedro Dam and Reservoir on the Tuolumne River; and New Exchequer Dam and Lake McClure on the Merced River.

4.2.11 Alternatives, Adaptive Implementation, and Analysis

The State Water Board has revised the proposed plan amendments in Appendix K, in *Revised Water Quality Control Plan.* Chapter 3, *Alternatives Description*, describes LSJR Alternatives 2, 3, and 4, and SDWQ Alternatives 2 and 3. This SED has been revised to evaluate the impacts of the revised alternatives. Major changes with respect to the SED regarding the revised alternatives are discussed below.

Preferred Alternative

The evaluation of the preferred alternatives was included in Chapter 20, *Preferred LSJR Alternative and SDWQ Alternative* of the 2012 Draft SED. This chapter has been eliminated. The different alternatives are evaluated in a manner to inform the decision makers and the public about the effects associated with each alternative.

No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)

The metrics and criteria used to evaluate the No Project Alternative are changed to be consistent or similar to those used in Chapters 5–14. In addition, where necessary, the analysis references the different LSJR alternatives to provide comparisons to what would occur if an LSJR alternative was not selected.

LSJR Flow Objectives

This SED evaluates four alternatives for LSJR flows during the February–June time frame, including the No Project Alternative (LSJR Alternative 1), and three other LSJR alternatives (LSJR Alternatives 2, 3, and 4). Each of the LSJR alternatives includes an unimpaired flow range (e.g., 30 percent to 50 percent under LSJR Alternative 3), and the ability to adaptively manage flows within this range. LSJR Alternative 2, 3, and 4 also include common elements, such as a the minimum base flow requirement at Vernalis and the monitoring and reporting program, which are discussed in more detail in Chapter 3, *Alternatives Description.*

The program of implementation for LSJR Alternatives 2, 3, and 4 includes adaptive implementation that allows adaptive adjustments to the flow requirements, such as the magnitude and timing of flows, if information produced through monitoring and review processes, or other best scientific information supports that such changes would be sufficient to support and maintain the natural production of viable native SJR Watershed fish populations migrating through the Delta and meet any existing biological goals approved by the State Water Board. Adaptive implementation could optimize flows to achieve the flow objectives while allowing for consideration of other beneficial uses, such as agricultural, municipal, and recreational uses, provided that these other considerations do not reduce intended benefits to fish and wildlife.

Four different methods of adaptive implementation are analyzed under each LSJR alternative. In general, the methods are as follows: method 1, adjusting the required percent of unimpaired flow within the approved range (e.g., increasing or decreasing the percent of unimpaired flow required by 10 percent depending on the LSJR alternative selected); method 2, managing the required percent of unimpaired flow for February–June as a total volume of water; method 3, allowing a portion of the required unimpaired flow to be shifted outside of February–June, depending on the

LSJR alternative selected; and method 4, allowing adjustments in base flow for February–June in the SJR at Vernalis.

While adaptive implementation is a part of LSJR Alternatives 2, 3, and 4, this SED provides an analysis of these alternatives with and without adaptive implementation. This is because adaptive implementation may take place on either a short-term (e.g., monthly or annually) or a longer-term basis, depending on the method, and would require the coordination, and cooperation stakeholders or the State Water Board. It is also possible that, at times, adaptive implementation would not occur. As such, the frequency, duration, and extent to which adaptive implementation would be used, if at all, within a year or between years under each LSJR alternative is unknown. The analysis, therefore, discloses the full range of impacts that could occur under an LSJR alternative, from no adaptive implementation to full adaptive implementation.

The methodology sections in the chapters summarize the four methods of adaptive implementation and describe how they are analyzed. Impacts are generally assessed by comparing the baseline flow results with the results for LSJR Alternatives 2, 3, and 4. Typically, the quantitative results included in the figures, tables, and text of the chapters present WSE modeling of the specified unimpaired flow requirement for each LSJR alternative (i.e., 20, 40, or 60 percent). Most chapters incorporate a qualitative discussion of adaptive implementation under each of the LSJR alternatives that includes the potential environmental effects associated with adaptive implementation. To inform the qualitative discussion and account for the variability allowed by adaptive implementation, modeling was performed to predict conditions at 30 percent and 50 percent of unimpaired flow (as reported in Appendix F.1). The modeling also allows some inflows to be retained in the reservoirs until after June, as could occur under adaptive implementation method 3, to prevent adverse temperature effects to fish. This variety of modeling scenarios provides information to support the analysis and evaluation of the effects of the alternatives and adaptive implementation. However, some chapters (i.e., Chapter 5, *Surface Hydrology and Water Quality*; Chapter 9, *Groundwater Resources*; Chapter 10, *Recreational Resources and Aesthetics*; Chapter 13*, Service Providers*, and Chapter 14, *Energy and Greenhouse Gases*) provide a more quantitative discussion of adaptive implementation by evaluating modeling results at either 30 percent or 50 percent unimpaired flow, or both. Most of the significant impacts at the 40 percent or 60 percent unimpaired flow are also significant at 30 percent or 50 percent unimpaired flow, respectively. While the impact determination may not change, there may be a slight change to the magnitude of the impact (less severe as the required percent of unimpaired flow decreases), which is described where necessary. Because the analysis includes a wide range of unimpaired flows for each of the LSJR alternatives with adaptive implementation, the analysis inherently covers the different mixes of adaptive implementation methods 1, 2, 3, and 4 that could occur.

Baseline

As described in Section 4.2.1, *Hydrologic Modeling,* the WSE model now represents both baseline and LSJR alternative conditions, whereas previously, in the 2012 Draft SED, CALSIM provided the baseline condition. Section 4.7, *Baseline*, describes the characterization of baseline.

Methods of Compliance and Other Indirect and Additional Actions

The 2012 Draft SED evaluated different methods of compliance in Appendix H, *Supporting Materials for Chapter 16*. This SED modifies the discussion of the methods of compliance for LSJR Alternatives 2, 3, and 4. It also expands the discussion to include other indirect and additional actions that could be undertaken by the regulated community. The methods of compliance evaluated for the LSJR alternatives include the methods listed below.

- Releasing or bypassing flow at existing reservoir or at existing diversion points—flows being released into the rivers to meet the unimpaired flows as defined by the LSJR alternatives with or without adaptive implementation.
- Reoperating reservoirs—modifying reservoir operations to meet the unimpaired flows as defined by the LSJR alternatives with or without adaptive implementation.
- Reducing surface water diversions—reducing surface water diversions to allow for the release or bypass of flows or reoperation of reservoirs meet the unimpaired flows as defined by the LSJR alternatives with or without adaptive implementation.

The State Water Board also provides an evaluation of other actions associated with LSJR Alternatives 2, 3, and 4. These include different actions that the regulated community could take to reduce potential reservoir or water supply effects associated with implementing LSJR Alternatives 2, 3, and 4. These actions are evaluated in Chapter 9, *Groundwater Resources*, Chapter 11, *Agricultural Resources*, Chapter 13, *Service Providers*, Chapter 14, *Energy and Greenhouse Gases*, and Chapter 16, *Evaluation of Other Indirect and Additional Actions*, as well as Appendix H, *Supporting Materials for Chapter 16*, and Appendix L, *City and County of San Francisco Analyses*. There are also additional actions (i.e., non-flow measures) that would inform the body of scientific information used to make adaptive implementation decisions under LSJR Alternatives 2, 3, and 4; these are evaluated in Chapter 16, *Evaluation of Other Indirect and Additional Actions.* The other actions are listed below.

- Transfer or sale of surface water.
- Substitution of surface water with groundwater.
- Aquifer storage and recovery.
- Recycled water sources for water supply.
- In-Delta diversions.
- Water supply desalination.
- New surface water supplies.
- Floodplain and riparian habitat restoration.
- Reduce vegetation-disturbing activities in floodplains and floodways.
- Gravel augmentation.
- Enhanced in-channel complexity.
- Improve temperature conditions.
- Fish passage—fish screens (screen unscreened diversions in tributaries and LSJR).
- Fish passage—physical barrier in the southern Delta.
- Fish passage—human-made barriers to fish migration.
- Predatory fish control.
- Invasive aquatic vegetation control.

Cumulative Analysis

Cumulative impacts are analyzed in this SED in Chapter 15, *No Project Alternative* (*LSJR Alternative 1 and SDWQ Alternative 1)*, for the No Project Alternative, Chapter 16, *Evaluation of Other Indirect and Additional Actions*, and in Chapter 17, *Cumulative Impacts, Growth-Inducing Effects, and Irreversible Commitment of Resources*.

4.3 Analytical Framework

This section describes the analytical framework in this SED used to evaluate the environmental impacts of the LSJR and SDWQ alternatives, as well as economic effects, benefits to fish, and other considerations.

This SED evaluates the potentially significant environmental impacts associated with the LSJR and SDWQ alternatives. The assessment of environmental effects in this SED was conducted at a programmatic level, which is a broader level than a project-specific analysis. The State Water Board's adoption of amendments to the 2006 Bay-Delta Plan will not result in direct physical changes in the environment. Rather, it is through the implementation of the Bay-Delta Plan that physical changes in the environment potentially may occur. Accordingly, all potential environmental effects evaluated in this SED are indirect effects associated with implementation, which would occur later in time and would be subject to project-specific environmental review, in compliance with CEQA.

The evaluation of the impacts of the LSJR and SDWQ alternatives on particular resources is contained in Chapters 5–18 and Appendix B, *State Water Board's Environmental Checklist*. Appendix B is based on the template contained in Appendix A of the State Water Board's CEQA regulations. (Cal. Code Regs., tit. 23, §§ 3720–3781.)

As required by Public Resources Code Section 21159 and the State Water Board's regulations (Cal. Code Regs., tit. 23, § 3777), this SED evaluates the environmental impacts related to reasonably foreseeable methods of compliance with plan amendments. It programmatically evaluates indirect actions and additional actions, including reasonably foreseeable methods of compliance, in Chapters 5–16*.* Chapter 16, *Evaluation of Other Indirect and Additional Actions,* augments the analyses in the preceding chapters to include an evaluation of the methods of compliance for the SDWQ alternatives. Chapter 16 also evaluates indirect actions that the regulated community may take in response to complying with the LSJR alternatives, such as transferring or selling surface water, substituting surface water with groundwater, practicing aquifer storage and recovery, recycling water sources for water supply, diverting in-Delta water, desalinating for water supply, and utilizing new surface water supplies.

In addition, this SED contains additional information, including economic information, to support evaluations such as those under Public Resources Code, Section 21159 and the Porter-Cologne Water Quality Control Act. (Wat. Code, § 13000 et seq.) For example, Water Code Section 13141 requires an estimate of total cost of an agricultural water quality control program before implementing such a program. This information can be found in Chapter 16, *Evaluation of Other Indirect and Additional Actions*, and Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*, which provides an evaluation of the agriculture economic-related effects of reduced surface water diversions. Because the State

Water Board wishes to understand the water supply effects associated with LSJR Alternatives 2, 3, and 4, this SED also evaluates the related indirect and induced effects on the regional economy. Chapter 20, *Economic Analyses*, provides a summary of the economic effects of the LSJR and SDWQ alternatives, methods of compliance, and other indirect and additional actions.

4.3.1 Impacts Associated with LSJR Alternatives

The existing water quality objectives identified in the 2006 Bay-Delta Plan would be amended to protect the beneficial uses of fish and wildlife on the three eastside tributaries and the LSJR. Three of the four LSJR alternatives evaluated in this SED include a narrative and numeric objective to establish flow sufficient to support and maintain the natural production of fish populations in the plan area that mimic the natural hydrograph with respect to relative magnitude, duration, timing, and spatial extent of flows. The LSJR alternatives are as follows.

- LSJR Alternative 1, the No Project Alternative, would continue the flow requirements as established in the 2006 Bay-Delta Plan and implemented through D-1641; this also includes continuation of, and full compliance with, the southern Delta salinity objective as described in SDWQ Alternative 1.
- LSJR Alternative 2 would establish a range between 20 and 30 percent, with 20 percent as the starting percentage of unimpaired flow in the program of implementation.
- LSJR Alternative 3 would establish a range between 30 and 50 percent, with 40 percent as the starting percentage of unimpaired flow in the program of implementation.
- LSJR Alternative 4 would establish a range between 50 and 60 percent, with 60 percent as the starting percentage of unimpaired flow in the program of implementation.

Details of these four LSJR alternatives are provided in Chapter 3, *Alternatives Description*, and the language of the updated 2006 Bay-Delta Plan is included in Appendix K, *Revised Water Quality Control Plan.*

Mechanisms Causing Potential Impacts

The following list summarizes the physical changes that could result from the plan amendments and have the potential for quantifiable impacts on environmental resources.

- River flows—changes in river flows could result in impacts (e.g., reduction in aquatic resource habitat).
- Reservoir operations—changes to reservoir operations could result in impacts.
- Surface water diversions—changes to surface water diversions could result in impacts (e.g., reduction of irrigated agricultural land).
- Groundwater pumping rates—changes to surface water diversions could result in increased groundwater pumping.

The potential environmental impacts of these physical changes are evaluated in Chapters 5–17 of this SED. The agricultural economic effects of surface water diversion reductions are summarized, along with all other economic impacts, in Chapter 20, *Economic Analyses*, and are evaluated in detail in Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*.

Methods of Compliance

The following list summarizes the methods of compliance that could be implemented by irrigation districts or reservoir operators to comply with the LSJR alternatives. The potential environmental impacts of these methods of compliance are evaluated further in Chapters 5–17 of this SED. The agricultural economic effects of surface water diversion reductions are summarized, along with all other economic impacts, in Chapter 20, *Economic Analyses*, and are evaluated in detail in Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*.

- Releasing or bypassing flow at existing reservoir or at existing diversion points—flows being released into the rivers to meet the unimpaired flows as defined by the LSJR alternatives with or without adaptive implementation.
- Reoperating reservoirs—modifying reservoir operations to meet the unimpaired flows as defined by the LSJR alternatives with or without adaptive implementation.
- Reducing surface water diversions—reducing surface water diversions to allow for the release or bypass of flows or reoperation of reservoirs meet the unimpaired flows as defined by the LSJR alternatives with or without adaptive implementation.

Other Indirect and Additional Actions

The following list summarizes the other indirect and additional actions that could be implemented by irrigation districts, water districts, or municipalities to respond to the LSJR alternatives and methods of compliance.

- Transfer/sale of surface water—water transfers or sales between water users.
- Substitution of surface water with groundwater—construction and operation of new groundwater wells.
- Aquifer storage and recovery—increased conjunctive groundwater use by agricultural and municipal and industrial water suppliers.
- Recycled wastewater sources for water supply—construction and operation of new recycled wastewater facilities or increased utilization of existing facilities.
- In-Delta diversions—construction and operation of new in-delta diversion for SFPUC service area.
- Water supply desalination—construction and operation of desalination plant for SFPUC service area.
- New surface water supplies—construction and operation of new surface water reservoirs.
- Floodplain and riparian habitat restoration—actively restoring floodplain or riparian habitat adjacent to rivers by creating or expanding existing natural or engineered floodways or flood bypasses; modifying river or floodplain geometry; planting riparian vegetation; hydrologically reconnecting historic floodplain; or removal or riprap.
- Reduce vegetation-disturbing activities in floodplains and floodways—actions may be included among discretionary or non-discretionary permit conditions, guidelines, or policies governing existing levee and floodway maintenance activities, as well as implementation of floodplain,

floodway, or riparian management and restoration plans in areas adjacent or within the Stanislaus, Tuolumne, and Merced River channels.

- Gravel augmentation—artificially adding spawning-size gravel to streams by adding gravel to streams; modifying river and then adding gravel to streams; or adding larger structures to river to create hydraulic conditions conducive to gravel deposition and retention.
- Enhanced in-channel complexity—placement of large wood or boulder structures in rivers.
- Improve temperature conditions—installation or modification of temperature curtains or shutters in reservoirs.
- Fish passage—fish screens (screen unscreened diversions in tributaries and LSJR)—Screen existing unscreened diversions with different types of screens in accordance with established design, operational, and maintenance criteria and guidelines from wildlife and resource agencies.
- Fish passage—physical barrier in the southern Delta—construction and operation of a permanent operable barrier at the e Head of Old River (HORB) barrier in the Southern Delta.
- Fish passage—human-made barriers to fish migration—feasibility and design studies to explore the feasibility of modifying existing barriers on the three eastside tributaries that restrict fish migration, including trucking and hauling and elevators.
- Predatory fish control—directly remove known predators within the Delta or three eastside tributaries or modify habitat to remove predator habitat.
- Invasive Aquatic Vegetation Control—small scale and large scale applications of herbicides in the Delta and small scale mechanical removal of invasive species in the Delta.

A site-specific, project-level analysis of these actions is not possible due to uncertainty about timing, duration, and magnitude of the actions. Therefore, a conceptual environmental evaluation and cost evaluation are provided primarily in Chapter 16, *Evaluation of Other Indirect and Additional Actions*. Chapter 9, *Groundwater Resources*; Chapter 11, *Agricultural Resources*; Chapter 13, *Service Providers*; Chapter 14, *Energy and Greenhouse Gases*, as well as Appendix H, *Supporting Materials for Chapter 16*, and Appendix L, *City and County of San Francisco Analyses* also provide some evaluation. Cost evaluations associated with these actions are summarized with all other economic impacts in Chapter 20, *Economic Analyses*, and Appendix L, *City and County of San Francisco Analyses*. Many of the actions described above may require permits or other approvals from other agencies prior to implementation. Their inclusion in this SED does not equate to an expression of jurisdiction over, or approval by, the State Water Board.

4.3.2 Impacts Associated with SDWQ Alternatives

The SDWQ alternatives would amend the existing water quality objectives for salinity identified in the 2006 Bay-Delta Plan to protect agricultural beneficial uses in the southern Delta. The alternatives evaluated in this SED are listed below.

- SDWQ Alternative 1, the No Project Alternative, would continue the existing salinity (electrical conductivity [EC][8]) objective as 1.0 deciSiemens per meter (dS/m) September–March and 0.7 dS/m April–August in the southern Delta; include continued conditioning of the DWR's and USBR water rights to meet the objectives at certain locations.
- SDWQ Alternative 2 would establish a numeric salinity objective of 1.0 dS/m as a maximum 30-day running average of mean daily EC for all months in the SJR between Vernalis and Brandt Bridge, Middle River from Old River to Victoria Canal, and Old River/Grant Line Canal from the Head of Old River to West Canal. The SJR at Airport Way Bridge near Vernalis compliance location would not change. Revised D-1641 imposes conditions on USBR's water rights requiring implementation of EC levels of 0.7 mmhos/cm from April–August and 1.0 mmhos/cm from September–March at Vernalis (units of mmhos/cm are equal to units of dS/m). USBR would continue to be required to comply with these salinity levels, as a condition of their water rights, in order to implement and meet the proposed salinity water quality objectives in the interior southern Delta.
- SDWQ Alternative 3 is similar to SDWQ Alternative 2 but would establish a salinity objective of 1.4 dS/m maximum 30-day running average of mean daily EC for all months for the southern Delta and include continued conditioning of USBR water rights to meet its current salinity D-1641 compliance requirement at Vernalis. The compliance locations and all other provisions of SDWQ Alternative 3 are the same as for SDWQ Alternative 2.

Details of these three SDWQ alternatives are provided in Chapter 3, *Alternatives Description*, and the language of the amended Bay-Delta Plan is included in Appendix K, *Revised Water Quality Control Plan.*

Mechanisms Causing Potential Impacts

The following summarizes the physical changes that could result from the SDWQ alternatives and have the potential for impacts on environmental resources and the economy.

- EC/salinity concentrations—changes in surface water EC resulting from the LSJR or SDWQ alternatives could result in impacts.

The potential environmental impacts of these physical changes are evaluated in Chapters 5–17 of this SED. The associated economic impacts were evaluated and summarized together with all other economic impacts in Chapter 20, *Economic Analyses.*

Methods of Compliance

The following summarizes the potential methods of compliance that could be implemented by municipalities, agricultural producers, and the CVP and SWP to comply with the SDWQ alternatives. A site-specific, project-level analysis of these potential methods of compliance is not possible due to uncertainty about which actions would be taken, and the timing, duration, and magnitude of the actions. Therefore, a conceptual environmental evaluation of these methods of compliance and

---

[8] In this document, EC is *electrical conductivity*, which is generally expressed in deciSiemens per meter (dS/m). Measurement of EC is a widely accepted indirect method to determine the salinity of water, which is the concentration of dissolved salts (often expressed in parts per thousand or parts per million). EC and salinity are therefore used interchangeably in this document.

a cost evaluation of each are provided in Chapter 16, *Evaluation of Other Indirect and Additional Actions*. Economic impacts associated with these methods of compliance are summarized with all other economic impacts in Chapter 20, *Economic Analyses*. Many of the actions described below may require permits or other approvals from other agencies prior to implementation, and their inclusion in this SED does not equate to an expression of jurisdiction over, or approval by, the State Water Board.

Municipal Wastewater Treatment Plants

Although other actions could be undertaken, it is reasonably foreseeable that municipalities would take one or more of the following actions to comply with National Pollutant Discharge Elimination System (NPDES) effluent limits established by the Central Valley Regional Water Quality Control Board (Central Valley Water Board), which would use the numeric salinity objectives in the SDWQ alternatives.

- New source water supplies—develop and utilize alternate low-salinity municipal water supplies.
- Salinity pretreatment programs—implement industrial and residential salinity source controls.
- Desalination—construct and operate salinity removal facilities at municipal wastewater treatment plants.

Agricultural Producers

Although other actions could be undertaken, it is reasonably foreseeable that drainage districts and/or farmers would take the following action to control salinity loads in agricultural return flows to comply with salinity load allocations.

- Real-time management—Shift the agricultural discharge timing such that the agricultural return flow released from agricultural lands would occur during times of high assimilative capacity for the receiving waters. This would require the construction and operation of detention ponds.

CVP and SWP

Although they could undertake other actions, it is reasonably foreseeable that DWR for SWP operations and USBR for CVP operations would take the following actions to comply with the water level and flow conditions of the SDWQ alternatives in the event that such modifications are warranted.

- Continuation of the Temporary Barriers Program—continuation of the existing program of four temporary barriers (three for agriculture, one for fish) for an unknown duration.
- Low-lift pumping stations—construct and operate either temporary or permanent pumping system(s) near the Middle River, Grant Line Canal, and/or Old River at Tracy Temporary Barriers Project in the southern Delta.

4.4 Chapter Organization

This section describes how the chapters in this SED are organized, the type of information they contain, and where information can be found.

4.4.1 Resource Chapters

The discussion in Chapters 5–14 is divided into several parts, including an introduction, a description of the environmental and regulatory setting, and analysis of environmental impacts.

Introduction

The introduction provides an overview of the existing environmental setting and impacts evaluated for the resource. A summary of the impacts on the resource is presented in a table at the end of the introduction. These tables provide each impact statement for the resource, summarize the impacts and their levels of significance in relation to each of the LSJR or SDWQ alternatives, and identify the significance determination after implementation of all feasible mitigation. This information is also summarized in Chapter 18, *Summary of Impacts and Comparison of Alternatives*, Tables 18-1, 18-2, and 18-3.

Environmental Setting

The environmental setting section provides a historical perspective and a detailed description of the current conditions for the resource. This section also presents specific baseline information, including information obtained from published environmental documentation, books, websites, research and journal articles, and personal communications with field experts.

Regulatory Background

The regulatory background section lists and describes laws, regulations, and policies that are relevant to the State Water Board's plan amendments, the assessment of impacts, or development of mitigation. Often, as in aquatic or terrestrial biological resources, the regulatory framework is the basis for the conclusion of the level of significance and, therefore, plays a role in impact assessment.

Environmental Impacts

A reasonable range of alternatives are evaluated in this SED to show differences in environmental consequences of the alternatives. The alternatives are feasible and satisfy the objectives and goals of amending the 2006 Bay-Delta Plan. This SED analyzes all alternatives identified in Chapter 3, *Alternatives Description*.

Thresholds

The thresholds section describes thresholds of significance used for the resource to determine the significance of impacts as required in an SED.

Methods and Approach

The methods and approach section in the resource chapters describes the resource-specific assessment methods, approach, and analytical models used to identify and evaluate the environmental impacts for the resource. It also describes any specific significance criteria used in the assessments to determine the level of significance of an impact. It also describes how the four methods of adaptive implementation are integrated into the analysis of the resource and what information is used to evaluate adaptive implementation.

Mitigation Measures

An SED must identify feasible mitigation measures for each significant environmental impact identified in the SED. (Cal. Code Regs., tit. 23, § 3777 (b)(d).) Feasible mitigation measures are intended to avoid, reduce, or compensate for adverse impacts on a resource. For each impact identified as significant, a mitigation measure to reduce that impact to a less-than-significant level is described, if appropriate, or the infeasibility of mitigation is discussed.

4.4.2 No Project Alternative Impacts

Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)* and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*, discuss the No Project Alternative. As State CEQA Guidelines Section 15126.6(e)(3)(A) states, “when the project is revision of an existing regulatory plan ... the ‘no project' alternative will be the continuation of the existing plan ... into the future.” The No Project Alternative represents the likely future conditions without adoption and implementation of the flow or salinity amendments to the 2006 Bay-Delta Plan. The No Project Alternative assumes continued implementation of the 2006 Bay-Delta Plan, which includes flow objectives implemented through D-1641 and flow objectives to comply with the salinity objective for the SJR at Vernalis and the three interior compliance stations (Brandt Bridge on the SJR, Old River near Middle River, and Old River at Tracy Road Bridge). Chapter 15 describes LSJR Alternative 1 and SDWQ Alternative 1, summarizes technical results, and describes the environmental impacts of LSJR Alternative 1 and SDWQ Alternative 1. Appendix D presents the technical assumptions for the No Project Alternative. Because the No Project Alternative is discussed in Chapter 15 and Appendix D, any reference to LSJR alternatives or SDWQ alternatives in Chapters 5–14 refers to LSJR Alternatives 2, 3, or 4, or SDWQ Alternatives 2 and 3, respectively.

4.4.3 Evaluation of Other Indirect and Additional Actions

Chapter 16, *Evaluation of Other Indirect and Additional Actions*, discusses those other indirect and additional actions that could occur under the LSJR alternatives and the methods of compliance that could occur under the SDWQ alternatives, as described below.

LSJR Alternatives

Chapter 16 describes actions that the regulated community could take to reduce potential reservoir or water supply effects associated with implementing LSJR Alternatives 2, 3, and 4The cost and potential environmental effects of these actions are programmatically evaluated in this chapter using reference projects, standard assumptions regarding the type and potential location of these measures, and impact mechanisms likely to occur under these activities. Potential mitigation measures are proposed for those actions that may have potentially significant environmental impacts.

- Transfer/sale of surface water.
- Substitution of surface water with groundwater.
- Aquifer storage and recovery.
- Recycled water sources for water supply.
- In-Delta diversions.
- Water supply desalination.
- New surface water supplies.

Chapter 16 also describes actions that would inform the body of scientific information potentially used to make adaptive implementation decisions under LSJR Alternatives 2, 3, and 4 (i.e., non-flow actions).The cost and potential environmental effects of non-flow actions are programmatically evaluated using reference projects, standard assumptions regarding the type and potential location of these actions, and impact mechanisms likely to occur under these actions. The non-flow actions are listed below. Potential mitigation measures are proposed for those actions that may have potentially significant environmental impacts.

- Floodplain and riparian habitat restoration.
- Reduce vegetation-disturbing activities in floodplains and floodways.
- Gravel augmentation.
- Enhanced in-channel complexity.
- Improve temperature conditions.
- Fish passage—fish screens (screen unscreened diversions in tributaries and LSJR).
- Fish passage—physical and non-physical barriers in the southern Delta.
- Fish passage—human-made barriers to fish migration.
- Predatory fish control.
- Invasive species control (i.e., plant control).

SDWQ Alternatives

Chapter 16 also describes the methods of compliance that could be undertaken by the regulated community to comply with the SDWQ alternatives. The cost and potential environmental effects of these methods of compliance are programmatically evaluated using reference projects, standard assumptions regarding the type and potential location of these measures, and impact mechanisms likely to occur under these measures. The methods of compliance are listed below. Potential mitigation measures are proposed for those that may have potentially significant environmental impacts.

- New source water supplies.
- Salinity pretreatment programs.

- Desalination.
- Agricultural return flow salinity control.
- Southern Delta temporary barriers.
- Low-lift pumping stations.

Finally, Chapter 16 provides a brief summary of the federal and state sources of funding that could be used for those actions that could occur under the LSJR or SDWQ alternatives.

4.4.4 Cumulative and Growth-Inducing Impacts

Cumulative impacts are analyzed in this SED in Chapter 15, *No Project Alternative* (*LSJR Alternative 1 and SDWQ Alternative 1)*, Chapter 16, *Evaluation of Other Indirect and Additional Actions*, and in Chapter 17, *Cumulative Impacts, Growth-Inducing Effects, and Irreversible Commitment of Resources*.

4.5 Terminology

The following terms are used in this SED.

- No impact: No adverse changes in the environment are expected.
- Less-than-significant impact: The alternative would not result in a substantial adverse change in the environment (i.e., the impact would not reach the threshold of significance). Mitigation is not required.
- Significant: The alternative would result in a substantial, or potentially substantial, adverse change in the environment (i.e., the impact exceeds the applicable significance threshold established by the State Water Board). Mitigation measures or alternatives to the project must be provided, if feasible, in an attempt to reduce or avoid significant impacts.
- Significant and unavoidable: The alternative would result in a substantial adverse change in the environment, and there are no feasible alternatives or mitigation measures that would substantially lessen the impact to a less-than-significant level.
- Mitigation: Mitigation refers to measures that would be implemented to avoid or lessen potentially significant impacts. Mitigation measures would be proposed as a condition of plan approval and would be monitored to ensure compliance and implementation. Mitigation includes the following effects. (Cal. Code Regs., tit. 14, § 15370.)
    - Avoiding the impact altogether by not taking a certain action or parts of an action.
    - Minimizing the impact by limiting the degree or magnitude of the action and its implementation.
    - Rectifying the impact by repairing, rehabilitating, or restoring the affected environment.
    - Reducing or eliminating the impact over time by preservation and maintenance operations during the life of the action.
    - Compensating for the impact by replacing or providing substitute resources or environments.

4.6 Scope of Analysis

In developing the scope of the environmental analysis, , the State Water Board considered the potential effects of the proposed plan amendments, comments received in response to the notice of preparation (NOP) and during public consultation, other public comments and information, and the environmental issues identified in Appendix A of the State Water Board's CEQA regulations. (Cal. Code Regs., tit. 23, §§ 3720–3781.) The State Water Board's determinations regarding impacts that are not potentially significant and that are not addressed detail in this SED are explained in Appendix B, *State Water Board's Environmental Checklist*. The following chapters evaluate environmental impacts.

- Chapter 5: *Surface Hydrology and Water Quality*
- Chapter 6: *Flooding, Sediment, and Erosion*
- Chapter 7: *Aquatic Biological Resources*
- Chapter 8: *Terrestrial Biological Resources*
- Chapter 9: *Groundwater Resources*
- Chapter 10: *Recreational Resources and Aesthetics*
- Chapter 11: *Agricultural Resources*
- Chapter 12: *Cultural Resources*
- Chapter 13: *Service Providers*
- Chapter 14: *Energy and Greenhouse Gases*
- Chapter 15: *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*
- Chapter 16: *Evaluation of Other Indirect and Additional Actions*
- Chapter 17: *Cumulative Impacts, Growth-Inducing Effects, and Irreversible Commitment of Resources*
- Chapter 18: *Summary of Impacts and Comparison of Alternatives*

Each resource chapter describes the criteria or thresholds of significance used to evaluate the environmental impact and the significance determinations.

Chapter 19, *Analyses of Benefits to Native Fish Populations from Increased Flow Between February 1 and June 30*, describes biologically important and measurable benefits of providing higher and more variable flow during the February 1–June 30 time period, with a focus on improved water temperature conditions and enhanced floodplain inundation. This chapter is provided to assist the public with understanding the expected benefits of the LSJR alternatives to native fish. It does not evaluate impacts.

Several technical appendices support the analysis in the SED chapters.

- Appendix A: *NOP Scoping and Other Public Meetings*
- Appendix B: *State Water Board's Environmental Checklist*
- Appendix C: *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*

- Appendix D: *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*
- Appendix E: *Salt Tolerance of Crops in the Southern Sacramento–San Joaquin Delta*
- Appendix F.1: *Hydrologic and Water Quality Modeling*
- Appendix F.2: *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta*
- Appendix G: *Agricultural Economic Effects of Lower San Joaquin River Flow Alternatives*
- Appendix H: *Supporting Materials for Chapter 16*
- Appendix I: *Cultural Resources Overview*
- Appendix J: *Hydropower and Electric Grid Analysis of Lower San Joaquin River Flow Alternatives*
- Appendix K: *Revised Water Quality Control Plan*
- Appendix L: *City and County of San Francisco Analyses*
- Appendix M: *Summary of Public Comments on the 2012 Draft SED*

Appendix B, *State Water Board's Environmental Checklist*, also identifies and explains why the alternatives would result in either no impacts or less-than-significant impacts on particular resources.

4.7 Baseline

CEQA requires a description of the physical environmental conditions in the vicinity of the project as they exist at the time the NOP is published (February 13, 2009), or if no NOP is published, at the time environmental analysis is commenced. (Pub. Resources Code, § 15125.) This environmental setting will normally constitute the baseline physical conditions by which a lead agency determines whether an impact is significant. In general, the baseline used in this SED reflects the physical environmental conditions in 2009 as they existed under the 2006 Bay-Delta Plan, as implemented through D-1641. The WSE modeled baseline (as described in Appendix F.1, *Hydrologic and Water Quality Modeling*) allocates flow to comply with the 2006 Bay-Delta Plan flow objectives and other requirements that existed in 2009, including implementation of VAMP (which ended in 2011), the NMFS BO flow requirements on the Stanislaus River, FERC flow requirements on the Tuolumne River and on the Merced River, the Davis-Grunsky Contract between the State of California and Merced Irrigation District, and the Cowell Agreement. The baseline does not include the long-term SJRRP flow requirements, although these conditions are considered in the cumulative impacts analysis. Periodic exceedances of the interior southern Delta salinity objectives occur in the historical record, and likewise remain in the modeled baseline condition.

Each chapter describes the existing environmental conditions relevant to a particular resource. The baseline pertinent to each of the resource areas is included in the environmental setting section of each resource chapter. Below is a description of how different resource parameters may vary over time and how they may be incorporated into baseline conditions.

The environmental conditions in the Bay-Delta and SJR Basin are determined by numerous complex interactions and changing conditions. Defining baseline is challenging in such a variable environment. To take into account natural variability, while still representing shifts that have occurred over time, baseline conditions for surface hydrology, water diversions, water quality, aquatic resources, and other relevant resources are characterized based on recent historical conditions. The recent historical period used in the analysis differs for each resource considered, depending on the availability and suitability of data to represent existing conditions. Since hydrologic conditions vary naturally from year to year, sometimes dramatically, parameters strongly dependent on hydrology, such as water supply, are simulated using the WSE model for the long-term period of record 1922–2003 at the present level of development, an approach derived from CALSIM II, including the assumption that the major reservoirs were in existence for this entire period. Recent data and published reports in combination with WSE model output are also used to estimate baseline conditions for water supply.

Other parameters, such as cultural resources, also change over time but do not exhibit significant annual variability. These types of parameters are defined by the conditions present at the time the NOP was issued. This may be constrained in some instances by data availability; in those instances, the most current readily available information is used. It should be noted that a second NOP was released on April 1, 2011. This SED considers the relevance of changes of information that may have occurred since the issuance of the 2009 NOP, where appropriate.

Regulatory requirements, which may also affect existing conditions (e.g., surface water hydrology), are subject to change. Baseline conditions generally represent long-term flood control, water management, environmental, and other requirements applicable to the major water projects. These requirements are discussed in more detail in each appropriate chapter. Modeling and Technical Analyses

This SED relies on numerous modeling and technical analyses to describe and evaluate baseline conditions and impacts. This section provides a brief overview of the types of modeling and technical analyses performed. It identifies the chapters and appendices that describe this information in more detail and the chapters that primarily use the results of the modeling and technical analysis to determine impacts.

4.7.1 Peer-Reviewed Scientific Basis Report

The scientific basis of any statewide plan, basin plan, plan amendment, guideline, policy, or regulation must undergo external peer review before adoption by the state or regional board (Health and Safety Code, § 57004.) State Water Board staff, in accordance with Health and Safety Code Section 57004, submitted a peer review request for the report titled, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow Objectives for the Protection of Fish and Wildlife Beneficial Uses and Water Quality Objectives for the Protection of Southern Delta Agricultural Beneficial Uses and the Program of Implementation for Those Objectives* (included in this document as Appendix C, *Technical Report On The Scientific Basis For Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*). This technical report provides the scientific basis for the LSJR and SDWQ alternatives. Also included as attachments to Appendix C are the peer reviews and a summary of the State Water Board staff's response.

4.7.2 Hydrologic and Water Quality Modeling

The analysis in this SED relies on the modeling output and results of the State Water Board's WSE model, which is described below. In addition, a temperature model was used to determine temperature changes as a result of the LSJR alternatives.

Water Supply Effects Model

The WSE model is a monthly water balance spreadsheet model based on the CALSIM II analysis framework that calculates for each tributary reductions in water supply diversions and changes in reservoir operations that could occur based upon user-defined diversion and reservoir operating rules, flood storage curves, and minimum river flow requirements, across 82 years of monthly historical watershed hydrology. The model estimates the amount of water available for diversion each year, based on the difference between estimates of available water for the year and the amount needed to satisfy downstream flow and other requirements. Available water is then compared to estimates of demands (primarily agricultural irrigation) for the year, with the lesser determining the amount diverted. The model uses estimates of reservoir inflows, downstream accretions and depletions, and other inputs as developed by DWR and USBR for the CALSIM model.

Appendix F.1, *Hydrologic and Water Quality Modeling*, provides a detailed description of the WSE model and the results from the modeling. Chapter 5, *Surface Hydrology and Water Quality*, also provides a summary of the WSE model and uses the modeling results to establish baseline conditions and analyze LSJR and SDWQ alternative surface hydrology and water quality impacts. Additional chapters, such as Chapter 7, *Aquatic Biological Resources*; Chapter 8, *Terrestrial Biological Resources*; Chapter 10, *Recreational Resources and Aesthetics*; Chapter 11, *Agricultural Resources*; and Chapter 13, *Service Providers*, use the WSE model-predicted river flows and diversion modifications to evaluate impacts on various environmental resources.

Temperature Model

To model effects on temperature in the LSJR and three eastside tributaries, the State Water Board modified the SJR Basin-Wide Water Temperature Model (temperature model), a model using the Hydrologic Water Quality Modeling System (HWMS-HEC5Q), a graphical user interface that employs the U.S. Army Corps of Engineers (USACE) Hydrologic Engineering Center (HEC) flow and water quality simulation model, HEC-5Q. The SJR temperature model was developed by the California Department of Fish and Wildlife (CDFW) and a group of consultants between 2003 and 2013 funded through a series of CALFED Bay-Delta Program contracts that included peer review and refinement (CALFED 2009; CDFW 2013). The temperature model was used to accurately simulate temperature for a range of reservoir operations, river flows, and meteorology. To determine effects of the LSJR alternatives on river temperatures, this model was adapted to run with streamflows from WSE model representations of the alternatives and baseline, with the resulting temperatures compared at key locations along each tributary.

Appendix F.1, *Hydrologic and Water Quality Modeling*, provides a detailed description of the temperature model and the modeling results. Chapter 5, *Surface Hydrology and Water Quality*, also provides a summary and uses modeling results to establish baseline conditions. Chapter 7, *Aquatic Biological Resources*, uses the temperature results to evaluate impacts on aquatic resources and Chapter 19, *Analyses of Benefits to Native Fish Populations from Increased Flow Between February 1 and June 30* to inform the benefits to temperature under the LSJR alternatives.

4.7.3 Agricultural and Economic Modeling

The WSE model estimates the amount of surface water diversion for the LSJR alternatives and baseline for agricultural irrigation across 82 years of historical watershed hydrology. These diversion estimates are used in the SWAP model to estimate the agricultural production and revenues associated with each of the LSJR alternatives and baseline. The SWAP model was selected to estimate the agricultural production (crop acreages) and revenues (total production value) associated with the surface water diversions under the LSJR alternatives and baseline conditions. SWAP is an agricultural production model that simulates the decisions of farmers at a regional level based on principles of economic optimization. The model assumes that farmers maximize profit (revenue minus costs) subject to resource, technical, and market constraints. The model selects those crops, water supplies, and irrigation technology that maximize profit subject to these equations and constraints. The model accounts for land and water availability constraints given a set of factors for production prices and calibrates exactly to observed yearly values of land, labor, water, and supplies use for each region.

The results of SWAP were then used as inputs for IMPLAN. IMPLAN is an input-output multiplier model that considers interrelationships among sectors and institutions in the regional economy. Production in the different economic sectors is simulated in IMPLAN by using fixed factors. The model then applies these factors in a matrix that accounts for changes in transactions between producers and intermediate and final consumers in other sectors of the economy. The IMPLAN approach also considers nonmarket transactions, such as unemployment insurance payments and associated changes in tax revenues for government.

Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*, provides a detailed description of SWAP and IMPLAN and their results. Chapter 11, *Agricultural Resources*, and Chapter 20, *Economic Analyses*, use the results of SWAP to analyze potential impacts of the LSJR alternatives on agricultural resources and economics, respectively.

4.7.4 SalSim

SalSim is a life-history population simulation model for fall-run Chinook salmon originating from the Stanislaus, Tuolumne, and Merced Rivers, and is used to evaluate the effects of potential water management scenarios on salmon from these rivers. SalSim was developed by CDFW (2014), and is intended as a user-friendly web-based application. Users can interactively perform simulation runs for different water management scenarios, view results on the screen (GUI output) and download results for further analysis using third party software, such as HEC-DSS (USACE Data System Storage) and Microsoft Excel (via CSV output files). SalSim can also use external data generated by other basin-wide operational and/or water temperature models, such as CALSIM II, the WSE model, and the San Joaquin River Basin-Wide Water Temperature Model (HEC-5Q).

To provide insight into population level changes that could be expected under a variety of unimpaired flows which are being evaluated for this Bay-Delta Plan update, the State Water Board used SalSim to compare effects of unimpaired and baseline flows on fall-run Chinook salmon by evaluating potential changes in annual salmon production. Chapter 19, *Analyses of Benefits to Native Fish Populations from Increased Flow Between February 1 and June 30,* describes the SalSim results.

4.7.5 Salt Tolerance of Crops in the Southern Sacramento–San Joaquin Delta

Appendix E, *Salt Tolerance of Crops in the Southern Sacramento–San Joaquin Delta,* prepared by Dr. Glen Hoffman, describes the scientific literature and information on subjects that impact crop productivity with saline irrigation water and analyzes the existing information from the southern

Delta and quantifies how the various factors influencing the use of saline water apply to conditions in the southern Delta.

Information from Appendix E is used to determine potential impacts on agriculture as a result of implementing the SDWQ alternatives in Chapter 11, *Agricultural Resources*.

4.7.6 Hydropower Modeling

To assess the potential impacts of the LSJR alternatives on California's electric grid, the Capacity Reduction Calculation and Power Flow Assessment was used to simulate the operation of the electric grid under peak summer demand conditions. These two technical analyses use the input of the WSE model to determine if hydropower capacity reductions and violations of California's transmission grid would occur. Appendix J, *Hydropower and Electric Grid Analysis of Lower San Joaquin River Flow Alternatives*, describes the methods and results associated with these two analyses. Information from Appendix J is used to determine potential impacts on energy and climate change from implementing the LSJR alternatives in Chapter 14, *Energy and Greenhouse Gases*.

Chapter 5
Surface Hydrology and Water Quality

5.1 Introduction

This chapter describes the environmental setting for water supply, surface hydrology, water quality, and the regulatory framework associated with these resource areas. In this document, water supply refers to surface water diversions, and not the quantity of surface water in the watershed. This chapter also evaluates the environmental impacts, and the significance of those impacts, on surface hydrology and water quality that could result from the Lower San Joaquin River (LSJR) alternatives and southern Delta water quality (SDWQ) alternatives, and, if applicable, describes mitigation measures that would reduce or avoid any significant impacts. In addition, this chapter evaluates other potential hydrologic changes that could impact other resources, which are further evaluated in the appropriate resource chapter.

Chapter 1, *Introduction*, defines the plan area. The study area for this chapter includes all areas that may be affected by the alternatives, including: the plan area and the San Joaquin River (SJR) from Brandt Bridge through the Stockton Deepwater Ship Channel near the city of Stockton. This chapter also describes the surface hydrology and water quality of the Upper San Joaquin River (Upper SJR) (upstream of the Merced River confluence), since it flows into the LSJR, influencing flows and water quality at Vernalis. However, the Upper SJR is not considered part of the plan area for the purposes of evaluating the LSJR alternatives. Figure ES-1 depicts the SJR Basin, and Figure ES-2 depicts the plan area.

As described in Chapter 1, *Introduction*, the extended plan area generally includes the area upstream of the rim dams. The area of potential effects for this area is similar to that of the plan area and includes the zone of fluctuation around the numerous reservoirs that store water on the Stanislaus and Tuolumne Rivers (Merced does not have substantial upstream reservoirs that would be affected). It also includes the upper reaches of the Stanislaus, Tuolumne, and Merced Rivers. Unless otherwise noted, all discussion in this chapter refers to the plan area. Where appropriate, the extended plan area is specifically identified.

As shown in more detail in the impacts analysis below, the LSJR alternatives would change the three eastside tributary river flows and the LSJR flows, primarily during February–June. Changing river flows changes the water volume in the river, which can affect the concentration of constituents in the water, including pollutants and the component ions that contribute to salinity (or electrical conductivity [EC]). Changes in flows also have the potential to affect water temperatures, surface water diversions, reservoir operations, and salinity. Methods for estimating hydrologic impacts and results are presented in detail in Appendix F.1, *Hydrologic and Water Quality Modeling*, and measured data are presented in Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta*.[1]

---

[1] The analyses in Appendix F.1, *Hydrologic and Water Quality Modeling*, and Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta*, describe salinity (EC) using microSiemens per centimeter (µS/cm). This chapter primarily describes salinity using deciSiemens per meter (dS/m) or µS/cm. The units in the 2006 Bay-Delta Plan (mmhos/cm) are equivalent to the dS/m units used in this document; the conversion is 1 dS/m = 1000 µS/cm. EC is electrical conductivity; a widely accepted indirect method

In Appendix B, *State Water Board's Environmental Checklist*, the State Water Board provides a preliminary determination regarding whether a proposed project would cause any potentially significant impact for each environmental category in the Checklist and provides a brief explanation for each determination. Impacts identified in Appendix B as "Potentially Significant" are discussed in are discussed in detail in this chapter. If an impact was considered to be less than significant or have no impact in Appendix B, it is not discussed any further.

Section IX of the checklist in Appendix B addresses hydrology and water quality impacts. Section IX impacts were addressed as follows.

- Impacts in Section IX(a) and (f) of Appendix B regarding water quality objectives, waste discharge requirements, or the degradation of water quality, are discussed in detail in this chapter. The potential impact that increased water temperature or other changes to water quality associated with the plan alternatives have on fisheries resources in the Lower SJR and the three eastside tributaries[2] is discussed in detail in Chapter 7, *Aquatic Biological Resources*; therefore, the discussion of water temperature in this chapter covers only a description of the baseline conditions and modeling results.
- Impacts in Section IX(c), (d), and (i) of Appendix B regarding erosion, sediment, and flooding are addressed in Chapter 6, *Flooding, Sediment, and Erosion*.
- Impacts in Section IX(b) regarding hydrologic impacts on groundwater are addressed in Chapter 9, *Groundwater Resources.*
- Impacts in Section IX(e), (g), (h), (i), and (j) were determined by the State Water Board to either be less than significant or have no impact and are briefly discussed in Appendix B.

In addition to the Section IX hydrologic impacts listed above, hydrologic changes could also impact other resources. The impacts on these resources are discussed and disclosed in Chapters 6 through 17 of this document.

Sections IX(a) and (f) of Appendix B ask if a proposed project would "[v]iolate any water quality standards or waste discharge requirements" and "[o]therwise substantially degrade water quality," respectively. The State's Water Board regulations allow the checklist (Appendix B) to be modified as appropriate to meet the particular circumstances of a project. (Cal. Code Regs., tit. 23, § 3777, subd. (a)(2).) The water quality analysis in this chapter emphasizes how potential changes in salinity associated with the LSJR and SDWQ alternatives affect agricultural beneficial uses. Salinity is emphasized because agricultural beneficial use is the most sensitive to salinity, salinity is the main water quality constituent likely to be affected by the plan amendments[3], salt is a constituent of great concern in the southern Delta because salinity (EC) values sometimes exceed water quality objectives, and there are sufficient EC data available to evaluate effects quantitatively. Changes to flow are also emphasized because they could increase other pollutant concentrations such that water quality objectives are exceeded. Therefore, specific impacts determined to be potentially significant include the following: (1) the LSJR flow alternatives could violate water quality objectives for salinity if they resulted in an increase in the number of months with EC above the water quality objectives for salinity

---

to determine the salinity of water, which is the concentration of dissolved salts (often expressed in parts per thousand or parts per million). EC and salinity are therefore used interchangeably in this document.

[2] In this document, the term *three eastside tributaries* refers to the Stanislaus, Tuolumne, and Merced Rivers.

[3] These plan amendments are the *project* as defined in State CEQA Guidelines, Section 15378.

at Vernalis or southern Delta compliance stations (i.e., Old River near Middle River, Old River at Tracy Road Bridge, and SJR at Brandt Bridge); (2) if they degrade water quality by increasing Vernalis and/or southern Delta EC such that agricultural beneficial uses are impaired; and (3) if they substantially degrade water quality due to increases in pollutant concentrations caused by reduced river flows. For water quality impacts associated with temperature refer to Chapter 7, *Aquatic Biological Resources*, and to service providers refer to Chapter 13, *Service Providers*.

The potential impacts of the LSJR on flow and SDWQ alternatives on water quality that are analyzed in this chapter are summarized in Table 5-1. The impact analysis presented in Section 5.4, *Impact Analysis*, below describes the significance thresholds for determining whether a potential impact on water quality is significant. This recirculated substitute environmental document (SED) provides an analysis with and without adaptive implementation because the frequency, duration, and extent to which each adaptive implementation method would be used, if at all, within a year or between years under each LSJR alternative is unknown. The analysis, therefore, discloses the full range of impacts that could occur under an LSJR alternative, from no adaptive implementation to full adaptive implementation. As such, Table 5-1 summarizes impact determinations with and without adaptive implementation.

Impacts related to the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) are presented in Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* and the supporting technical analysis is presented in Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1).* Chapter 16, *Evaluation of Other Indirect and Additional Actions*, includes discussion of impacts related to actions and methods of compliance.

Table 5-1. Summary of Impact Determinations

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
Impact WQ-1: Violate water quality standards by increasing the number of months with EC above the water quality objectives for salinity at Vernalis or southern Delta compliance stations			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note.[b]	Less than significant	NA
LSJR Alternatives 2, 3, and 4	There would be an overall reduction in monthly exceedances of EC values for the interior southern Delta compliance stations.	Less than significant	Less than significant
SDWQ Alternative 2	There would be an overall reduction of EC values above the new constant 1.0 dS/m EC objective when compared to existing EC objectives.	Less than significant	NA
SDWQ Alternative 3	There would be a reduction of EC values above the new constant 1.4 dS/m EC objective when compared to existing EC objectives such that there would no longer be any violations.	Less than significant	NA

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
Impact WQ-2: Substantially degrade water quality by increasing Vernalis or southern Delta salinity (EC) such that agricultural beneficial uses are impaired			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note.[b]	Less than significant	NA
LSJR Alternatives 2, 3, and 4	The range of average EC values during the irrigation season of April–September in the SJR at Vernalis and in the southern Delta channels is expected to be reduced; accordingly, it is not anticipated that agricultural beneficial uses would be impaired.	Less than significant	Less than significant
SDWQ Alternatives 2 and 3	These alternatives do not have the ability to result in an increase in EC because the baseline 0.7 dS/m Vernalis EC objective would continue to be maintained as part of the program of implementation. Therefore, these alternatives would not cause a change in flow or water quality. Accordingly, it is not anticipated that agricultural beneficial uses would be impaired.	No Impact	NA
Impact WQ-3: Substantially degrade water quality by increasing pollutant concentrations caused by reduced river flows			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note.[b]	Significant	NA
LSJR Alternatives 2, 3, and 4	Flows would generally increase, and no months with low to median flows (10th and 50th percentiles) would experience flow reductions greater than 33% of the baseline flows on the Stanislaus, Tuolumne, or Merced Rivers or the LSJR. Therefore, the change in concentrations would not substantially degrade water quality.	Less than significant	Less than significant

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
SDWQ Alternatives 2 and 3	These alternatives do not have the ability to result in an increase in pollutant concentrations because the baseline 0.7 dS/m Vernalis EC objective would continue to be maintained as part of the program of implementation. These alternatives would not cause a change in flow or water quality.	No impact	NA

1 dS/m = 1000 microSiemens per centimeter (1000 µS/cm)
dS/M = deciSiemens per meter
EC = salinity (electrical conductivity)
NA = Not applicable

[a] Four adaptive implementation methods could occur under the LSJR alternatives, as described in Chapter 3, *Alternatives Description,* and summarized in Section 5.4.2, *Methods and Approach*, of this chapter. There are no adaptive implementation or adaptive implementation methods for the SDWQ alternatives.

[b] The No Project Alternative (LSJR/SDWQ Alternative 1) would result in the continued implementation of flow objectives and salinity objectives established in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

5.2 Environmental Setting

This section describes the surface water hydrologic conditions (reservoir operations, stream flows, and diversions) and water quality conditions for the SJR basin as a whole, the Upper SJR, the LSJR, the three eastside tributaries, and the southern Delta. The following topics, which are important to the modeling approach and subsequent impact analysis, are included: unimpaired flows;[4] watershed infrastructure; historic river flows and the regulations and diversions that affect flow; hydropower; and water quality. Additional information about unimpaired and historical flows is in Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta*.

Some additional topics are discussed for the southern Delta including the effect of Delta operations on flow and water surface elevation. The hydrology and water quality of the southern Delta is strongly influenced by the SJR inflow at Vernalis and the Central Valley Project (CVP) and the State Water Project (SWP) export pumping near Tracy.

This information is provided to establish the baseline physical conditions for comparison with the changes that are expected for the LSJR and SDWQ alternatives in Section 5.4, *Impact Analysis*.

---

[4] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.

5.2.1 San Joaquin River Basin and Southern Delta Hydrology and Water Quality

Following is a summary of unimpaired flow and the measured (historical) flows of the SJR Basin and southern Delta as a whole, as well as a general discussion of existing water quality conditions, including water quality impairments identified within the SJR Basin and southern Delta. Specific details of flow and water quality associated with the Upper SJR, the three eastside tributaries, the LSJR, and the southern Delta are presented in Sections 5.2.2 through 5.2.8.

Unimpaired and Historical Flow

In the Sierra Nevada, with the combination of rainfall runoff, winter snowpack accumulation, and spring snowmelt, there is a typical monthly progression of fall storm flows, winter storm flows and snowpack accumulation, spring snowmelt, and summer groundwater discharge (i.e., baseflow) (McBain and Trush 2000; Kondolf et al. 2001; Stillwater Sciences 2001; Cain et al. 2003). These seasonal flow characteristics are observed in all three eastside tributaries to the SJR in nearly all years, with wide variations in runoff volume from year to year.

The hydrology of the SJR as measured at Vernalis is greatly altered from the unimpaired runoff conditions. Unimpaired flow is the river flow at a specified location that would occur if all runoff from the watershed remained in the river, without storage or diversion. Construction of many dams and agricultural diversions have altered the natural hydrology of the SJR and its major tributaries (McBain and Trush 2000; Kondolf et al. 2001; Cain et. al 2003; Brown and Bauer 2009). The unimpaired monthly hydrology is used to describe the LSJR alternatives, which reflect the year-to-year variations in monthly runoff that are observed in Central Valley hydrology and approximate flows of a more natural pattern. Therefore, it is important to describe and understand the unimpaired flows of the SJR Basin and three eastside tributary watersheds. Runoff from the SJR Basin and three eastside tributary watersheds shows wide annual, monthly (i.e., seasonal changes), and daily (i.e., storm events) variations and is modified by reservoir storage, diversions, and agricultural return flows from irrigated lands.

The SJR Basin is subject to two types of floods; prolonged rainstorms during the winter and rapid snowpack melting in the late spring and early summer of heavy snowfall years. Floods along foothill streams (without storage dams) and the LSJR often exceed channel capacities and damage urban and agricultural levees or flood portions of these areas. Floods are generally controlled below dams because the reservoir operations include sufficient flood storage space to reduce the reservoir releases to the specified maximum flood control flows, except for rare events when the spillways must be used (e.g., January 1997). Table 5-2 shows the watershed areas, median annual unimpaired runoff, and storage reservoirs for the SJR at Friant Dam and the three eastside tributaries.

Table 5-2. Watershed Characteristics for the SJR at Friant Dam and the LSJR Eastside Tributaries

Characteristic	Stanislaus River	Tuolumne River	Merced River	SJR at Friant Dam
Drainage Area of Tributary at Confluence with the SJR	1,195 square miles (980 square miles [82%] upstream of Goodwin Dam)	1,870 square miles (1,533 square miles [82%] upstream of La Grange Dam)	1,270 square miles (1,067 square miles [84%] upstream of Merced Falls)	1,660 square miles

Water Quality and Impairments

Beneficial uses are designated for waters within a specified area by the State Water Board and each regional water board in their respective water quality control plans (WQCPs). The 2006 *Water Quality Control Plan for the San Francisco Bay/Sacramento–San Joaquin Delta Estuary* (2006 Bay-Delta Plan) identifies beneficial uses within the Bay-Delta Estuary (See Section 5.3, *Regulatory Background*, for a discussion of the 2006 Bay-Delta Plan). Additionally, the Central Valley Regional Water Quality Control Board's *Fourth Edition Water Quality Control Plan for the Sacramento River and San Joaquin River Basins* (Basin Plan) (Central Valley Water Board 2011) identifies beneficial uses of the Delta and SJR areas within its jurisdiction. Water bodies in the plan area are used for many purposes, as evidenced by the number of beneficial uses shown in Table 5-3.

Table 5-3. Designated Beneficial Uses for Waterbodies in the Bay-Delta and the SJR Basin

Name[a]	Abbreviation[a]	Beneficial Uses[b]
Municipal and Domestic Supply	MUN	Uses of water for community, military, or individual water supply systems including drinking water supply
Agricultural Supply	AGR	Uses of water for farming, horticulture, or ranching including irrigation (including leaching of salts), stock watering, or support of vegetation for range grazing
Industrial Service Supply	IND	Uses of water for industrial activities that do not depend primarily on water quality, including mining, cooling water supply, hydraulic conveyance, gravel washing, fire protection, and oil well pressurization
Industrial Process Supply	PRO	Uses of water for industrial activities that depend primarily on water quality
Hydropower Generation	POW	Uses of water for hydropower generation
Groundwater Recharge	GWR	Uses of water for natural or artificial recharge of groundwater for purposes of future extraction, maintenance of water quality, or halting of saltwater intrusion into freshwater aquifers
Navigation	NAV	Uses of water for shipping, travel, or other transportation by private, military, or commercial vessels
Water Contact Recreation	REC-1	Uses of water for recreational activities involving body contact with water where ingestion of water is reasonably possible, including swimming, wading, water-skiing, skin and scuba diving, surfing, white-water activities, fishing, and use of natural hot springs
Non-Contact Water Recreation	REC-2	Uses of water for recreational activities involving proximity to water but where there is generally no body contact with water or any likelihood of ingestion of water, including picnicking, sunbathing, hiking, beachcombing, camping, boating, tide pool and marine life study, hunting, sightseeing, and aesthetic enjoyment in conjunction with the above activities
Commercial and Sport Fishing	COMM	Uses of water for commercial or recreational collection of fish, shellfish, or other organisms, including uses involving organisms intended for human consumption or bait purposes
Warm Freshwater Habitat	WARM	Uses of water that support warm water ecosystems, including preservation or enhancement of aquatic habitats, vegetation, fish, and wildlife, including invertebrates
Cold Freshwater Habitat	COLD	Uses of water that support cold water ecosystems, including preservation or enhancement of aquatic habitats, vegetation, fish, and wildlife, including invertebrates
Wildlife Habitat	WILD	Uses of water that support terrestrial or wetland ecosystems, including preservation and enhancement of terrestrial habitats or wetlands, vegetation, wildlife (e.g., mammals, birds, reptiles, amphibians, invertebrates), and wildlife water and food sources

Name[a]	Abbreviation[a]	Beneficial Uses[b]
Rare, Threatened, or Endangered Species	RARE	Uses of water that support aquatic habitats necessary, at least in part, for the survival and successful maintenance of plant and animal species established under state or federal law as rare, threatened, or endangered
Migration of Aquatic Organisms	MIGR	Uses of water that support habitats necessary for migration and other temporary activities by aquatic organisms, such as anadromous fish
Spawning, Reproduction, and/or Early Development	SPWN	Uses of water that support high quality aquatic habitats suitable for reproduction and early development of fish
Shellfish Harvesting	SHELL	Uses of water that support habitats suitable for the collection of filter feeding shellfish (e.g., clams, oysters, mussels) for human consumption, commercial, or sport purposes
Estuarine Habitat	EST	Uses of water that support estuarine ecosystems, including preservation or enhancement of estuarine habitats, vegetation, fish, shellfish, and wildlife (e.g., estuarine mammals, waterfowl, shorebirds)

[a] The names, abbreviations, and beneficial use descriptions are not identical in each water quality control plan.

[b] Potential beneficial use identified in the Basin Plan.

Under Clean Water Act (CWA) Section 303(d),[5] states, territories, and authorized tribes are required to develop a ranked list of water-quality limited segments of rivers and other water bodies under their jurisdictions where effluent limitations in point-source discharge permits are not stringent enough to implement applicable water quality standards. Listed waters are those that do not meet water quality standards. The law requires that action plans, or total maximum daily loads (TMDLs), be developed to attain and maintain water quality. TMDL is defined as the sum of the individual waste load allocations from point sources, load allocations from nonpoint sources and background loading, plus an appropriate margin of safety.

State and Regional Water Boards develop lists of Section 303(d) state water bodies that do not meet applicable water quality standards (in California, beneficial uses, water quality objectives, and the state's anti-degradation policy serve as water quality standards for purposes of the CWA) and waters not expected to meet those standards with the implementation of technology-based controls. In October 2011, United States Environmental Protection Agency (USEPA) issued its final decision and gave final approval to the water bodies and pollutants added to California's Section 303(d) list. Table 5-4 shows the constituents identified in the Section 303(d) list for impaired waters in the study area plus portions of the Upper SJR.

---

[5] Clean Water Act section 303(d) requires states, territories, and authorized tribes to develop a ranked list of water quality limited segments of rivers that do not meet water quality standards.

Table 5-4. Clean Water Act Section 303(d) Listed Pollutants and Sources for the Study Area and the Upper SJR

Pollutant/Stressor	Listed Source	Location of Listing
Arsenic	Source unknown	Upper SJR (Bear Creek to Mud Slough)
Benzenehexachloride (alpha-HCH)	Source unknown	LSJR (Merced River to Tuolumne River)
Boron	Agriculture	LSJR (Merced River to Tuolumne River), Upper SJR (Mendota Pool to Bear Creek), Upper SJR (Bear Creek to Mud Slough), Upper SJR (Mud Slough to Merced River)
Chlorpyrifos	Agriculture, urban runoff/ storm sewers	Merced River (Lower), Tuolumne River (Lower), Stanislaus River (Lower), LSJR (Merced River to Tuolumne River), LSJR (Tuolumne River to Stanislaus River), LSJR (Stanislaus River to Delta boundary), southern Delta, Stockton Ship Channel, Upper SJR (Mendota Pool to Bear Creek), Upper SJR (Bear Creek to Mud Slough), Upper SJR (Mud Slough to Merced River)
Dacthal	Agriculture	LSJR (Stanislaus River to Delta boundary), Upper SJR (Bear Creek to Mud Slough)
Dichlorodiphenyldichloroethylene (DDE)	Agriculture	LSJR (Merced River to Tuolumne River), LSJR (Stanislaus River to Delta boundary)
Dichlorodiphenyltrichloroethane (DDT)	Agriculture	LSJR (Merced River to Tuolumne River), LSJR (Tuolumne River to Stanislaus River), LSJR (Stanislaus River to Delta boundary), Southern Delta, Stockton Ship Channel, Upper SJR (Mendota Pool to Bear Creek), Upper SJR (Bear Creek to Mud Slough), Upper SJR (Mud Slough to Merced River)
Dissolved Oxygen (low DO)	Source unknown, organic enrichment, municipal point sources, urban runoff/ storm sewers, hydromodification	Middle River (in southern Delta), Old River (SJR to Delta-Mendota Canal), Stockton Ship Channel
Diazinon	Agriculture, urban runoff/ storm sewers	Merced River (Lower), Tuolumne River (Lower), Stanislaus River (Lower), LSJR (Tuolumne River to Stanislaus River), southern Delta, Stockton Ship Channel, Upper SJR (Mendota Pool to Bear Creek), Upper SJR (Mud Slough to Merced River)
Diuron	Agriculture	LSJR (Stanislaus River to Delta boundary)
Escherichia coli (E. coli)	Source unknown	Merced River (Lower), LSJR (Stanislaus River to Delta boundary), Upper SJR (Bear Creek to Mud Slough), Upper SJR (Mud Slough to Merced River)
Group A pesticides	Agriculture	Merced River (Lower), Tuolumne River (Lower), Stanislaus River (Lower), LSJR (Merced River to Tuolumne River), LSJR (Tuolumne River to Stanislaus River), LSJR (Stanislaus River to Delta boundary), southern Delta, Stockton Ship Channel, Upper SJR (Mendota Pool to Bear Creek), Upper SJR (Bear Creek to Mud Slough), Upper SJR (Mud Slough to Merced River)

Pollutant/Stressor	Listed Source	Location of Listing
Invasive species	Source unknown	Southern Delta, Stockton Ship Channel, Upper SJR (Friant Dam to Mendota Pool)
Mercury	Resource extraction, industrial-domestic wastewater, atmospheric deposition, nonpoint source	Lake McClure, New Don Pedro Reservoir, New Melones Reservoir, Tulloch Reservoir, Woodward Reservoir, Merced River (Lower), Tuolumne River (Lower), Stanislaus River (Lower), LSJR (Merced River to Tuolumne River), LSJR (Tuolumne River to Stanislaus River), LSJR (Stanislaus River to Delta boundary), southern Delta, Stockton Ship Channel, Upper SJR (Bear Creek to Mud Slough), Upper SJR (Mud Slough to Merced River)
Salinity (EC)	Agriculture	LSJR (Merced River to Tuolumne River), LSJR (Tuolumne River to Stanislaus River), LSJR (Stanislaus River to Delta boundary), southern Delta, Upper SJR (Bear Creek to Mud Slough), Upper SJR (Mud Slough to Merced River)
Selenium	Agriculture	Upper SJR (Mud Slough to Merced River)
Temperature, water	Source unknown	Merced River (Lower), Tuolumne River (Lower), Stanislaus River (Lower), LSJR (Merced River to Tuolumne River), LSJR (Tuolumne River to Stanislaus River), LSJR (Stanislaus River to Delta boundary)
Total dissolved solids (TDS)	Source Unknown	Old River (SJR to Delta-Mendota Canal)
Toxaphene	Source unknown	LSJR (Stanislaus River to Delta boundary)
Unknown toxicity	Source unknown, agriculture	Merced River (Lower), Tuolumne River (Lower), Stanislaus River (Lower), LSJR (Merced River to Tuolumne River), LSJR (Tuolumne River to Stanislaus River), LSJR (Stanislaus River to Delta boundary), southern Delta, Stockton Ship Channel, Upper SJR (Mendota Pool to Bear Creek), Upper SJR (Bear Creek to Mud Slough), Upper SJR (Mud Slough to Merced River)

Source: State Water Board 2011.
Note: In addition to the pollutants listed here, the Stockton Ship Channel was on the 303 (d) list for several additional pollutants, including: dioxin, furan compounds, pathogens, and PCBs (polychlorinated biphenyls).

Section 303(d) requires that states evaluate and rank water quality impairments that cannot be resolved through point source controls and, in accordance with the priority ranking, develop a TMDL for those pollutants USEPA identifies under Section 304(a)(2) as suitable for such calculation. Table 5-5 contains a list of completed or ongoing TMDL projects in the SJR Basin and southern Delta.

Table 5-5. Summary of Completed and Ongoing Total Maximum Daily Loads in the SJR Basin and the Southern Delta

Pollutant/Stressor	Water Bodies Addressed	TMDL Status
Dissolved Oxygen	SJR-Stockton Deep Water Ship Channel (DWSC) from Stockton to Disappointment Slough	TMDL report completed—January 2005 State-Federal approval—February 2007
Chlorpyrifos and diazinon	LSJR	TMDL report completed—October 2005 State-Federal approval—December 2006
Chlorpyrifos and diazinon	SJR and Delta	TMDL report completed—June 2006 State-Federal approval—October 2007
Mercury/methylmercury	Delta	TMDL report completed—April 2010
Mercury/methylmercury	Reservoirs	Ongoing
Pesticides	Basin-wide	Ongoing
Organochlorine pesticides	SJR tributaries; Delta	Ongoing
Salt and boron	LSJR	TMDL report completed—October 2005 State-Federal approval—February 2007
Selenium	LSJR	TMDL report completed—August 2001 State-Federal approval—March 2002

Source: Central Valley Water Board 2013.
TMDL = total maximum daily load

There are numerous constituents of concern that impair water quality in the study area, as identified in Table 5-4. For example, salinity is an important parameter of concern for the southern Delta and Bay-Delta that reflects the total ionic content of the water, ranging from very low levels deemed fresh water, like those present in the plan area, to the high salinity content of seawater in SF Bay.

The SJR is unusual because salinity tends to be lower downstream (e.g., at Vernalis) than upstream of the Merced River confluence. High salinity upstream of the Merced River confluence is due to heavy contributions of salts from Salt and Mud Sloughs, as well as water re-circulated from the Delta via the Delta-Mendota Canal (DMC) and agricultural return flows. As water moves downstream, the Stanislaus, Tuolumne, and Merced Rivers dilute the salinity in the SJR because they have relatively high flows, but contribute little salt to the system. Current water quality objectives specify that SJR water entering the southern Delta at Vernalis should remain at or below 1.000 dS/m during September through March and at or below 0.700 dS/m during April through August. Because of the relatively low salinity in the three eastside tributaries, it has been possible to attain this objective by increasing releases from New Melones Reservoir on the Stanislaus River when necessary. Salinity conditions in the LSJR, Stanislaus, Tuolumne, and Merced Rivers are described in more detail below and in Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta*.

A TMDL for controlling salt and boron loads to the LSJR was adopted in 2005. Implementation of the TMDL is described in the Central Valley Water Board's 2004 final staff report on amendments to the Basin Plan for the Central Valley (Central Valley Water Board 2004). The amendment recommends the implementation of a real-time water quality management program (RTMP) that would facilitate the control and timing of wetland and agricultural drainage to coincide with periods when dilution flow in the SJR is sufficient to meet Vernalis salinity objectives. The U.S. Bureau of Reclamation

(USBR) entered into an updated Management Agency Agreement with the Central Valley Water Board in 2014 that details USBR's responsibility to assist in the development and implementation of the RTMP. However, even with the TMDL load allocations, water quality objectives at Vernalis could still be exceeded. When this occurs, USBR would continue to be responsible for ensuring that the Vernalis salinity objectives are met in accordance with its water rights. Responsibility is assigned to the USBR because of the agency's large contribution to the salinity problem in the SJR basin. The water development programs of the USBR have been responsible for reducing flows in the SJR (by operating Millerton Reservoir and the Madera and Friant-Kern canals) and replacing some of that water with relatively saline water from the Delta-Mendota Canal. The main way that USBR currently fulfills its obligation to attain water quality objectives at Vernalis is by releasing relatively clean Stanislaus River water from New Melones.

Chloride, bromide, sulfate, and boron are specific ions that contribute to overall salinity and are constituents of concern; however, in the plan area, only boron is included on the 303(d) and TMDL lists. Salinity can affect multiple beneficial uses. As a habitat feature, salinity can define the types and distribution of aquatic organisms based on their adaptation to fresh water versus brackish, or saline water in the Delta. Agricultural users are also concerned with boron and salinity, since some crops are sensitive to these constituents, which can affect crop yields. Municipal water users have concerns regarding the ability to utilize recycled water when the source water has high EC values. The presence of bromide in municipal water sources is a concern since bromide is the precursor to the formation of harmful byproducts of the water disinfection process, however there are no 303(d) listing for bromide in the plan area.

As indicated above in Table 5-4, the lower portions of the Stanislaus, Tuolumne, and Merced Rivers, and the SJR to the Delta are listed as impaired due to elevated water temperatures. Water temperature conditions in the eastside tributaries and the LSJR are affected by the operation of the reservoirs and by river diversions used for agriculture. During the warmer months, water released from the three large reservoirs on the Stanislaus, Tuolumne, and Merced Rivers is relatively cool. Cool water accumulates in the reservoirs during the rainy season and during spring runoff. The cool water at the bottom of the reservoirs is minimally affected by seasonal warming that occurs at the surface during the warmer months. However, when cool water is released from the bottom of the reservoirs through the late spring, summer, and fall, the cool water supply can become depleted, potentially causing the temperature of the water that is released to the river to become warmer. While large releases may deplete cool water in reservoirs, they can also help to reduce warming along the length of a river during the warmer months. Higher flows result in faster travel times, which allow water to move farther downstream before warming to reach equilibrium with environmental conditions. Baseline water temperature conditions are described in detail in Appendix F.1, *Hydrologic and Water Quality Modeling*.

Temperature and salinity are the two main water quality parameters that may be affected by the alternatives. The plan alternatives involve changing flow in the eastside tributaries, LSJR and the southern Delta, which would affect these parameters. A discussion of the LSJR flow alternatives and the water temperature modeling results that show expected changes in water temperature is included in this chapter; however, the discussion of the potential impacts on fisheries associated with changes to water temperature can be found in Chapter 7, *Aquatic Biological Resources*.

In addition to salinity and water temperature, other water quality impairments in the SJR Watershed and southern Delta, include turbidity and suspended sediment, dissolved oxygen (DO), pesticides, herbicides, nutrients, and trace metals. The entire Delta is identified on the Section

303(d) list as impaired by unknown toxicity, which refers to the mortality of aquatic organisms and/or sublethal effects (e.g., reduced growth or reproductive success) observed during aquatic toxicity bioassays. The unknown toxicity can be caused by one or more individual toxicants that have not been identified. Poor water quality associated with the presence of pollutants can result in significant impacts on aquatic life. Trace metals, pesticides, and herbicides can be toxic to aquatic life at relatively low concentrations. Temperature and DO are of concern because the eastside tributaries, LSJR, and southern Delta serve as a migration and rearing corridor for anadromous salmonids, which are sensitive to these parameters. In the past, low DO concentrations in the Stockton Deepwater Ship Channel are thought to have negatively affected migrating adult salmonids in the fall. Excess nutrients can cause blooms of nuisance algae and aquatic vegetation, and their decay can result in low DO concentrations. Several locations in the southern Delta are listed as impaired due to low DO concentrations and a TMDL for DO was adopted in 2005 that includes measures to improve DO conditions in the Stockton Deepwater Ship Channel that include aeration facilities at the Port of Stockton.

5.2.2 Upper San Joaquin River

Unimpaired and Historical Flow

The SJR Watershed upstream of Friant Dam covers an area of about 1,660 square miles. The SJR Watershed upstream of the Merced River confluence is approximately 5,800 square miles, but most of the runoff originates upstream of Friant Dam. Several reservoirs in the upper portion of the SJR Basin, including Edison, Florence, Huntington, Mammoth Pool, and Shaver Lake, are primarily used for seasonal storage for hydroelectric power generation. These upstream reservoir operations affect inflows to Millerton Lake, the reservoir behind Friant Dam. The average annual unimpaired runoff estimated at Friant Dam is about 1,732 thousand acre-feet (TAF) and the median runoff is about 1,453 TAF. The reservoir provides a maximum storage of 520 TAF, provides flood control for the SJR, provides downstream releases to supply senior water rights diversions, and provides diversions into the Madera and Friant-Kern Canals. Flood control storage space in Millerton Lake is limited, and additional flood control is provided by the upstream reservoirs.

USBR must maintain sufficient flow between Friant Dam and Gravelly Ford to meet the needs of downstream prior water rights holders. USBR must supply a minimum flow of 5 cubic feet per second (cfs) below the last water right diversion located about 40 miles downstream of Friant Dam near Gravelly Ford. A maximum river release of about 125 cfs in the summer months supplies these downstream riparian and water right users. The maximum flood control release from Friant Dam (established by the U.S. Army Corps of Engineers (USACE) is 8,000 cfs. USBR is undertaking the SJR Restoration Program[6] which will eventually provide water throughout the year to reconnect the upstream river below Friant to the SJR at the mouth of the Merced River. In 2006, parties to *NRDC v. Rodgers* executed a stipulation of settlement that calls for, among other things, restoration of flows on the Upper SJR from Friant Dam to the confluence of the Merced River. Required release flows from Friant Dam for each water year type have been identified, but the amount of this Upper SJR water that would be observed at the mouth of the Merced River is as yet uncertain.

---

[6] Implementation of the settlement and the Friant Dam release flows required by the San Joaquin River Restoration Program are expected to increase the existing SJR flows at Stevinson in the near future.

Hydrologic conditions are often described using cumulative distribution. The cumulative distribution of a particular variable (e.g., flow at a location) provides a basic summary of the distribution of values. The percentile (percent cumulative distribution) associated with each value indicates the percent of time that the values were less than the specified value. For example, a 10th percentile value of 2 indicates that 10 percent of the time, the values were less than 2. The 0th percentile is the minimum value, the 50th percentile is the median value, and the 100th percentile is the maximum value. In many cases, the 10th and 90th percentiles are selected to represent relatively low and relatively high values rather than the minimum and maximum because they are representative of multiple years rather than the 1 year with the highest value and the 1 year with the lowest value. A monthly year-by-year assessment is not necessary because increases in monthly values during some years may be counteracted by decreases during other years. Therefore, the evaluation of change in hydrologic parameters in this chapter and other chapters of this SED was based on the monthly cumulative distribution of values rather than individual changes in monthly values.

Table 5-6a shows the monthly cumulative distribution of SJR unimpaired runoff (cfs) at Friant Dam for 1922–2003. The range of monthly runoff is summarized with a cumulative distribution at each 10th percentile from the minimum to the maximum. The median (50 percent cumulative) monthly values provide a good summary of the seasonal pattern. The maximum runoff was in April, May, and June. The minimum runoff was in September, October, and November. The estimated median unimpaired flow pattern in the February–June period was 1,340 cfs in February, 1,925 cfs in March, 3,966 cfs in April, 6,916 cfs in May, and 5,430 cfs in June. The range of flows in these months is quite large from year to year.

Table 5-6b shows the monthly cumulative distribution of historical (observed) flow below Friant Dam (cfs) for 1985–2009 (most recent 25-year period). The highest median flows of 200 cfs are in June, July, and August. The highest historical flows (90 percent cumulative) were greater than 2,000 cfs in February–June, indicating that flood control releases were made in a few years for each of these months. The historical average annual flow volume released from Friant Dam was approximately 400 TAF, which was 25 percent of unimpaired flow. The median annual flow volume was approximately 130 TAF, indicating that the flood releases in a few years raised the average flow volume below Friant Dam to approximately three times the median flow.

Table 5-6a. Monthly Cumulative Distribution of SJR Unimpaired Flow (cfs) at Friant Dam for 1922–2003

Figure 2-7 shows the monthly unimpaired and historical SJR flows below Friant Dam for the most recent 10-year period of 2000–2009. The average unimpaired flow for this 10-year period was 1,687 TAF (97 percent of the 1922–2003 average). The historical flows were much less than the unimpaired flows except in wet years when flood releases were more than half of the unimpaired runoff (e.g., 2005 and 2006). Most of the runoff was seasonally stored in upstream reservoirs and in Millerton Lake and diverted to the Friant-Kern and Madera canals for irrigation. During high-flow years, however, there are considerable flood control releases from Friant Dam.

Additional flow enters the SJR from the Chowchilla and the Fresno Rivers and smaller creeks. These two rivers have smaller watersheds that do not extend to the crest of the Sierra Nevada and, consequently, have much less runoff, most of which is stored for irrigation uses. In wet years, some flood flows from the Tulare Lake Basin (i.e., Kings River) enter the SJR through Fresno Slough to the Mendota Pool. Local runoff from the Bear Creek Watershed in the vicinity of Merced and runoff with agricultural drainage and managed wetlands and wildlife refuges in the Grasslands Watershed provides additional SJR flow upstream of the Merced River. Flow and water quality in the SJR upstream of the Merced River is measured at Stevinson, upstream of Salt Slough, and at Fremont Ford, upstream of Mud Slough. Mud Slough is a combination of runoff, irrigation drainage, and discharge from the San Luis Drain that bypasses tile drainage around the Grasslands wildlife refuges and waterfowl clubs.

Water Quality

Water upstream from Friant Dam has low mineral and nutrient concentrations due to the insolubility of granitic soils in the watershed and the river's granite substrate (SCE 2007). As the SJR and tributary streams flow from the Sierra Nevada foothills across the eastern valley floor, their mineral concentration increases. Sediment is likely captured behind the many dams. Water quality in various segments of the SJR below Friant Dam is degraded because of low flow and discharges from agricultural areas and wastewater treatment plants. Water quality downstream is generally influenced by releases from Friant Dam, with contributions from agricultural and urban return flows as the river approaches the Merced River confluence. It generally becomes degraded the farther downstream it gets from the dam. Downstream of the dam, the river is identified on the 303(d) list for constituents associated with agricultural uses, such as pesticides (chlorpyrifos, diazinon, Dichlorodiphenyltrichloroethane [DDT]), salinity (EC), and unknown toxicity (State Water Board 2011) (Table 5-4).

Water temperatures below Friant Dam and Mendota Dam are dependent on water temperatures of inflow from the Delta Mendota Canal and, occasionally, the Kings River system via James Bypass. Water temperature conditions downstream are also dependent on inflow water temperatures during flood flows from upstream. SJR water temperatures south of the confluence of the Merced River are influenced greatly by the water temperature of Salt Slough inflow, which contributes the majority of streamflow in this area (USBR 2007).

5.2.3 Merced River

Unimpaired and Historical Flow

The Merced River flows into the SJR at river mile (RM) 118 and is the most upstream of the three eastside tributaries with existing fish populations. The Merced River is 135 miles long and drains a

1,270 square-mile watershed. Approximately 52 miles of the Merced River are downstream of the Crocker-Huffman Dam, the most downstream barrier to fish migration. Three of the four dams on the Merced River, known collectively as the Merced River Development Project, are owned by Merced Irrigation District (Merced ID), and Merced Falls Dam is owned by Pacific Gas and Electric Company (PG&E). Three of the dams are licensed by the Federal Energy Regulatory Commission (FERC). The Merced River unimpaired flow is essentially the same as the Lake McClure inflow because there are no major storage reservoir or diversions upstream. The runoff from the Yosemite Valley flows unimpaired downstream to Lake McClure.

Merced ID provides surface water and electric service to approximately 164,000 acres in Merced County (Merced ID 2008a). Merced ID diverts from the Merced Falls reservoir via the Northside Canal and from the Merced River via the Main Canal at the Crocker-Huffman Diversion Dam during the irrigation season. These diversions have averaged approximately 525 TAF per year (TAF/y) (Stillwater Sciences 2001).

Flows released from the Crocker-Huffman Dam to the Merced River must satisfy FERC requirements, as well as the Davis-Grunsky Contract and the Cowell Agreement requirements. Merced ID holds the FERC license (Project Number 2179) for the Merced River Hydroelectric Project, which was issued on April 18, 1964. FERC Project Number 2179 required the licensee to provide minimum stream flows (Table 5-7) in the Merced River at Shaffer Bridge, approximately 24 miles downstream from the Crocker-Huffman Dam.

Table 5-7. FERC Project Number 2179 Stream Flow Requirements for the Merced River at Shaffer Bridge (cfs)

Period	Normal Year	Dry Year
June 1–October 15	25	15
October 16–October 31	75	60
November 1–December 31	100–200	75–150
January 1–May 31	75	60

Note: On December 4, 2015, FERC released a final EIS for the relicensing of the Merced Irrigation District's and PG&E's hydroelectric projects. A new FERC license could alter the existing Merced River flow requirements.
cfs = cubic feet per second
FERC = Federal Energy Regulatory Commission

Releases from the Crocker-Huffman Dam must be greater than the FERC minimum flow requirements at Shaffer Bridge to satisfy the Cowell Agreement and the Davis-Grunsky Contract. The 1926 Cowell Agreement (pursuant to a Merced Superior Court order) calls for the Merced ID to maintain monthly flows downstream of the Crocker-Huffman Dam to satisfy water right adjudications for downstream water users. The flows are 50 cfs October–February and are 100 cfs to 250 cfs during the March–September irrigation season. This water is diverted from the river at a number of private ditches between Crocker-Huffman Dam and Shafter Bridge in accordance with the Cowell Agreement beneficiaries so that the FERC minimum flows at Shaffer Bridge are satisfied. The Davis-Grunsky Contract provides minimum flow standards of 180 cfs in dry years (less than 450,000 AF runoff) and 220 cfs in all other years from November–March at Crocker-Huffman Dam (and Shaffer Bridge) for Chinook salmon spawning and rearing. A flood control release limit of 6,000 cfs was established by USACE for the combination of Dry Creek and the Merced River flows at Stevinson.

Table 5-8a shows the monthly cumulative distribution of Merced River unimpaired runoff (flow, cfs) at New Exchequer Dam for 1922–2003. The range of monthly runoff is summarized with a cumulative distribution at each 10th percentile from the minimum to the maximum. The maximum runoff was in April, May, and June. The minimum runoff was in August, September, October, and November. The estimated median unimpaired flow pattern in the February–June period was 969 cfs in February, 1,303 cfs in March, 2,391 cfs in April, 3,955 cfs in May, and 2,451 cfs in June. The range of flows in these months is quite large from year to year.

Table 5-8b shows the monthly cumulative distribution of historical (observed) Merced River flow (cfs) at Stevinson (downstream of Dry Creek) for 1985–2009 (most recent 25-year period). The average unimpaired flow for this 25-year period was 937 TAF (98 percent of the 1922-2003 average). The highest median flows were in April and May, which are the months with highest unimpaired runoff. The highest historical Merced River flows (90 percent cumulative) were greater than 1,500 in February–June, indicating that flood control releases were made in a few years in each of these months. The monthly ranges of historical Merced River flows were large only in the months with flood control releases. The median flows in the summer months of July–September were less than 150 cfs. The historical average annual flow volume for the Merced River at Stevinson was 438 TAF, approximately 47 percent of the average unimpaired flow for this period. The median annual flow volume was 267 TAF, indicating that flood releases in a few years raised the average flow volume in the Merced River to approximately 1.5 times the median flow.

Figure 2-8 shows the monthly unimpaired and historical Merced River flow at Stevinson for the recent 10-year period of 2000–2009. Unimpaired flow at New Exchequer Dam averaged 884 TAF/y, and the historical releases (including flood flows in 2000, 2005 and 2006) averaged 403 TAF/y. The peak historical flows were in April and May of 2006 because Lake McClure was nearly full, and this relatively high flow of 4,500 cfs was for flood control purposes. The majority of the historical flow volume was observed in the wet years with flood control releases. Lake McClure is the smallest of the tributary reservoirs and is generally filled and drawn down each year.

Major Dams and Reservoirs

The New Exchequer powerhouse has a capacity of approximately 95 megawatts (MW) with a maximum head of 400 feet (ft) and a maximum flow of approximately 3,200 cfs (Merced ID 2008b). The hydropower facilities at the rim dams[7] operate each day to maximize energy generation efficiency and revenue, thereby giving preference to full generation during peak energy demand periods (generally 9AM–9PM). This is done by operating the turbine-generators at a constant high flow for a portion of the day and shutting them off for the remainder of the day. Water released for peaking power is regulated downstream at the approximately 10 TAF McSwain Reservoir, with a normal daily fluctuation of several feet. The McSwain Dam powerhouse has a capacity of 9 MW, with a maximum head of approximately 55 f., and a maximum flow of approximately 2,700 cfs (Merced ID 2008c). Merced Falls Dam, downstream of McSwain Dam is a small diversion dam (for MID's Northside Canal) with a small hydroelectric generator owned by Pacific Gas & Electric with a capacity of approximately 3.4 MW, a maximum head of about 50 ft., and a maximum flow of approximately 1,750 cfs (Merced ID 2008b). The Crocker-Huffman Dam, the furthest downstream

---

[7] In this document, the term *rim dams* is used when referencing the three major dams and reservoirs on each of the eastside tributaries: New Melones Dam and Reservoir on the Stanislaus River; New Don Pedro Dam and Reservoir on the Tuolumne River; and New Exchequer Dam and Lake McClure on the Merced River.

dam on the Merced River, diverts water to the Merced ID main canal and Merced River Hatchery and releases water to the Merced River.

Water Quality

Some water quality characteristics in the Merced River, such as water temperature, are affected by reservoir operations and by changes in river flow attributable to water supply and hydropower generation activities. Appendix F.1, *Hydrologic and Water Quality Modeling*, contains a description of baseline water temperatures on the Merced River, and Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta*, includes a presentation of existing salinity conditions.

EC generally increases as water moves downstream in the Merced River because of the relatively high EC in agricultural drainage and groundwater discharge to the river. The increase in EC is generally greater when the river flow is low due to the reduced dilution of the agriculture drainage under low flow conditions. However, near the confluence with the SJR, the measured monthly EC in the Merced River (at Stevinson) is still generally low, usually ranging from approximately 0.050 to 0.400 dS/m.

5.2.4 Tuolumne River

Unimpaired and Historical Flow

The Tuolumne River flows into the SJR at RM 83, approximately 8 miles upstream of the Stanislaus River confluence and 35 miles downstream of the Merced River. The Tuolumne River is 155 miles long and drains a 1,870 square mile watershed from its headwaters in the Sierra Nevada to its confluence with the SJR, approximately 10 miles west of Modesto. Approximately 52 miles of the river are downstream of La Grange Dam, the furthest downstream impediment to fish passage. Existing dams, water diversions, and downstream minimum flow agreements influence the hydrology of the Tuolumne River. Hetch Hetchy (360 TAF), Cherry Lake (270 TAF) and Lake Eleanor (27 TAF) in the Upper Tuolumne River Watershed provide hydropower and water supply for San Francisco and other Bay Area cities.

New Don Pedro, which is owned and operated by the Turlock Irrigation District (TID) and Modesto Irrigation District (MID), is the major storage reservoir on the Tuolumne River. The 2.0 MAF reservoir stores water for irrigation, hydroelectric generation, fish and wildlife enhancement, recreation, and flood control (340 TAF for flood control). Water released from the New Don Pedro Dam is impounded and regulated by the LaGrange Dam and Reservoir. LaGrange Dam, located 2.5 miles downstream of New Don Pedro, is the diversion point for the TID and MID canals.

TID and MID have senior water rights on the Tuolumne River and control much of the river flow in most years. Under the Raker Act, which authorized the construction of the Hetch Hetchy system, the City and County of San Francisco (CCSF) must recognize the prior rights of TID and MID to receive a certain amount of the daily natural flow of the Tuolumne River as measured at La Grange Dam when the water can be beneficially used by the districts. Under the Raker Act, CCSF must bypass 2,350 cfs, or the entire natural daily flow of the Tuolumne River whenever the flow is less than that amount. From April 15–June 13 (peak snowmelt) CCSF must bypass 4,066 cfs (FERC 1996).

The 1966 Fourth Agreement, between CCSF, TID, and MID, in part, sets forth the parties' responsibilities for water banking and operations involving New Don Pedro Reservoir, including sharing responsibility for additional instream flow requirements imposed as a result of FERC licensing. CCSF does not actually divert or store water in New Don Pedro Reservoir; instead it has a water bank account in the reservoir that provides flexibility in satisfying TID's and MID's Raker Act entitlements and its Fourth Agreement obligations. Under the Fourth Agreement, CCSF is allocated 570,000 AF of storage in Don Pedro Reservoir, with an additional 170,000 AF of storage when flood control is not required, to a maximum of 740,000 AF of storage space. Certain excess flows above the Raker Act requirements are credited to CCSF, which then "banks" the amount of water for later use. CCSF debits the water bank account when it diverts or stores water that would otherwise be within the districts' entitlements. A negative balance (CCSF bank depleted) would require prior agreement with the two irrigation districts. The Fourth Agreement also states that in the event any future changes to the New Don Pedro FERC water release conditions negatively impact the two irrigation districts, CCSF, MID, and TID would apportion the burden prorated at 51.7121 percent to CCSF and 48.2879 percent to MID and TID (CCSF/TID/MID 1966).

Figure 5-1 shows two examples of how water supplies are divided (on a daily basis) between TID and MID and CCSF under different hydrologic regimes. During a dry year in 1992, only 68 TAF (mostly in April) accrued for CCSF (68 TAF is equivalent to 1,143 cfs for 30 days). CCSF asked customers to conserve water and bought additional supplies from the California Department of Water Resources' (DWR's) emergency drought water bank due to the drought conditions that year. Rain and snow returned to the Sierra Nevada in 1993, allowing full water deliveries and replenishing surface storage in the Tuolumne River Watershed (including water banked by CCSF in New Don Pedro) and the Bay Area.

The 1922-2003 average calculated volume of water potentially available to CCSF under the Raker Act was approximately 750 TAF/y, roughly the amount CCSF can bank in New Don Pedro Reservoir under the Fourth Agreement between CCSF and MID and TID, which represents approximately 40 percent of the Tuolumne River unimpaired flow at La Grange of 1,853 TAF/y for the 1922–2003 evaluation period. According to a San Francisco Public Utilities Commission (SFPUC) planning document, an average of 244 TAF/y is diverted from the Tuolumne River at Early Intake, located below Hetch Hetchy, Cherry, and Eleanor Reservoirs, based on data from 1989-2005, which represents 32.5 percent of the average annual unimpaired flow at that location (City and County of San Francisco 2008). This CCSF diversion represents approximately 13 percent of the 1,853 TAF/y average annual unimpaired flow at La Grange.

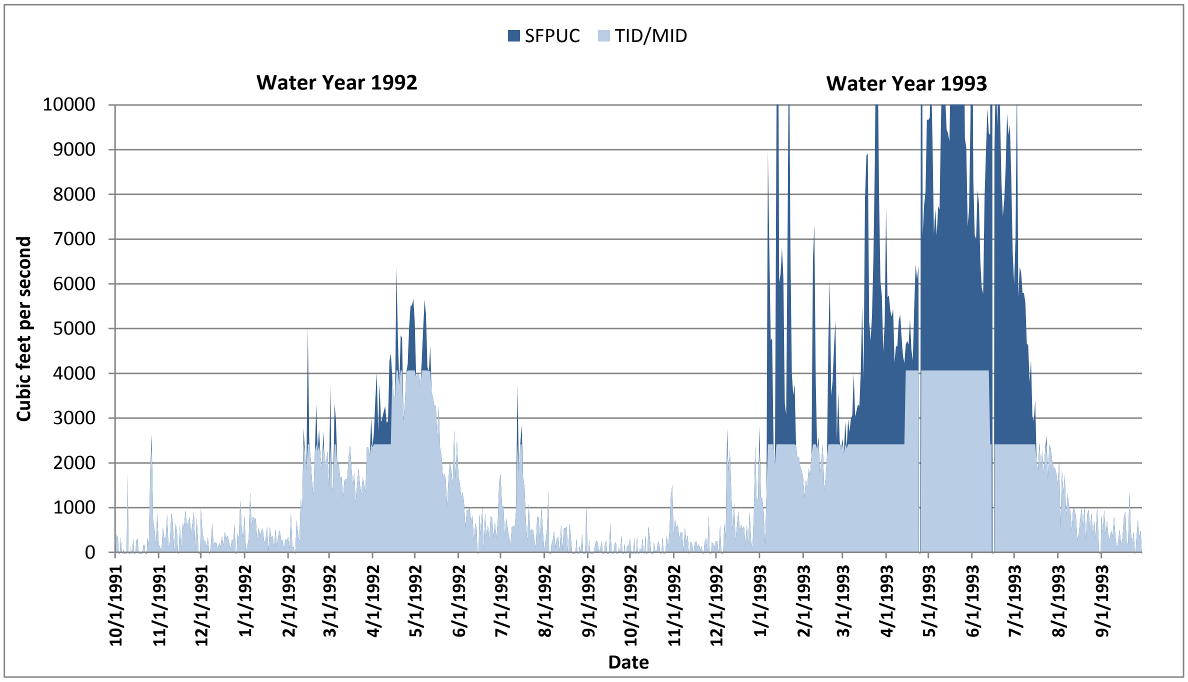

Figure 5-1. Division of Water Supply between Turlock and Modesto Irrigation Districts (TID/MID) and the City and County of San Francisco (CCSF) for 1992 and 1993 (Source: California Department of Water Resources in Environmental Defense 2004)

The average diversion into TID's canal into Turlock Lake is 575 TAF/y and another 310 TAF/y are diverted to MID's canal into the Modesto Reservoir. These diversions (885 TAF/y) represent approximately 50 percent of the median unimpaired flow of 1,776 TAF. A total of 1,175 TAF/y are diverted from the Tuolumne River, representing approximately 65 percent of the average unimpaired runoff. The FERC license (Project Number 2299) for the New Don Pedro Project was amended in 1995 to establish higher release flows on the Tuolumne River below La Grange Dam. Higher flows are required when the runoff is greater. Approximately 95 TAF are allocated on a monthly pattern in the driest years, with a maximum of approximately 300 TAF allocated in years with higher runoff. Pulse flows were specified for fish attraction to their spawning grounds in October and outmigration in April and May.

Table 5-9a gives the monthly cumulative distribution of Tuolumne River unimpaired flows for 1922–2003. Each month has a range of runoff depending on the rainfall and accumulated snowpack. The peak runoff for the Tuolumne River is observed in May and June, and relatively high runoff (median monthly runoff greater than 2,000 cfs) is observed February–June. The minimum flows are observed in August, September, and October. The median runoff for the February–June period was 2,085 cfs in February, 2,566 cfs in March, 4,498 cfs in April, 7,343 cfs in May, and 5,648 cfs in June. The average Tuolumne River runoff represents approximately 30 percent of the unimpaired flow at Vernalis. Because 290 TAF/y is diverted upstream of New Don Pedro Reservoir, the average inflow to New Don Pedro is approximately 1,563 TAF/y (85 percent of the Tuolumne River unimpaired flow).

Table 5-9b gives the monthly cumulative distribution of the historical flows for the Tuolumne River observed at Modesto for the recent period of 1985–2009. The average unimpaired flow for this 25-year period was 1,823 TAF (98 percent of the 1922–2003 average). The release flow requirements changed in 1995, as described above. The average monthly historical flows were approximately 500 cfs in the summer and fall (July–December), and were 1,000 cfs–2,000 cfs in the winter and spring (January–June). The median historical annual river flow was 361 TAF. The average annual historical flow was 811 TAF, more than 2.25 times the median, suggesting that the majority of the historical flow was the result of flood control releases in wet years. The average historical flow was approximately 45 percent of the average unimpaired flow, but the majority of this historical flow was observed in the wet years with flood control releases. New Don Pedro Reservoir allows considerable carryover storage from one year to the next.

Figure 2-9 shows the monthly unimpaired and the historical Tuolumne River flow at Modesto for the recent 10-year period of water years 2000–2009. The historical monthly flows at Modesto were generally lower than the unimpaired flows in the winter and spring months and were often slightly higher than the unimpaired flows in the late summer and fall months. The peak historical flow was in April and May of 2006 because New Don Pedro Reservoir was nearly full, and the high release flow of 8,000 cfs was for flood control purposes. The unimpaired flow at New Don Pedro Dam averaged 1,738 TAF/y and the historical releases (including flood flows in 2000, 2005, and 2006) averaged 695 TAF/y for the 10-year period. On an annual basis, the historical La Grange Dam releases averaged approximately 40 percent of the unimpaired flow, but on a daily basis the releases were usually much less than 40 percent of the unimpaired flow, with flood control releases providing the majority of the flow below LaGrange Dam.

Major Dams and Reservoirs

The hydroelectric power plant of New Don Pedro Dam has four units with a combined capacity of 203 MW and a maximum flow of 5,500 cfs (TID and MID 2011). Water released from the New Don Pedro Dam is regulated at La Grange Dam and Reservoir, which is also the diversion point for the MID and TID canals. A small hydroelectric power plant with a capacity of 4 MW and a maximum flow of 750 cfs is used to release water from the TID canal to the Tuolumne River, just downstream of La Grange Dam. Because New Don Pedro turbine capacity is generally greater than the canal diversions and river releases, it is operated for only part of each day (peaking energy); daily fluctuations in flow and water elevation in La Grange Reservoir are normal.

Water Quality

Water quality is generally considered somewhat degraded below Don Pedro Reservoir as a result of agricultural irrigation return flow and some urban and agricultural runoff (CCSF 2008). Total dissolved solids (TDS) content and turbidity generally increase in a downstream direction (CCSF 2008). The Tuolumne is identified on the 303(d) list for constituents associated with agricultural uses, such as pesticides (e.g., chlorpyrifos, diazinon, DDT), and temperature (State Water Board 2011).

Reservoir operations and changes in river flow attributable to water supply and hydropower generation activities affect some water quality characteristics in the Tuolumne River. Primary among them is water temperature. Water temperature in flowing streams depends on the temperature of the water source, air temperature, flow, surface area, and exposure to solar radiation. Reductions in stream flow when air temperature is high usually result in increases in water temperature. Storage of water in reservoirs may increase or decrease water temperatures. In the warmer months, water temperature increases in a downstream direction as the river leaves the foothills of the Sierra Nevada and flows to the floor of the San Joaquin Valley (CCSF 2008).

EC generally increases as water moves downstream in the Tuolumne River because of the relatively high EC in agricultural drainage and groundwater discharge to the river. The increase in EC is generally greater when the river flow is low. However, near the confluence with the SJR, the measured monthly EC in the Tuolumne River (at Modesto) is still generally low. The Tuolumne River EC values generally have been 0.050–0.300 dS/m (Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta*).

5.2.5 Stanislaus River

Unimpaired and Historical Flow

Stanislaus River joins the SJR about 3 miles upstream of Vernalis at RM 75 and 8 miles downstream of the Tuolumne River mouth. The Stanislaus River is 161 miles long and drains approximately 1,195 square miles of mountainous and valley terrain. New Melones Reservoir, which is located just downstream of the confluence of the three forks of the Stanislaus River, is the major storage reservoir on this river. It has a storage capacity of approximately 2.4 MAF. Tulloch Dam and power plant, located 6 miles downstream of New Melones Dam, is part of the Tri-Dam Project, which is a power generation project that includes Donnells and Beardsley Dams, located upstream of New Melones Reservoir. The water released from New Melones Dam (for peaking power) is regulated in Tulloch Reservoir. Goodwin Dam is located approximately 2 miles from Tulloch Reservoir, and approximately 59 miles of the Stanislaus River are downstream of Goodwin Dam to the confluence with the LSJR.

South San Joaquin Irrigation District (SSJID), Oakdale Irrigation District (OID), Stockton East Water District (SEWD), and Central San Joaquin Water Conservation District (CSJWCD) divert water from the Stanislaus River at Goodwin Dam. SSJID and OID jointly hold rights with USBR to divert 600 TAF when the projected annual inflow to New Melones is greater than 600 TAF. OID and SSJID have an agreement to equally divide the available water, each receiving 300 TAF. USBR contracted with SEWD and CSJWCD for delivery of 155 TAF/y. The maximum diversion from the Stanislaus River is therefore 755 TAF/y. This represents approximately 67 percent of the average unimpaired Stanislaus River runoff of 1,120 TAF/y. If annual inflow to New Melones is projected to be less than 600 TAF, the OID and SSJID diversions are governed by the 1988 Agreement, which limits OID and SSJID diversions to the inflow plus one-third of the inflow deficit (600 TAF minus the inflow in TAF) (OID 2012).

The inflow to New Melones is seasonally shifted from the unimpaired flow by the upstream hydropower operations. The annual inflow to New Melones is about the same as the unimpaired runoff because, although there are several upstream storage reservoirs for hydroelectric generation, there are no major upstream diversions for consumptive uses.

Table 5-10a gives the monthly cumulative distribution of Stanislaus River unimpaired flows for 1922–2003. Each month has a range of runoff depending on the rainfall and accumulated snowpack. The peak runoff for the Stanislaus River is observed in May and June and relatively high runoff (median monthly runoff greater than 1,000 cfs) is observed February–June. The lowest median flows of approximately 150 cfs are observed in August, September, and October. The median runoff for the February–June period was 1,251 cfs in February, 1,704 cfs in March, 3,247 cfs in April, 4,657 cfs in May, and 2,757 cfs in June. The average Stanislaus River runoff represents approximately 18 percent of the average unimpaired flow at Vernalis.

Table 5-10b gives the monthly cumulative distribution of the historical flows for the Stanislaus River observed at Ripon for the recent period of 1985–2009. The average unimpaired flow for this 25-year period was 1,081 TAF (97 percent of the 1922–2003 average). The Stanislaus release flow requirements have generally increased during this period. The average monthly historical flows were approximately 500–600 cfs in the summer and fall (July–December) and were approximately 850–1,250 cfs January–June. The average annual historical flow was 584 TAF, approximately 1.5 times the median flow, suggesting that a few years had substantial flood control releases. The average historical flow was approximately 52 percent of the average unimpaired flow, but the majority of this historical flow was observed in a few wet years with flood control releases. New Melones Reservoir allows considerable carryover storage from one year to the next.

Figure 2-10 shows the monthly unimpaired and historical Stanislaus River flow at Ripon for the recent 10-year period of water years 2000–2009. The historical (observed) monthly flows at Ripon are generally lower than the unimpaired flows in the winter and spring months and are often slightly higher than the unimpaired flows in the summer and fall months. The peak historical flows during this period were in 2006 because New Melones Reservoir was nearly full, and relatively high flows of 2,000 cfs–4,500 cfs were released for flood control purposes. The average unimpaired flow was 1,100 TAF/y and the average historical flow was 611 TAF/y for this 10-year period. The historical flow therefore averaged approximately 55 percent of the unimpaired flow on an annual basis, but the daily releases were usually less than 55 percent of the unimpaired flow, with flood control releases providing the majority of the flow below Goodwin Dam.

Major Dams and Reservoirs

New Melones reservoir has two hydroelectric generators with a combined capacity of approximately 300 MW (CEC 2012) and a maximum flow of 8,300 cfs. Tulloch Dam and power plant are located approximately 6 miles downstream of New Melones Dam. The water released from New Melones Dam (for peaking power) is regulated in Tulloch Reservoir, which has a capacity of 67 TAF (CALFED 2009). Tulloch reservoir operates with a seasonal variation in water depth and has a 3-foot daily fluctuation (from peaking hydropower releases)(Lake Tulloch Alliance 2007). The Tulloch hydroelectric plant has a capacity of 17 MW, with a maximum flow of approximately 2,000 cfs (CALFED 2009). Goodwin Dam is approximately two miles downstream of Tulloch Dam and is the diversion dam for the OID and SSJID canals. Water may also be gravity fed into the Goodwin Tunnel for deliveries to the CSJWCD and SEWD. The water supply diversions and river releases pass through Tulloch powerhouse. Because New Melones hydroelectric units are operated for only part of each day to release the daily diversions and river flow, daily fluctuations in flow and water elevations in Tulloch Reservoir are normal.

Water Quality

Some water quality characteristics in the Stanislaus River are affected by reservoir operations and by changes in river flow attributable to water supply and hydropower generation activities. Appendix F.1, *Hydrologic and Water Quality Modeling*, contains a description of baseline water temperatures on the Merced River, and Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta*, includes a presentation of measured salinity conditions.

On July 2, 1969, USBR signed a Memorandum of Agreement (MOA) with the Central Valley Water Board to provide for the scheduled releases of water from New Melones Dam for water quality purposes in order to maintain DO and TDS concentrations in the Stanislaus River and the SJR, respectively. Under this MOA, releases from New Melones Dam up to 70 TAF in any one year must be scheduled to maintain DO at or above 5 mg/L in the Stanislaus River and the TDS mean monthly concentration at a maximum of 500 mg/L in the SJR immediately below the mouth of the Stanislaus River (Central Valley Water Board 2011).

EC generally increases as water moves downstream in the Stanislaus River because of the relatively high EC in agricultural drainage and groundwater discharge to the river. The increase in EC is generally greater when the river flow is low. However, near the confluence with the SJR, the measured monthly EC in the Stanislaus River (at Ripon) is still generally low, usually ranging from approximately 0.075 to 0.150 dS/m.

5.2.6 Lower San Joaquin River

Unimpaired and Historical Flow

The drainage area of the SJR above Vernalis includes approximately 12,250 square miles. Vernalis is the measurement location for SJR inflow to the southern Delta. The flow from upstream of the Merced River together with the tributary flows from the Stanislaus, Tuolumne, and Merced Rivers, intermittent flows from the westside creeks, and agricultural drainage and groundwater seepage flows, contribute to the SJR flow at Vernalis.

The State Water Board initially established SJR at Vernalis flow objectives in the 1995 Bay-Delta Plan, which are also included in the current 2006 Bay-Delta Plan and in Revised Water Right Decision 1641 (D-1641), which is the decision that implements the water quality objectives of the 1995 Bay-Delta Plan). These flow objectives require minimum flows February 1–June 30 that depend on the SJR water year type and the Delta outflow (i.e., X2[8] requirements), which depend on the Eight River Index (the sum of unimpaired Sacramento River and SJR runoff)[9]. The 30-day April–May pulse flow requirements increase when the X2 requirement is at or west of Chipps Island (75 kilometers [km], requiring an outflow of approximately 11,400 cfs). The SJR flow objectives are given in Table 5-11. In addition, the Vernalis flow objective in October is 1,000 cfs with an additional pulse flow requirement (for attraction of adult Chinook salmon) that increases the monthly average flow to 2,000 cfs in most years.[10]

D-1641 and the 2006 Bay-Delta Plan authorized a staged implementation of the April 15–May 15 pulse flow objectives to allow for scientific experimentation by conducting the Vernalis Adaptive Management Plan (VAMP). D-1641 also established the condition for the water rights of various San Joaquin River Group Authority members to provide water for VAMP and the October pulse flow objective. As a result of the implementation of VAMP, the Vernalis flow objectives have not been fully implemented because alternative pulse flows were provided under VAMP (2000–2011), which now has ended. The VAMP flows are considered baseline and are included in the modeling described below.

---

[8] X2 is the location of the 2 parts per thousand salinity contour (isohaline), 1 meter off the bottom of the estuary measured in kilometers upstream from the Golden Gate Bridge. The abundance of several estuarine species has been correlated with X2. In the 2006 Bay-Delta Plan, a salinity value--or electrical conductivity (EC) value--of 2.64 millimhos/centimeter (mmhos/cm) is used to represent the X2 location. Note, in this SED, EC is generally expressed in deciSiemens per meter (dS/m). The conversion is 1 mmhos/cm = 1 dS/cm.

[9] The *Eight River Index* is the sum of the unimpaired runoff for the Sacramento River at Bend Bridge, Feather River inflow to Oroville, Yuba River at Smartville, American River inflow to Folsom Reservoir, Stanislaus River inflow to New Melones Reservoir, Tuolumne River inflow to Don Pedro Reservoir, Merced River inflow to Lake McClure, and SJR inflow to Millerton Lake.

[10] The October flow requirement includes up to an additional 28 TAF pulse/attraction flow during all water year types. The amount of additional water will be limited to that amount necessary to provide a monthly average flow of 2,000 cfs. The additional 28 TAF is not required in a critical year following a critical year.

Table 5-11. 2006 Bay-Delta Plan Flow Requirements at Vernalis

Water Year Type	Feb–June Flows (cfs)	April–May, 30-day Pulse Flows (cfs)
Critical	710 or 1,140	3,110 or 3,540
Dry	1,420 or 2,280	4,020 or 4,880
Below Normal	1,420 or 2,280	4,620 or 5,480
Above Normal	2,130 or 3,420	5,730 or 7,020
Wet	2,130 or 3,420	7,330 or 8,620

cfs = cubic feet per second

Table 5-12a gives the monthly cumulative distribution of the SJR at Vernalis unimpaired flows for 1922–2003. Each month has a range of runoff depending on the seasonal rainfall and accumulated snowpack. The median (50 percent) monthly flows generally characterize the seasonal runoff pattern and are largely the sum of the unimpaired runoff from the rivers draining the Sierra Nevada described above. The peak runoff for the SJR at Vernalis is observed in May, with relatively high median monthly runoff (> 15,000 cfs) observed in April, May, and June. The lowest median flows of approximately 500 cfs are observed in September and October. The median flows for the February–June period were 6,294 cfs in February, 8,227 cfs in March, 15,205 cfs in April, 23,054 cfs in May, and 16,240 cfs in June. The majority of the average SJR at Vernalis runoff originated above the four major storage dams (Friant, New Melones, New Don Pedro, and Exchequer Dams), since only approximately 500 TAF (8 percent) of the Vernalis flow was from the westside creeks and the valley floor watersheds located below the four major storage dams.

Table 5-12b gives the monthly cumulative distribution of the historical SJR flows observed at Vernalis for the recent period of 1984–2009. The average unimpaired flow for this 25-year period was 5,964 TAF (97 percent of the 1922–2003 average). The release flow requirements on the three eastside tributaries have generally increased during this period. The average monthly historical flows were approximately 2,000–2,500 cfs in the summer and fall (Jul–December) and were approximately 4,000–6,000 cfs January–June. The median historical annual SJR flow volume at Vernalis was 1,707 TAF. The average annual historical SJR at Vernalis flow volume was 2,777 TAF, approximately 1.5 times the median flow, suggesting that a few years had substantial flood control releases. The average historical SJR flow at Vernalis was approximately 46 percent of the average unimpaired flow for this 25-year period, but the majority of this historical flow was observed in a few wet years with flood control releases.

cfs = cubic feet per second
TAF = thousand acre-feet

Figure 2-11 shows the monthly unimpaired historical flow at Vernalis for the recent 10-year period of water years 2000–2009. The unimpaired flows at Vernalis averaged 6,056 TAF/y and the historical releases (including flood flows in 2000, 2005, and 2006) average 2,915 TAF/y. The historical Vernalis flows average approximately 48 percent of the unimpaired flow, but the releases were usually much less than 48 percent of the unimpaired, with flood control releases providing the majority of the flow. The historical monthly flows at Vernalis were generally lower than the unimpaired flows in the winter and spring months and were often slightly higher than the unimpaired flows in the fall months.

Water Quality

Salinity and water temperature are the two main water quality constituents of concern that might be affected by the alternatives. Appendix F.1, *Hydrologic and Water Quality Modeling*, contains a description of baseline water temperatures on the LSJR, and Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta*, includes a presentation of measured salinity conditions. Both water temperature and salinity are constituents included on the 303(d) list as impairments for the LSJR (Table 5-4) (State Water Board 2011).

The EC measurements at three stations located on the LSJR between the Merced River and the Tuolumne River (Newman, Crows Landing, and Patterson) were generally similar, usually ranging from 1.000 to 1.500 dS/m but with higher values of 1.500–2.000 dS/m in the dry years of 1988–1994 and EC values of less than 0.500 dS/m during high flows of more than 5,000 cfs (Appendix F.2).

In the SJR between the Tuolumne River and the Stanislaus Rivers, EC values were measured at Maze by DWR prior to 1992 and since 2007. Values were estimated from the Vernalis flow and EC subtracting the Stanislaus flow and EC for the intermediate years. During wet years, the Maze EC measurements ranged from less than 0.250 dS/m to approximately 1.000 dS/m. In contrast, the Maze EC ranged 1.000 dS/m–2.000 dS/m in the 1988–1994 dry period, but the EC has been less than 1.250 dS/m since 2000. This EC data suggests that the SJR at Maze has a moderate salinity with EC values generally less than 1.000 dS/m, except when the flow is less than 1,000 cfs.

5.2.7 Extended Plan Area

Water quality in upstream reservoirs above populated areas in the Stanislaus and Tuolumne Watersheds is good (Kennedy-Jenks Consultants 2013). There are no substantial reservoirs upstream on the Merced River. The Stanislaus and Tuolumne Rivers both have 303(d) listings for mercury in different locations in the extended plan area and the Tuolumne River has some listings for *E.coli (*Kennedy-Jenks Consultants 2013). In addition, taste and odor complaints have been identified (but not listed on 303(d)) at Phoenix Lake reservoir on Sullivan Creek, which flows into the northern arm of Don Pedro Reservoir but not directly to the Tuolumne River (Kennedy-Jenks Consultants 2013). Much of the Upper Merced River Watershed is in Yosemite National Park and water quality is good (Kennedy-Jenks Consultants 2014). There are no 303(d) listed water bodies above Lake McClure on the Merced River (Kennedy-Jenks Consultants 2014).

5.2.8 Southern Delta

This section describes the environmental setting with regards to southern Delta flows and exports. There are four major channels in the southern Delta: the SJR from Vernalis past Stockton; Old River from the head of Old River to Clifton Court Forebay, Grant Line Canal from Old River to Clifton Court Forebay, and Middle River from Old River to Victoria Canal. Old River, between Clifton Court Forebay and Franks Tract, and Middle River downstream of Victoria Canal are also important southern Delta channels (Figure 2-12). While it mostly falls within the boundaries of the South Delta Water Agency (SDWA), the southern Delta generally includes all channels south or west of the SJR channel, some of which may be outside of SDWA boundaries.

Flows and CVP and SWP Exports

As mentioned earlier, the SJR enters the Delta at Vernalis. The Old River channel diverges from the SJR downstream of Mossdale and connects with Middle River and Grant Line Canal. The CVP and SWP intakes are located on Old River at the western end of the southern Delta. About half of the SJR flow is diverted west into Old River and about half of the SJR flow continues north toward Stockton. Water flows in the southern Delta are influenced by SJR inflow at Vernalis, channel flow splits, tidal flows, temporary barriers, water export facilities, local agricultural diversions, agricultural drainage, and municipal treated wastewater discharges.

Downstream of Vernalis, flow from the SJR splits at the head of Old River and either continues downstream in the SJR toward Stockton or enters Old River and flows toward the CVP and SWP pumps. When Vernalis flow is greater than approximately 17,500 cfs, a portion of the flow entering the southern Delta enters through Paradise Cut, about 5 miles upstream of the head of Old River. The amount of flow entering Old River (including flow through Paradise Cut) is affected by the agricultural barriers and the combined pumping rates of CVP and SWP relative to SJR inflows at Vernalis. When the combined CVP and SWP pumping rates are low, the flow split to Old River is roughly 50/50. The flow into Old River increases by approximately 5 percent of the combined CVP and SWP pumping. When the rock barrier at the head of Old River is installed for SJR fish protection, the flow into Old River is reduced to approximately 250 cfs of leakage through the rock barrier (Jones and Stokes 2001) or approximately 500 cfs if the culverts are open.

The South Delta Temporary Barriers Project was initiated by DWR in 1991 and consists of four rock barriers placed at various locations across southern Delta channels. Three of the barriers are installed to increase the channel water elevations for agricultural diversions. The head of Old River barrier has been installed in April and May of many years since 1992 (not in years with flows above 5,000 cfs) to improve juvenile Chinook salmon fish migration from the SJR. As discussed further Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives,* this barrier has been installed during the fall of most years since 1963 to improve flow and DO conditions in the downstream SJR near Stockton for the benefit of adult fall-run Chinook salmon migrating to upstream spawning locations.

The two major water diversions in the southern Delta are the SWP (Banks Pumping Plant) and the CVP (Jones Pumping Plant). The Contra Costa Water District (CCWD) also diverts water from the southern Delta. Many small agricultural diversions (siphons and pumps) divert water from throughout the Delta during the spring and summer irrigation season. The CVP Jones Pumping Plant, formerly known as Tracy Pumping Plant, is located about 5 miles northwest of Tracy. The Jones Pumping Plant consists of six pumps with a permitted diversion capacity of 4,600 cfs. The total CVP water supply contracts total approximately 3,500 TAF/y for the Jones Pumping Plant. Most of the CVP water exports come from the SJR when SJR flows at Vernalis are greater than CVP exports.

The Banks Pumping Plant has a physical pumping capacity of 10,300 cfs. However, flow diverted from the Delta into Clifton Court Forebay is limited by a USACE permit to a maximum of 6,680 cfs during much of the year. SWP water is either pumped into the South Bay aqueduct, pumped into San Luis Reservoir for seasonal storage, pumped further south in the California Aqueduct to Kern County Water agency, pumped over the Coastal Range in the Coastal Aqueduct, or pumped over the Tehachapi Pass to southern California contractors. Based on SWP contracts, the total water supply demand for the Banks Pumping plant is approximately 4,000 TAF/y.

The CVP and SWP export pumping are controlled under the 2006 Bay-Delta Plan objectives (as implemented through D-1641). Both the CVP and the SWP have maximum permitted pumping (or diversion) rates. Delta outflow requirements may limit pumping if the combined Delta inflow is not enough to satisfy the in-Delta agricultural diversions and the full capacity CVP and SWP pumping. When pumping is limited by hydrology, the Cooperative Operating Agreement (COA) governs the CVP and SWP share in reservoir releases and Delta pumping. When pumping is limited for fish protection (e.g., Old and Middle River [OMR] limits) the CVP and SWP generally share the allowable pumping.

The 1995 Bay-Delta Plan introduced the E/I ratio, which limits the combined export rate to a specified monthly fraction of the combined Delta inflow. The E/I ratio is 35 percent February–June and 65 percent June–January. The February E/I can be increased to 45 percent under low-flow conditions. This E/I objective allows a maximum pumping amount that is often similar to the allowable exports under the Delta outflow objectives, but sometimes the E/I ratio is more limiting than the required outflow. Sometimes the exports must be further reduced to increase the Delta outflow to satisfy the salinity requirements at Emmaton and Jersey Point or at the CCWD Rock Slough diversion. The SJR/export ratio was introduced as part of the 2009 National Marine Fisheries Service's Biological Opinion Stanislaus River Reasonable and Prudent Alternative (RPA), including Action 3.1.3 (NMFS BO), and limits exports to be 100 percent of the SJR inflow in critical years, 50 percent of the SJR inflow in dry years, 33 percent of the SJR inflow in below normal years, and 25 percent of the SJR inflow in above normal or wet years. These ratios effectively limit exports to 1,500 cfs for April and May unless the SJR is higher than the minimum flow required in these months (also discussed in Chapter 2, *Water Resources*). More detail about Delta regulations is provided in Appendix F.1, *Hydrologic and Water Quality Modeling.*

Tables 5-13a through 5-13c show the monthly historical CVP and SWP export pumping for 1985–2009. The CVP pumping was relatively constant through the year, with median monthly pumping of 3,500–4,200 cfs October–March. This water was used to fill the CVP portion of San Luis Reservoir to allow peak CVP water deliveries April–September. CVP pumping has been reduced April–June of most years for fish protection, with a median pumping of 2,133 cfs in April, 1,270 cfs in May, and 2,991 cfs in June. CVP pumping has been highest in July–September, with median pumping of more than 4,000 cfs. The median CVP annual pumping was approximately 2,500 TAF, which is considerably less than the total CVP demands (contracts) of 3,500 TAF. The SWP median monthly pumping was similar to the CVP pumping; the median SWP pumping was 3,000 cfs to 3,800 cfs October–March. The majority of this water was used to fill the SWP portion of San Luis Reservoir to allow peak SWP water deliveries April–September, although some water is pumped over the Tehachapi Mountains to southern California through the fall and winter months. SWP pumping has been reduced April–June of most years for fish protection, with a median pumping of 2,101 cfs in April, 1,031 cfs in May, and 1,911 cfs in June. SWP pumping has been highest in July–September with median pumping of 5,586 cfs in July, 5,539 in August, and 4,746 cfs in September. The median SWP annual pumping was approximately 2,600 TAF which is considerably less than the total SWP south-of-Delta demands (contracts) of 4,100 TAF.

The combined pumping is almost always greater than the SJR flow at Vernalis, so a considerable volume of Sacramento River water flows toward the pumps through OMR channels in almost all months. The median monthly pumping was 6,800 cfs–7,500 cfs October–March. The combined pumping was reduced for fish protection April–June, with a median pumping of 4,227 cfs in April, 2,810 cfs in May, and 4,630 cfs in June. The highest combined pumping was in the summer, with a median pumping of 9,000 cfs–10,000 cfs July–September.

Southern Delta Water Levels and Flows

This section summarizes the baseline water level and flow conditions in the southern Delta channels as currently managed with the DWR Temporary Barrier Program (TBP). The temporary barriers are installed during the irrigation season in Old River near the DMC, in Grant Line Canal at Tracy Boulevard Bridge, and in Middle River upstream of Victoria Canal. The temporary barriers (weirs) block the tidal flows during ebb tide (falling water elevations, water moving downstream towards the estuary) and thereby maintain higher elevations during ebb tides. This section also summarizes modeling results that show how tidal elevations and flows in the southern Delta channels are affected by CVP and SWP pumping and by the TBP (DWR and USBR 2005). Some recent changes in the operational design of the barriers would affect these results slightly, but not materially.

Because water levels in the southern Delta channels are tidally influenced, they are always changing (fluctuating). Because agricultural diversions (siphons and pumps) may be limited at lower water levels (elevations) a general goal in the southern Delta channels has been to maintain suitable water elevations for the beneficial use of water for agriculture. Flow conditions in a tidal channel are more difficult to determine than for a river. Water elevations in a river will always increase with higher flows, whereas fluctuations in tidal elevations and tidal flows would be gradually reduced with higher net channel flows. Tidal elevations can be averaged over a monthly lunar cycle, with the average high tide (mean high water [MHW]) or the average low tide (mean low water [MLW]) calculated. Because low water levels in the southern Delta channels have the greatest effect on agricultural diversions, the MLW provides a good measure of water level conditions.

In a river, the direction of flow is downstream and flows typically dilute any salt discharge and transports the salt downstream. However, the direction and magnitude of flow for a network of tidal channels is more difficult to calculate. The tidal flow during each ebb tide moves water one direction (towards the estuary) and the tidal flow during each flood tide moves water in the opposite direction (away from the estuary). EC will increase in a tidal channel having a high salinity discharge both upstream and downstream; the increase in salinity will be less if the tidal flows are large (from a greater tidal mixing volume) or if the net flow is large (from greater dilution).

Effects of Pumping and Barriers on Water Levels and Flows

The natural tidal elevations and tidal flows that would occur in the southern Delta channels with a specific SJR inflow at Vernalis but without the CVP Jones and SWP Banks pumping diversions would be the highest possible water elevations, the greatest possible tidal flows, and the highest net flows in the southern Delta channels. This maximum possible combination of water levels, tidal flows, and net flows can be used to compare the changes (reductions) in water levels and flows in the southern Delta channels caused by exports or TBP conditions. This summary of the southern Delta channel tidal elevations and tidal flows is based on Section 5.2, *Delta Tidal Hydraulics*, of the *Draft South Delta Improvement Program Environmental Impact Statement/Environmental Impact Report* (SDIP EIS/EIR) (DWR and USBR 2005).

The major effect on southern Delta tidal elevations and tidal flows results from CVP and SWP pumping. The CVP Jones plant maximum pumping capacity is 4,600 cfs, and these pumps operate throughout the tidal cycle. The SWP Banks plant is operated to use off-peak energy, and the Clifton Court Forebay (CCF) gates are typically closed during the flood tide prior to the high tide each day to allow the maximum possible high tide elevations in the southern Delta channels (with CVP pumping). The CCF gates are also closed during low tide elevations if the water level in Old River is less than the CCF water elevation. CVP and SWP pumping will reduce the tidal elevations, with current maximum pumping of approximately 12,000 cfs lowering the high tide elevations by 1.5 ft. and lowering the low tide elevations by approximately 0.75 ft. The tidal flows in the channels are reduced substantially (50 percent less with full pumping). The net flows in Old River and Grant Line Canal (from the SJR diversion to Old River) are not changed substantially by pumping. Slightly more SJR water is diverted into Old River by CVP and SWP pumping (approximately 5 percent of the pumping flow). Most of the water needed to supply higher CVP and SWP pumping moves south in the Old and Middle River (OMR) channels from the central Delta; the net flows are increased, while the tidal flows are only reduced slightly in OMR channels downstream (i.e., north) of the pumping plants. The tidal elevations and tidal flows are more substantially affected by the temporary barriers, which block tidal flow.

Figure 5-2 shows the actual (measured) effects of the temporary barriers on tidal elevations at the Old River at the DMC barrier, located just upstream of the DMC intake in 2003. The measured daily minimum and maximum tidal elevations in Old River upstream and downstream of the temporary barrier near the DMC intake demonstrate the effect of the barrier (weir), which was installed with an elevation of approximately +2 ft. MSL (mean sea level). All of the tidal elevations show the typical lunar-cycle fluctuations (i.e., 14-day period). The minimum tidal elevations were between 0.0 and -1.0 ft. downstream of the barrier, and were increased to between 0.0 and +1 ft. MSL above the barrier when the barrier was installed (with culverts open) in early April. The minimum elevations were increased to between 1.0 and 2.0 ft. MSL above the barrier when the culverts were closed in early June (after the VAMP period). The minimum and maximum tidal elevations at Martinez for 2003 are shown for reference as the full tidal elevation range. The effect of the temporary barrier on minimum tidal elevations (MLW) was an increase of approximately 2 ft. above the barrier. Pumping does not appear to have any large effect on tidal elevations near the DMC. The temporary barrier affects flow in Old River upstream of the barrier, as discussed below.

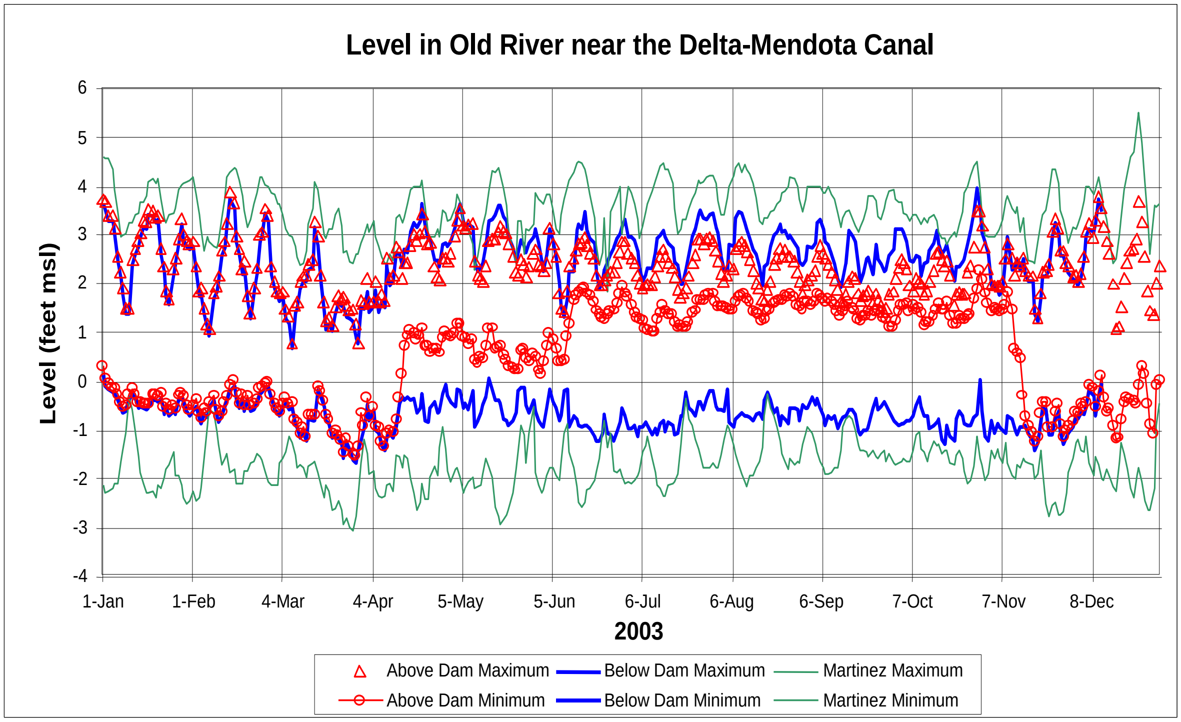

Figure 5-2. Measured Daily Minimum and Maximum Tidal Elevations in Old River Upstream and Downstream of the Temporary Barrier (near the DMC Intake) Compared to the Tidal Elevations at Martinez for 2003 (Source: DWR and USBR 2005 Figure 5.2-46) (msl = mean sea level)

A series of 1-month Delta Simulation Model II (DSM2) simulations for representative historical tidal variations of July 1985 were used in the SDIP to show the effects of CVP and SWP pumping and the effects of the temporary barriers. The simulated SJR at Vernalis flow was 1,640 cfs, the CVP pumping was 4,530 cfs, and the SWP pumping was 7,150 cfs for July 1985. The natural tidal level and flow variations in the southern Delta channels without any CVP or SWP pumping or temporary barriers were simulated as a reference. Figures 5-3a and 5-3b shows the DSM2-simulated tidal level and tidal flow volumes at the Old River at the DMC barrier location (upstream of the DMC entrance), with no CVP and no SWP pumping. The tidal flow volume was calculated from the tidal flow during each ebb or flood tide period. The daily ebb-tide or flood-tide flow volume (acre-feet [AF]) is equivalent to the average tidal flow (cfs) for the 12-hour period of flood tide (positive) or ebb tide (negative) during each day. The water level ranged from approximately –0.8 ft. to approximately 4.0 ft. MSL, with a median of 1.4 ft. MSL. The DSM2-simulated average downstream tidal flow was 1,340 cfs (during 12 hours each day), the average upstream tidal flow was –1,480 cfs (during 12 hours each day), and the net (upstream) tidal flow was –70 cfs. The simulated SJR diversion to Old River was 975 cfs, and the net flow in Grant Line Canal was 395 cfs (much less than the SJR diversion to Old River because of agricultural diversions); therefore, this upstream flow in Old River at the DMC barrier location resulted from agricultural diversions along Old River upstream of the barrier.

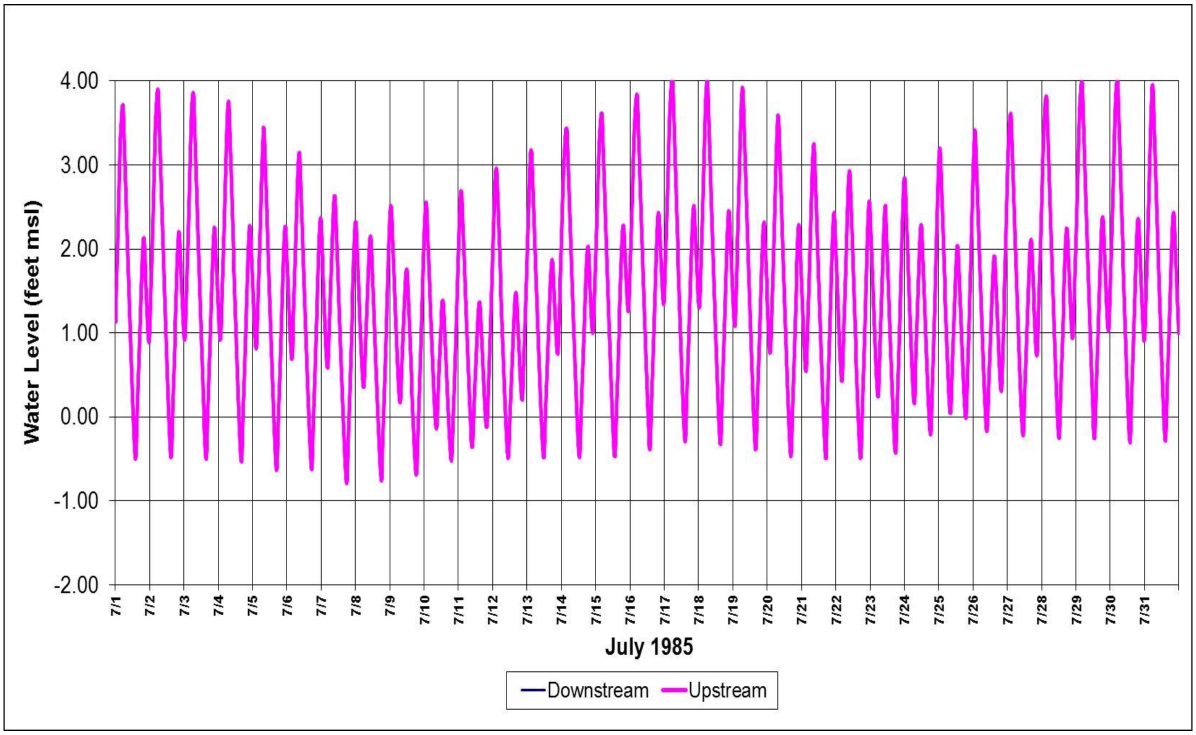

Figure 5-3a. DSM2-Simulated Tidal Elevations for Old River at the DMC Temporary Barrier Location with No CVP or SWP Pumping and No Barrier for July 1985 (Source: DWR and USBR 2005 Figure 5.2-29) (msl = mean sea level)

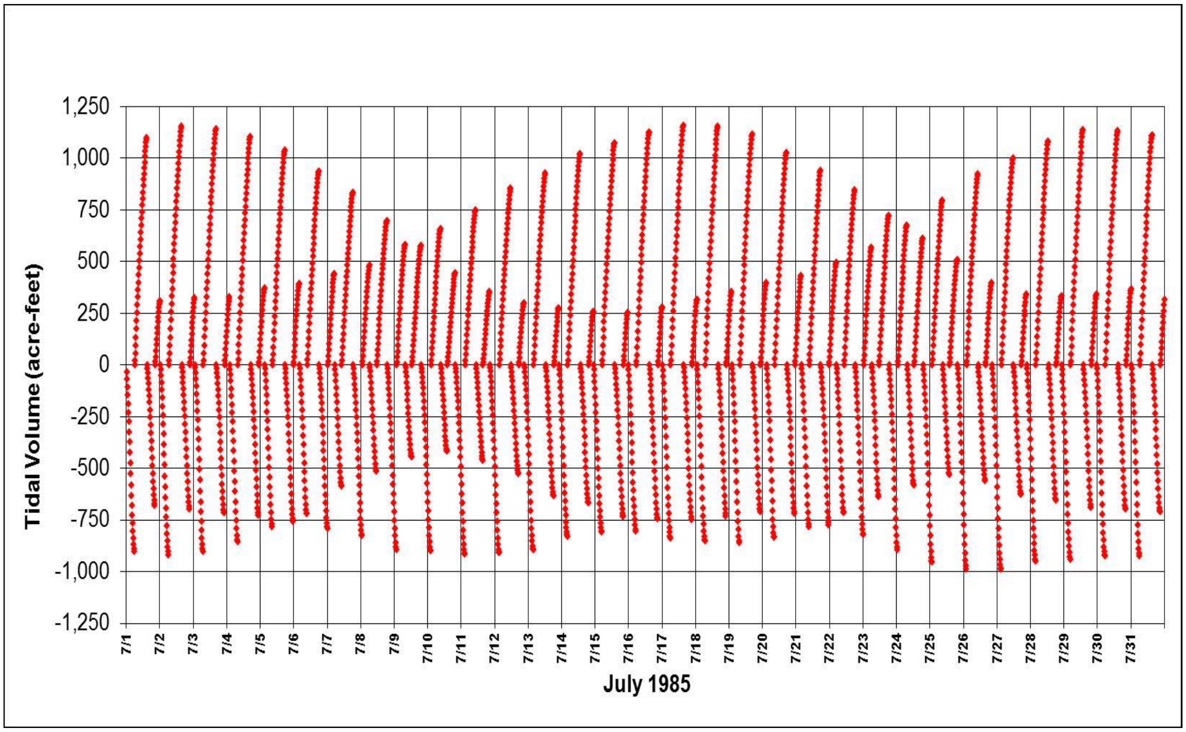

Figure 5-3b. DSM2-Simulated Tidal Flow Volumes (acre-feet) for Old River at the DMC Temporary Barrier Location with No CVP or SWP Pumping and No Barrier for July 1985 (Source: DWR and USBR 2005 Figure 5.2-29)

Figures 5-4a and 5-4b show the DSM2-simulated tidal level and tidal flow volumes at the Old River barrier location with CVP and SWP pumping (but no temporary barrier). The DSM2-simulated average downstream tidal flow was 680 cfs, and the average upstream tidal flow was −712 cfs, with a net (upstream) flow of −17 cfs. The tidal flows in Old River at the DMC barrier location were about half of the tidal flows without any CVP or SWP pumping, but the net flow was slightly increased as a result of the pumping. The simulated SJR diversion to Old River was 1,470 cfs (increased to 90 percent of the SJR flow as a result of the pumping) and the Grant Line Canal net flow was 1,017 cfs (increased because of higher SJR diversion to Old River). The CVP and SWP pumping reduced the tidal flows but increased the SJR diversion to Old River and the net flows in these southern Delta channels.

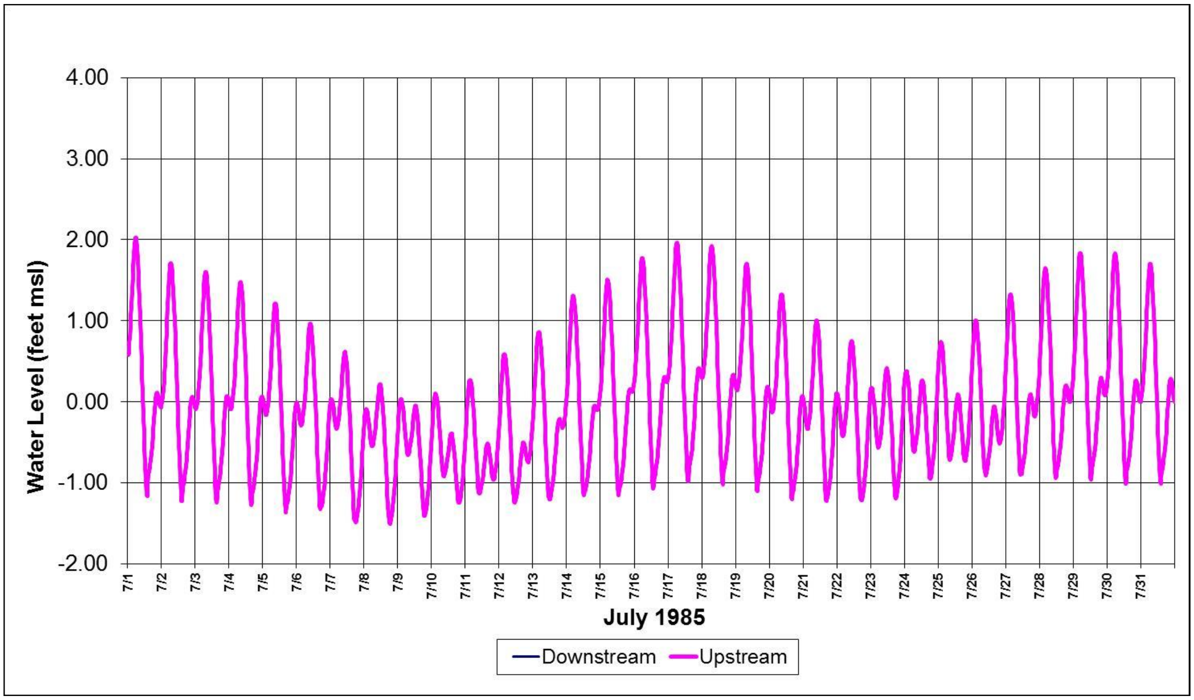

Figure 5-4a. DSM2-Simulated Tidal Elevations for Old River at the DMC Temporary Barrier Location with CVP Pumping (4,533 cfs) and SWP Pumping (7,180 cfs) with No Barriers for July 1985 (Source: DWR and USBR 2005 Figure 5.2-33) (msl = mean sea level)

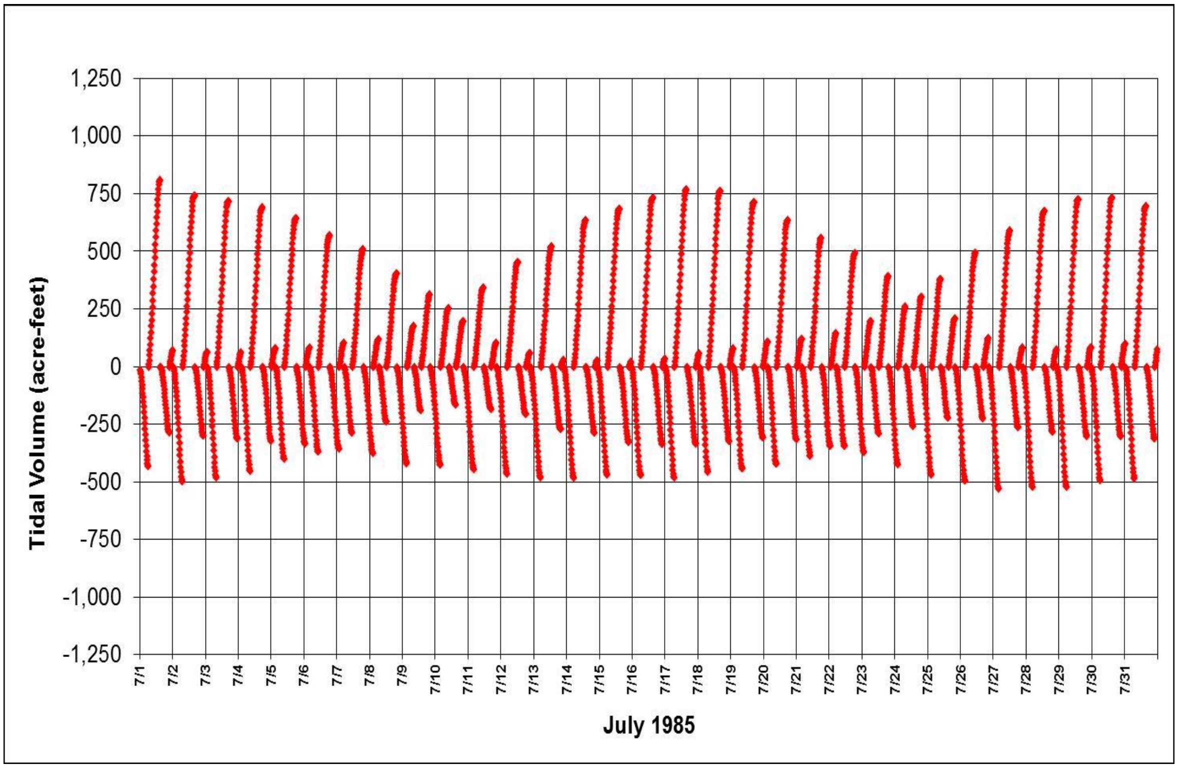

Figure 5-4b. DSM2-Simulated Tidal Flow Volumes (acre-feet) for Old River at the DMC Temporary Barrier Location with CVP and SWP Pumping with No Barriers for July 1985 (Source: DWR and USBR 2005 Figure 5.2-33)

Figures 5-5a and 5-5b show the DSM2-simulated tidal level and tidal flow volumes at the Old River temporary barrier location near the DMC with CVP and SWP pumping and with the TBP barriers. The downstream tidal level ranged from -1.8 ft. MSL to approximately 3.6 ft. MSL, with a median of 0.0 ft. MSL. The upstream water level during low tide was maintained by the temporary barrier weir, which had a simulated crest elevation of approximately 2.0 ft. The upstream tidal level varied from approximately 0.8 ft. to approximately 2.7 ft, with a median of 1.3 ft MSL. Upstream flow through the weir culverts can begin with the flood tide, although the greatest upstream flow occurs when the tidal elevation downstream of the weir rises above the weir height. The downstream tide reached a maximum of 3.5 ft MSL on many days, but the flow over the weir (of approximately 1,000 cfs) was not sustained for long and was not sufficient to raise the upstream level to more than 2.5 ft MSL. Upstream flow over the barrier did not begin until the downstream level reached the weir crest at 2.0 ft MSL. This did not occur during the neap-tide periods July 7–July 11 and again July 23–July 25. Downstream flow was blocked once the upstream level dropped to 2.0 ft MSL. The tidal flow at the Old River at DMC barrier was very restricted compared to conditions without the temporary barrier. The DSM2-simulated average downstream tidal flow was 24 cfs, and the average upstream tidal flow was -171 cfs, with a net (upstream) flow of -73 cfs. The upstream tidal flows in Old River at the DMC barrier location were approximately 25 percent of the tidal flows with CVP and SWP pumping but without the temporary barriers, but the net flow was about the same as without pumping and without barriers. The simulated SJR diversion to Old River was 930 cfs (reduced compared to without the barriers) and the Grant Line Canal net flow was 460 cfs (reduced because of less SJR diversion to Old River). The TBP barriers greatly reduced the tidal flows and also reduced the DSM2-simulated SJR diversion and net flows in these southern Delta channels. Recent tidal flow measurements at the head of Old River indicate that the effects of the temporary barriers on reducing the SJR diversions are not as large as the DSM2 model indicated; the temporary barriers may not change the net flows in the southern Delta channels, but they reduce the tidal flows upstream of the temporary barriers by approximately 50 percent. The TBP does increase the low tidal levels (MLW) by approximately 1–2 ft, but the TBP may also cause increased salinity in portions of the channels upstream of the barriers, because of reduced tidal flow mixing (dilution).

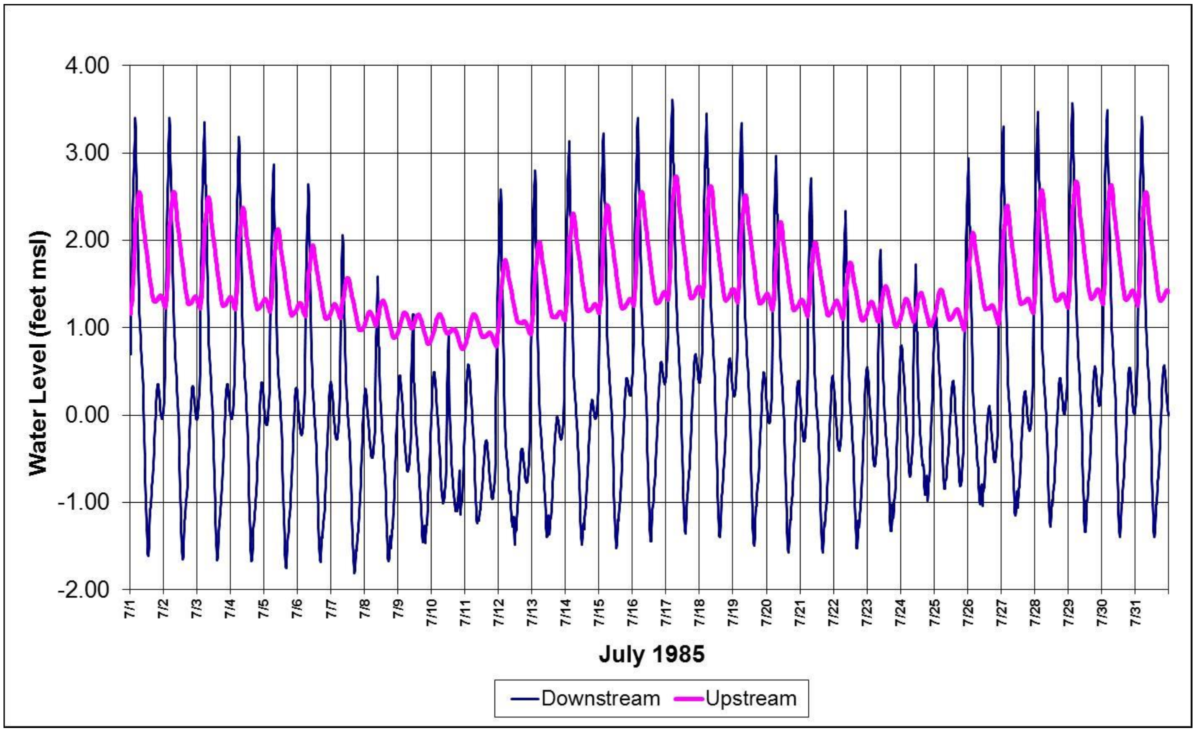

Figure 5-5a. DSM2-Simulated Tidal Elevations for Old River at the DMC Temporary Barrier with Full CVP and SWP Pumping with the Barrier Installed for July 1985 (Source: DWR and USBR 2005 Figure 5.2-37) (msl = mean sea level)

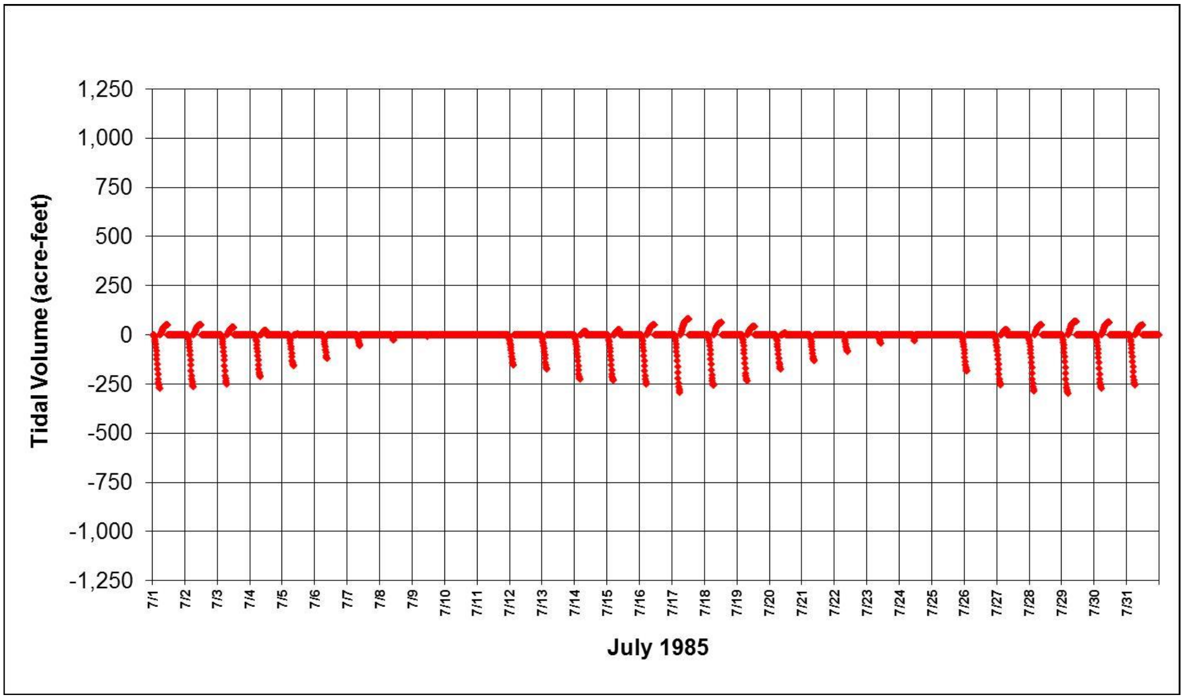

Figure 5-5b. DSM2-Simulated Tidal Flow Volumes (acre-feet) for Old River at the DMC Temporary Barrier with Full CVP and SWP Pumping with the Barrier Installed for July 1985 (Source: DWR and USBR 2005 Figure 5.2-37)

Water Quality and Salinity

The range of salinity conditions that exist across the large majority of the Delta are sufficiently low that the SJR Watershed and southern Delta channels are subject to freshwater regulatory water quality objectives. Salinity conditions in the southern Delta and SJR Watershed fall within the range of values that are adequate for freshwater aquatic life. Consequently, potential impacts on agricultural beneficial uses are the primary focus in the discussion of salinity changes in this chapter since EC values in the study area are sometimes exceed the EC objectives for the protection of agriculture beneficial uses.

A synopsis of the current Bay-Delta plan water quality objectives for the protection of agricultural water use is presented here. Further detail regarding the regulatory background with respect to water quality and other legal requirements is provided below in Section 5.3. Tables 2 and 3 of the 2006 Bay-Delta Plan include objectives for flow and EC for the southern Delta and Lower SJR to protect the beneficial uses of fish and wildlife and agriculture, respectively. The water quality objectives include the following.

> Under all water year types, the three interior southern Delta compliance stations (i.e., Old River near Middle River, Old River at Tracy Rd. Bridge, and SJR at Brandt Bridge) and the SJR at Airport Way Bridge, Vernalis station have a maximum 30-day running average of mean daily EC (dS/m) of 0.7 April–August and 1.0 September–March.[11]

---

[11] Although the 0.700 dS/m salinity objective was included in the 1978 and the 1995 Bay-Delta Plans, implementation of the objective was postponed. Water Right Decision 1641 assigned responsibility to DWR and USBR to meet the 1.0/0.7 dS/m EC objective at the three southern Delta locations, and this requirement became effective on April 1, 2005. The 1.0/0.7 dS/m EC objectives at Vernalis have been implemented since 1995 when

> Under all water year types, the Stockton Deepwater Ship Channel section of the SJR between Turner Cut and the City of Stockton maintains DO levels that are above 6.0 mg/l during the months of September, October, and November for the protection migrating adult salmon.

EC values in the southern Delta are affected primarily by the salinity of water flowing into the southern Delta from the SJR at Vernalis, salt discharged back into southern Delta channels that was previously diverted for irrigation, the combined CVP and SWP pumping influencing salinity in the southern Delta, and tidal mixing of inflow from the Pacific Ocean. Municipal treated wastewater discharges have some effect on the southern Delta salinity. The SJR flow at Vernalis has a large effect on the SJR salinity at Vernalis. Higher flows will generally reduce the salinity, following a dilution relationship in which salinity is inversely proportional to the flow. Higher CVP and SWP pumping also has an effect on southern Delta salinity by bringing more low-salinity Sacramento River water across the Delta to the export pumps. However, periods of low Delta outflow (in the fall months) causes increased seawater intrusion and higher EC at the southern Delta export and CCWD intakes.

EC at the three southern Delta compliance stations downstream of Vernalis (SJR at Brandt Bridge, Old River at Middle River [Union Island], and Old River at Tracy Boulevard) are generally higher than the Vernalis EC because of agricultural drainage and municipal discharges. All of the agricultural land in the southern Delta diverts irrigation and salt leaching water (during winter months) from the southern Delta channels. The total amount of diverted water can generally be estimated from the irrigated acreage, with approximately 3–4 AF per acre applied. The withdrawal of water from channels for use on agricultural fields (i.e., agricultural diversions) does not change the salinity of the channel water. But because agricultural drainage (i.e., runoff from agricultural fields) eventually returns the diverted salt that is applied to the soils back to the channels (often during rainfall runoff and salt leaching periods in the winter), there is an indirect and/or delayed increase in southern Delta salinity. In some channel locations (e.g., Old River at Tracy Boulevard) there can be an increase in the channel salinity during the irrigation season as a result of the agricultural drainage returning to the channels (Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta*).

There are several treated wastewater discharges in the southern Delta. Figure 2-12 identifies their locations. The effects of the wastewater discharges depend on the difference between the discharge EC and the river EC. All of the salt from agricultural drainage and wastewater discharges, as well as from the SJR at Vernalis, is generally exported at the CVP and SWP export pumping plants. Because CVP and SWP export pumping draws a majority of the exported water from the Sacramento River, thereby reducing the salinity in the channels near the pumping plants, it is difficult to detect the effects of agricultural drainage or treated municipal wastewater discharged in the southern Delta. Table 5-14 lists the major wastewater dischargers (greater than 1 million gallons per day) and their effect on existing EC concentrations in the southern Delta.

Water Right Order 95-6 assigned responsibility to USBR to meet the Vernalis EC objectives. D-1641 continued the requirement for USBR to meet the Vernalis EC objectives.

Table 5-14. Effect of Wastewater Dischargers on Existing Salinity Concentrations in the Southern Delta

Wastewater Discharger	Permitted Discharge (cfs)	2014 Annual Average EC (dS/m)	Daily Salt Load (Tons)	Annual Salt Load (Tons)	Effects on SJR
Manteca	27.1	0.7	33	12,140	The effect of the Manteca discharge on EC of the SJR is minimal because the average discharge EC of 0.7 dS/m is not above the irrigation season salinity objective.
Stockton	85.1	1.0	149	54,460	The effects of the Stockton discharge on EC of the SJR can be estimated for any river flow and EC value. For example, with a river flow past Stockton of 750 cfs with an EC of 0.7 dS/m (irrigation season), the Stockton discharge would increase the river EC by about 0.031 dS/m (i.e., [1.0 -0.7] x 85 / [750+85]).
Tracy	24.8	1.3	57	20,630	If the Old River flow was 750 cfs with an EC of 0.7 dS/m, the City of Tracy discharge would increase the Old River EC by about 0.019 dS/m (i.e., [1.3-0.7] x 25 / [750+25]).
Mountain House	8.4	1.0	15	5,380	The effects of the Mountain House treated wastewater discharge on EC are more difficult to estimate because the flows in this section of Old River are tidal, so water may enter and leave this Old River channel section from both ends. The net summer flows at the upstream end (near Tracy Boulevard Bridge) tend to be positive (i.e., downstream) but less than 100 cfs, because the agricultural diversions in Old River of about 100–250 cfs are drawing water from both ends of the Old River channel.
Discovery Bay	3.2	2.0	11	4,100	Because the pumping at the CVP and SWP pumps is generally greater than the Old River flow from the SJR, net flows are generally upstream and the wastewater discharge is mixed with the southern Delta exports, just like the other southern Delta discharges.

Source: Chapter 13, *Service Providers*, Tables 13-4 and 13-5.
Note: Only discharges of greater than 1 million gallons per day (1.5 cfs) are included in this table.
1 dS/m = 1000 microSiemens per centimeter (1000 µS/cm)
cfs = cubic feet per second
EC = salinity (electrical conductivity)
dS/m = deciSiemens per meter

Historical Salinity (EC) Measurements

The measured EC values throughout the southern Delta indicate that the monthly patterns of EC are generally below the existing Bay-Delta Plan EC objectives. There have been periodic exceedances of the objectives in recent dry years at one or more of these stations, but high salinity is not the general pattern. High salinity that exceeds the existing EC objectives in about half of the years in the irrigation months of April–August has been routinely measured only at Tracy Boulevard Bridge. The monthly salinity is controlled by the Vernalis EC and is then slightly increased by agricultural drainage and treated municipal wastewater. Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta*, describes the salinity conditions in the Lower SJR and southern Delta using the available flow, EC, and salt load data.

Baseline salinity conditions in the SJR and southern Delta channels can be summarized with the USGS and DWR monitoring data from the period 1985–2011. Tables 5-15a through 5-15d show the distribution of monthly average EC values that have been measured during that period at Vernalis, the SJR at Brandt Bridge, Old River at Middle River (Union Island), and Old River at Tracy Boulevard, respectively. The lowest values have only occasionally been below 0.200 dS/m. The highest 90th percentile value was 1.174 dS/m (in Old River at Tracy Boulevard in February). Maximum monthly values have rarely been greater than 1.200 dS/m, with the highest monthly value of 1.326 dS/m again occurring in Old River at Tracy Boulevard during February. These data show that the EC values in the southern Delta rarely fall outside of a range of 0.200–1.200 dS/m.

Table 5-15a shows the historical EC data from Vernalis for 1985–2011 (27 years), presented in the monthly cumulative distribution format. The monthly median values provide the general seasonal pattern. The highest monthly median values were in December–March, when the salinity objective in the 2006 Bay-Delta Plan is 1.000 dS/m. The lowest monthly median EC values were measured in the irrigation season of April–August, when the salinity objective in the Bay-Delta Plan is 0.700 dS/m. The average Vernalis EC was lower in months with higher flows and higher in months with lower flows. The lowest EC (10 percent cumulative values) were 0.200–0.400 dS/m during the April–August irrigation season and were 0.250–0.500 dS/m September–March.

The January and February EC values were greater than 1.000 dS/m, the current 2006 Bay-Delta Plan salinity objective, in approximately 10 percent of the years. The March and April EC values were greater than 1.000 dS/m in just a few years. The measured EC values were greater than 0.700 dS/m April–August, the current 2006 Bay-Delta Plan salinity objective, in approximately 10 percent to 30 percent of the years depending on the month (e.g., less than 10 percent for May and almost 30 percent for July). The Vernalis EC approached the 1.000 dS/m objective in January–March 2003 and January–March 2009. The Vernalis EC has been above 0.650 dS/m in only approximately 6 months during the April–August period since 1996 because New Melones releases water to meet the EC objective at Vernalis.

1000 µS/cm = 1 deciSiemen per meter (1 dS/m)
µS/cm = microSiemens per centimeter

Table 5-15b shows the historical EC data from Brandt Bridge for 1985–2009 (25 years), presented in the monthly cumulative distribution format. The monthly median EC values at Brandt Bridge show the same seasonal pattern as Mossdale and Vernalis. There is some agricultural drainage between Vernalis and Brandt Bridge, but the monthly EC at Brandt Bridge was similar to the EC at Vernalis and at Mossdale. The median monthly EC values were approximately 0.025–0.050 dS/m greater than the median monthly Vernalis EC values during the non-irrigation season of September–March and were 0.050–0.100 dS/m higher than the median Vernalis EC values during the irrigation season of April–August. The monthly EC values were greater than the 0.700 dS/m objective in approximately 30 percent of the years during April; in approximately 20 percent of the years during May, in approximately 40 percent of the years during June, in approximately 40 percent of the years during July, and in approximately 30 percent of the years during August. Most of the EC values greater than 0.700 dS/m were in years prior to 1995, when the salinity objective in effect at the time was 1.0 dS/m as a 30-day running average.

1000 µS/cm = 1 deciSiemen per meter (1 dS/m)
µS/cm = microSiemens per centimeter

Table 5-15c shows the monthly cumulative distribution of historical EC data from Old River at Middle River (Union Island), located just upstream of the city of Tracy discharge. The monthly median EC values were similar to Vernalis, Mossdale, and Brandt Bridge. The median EC values for 1993–2009 (17 years) were 0.588 dS/m in September, 0.510 dS/m in October, 0.711 dS/m in November, 0.818 dS/m) in December, 0.761 dS/m in January, 0.695 dS/m in February, and 0.682 dS/m in March. The monthly median EC values were 0.543 dS/m in April, 0.402 dS/m in May, 0.565 dS/m in June, 0.634 dS/m in July, and 0.630 dS/m in August. The median EC values at Union Island were sometimes greater and sometimes less than the Vernalis EC values, and were generally lower than the median EC values at Mossdale. Because the SJR water at Mossdale flows past both Brandt Bridge and Union Island, the EC values at these two stations are similar.

µS/cm = microSiemens per centimeter

Table 5-15d shows the historical EC data from Old River at Tracy Boulevard Bridge, located downstream of the City of Tracy discharge and downstream of Doughty Cut, which diverts most of the Old River flow to Grant Line Canal. This section of Old River has less tidal movement and less net flow but is influenced by several agricultural drainage pumps that discharge into Old River. The monthly median EC values for 1985–2009 (25 years) were 0.761 dS/m (170 higher than Vernalis) in September, 0.730 dS/m (223 higher than Vernalis) in October, 0.801 dS/m (128 higher) in November, 0.870 dS/m (99 higher) in December, 0.872 dS/m (120 higher) in January, 0.877 dS/m (127 higher) in February, and 0.906 dS/m (159 higher) in March. The monthly median EC values were 0.721 dS/m (186 higher) in April, 0.591 dS/m (211 higher) in May, 0.697 dS/m (122 higher) in June, 0.815 dS/m (204 higher) in July and 0.776 dS/m (168 higher) in August. These EC values are much higher than the Old River at Middle River (Union Island) EC values measured just a few miles upstream. The Tracy Boulevard Bridge location may not accurately indicate the salinity of the water being diverted from other sections of Old River for irrigation use.

Compliance with the 1995 Bay-Delta salinity objectives at Vernalis has been consistently achieved over the past 15 years (a subset of the data presented below in Table 5-15d). However, compliance with the interior southern Delta salinity objectives has not always been achieved. There is a strong relationship between salinity concentrations at Vernalis and salinity concentrations at Brandt Bridge and Old River at Middle River under most conditions. Salinity increases between Vernalis and Brandt Bridge averaged approximately 0.050 dS/m (Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives)*. The historical salinity increase for Old River at Tracy Boulevard has been greater, averaging approximately 0.150 dS/m, with several monthly increases of more than 0.200 dS/m. The monthly increases in downstream EC are greatest when the SJR flow is low because the dilution of the drainage EC or municipal discharge EC is less when the SJR flow is low.

µS/cm = microSiemens per centimeter

5.3 Regulatory Background

5.3.1 Federal

Relevant federal programs, policies, plans, or regulations related to water supply, surface hydrology, and water quality are described below.

Clean Water Act

The federal CWA (33 U.S.C., § 1251 et seq.) places primary responsibility for developing water quality standards on the states. The CWA established the basic structure for regulating point and nonpoint discharges of pollutants into the waters of the United States and gave USEPA the authority to implement pollution control programs, such as setting wastewater standards for industry. The statute employs a variety of regulatory and non-regulatory tools to reduce pollutant discharges into waters of the United States, finance municipal wastewater treatment facilities, and manage polluted runoff.

Section 303(d)

Section 303(d) of the Clean Water Act requires states to identify waters within their jurisdiction that are not attaining water quality standards and include a priority ranking of such waters. The priority ranking takes into account the severity of the pollution and the uses to be made of such waters. The State Water Board and USEPA have approved TMDLs for several pollutants and/or stressors in the plan area (Table 5-4). The 303(d) listed waters in the study area could be affected by the LSJR alternatives.

Section 401: Water Quality Certification

Under Section 401 of the Clean Water Act, applicants for a Federal license or permit to conduct activities that might result in the discharge of a pollutant into waters of the United States must obtain certification from the state in which the discharge would originate or, if appropriate, from the interstate water pollution control agency with jurisdiction over affected waters at the point where the discharge would originate. The FERC relicensing processes that are taking place on the Merced and Tuolumne Rivers would require issuance of water quality certifications by the State Water Board, which may include conditions to implement the flow objectives adopted in the Bay-Delta Plan update.

Federal Antidegradation Policy

The federal anti-degradation policy is designed to provide the level of water quality necessary to protect existing uses and provide protection for higher quality and outstanding national resources waters (40 CFR 131.12). Federal regulations require that state water quality standards include an anti-degradation policy consistent with the federal policy. The State Water Board has interpreted State Water Board Resolution No. 68-16 to incorporate the federal anti-degradation policy (see Chapter 23, *Antidegradation Analysis*).

HR2828 (Public Law 108-361)

H.R. No. 2828, the Water Supply, Reliability, and Environmental Improvement Act (Pub. L. No. 108-361), requires the Secretary of the Interior to develop a program to meet water quality standards and objectives for which the Central Valley Project has responsibility while reducing reliance on water releases from New Melones Reservoir made for water quality purposes. USBR is also required to develop a plan to meet its obligations for water quality and is currently initiating a process to revise the operating plan of the New Melones Reservoir. While H.R. No. 2828 affords flexibility to USBR in meeting its water quality obligations, it does not relieve USBR from its responsibility to achieve those obligations as required by its water right permits. Per the 2015 Annual Work Plan, USBR continues to operate New Melones Reservoir to ensure that the D-1641 salinity standard at Vernalis is not exceeded and no other operations or actions are identified in the work plan related to these obligations (USBR 2015). The work plan includes the development of the real-time management program that would eventually (once implemented) lead to reduced salinity at Vernalis (USBR 2015).

5.3.2 State

Relevant state programs, policies, and regulations related to water supply, surface hydrology, and water quality are described below.

The State Water Board's 2006 Bay-Delta Plan and each regional water board's basin plan identifies beneficial uses, numeric and or narrative water quality objectives for the reasonable protection of the beneficial uses, a program of implementation to achieve the objectives, together with the beneficial uses assigned to water bodies and the state anti-degradation policy. Together, the beneficial uses and the water quality objectives established to reasonably protect the beneficial uses are called water quality standards under the terminology of the federal Clean Water Act.

Porter-Cologne Water Quality Control Act of 1969

Under the Porter-Cologne Water Quality Control Act (Porter-Cologne Act) (Wat. Code, § 13000 et seq.), the State Water Board has the authority to administer the CWA. USEPA retains oversight responsibilities. The State Water Board is updating the 2006 Bay-Delta Plan in accordance with the CWA and the Porter-Cologne Act.

Under the Porter-Cologne Act, water quality objectives are established for the purpose of protecting beneficial uses (e.g., agricultural beneficial uses or wildlife and fish beneficial uses). The Act requires the State Water Board and regional water boards to formulate and adopt WQCPs that designate the beneficial uses of the water to be protected, establish water quality objectives to reasonably protect these uses, and a program of implementation to meet the objectives.

California Water Plan

The California Water Plan is the state's strategic plan for managing and developing water resources statewide for current and future generations. DWR updates the California Water Plan every 5 years. The State Water Board considers the effect of its actions on the California Water Plan, looking toward the development, utilization, or conservation of water resources of the state. Once adopted, water quality control plans, such as the Bay-Delta Plan, become part of the California Water Plan. The California Water Plan identifies statewide resource management strategies that are grouped by different management objectives, including improving water quality and practicing resource stewardship. The Bay-Delta Plan complements the strategies and objectives identified in the California Water Plan by promoting multiple-benefit projects, such as matching water quality to beneficial uses, salt and salinity management, ecosystem restoration, and watershed management.

San Francisco Bay/Sacramento–San Joaquin Delta Estuary Water Quality Control Plan

The State Water Board's 2006 Bay-Delta Plan identifies beneficial uses of water in the Bay-Delta to be reasonably protected, water quality objectives for the reasonable protection of beneficial uses, and an implementation program to achieve the water quality objectives. The beneficial uses designated in the Bay-Delta plan are provided in Table 5-3. For additional information on the 2006 Bay-Delta Plan, see Chapter 1, *Introduction*.

Sacramento River and San Joaquin River Basins Water Quality Control Plan

The Central Valley Water Board's Basin Plan covers the entire Sacramento and SJR Basins, including an area bounded by the crests of the Sierra Nevada on the east and the Coast Range and Klamath Mountains on the west, and extending some 400 miles, from the California-Oregon border southward to the headwaters of the SJR.

The Basin Plan identifies the beneficial uses to be reasonably protected in the Sacramento and SJR Basin waterbodies, water quality objectives, implementation programs, and surveillance and monitoring programs. The Basin Plan contains specific numeric water quality objectives that are applicable to certain water bodies or portions of water bodies. Numerical objectives have been established for bacteria, DO, pH, pesticides, EC, TDS, temperature, turbidity, and trace metals. The Basin Plan also contains narrative water quality objectives for certain parameters that must be attained through pollutant control measures and watershed management. The Basin Plan includes TMDLs and the associated implementation plans adopted by the State and Regional Board and approved by USEPA pursuant to Clean Water Act Section 303(d), including those required for impairments that occur in the plan area (see Table 5-4). The State Water Board's Bay-Delta Plan supersedes the Central Valley Water Board's Basin Plan to the extent of any conflict and the Central Valley Water Board actions must conform to the Bay-Delta Plan.

State Antidegradation Policy

The goal of State Water Board Resolution No. 68-16 (Statement of Policy with Respect to Maintaining High Quality Waters in California), which applies to surface water and groundwater, is to maintain high quality waters of the State to the maximum extent possible. The State Water Board has interpreted Resolution No. 68-16 to incorporate the federal antidegradation policy (see Chapter 23, *Antidegradation Analysis*).

State Water Board Water Right Decision 1641

The Bay-Delta Plan (discussed previously) establishes water quality objectives for the Bay-Delta. State Water Board D-1641 contains the current water right requirements, applicable to DWR and USBR's operations of the SWP and CVP facilities, respectively to implement the Bay-Delta water quality objectives. D-1641 requirements pertaining to flow at Vernalis are discussed above in Section 5.2.6, *Lower San Joaquin River.*

5.4 Impact Analysis

This section identifies the thresholds or significance criteria used to evaluate the significance of potential impacts on surface hydrology and water quality resulting from the proposed alternatives. It describes the methods used to analyze changes in the environment and to evaluate the significance of those changes. Measures to mitigate (i.e., avoid, minimize, rectify, reduce, eliminate, or compensate for) significant impacts to less than significant accompany the impact discussion, if any significant impacts are identified. This section also summarizes results of hydrologic modeling for river flow, water supply, reservoir storage, and water temperature, under the LSJR alternatives relative to baseline to demonstrate the magnitude and timing of the effects and describe the interrelationship between flow and temperature. While these effects are summarized here, related impacts are described in other resource chapters.

5.4.1 Thresholds of Significance

The thresholds for determining the significance of impacts for this analysis are based on the State Water Board's Environmental Checklist in Appendix A of the Board's CEQA regulations. (Cal. Code Regs, tit. 23, §§ 3720–3781.) The thresholds derived from the checklist(s) have been modified, as appropriate, to meet the circumstances of the alternatives. (Cal. Code Regs., tit. 23, § 3777, subd. (a)(2).) Hydrology and water quality impacts were determined to be potentially significant in the State Water Board's Environmental Checklist (see Appendix B, *State Water Boards Environmental Checklist*) and therefore are discussed in this analysis as to whether the alternatives could result in the following:

- Violate water quality standards by increasing the number of months with EC above the water quality objectives for salinity at Vernalis or the southern Delta compliance stations.

- Substantially degrade water quality by increasing Vernalis or southern Delta EC such that agricultural beneficial uses are impaired.
- Substantially degrade water quality by increasing pollutant concentrations caused by reduced river flows.

Where appropriate, specific quantitative or qualitative criteria are described in Section 5.4.2, *Methods and Approach* for evaluating these thresholds.

As described in Appendix B, *State Water Board's Environmental Checklist,* the LSJR and SDWQ alternatives would result in either no impact or less-than-significant impacts on the following related to surface hydrology, and water quality and, therefore, are not discussed within this chapter.

- Create or contribute runoff water which would exceed the capacity of existing or planned storm water drainage systems or provide substantial additional sources of polluted runoff.

5.4.2 Methods and Approach

The effects of the LSJR alternatives on reservoir operations, flood control releases, water supply diversions, and water quality in the SJR at Vernalis and in the southern Delta were analyzed using the State Water Board's Water Supply Effects (WSE) model. Because flows are not expected to change in response to the SDWQ alternatives, the WSE model was not needed to assess effects of the SDWQ alternatives. The scientific basis for the WSE model is described in Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*, and the detailed methods and results for the LSJR alternatives are presented in Appendix F.1, *Hydrologic and Water Quality Modeling*.

Water Supply Effects Model

This section describes development of the WSE spreadsheet model and the assumptions used to model baseline and alternative conditions. General comparisons of the baseline and alternative results are presented in Section 5.4.3, *Hydrologic and River Temperature Modeling Results*. The initial scientific basis and methodologies for the WSE model are described in Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*. The methodologies, with additions and refinements to the WSE model, are summarized below. Appendix F.1, *Hydrologic and Water Quality Modeling* fully describes the development and calculation methodologies for specified unimpaired flow targets, diversions, river and reservoir water balances, and the results of the WSE model.

The WSE model is a monthly spreadsheet model that calculates monthly streamflow, reservoir storage levels, and water supply diversions for each eastside tributary based upon user-specified target flows, other user defined inputs, input from CALSIM II, flood storage rules, and an allocation of available water. The general approach is to calculate available water for diversion in each water year based on inflows, net available water from storage after carryover guidelines, and after streamflow targets are met.

The WSE model was developed because SWRCB staff determined that CALSIM II does not easily allow for the setting of monthly downstream flow targets as a fraction of unimpaired flows. Also, it is difficult to change operations and assess these changes rapidly in CALSIM. Furthermore, CALSIM and its data output are not readily understood by a wide variety of users. By utilizing a spreadsheet as the platform for the WSE model, changes in reservoir operations and the effects of changes to flow requirements can be rapidly assessed, and the model and its results are more understandable to users overall. Since the WSE model uses a similar mass balance and assumptions as CALSIM, and utilizes many of the same inputs, it produces similar results as CALSIM. The WSE model is considered a reasonably equivalent tool to CALSIM for the purposes of this analysis, and is sufficiently representative of baseline and potential alternative conditions to assess impacts. As with any model, the WSE model does not precisely re-create historic conditions, and it also does not precisely predict the potential future operations of the system. However, it can accurately depict baseline and alternative conditions such that relative comparisons can be made to analyze potential environmental impacts.

The WSE model baseline condition scenario was developed such that it would agree with CALSIM II SJR Module results when both models are subject to a similar set of assumptions and rules. The State Water Board conducted CALSIM II modeling using the CALSIM II SJR Module supplied by USBR (USBR 2013a, 2013b). This version of the model contained many of the same assumptions and inputs as the CALSIM II "Current Conditions" case used in the DWR 2009 Delivery Reliability Report (DWR 2010), a version of CALSIM II which closely represents the baseline conditions over 82 years of historic climate. The State Water Board used the USBR SJR Module, USBR Base, and made minor adjustments to operations on the Stanislaus River and Vernalis pulse flow requirements as described in Appendix F.1, *Hydrologic and Water Quality Modeling,* in order to make the CALSIM SJR Module most appropriately represent the baseline condition for this analysis. The results from this CALSIM run (SWRCB–CALSIM) can be compared to the WSE model results. Figure 5-6 contains an example of the WSE model to State Water Board-CALSIM comparison contained in Appendix F.1 for baseline regulatory conditions (the final WSE model baseline simulation contained some further modifications described in Appendix F.1, Section F.1.2.4, that resulted in divergence from CALSIM).

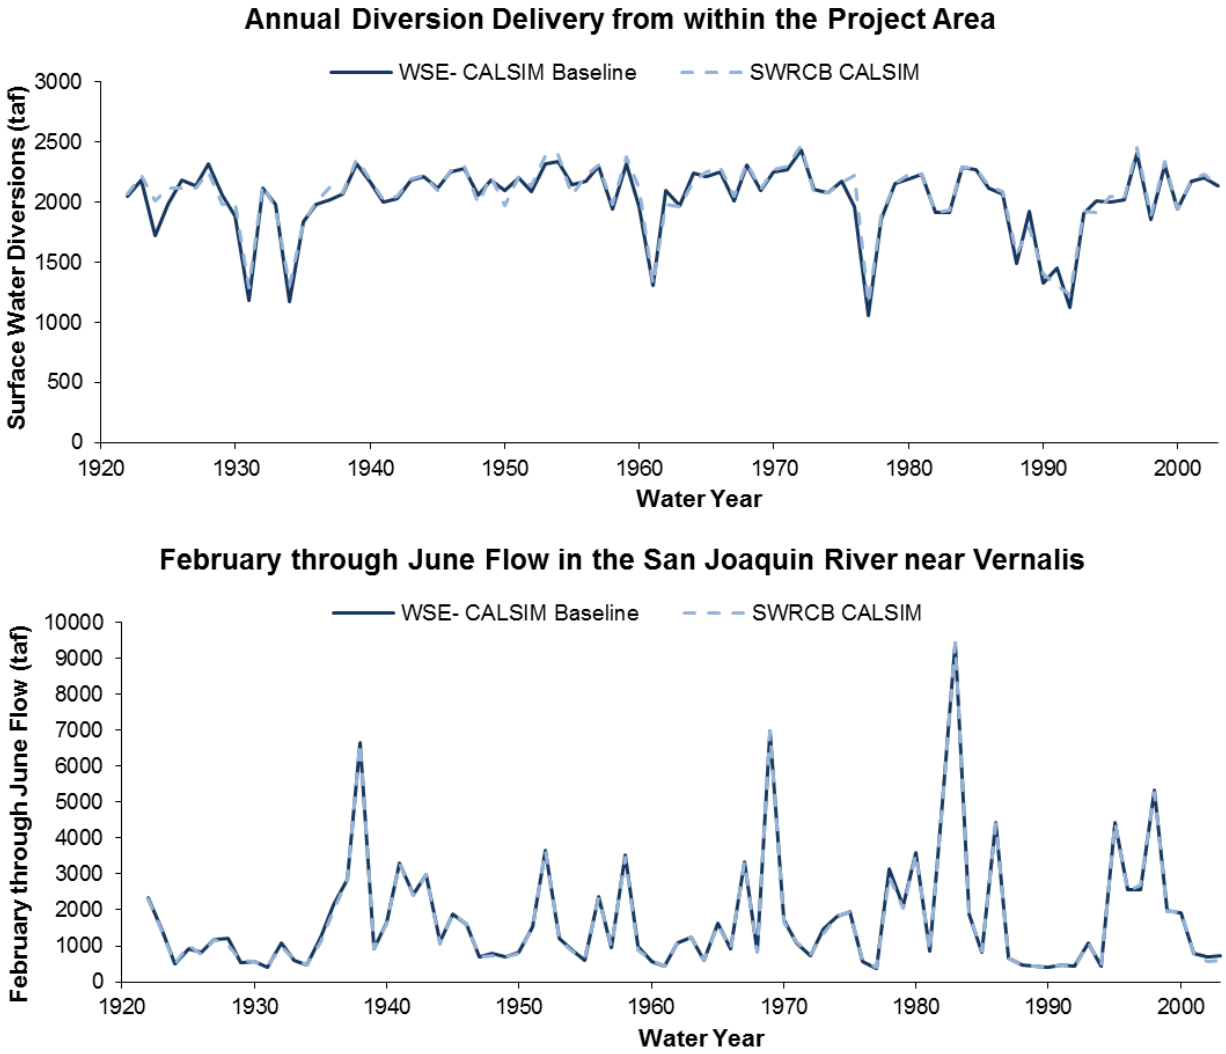

Figure 5-6. Annual WSE Model Baseline[12] SJR Flow at Vernalis and Three Tributary Total Diversion Compared to SWRCB CALSIM Results

The WSE model incorporates 82 years of hydrology that results in the monthly flows, reservoir storage levels, and water supply diversions for each eastside tributary based upon user-specified target flows, other user defined inputs, CALSIM data inputs and outputs, and flood storage rules. User defined inputs to the WSE model include those listed below.

- Months for which flow targets are to be set.
- Monthly flow targets as a percentage of unimpaired monthly flow for each eastside tributary.
- Monthly minimum flows for each eastside tributary.

---

[12] This example illustrates the close match between "SWRCB–CALSIM"—i.e., the SWRCB-modified version of USBR SJR Module, compared to WSE model results, prior to further modification of assumptions for surface water demand for the CEQA baseline described in Appendix F.1, *Hydrologic and Water Quality Modeling,* Section F.1.2.4, *Calculation of Monthly Surface Water Demand*.

- Maximum annual surface water diversion for each eastside tributary.
- Minimum annual surface water diversion (may supersede end-of-September storage guidelines).
- Minimum annual end-of-September storage guidelines.
- Maximum annual allowable draw from reservoirs as a percentage of the available storage.

Many CALSIM values used by the WSE model were adapted directly from the USBR CALSIM model run (USBR 2013a, 2013b). Some WSE model inputs not defined by the user include those listed below.

- Monthly surface water demand based on Consumptive Use of Applied Water (CUAW) estimates from CALSIM.
- CALSIM inflows to each major reservoir (New Melones, New Don Pedro, and Lake McClure), and SJR inflow from upstream of the Merced River confluence near Newman.
- CALSIM evaporation rates from each major reservoir.
- CALSIM accretions/depletions and return flows downstream from each major reservoir.
- Flood storage rule curves at each major reservoir.

Calculation of annual diversions for major irrigation districts depends on the amount of surface water available for diversion, which is based on: (1) reservoir storage (March 1 storage minus September 30 storage guideline); (2) projected reservoir inflow (for March 1–September 30); (3) water expected to be lost through evaporation; and (4) water required for instream flow. Surface water demand and minimum diversion requirements control the upper and lower limits of diversions. The available water for diversion is calculated annually using CALSIM hydrologic conditions (inflows) for water years 1922–2003. This methodology allows for maximizing annual diversions based on climate variations; reservoirs can be re-operated to allow additional draw-down relative to baseline and ensure a portion of storage is retained for maintaining river temperatures downstream. To distribute the calculated available seasonal diversion throughout the year, an allocation was determined as a fraction of surface water demands for each of the major irrigation district diversions, then applied to the each month of the irrigation year. More information regarding this calculation is provided in Appendix F.1, *Hydrologic and Water Quality Modeling*.

The following flow requirements are included in the baseline: NMFS BO flows on the Stanislaus River; FERC flows on the Tuolumne and Merced Rivers; and Davis-Grunsky and Cowell Agreement requirements on the Merced River. For the LSJR alternatives, the WSE model uses the maximum of these flow requirements or the percent of unimpaired flow specified for each LSJR alternative.

The modeled baseline is the basis for comparison and determination of water supply and water quality impacts under the LSJR alternatives described in this chapter (Impacts WQ-1–WQ-3).

Adaptive Implementation

Each LSJR alternative includes a February–June unimpaired flow requirement (i.e., 20, 40, or 60 percent) and methods for adaptive implementation to reasonably protect fish and wildlife beneficial uses, as described in Chapter 3, *Alternatives Description*. In addition, a minimum base flow is required at Vernalis at all times during this period. This base flow may be adaptively implemented as described below and in Chapter 3. State Water Board approval is required before any method can be implemented, as described in Appendix K, *Revised Water Quality Control Plan*. All methods may be implemented individually or in combination with other methods, may be applied differently to each tributary, and could be in effect for varying lengths of time, so long as the flows are coordinated to achieve beneficial results in the LSJR related to the protection of fish and wildlife beneficial uses.

The Stanislaus, Tuolumne, and Merced Working Group (STM Working Group) will assist with implementation, monitoring, and assessment activities for the flow objectives and with developing biological goals to help evaluate the effectiveness of the flow requirements and adaptive implementation actions. Further details describing the methods, the STM Working Group, and the approval process are included in Chapter 3 and Appendix K. Without adaptive implementation, flow must be managed such that it tracks the daily unimpaired flow percentage based on a running average of no more than 7 days. The four methods of adaptive implementation are described briefly below.

- Based on best available scientific information indicating that more flow is needed or less flow is adequate to reasonably protect fish and wildlife beneficial uses, the specified annual February–June minimum unimpaired flow requirement may be increased or decreased to a percentage within the ranges listed below. For LSJR Alternative 2 (20 percent unimpaired flow), the percent of unimpaired flow may be increased to a maximum of 30 percent. For LSJR Alternative 3 (40 percent unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 30 percent or increased to a maximum of 50 percent. For LSJR Alternative 4 (60 percent unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 50 percent.
- Based on best available scientific information indicating a flow pattern different from that which would occur by tracking the unimpaired flow percentage would better protect fish and wildlife beneficial uses, water may be released at varying rates during February–June. The total volume of water released under this adaptive method must be at least equal to the volume of water that would be released by tracking the unimpaired flow percentage from February–June.
- Based on best available scientific information, release of a portion of the February–June unimpaired flow may be delayed until after June to prevent adverse effects to fisheries, including temperature, that would otherwise result from implementation of the February–June flow requirements. The ability to delay release of flow until after June is only allowed when the unimpaired flow requirement is greater than 30 percent. If the requirement is greater than 30 percent but less than 40 percent, the amount of flow that may be released after June is limited to the portion of the unimpaired flow requirement over 30 percent. For example, if the flow requirement is 35 percent, 5 percent may be released after June. If the requirement is 40 percent or greater, then 25 percent of the total volume of the flow requirement may be released after June. As an example, if the requirement is 50 percent, at least 37.5 percent unimpaired flow must be released in February–June and up to 12.5 percent unimpaired flow may be released after June. If after June the STM Working Group determines that conditions have changed such that water held for release after June should not be released by the fall of that year, the water may be held until the following year. See Chapter 3 and Appendix K for further details.
- Based on best available scientific information indicating that more flow is needed or less flow is adequate to reasonably protect fish and wildlife beneficial uses, the February–June Vernalis base flow requirement of 1,000 cfs may be modified to a rate between 800 and 1,200 cfs.

The operational changes made using the adaptive implementation methods above may be approved if the best available scientific information indicates that the changes will be sufficient to support and maintain the natural production of viable native SJR Watershed fish populations migrating through the Delta and meet any biological goals. The changes may take place on either a short-term (for example monthly or annually) or longer-term basis. Adaptive implementation is intended to foster coordinated and adaptive management of flows based on best available scientific information in order to protect fish and wildlife beneficial uses. Adaptive implementation could also optimize flows to achieve the objective, while allowing for consideration of other beneficial uses, provided that these other considerations do not reduce intended benefits to fish and wildlife.

The quantitative results presented in the figures, tables, and text of this chapter present WSE modeling of the specified unimpaired flow requirement of each LSJR alternative (i.e., 20, 40, or 60 percent). This chapter also incorporates a qualitative discussion of adaptive implementation under each of the LSJR alternatives that includes the potential environmental effects associated with adaptive implementation. To inform the qualitative discussion and account for the variability allowed by adaptive implementation, modeling was performed to predict conditions at 30 percent and 50 percent of unimpaired flow (as reported in Appendix F.1, *Hydrologic and Water Quality Modeling*). The modeling also allows some inflows to be retained in the reservoirs until after June, as could occur under method 3, to prevent adverse temperature effects. This variety of modeling scenarios provides information to support the analysis and evaluation of the effects of the alternatives and adaptive implementation. This chapter incorporates a qualitative discussion of the potential water quality impacts of adaptive implementation under each of the LSJR alternatives. For more information regarding the modeling methodology and quantitative flow and temperature modeling results, see Appendix F.1. Because flow modification is not part of the SDWQ alternatives, there is no adaptive implementation component of the SDWQ alternatives and adaptive implementation does not have the potential to affect the impact determinations of the SDWQ alternatives.

Water Temperature Model

This section describes the development of the temperature model and the assumptions used to model baseline and LSJR alternative conditions. Comparisons of the baseline and LSJR alternative temperature results are presented in Section 5.4.3, *Hydrologic and River Temperature Modeling Results.* More details of the model development and results are described in Appendix F.1, *Hydrologic and Water Quality Modeling.* To model effects on temperature in the LSJR and three eastside tributaries, the State Water Board modified the *San Joaquin River Basin-Wide Water Temperature and EC Model* (SJR HEC-5Q model, or temperature model) developed by a group of consultants between 2003 and 2008 through a series of CALFED contracts that included peer review and refinement (CALFED 2009). The temperature model was most recently updated by the California Department of Fish and Wildlife (CDFW) and released in June of 2013 (CDFW 2013).

The SJR HEC-5Q temperature model uses the Hydrologic Water Quality Modeling System (HWMS-HEC5Q) to model reservoir and river temperatures subject to historical climate conditions and user-defined operations. The HWMS-HEC5Q is a graphical user interface that employs HEC-5Q, the USACE Hydrologic Engineering Center (HEC) flow and water quality simulation model. The temperature model was designed to provide a SJR basin-wide evaluation of temperature response at 6-hour intervals for alternative conditions, such as operational changes, physical changes, and combinations of the two. The extent of the model includes the Stanislaus, Tuolumne, and Merced River systems from their LSJR confluences to the upstream end of their major reservoirs (i.e., New

Melones, New Don Pedro, and Lake McClure, respectively). The upstream extent of the model is the Merced River confluence. The downstream extent of the model is the LSJR at Mossdale (which is downstream of Vernalis). The model simulates the reservoir stratification, release temperatures, and downstream river temperatures as a function of the inflow temperatures, reservoir geometry and outlets, flow, meteorology, and river geometry. Calibration data was used to accurately simulate temperatures for a range of reservoir operations, river flows, and meteorology.

The temperature model interfaces with CALSIM or monthly data formatted similarly to CALSIM output. A pre-processing routine converts the monthly output to a format compatible with the SJR HEC-5Q model. This routine serves two purposes: (1) to allow the temperature model to perform a long-term simulation compatible with the period used in CALSIM; and (2) to convert monthly output to daily values used in the temperature model.

The State Water Board used the CALSIM-to-HEC-5Q temperature model pre-processor, using the monthly output from the WSE model, and ran the temperature model to determine the river temperature effects of the LSJR alternatives within the Stanislaus, Tuolumne, and Merced Rivers and the LSJR. The temperature model was run for the years 1970–2003, a period with sufficient length and climatic variation to determine the effects of the LSJR alternatives on river temperatures.

Exports and Outflow

The LSJR alternatives have the potential to change the CVP and SWP exports and Delta outflow. Appendix F.1, *Hydrologic and Water Quality Modeling*, details the methodology used to estimate the change in southern Delta exports and Delta outflow. SJR at Vernalis flow changes primarily during the months of February–June. Changes in SJR flow at Vernalis either change exports or change outflow. Based on the existing Delta objectives and NMFS BO rules, the most likely changes in exports for each month were estimated based on the change in flow at Vernalis simulated by the WSE model and the most likely regulation to be controlling Delta exports for a given month (see Table F.1.7-1). To estimate the possible effects on exports, analysis related to exports and outflow assumes the State Water Board will not change the export constraints to protect any increased flows downstream of Vernalis because the LSJR Alternatives as described in Chapter 3, *Alternatives Description*, would not affect export regulations. Results of this analysis are summarized here in Chapter 5, but potential impacts on aquatic resources are discussed in Chapter 7, *Aquatic Biological Resources*, and potential impacts on service providers are discussed in Chapter 13, *Service Providers*. The State Water Board is currently in the process of reviewing the export restrictions included in the 2006 Bay-Delta Plan as part of its periodic review of the plan. Through that process, the State Water Board will determine what changes, if any, should be made to the export restrictions. The State Water Board will then determine what actions are needed to implement changes to the flow and export objectives.

Salinity Analysis

This section describes the methods used to analyze salinity in the southern Delta as a result of implementing the LSJR and SDWQ alternatives. Two potential mechanisms for salinity impacts are described: (1) changes to flow at Vernalis; and (2) changes to circulation, water levels, and tidal flow in the southern Delta.

The SDWQ alternatives would amend the southern Delta salinity objectives identified in the 2006 Bay-Delta Plan. The purpose of the salinity objective in the 2006 Bay-Delta Plan as well as the purpose of the SDWQ alternatives is to protect beneficial uses, specifically agricultural uses in the southern Delta. Currently, the attainment of the objective in the southern Delta is assessed by monitoring EC in the SJR at Vernalis and Brandt Bridge, and in Old River at Middle River (Union Island) and Tracy Boulevard. Under SDWQ Alternatives 2 and 3, the EC objective would be modified. In addition, under the program of implementation, the monitoring locations for assessing attainment of the objective could also be modified, except at Vernalis, to better assess salinity conditions attainment of the water quality objective.

While the monitoring locations could change under SDWQ Alternatives 2 and 3, the historic monitoring locations specified in the 2006 Bay-Delta Plan were used to assess water quality impacts. These historic monitoring locations were used because much data has been collected at these locations, which allows for a quantitative assessment of how the LSJR alternatives may affect water quality at these locations. Estimated changes in water quality at these locations are indicative of how water quality may change at other southern Delta locations.

The potential for changes in salinity to affect the beneficial use of water for aquatic resources, agricultural supply, and drinking water supply are discussed in Chapter 7, *Aquatic Biological Resources*, Chapter 11, *Agricultural Resources*, and Chapter 13, *Service Providers*, respectively.

Vernalis Flow Effects on Salinity

Potential southern Delta salinity impacts associated with LSJR Alternatives 2, 3, and 4 and SDWQ Alternatives 2 and 3 were assessed in two ways.

- By assessing whether the alternatives would increase the number of months with EC above the water quality objectives for salinity at Vernalis or southern Delta compliance stations (impact WQ-1).
- By assessing whether the alternatives would substantially increase southern Delta EC such that agricultural beneficial uses are impaired. The potential overall change in southern Delta salinity for agriculture was evaluated using the long term cumulative distribution for EC during the irrigation season (April–September)(Impact WQ-2).

Salinity at SJR at Vernalis was calculated within the WSE model using a flow-to-salinity ratio based on the CALSIM results. Increases in salinity within the southern Delta were empirically derived based on historic data at Vernalis and the interior southern Delta stations. These methods are summarized here and further discussed in Appendix F.1, *Hydrologic and Water Quality Modeling*.

The WSE model estimated Vernalis EC based on the assumption that the salt load at Vernalis is the same as that modelled by CALSIM using the following equation.

$$\text{Adjusted Vernalis EC} = \text{CALSIM EC} * (\text{CALSIM Flow}/\ \text{Adjusted Flow}) \qquad (\text{Eqn. 5-1})$$

Using this equation, EC decreases under high flow conditions and increases under reduced flow conditions. The Vernalis EC values were calculated in this manner for both baseline conditions and each of the LSJR alternatives. As necessary, the WSE model adjusted the flow releases from New Melones Reservoir on the Stanislaus River to ensure that the Vernalis EC objectives were met.

Appendix F.1, *Hydrologic and Water Quality Modeling,* shows the comparison of measured monthly average SJR at Vernalis EC values and the CALSIM EC results for water years 1994–2003 in Section F.1.42.1, *Salinity Modeling Methods*. This covers a period during which actual operations in the watershed(s) were relatively similar to those modeled in CALSIM.

Simple calculations of the southern Delta EC values were made based on the historical EC increases between Vernalis and the southern Delta stations for 1985–2009 (see Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta*). A review of the historical EC data indicated that the EC increment from Vernalis to Brandt Bridge or Old River at Middle River (Union Island) can be estimated with the following flow dilution relationship.

EC increase from Vernalis (dS/m) = 100/ SJR flow at Vernalis (cfs) *(Eqn. 5-2)*

Accordingly, for a flow of 1,000 cfs, the EC increase would be 0.10 dS/m. For a flow of 2,000 cfs, the EC increase would be 0.050 dS/m, and for a flow of 5,000 cfs, the EC increase would be 0.020 dS/m. The EC increase at Old River at Tracy Boulevard was assumed to be 3 times the EC increase at Brandt Bridge.

EC increase from Vernalis (dS/m) = 300/ SJR flow at Vernalis (cfs) *(Eqn. 5-3)*

The quantitative water quality impact analysis focusses on salinity because: (1) salinity is the main water quality constituent likely to be affected by the LSJR and SDWQ alternatives, (2) there is sufficient EC data available to evaluate effects quantitatively, and (3) it is a constituent of great concern in the southern Delta. Other water quality constituents are also included in the impact assessment below, but the analysis is less quantitative. Other water quality constituents are expected to respond to changes in flow in a manner similar to that which is estimated for salinity.

Circulation, Water Levels, and Tidal Flows Effects on Salinity

Salinity conditions in the southern Delta water bodies are affected by their capacity to assimilate upstream and local salt loading. This assimilative capacity is potentially affected by hydrodynamic conditions, such as water levels and the direction and magnitude of flow in the various channels of the southern Delta. CVP and SWP pumping operations in the southern Delta have the potential to affect water level and flow conditions there. To address these impacts, the temporary barriers are currently installed during the irrigation season in Old River near the DMC, in Grant Line Canal at Tracy Boulevard Bridge, and in Middle River at Victoria Canal. The temporary barriers block the tidal flows during ebb tide (falling water elevations, water moving downstream towards the estuary), and thereby maintain higher elevations during ebb tides. The Grant Line barrier is placed each year at a lower elevation than the other two barriers.

The SDWQ alternatives call for continuation of the temporary barriers, followed by special studies and development of a coordinated operations plan. The existing water levels in the southern Delta channels, therefore, would not change with the LSJR or SDWQ alternatives evaluated in this SED. As a result, barrier operations and associated effects on circulation, water level, and tidal flows would have either no impact or provide a slight improvement in salinity conditions in the southern Delta (due to the coordinated operations plan) and are not discussed further.

303(d) Pollutant Analysis

Pollutants identified by the 303(d) list for the various receiving waters in the study area (Table 5-4) are more likely to approach criteria levels when river flows are relatively low because concentrations of pollutants generally increase when flows are low. An increase in flows would not likely cause concentrations to exceed criteria levels. Although some data are available for these pollutants, there was not a sufficient number of water quality measurements for each month over the range of baseline flows to be able to calculate concentrations or loads; therefore, a generalized more qualitative evaluation of changes in pollutant concentrations, based on changes in flows expected for each of the LSJR alternatives, was used to evaluate whether the LSJR alternatives would result in an increase in 303(d) pollutant concentrations. The impact assessment for general pollutant concentrations is based on the changes in the monthly cumulative distributions of flows. The likely changes in pollutant concentration were assessed using the percent change in the 10th percentile and median flows (Impact WQ-3). The evaluation is conservative because it assumes that baseline concentrations of 303(d) pollutants would approach or exceed water quality criteria limits.

Plan Area and Water Supply Effects Model

The water supply effects analysis, WSE model, and overall analysis of impacts on other resources in the SED focus on the plan area downstream of the rim dams (New Melones Reservoir, New Don Pedro Reservoir, and Lake McClure), where the flow objectives attain the greatest benefits on the Stanislaus, Tuolumne, and Merced Rivers. The assessment of water supply effects in the plan area downstream of the rim dams provides an adequate means of identifying and evaluating effects for the overall analysis because the effects below the rim dams largely represent the potential effects of the LSJR alternatives overall. Upstream areas above the rim dam reservoirs are not included in the WSE model because upstream water rights are relatively small compared to the downstream rights and, thus, any changes in operations due to the project alternatives are assumed not to significantly affect inflows into New Melones Reservoir, New Don Pedro Reservoir, or Lake McClure. Although water rights in the extended plan area above the rim dams could also be affected by implementation of the flow objectives, the effect would be small compared to the effect downstream of the rim dams. The impact analysis therefore addresses those potential effects in less detail than for downstream areas.

An illustration of the proportion of water use below the rim dams compared to the proportion in the extended plan area can be shown using the face value of post-1914 water rights for consumptive use in each region. The allocation of responsibility to implement the objectives would generally follow water right priority and other applicable law. In general, the rule of priority requires junior water right holders to reduce water diversions when water is not available for diversion by all water right holders. The face-value of non-hydropower post-1914 water rights upstream of the rim dams in the extended plan area account for approximately 2 percent, 1 percent, and 6 percent of the post-1914, non-hydropower water in the Stanislaus, Tuolumne, and Merced River Watersheds, respectively.[13] Large post-1914 rights downstream of the rim dams, in the plan area, include the following.

- Three non-power water rights held by the Merced ID for water diverted at or downstream of Lake McClure account for approximately 98 percent of the post-1914 water authorized for diversion in the Merced River Watershed.
- Five non-power water rights held by TID and MID for water diverted at or downstream of New Don Pedro Reservoir account for approximately 99 percent of the post-1914 water authorized for diversion in the Tuolumne River Watershed (not including CCSF diversions at Hetch Hetchy authorized by the Raker Act of 1913).

---

[13] These numbers do not include upstream water rights that are owned and operated by major irrigation districts, e.g., Donnells and Beardsley Reservoirs operated by the Tri-Dam Project, to be used consumptively within the plan area downstream of the rim dams, and assessed as a portion of the rim dam inflows.

- 16 non-power water rights held by OID, SSJID, USBR, McMullin Reclamation District #2075, and River Junction Reclamation District #2064 for water to be consumptively used downstream of New Melones Reservoir account for 94 percent of the post-1914 water authorized for diversion in the Stanislaus River Watershed.

These and other water users downstream of the rim dams also rely on significant pre-1914 water rights. Given the small volume of water held in non-hydropower post-1914 rights for consumptive use in the extended plan area compared to the volume held in non-hydropower post-1914 water rights used below the rim dams, most of the effect of implementing LSJR alternatives would occur at, or downstream of, the major rim dams in the Stanislaus, Tuolumne, and Merced Rivers.

The Tuolumne River has a significant upstream diversion (e.g., CCSF, Hetch Hetchy aqueduct). The water rights and operating agreement for New Don Pedro Reservoir includes requirements for seasonal storage in the CCSF upstream reservoirs and water banking in New Don Pedro Reservoir allocated between TID, MID, and CCSF, as described above in Section 5.2.4, *Tuolumne River*. The water accounting for New Don Pedro Reservoir could be modified by the LSJR alternatives, but the upstream CCSF operations (storage, hydropower, and water diversion volume) are assumed to be mostly unchanged and therefore would not significantly affect the release of the flows required for the alternatives from New Don Pedro and, therefore, is not part of the WSE model. Depending on the operating agreements between MID, TID, and CCSF, there is some potential that CCSF water supply and operations could be affected during dry conditions. This potential effect is evaluated in Chapter 13, *Service Providers*, Chapter 20, *Economic Analyses*, and Appendix L, *City and County of San Francisco Analyses*.

Extended Plan Area

The primary means by which the extended plan area reservoirs and rivers might be affected is if water is bypassed by junior water rights holders, in accordance with the rules of priority and applicable law, to achieve the required flows in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR.

Under baseline, junior water rights holders who divert water to storage, including February through June, must cease diversion to storage if there is not enough water to satisfy the water rights of more senior water rights downstream. The frequency with which these junior water rights holders must cease diversion to storage would increase during some months of some years under LSJR Alternatives 2, 3, and 4 if water needed to meet the February–June flow requirements reduces the amount of water that can be diverted. A reduction in diversion to storage in the upstream reservoirs can result in reduced reservoir levels, which already occur in the baseline condition. The increased frequency with which reservoirs in the extended plan area are drawn down to lower storage levels would depend on seniority of water rights and how water rights are conditioned to implement the flow objectives in a future water right proceeding. While the effects may be greatest in critically dry and dry years, there may be some effects in below normal, above normal, and wet years. Table 5-19b shows the distribution of changes to annual average diversions under each of the LSJR alternatives.

The increased frequency of lower reservoir levels and the related physical changes, however, would be limited by the program of implementation, which states that the State Water Board will include minimum reservoir carryover storage targets or other requirements to help ensure that providing flows to meet the flow objectives will not have adverse temperature or other impacts on fish and wildlife or, if feasible, on other beneficial uses. It also states that the State Water Board will also take actions as necessary to ensure that implementation of the flow objectives does not impact supplies of water for minimum health and safety needs, particularly during drought periods. Accordingly, when the State Water Board implements the flow requirements, it will consider impacts on fish, wildlife and other beneficial uses and health and safety needs, along with water right priority. Any project-level proceeding would require compliance with CEQA, and the State Water Board would consider project-specific impacts associated with lower reservoir levels, and mitigate any significant impacts. This could, for example, result in establishing bypass limitations for reservoirs that store water for non-consumptive uses or providing flexibility, such as shifting the timing of release, in meeting such requirements for those reservoirs. Water required to satisfy senior rights could be temporarily retained in upstream reservoirs as long as it is released later when the water is needed for use under senior rights downstream. This approach is consistent with the physical solution doctrine, which allows for measures such as alternative supplies—in this case storage under upstream, junior water rights instead of bypassing that water for storage under downstream, senior water rights, while still making that water available when needed under the downstream, senior rights—that serve to maximize beneficial use while avoiding injury to water right holders.

The LSJR alternatives could temporarily increase river flows in the extended plan area relative to baseline as a result of bypassing direct diversions or reducing diversions to storage. The increases in flows could occur more frequently and be a larger volume of water under the higher unimpaired flow alternatives (e.g., LSJR Alternative 4). Later in the year, flows potentially could be reduced if reservoir storage is too low; however, as described in the program of implementation, there would be limits on, or shifting of the timing of, bypass requirements, which would reduce this effect.

In this chapter, the analysis of the extended plan area generally identifies how the impacts may be similar to or different from the impacts in the plan area (i.e., downstream of the rim dams) depending on the similarity of the impact mechanism (e.g., changes in reservoir levels, reduced water diversions, and additional flow in the rivers) or location of potential impacts in the extended plan area. Where appropriate, the program of implementation is discussed to help contextualize the potential impacts in the extended plan area.

Hydrologic and River Temperature Modeling Results

This section includes a summary of the hydrologic and river temperature modeling results, including an evaluation of the changes in flow, diversions, reservoir storage, and water temperature estimated to occur under LSJR Alternatives 2, 3, and 4 relative to baseline. These four hydrologic parameters are the primary parameters used to evaluate the impacts of many of the resources analyzed in this SED, but impacts on many of the resources are not evaluated based solely on these parameters. These parameters are discussed below to describe how they may change in response to the LSJR alternatives. The impacts driven by these parameters are discussed in the appropriate resource chapters of the SED. Water quality, however, is evaluated within specific impacts in this chapter in Section 5.4.4, *Impact and Mitigation Measures* (Impacts WQ-1, WQ-2, and WQ-3), and thus a summary and evaluation of those results are contained within those impact discussions.

Detailed hydrologic and river temperature results for the baseline and each of the LSJR alternatives can be found in Appendix F.1, *Hydrologic and Water Quality Modeling*. In later chapters, the analysis of the hydrologic conditions is tailored to the specific resource and the potential impact being evaluated. These later chapters either make use of the model result summaries provided here or evaluate the modeling results in a manner to focus on the resource of concern.

Potential project-related changes in river flow, surface water diversions, reservoir storage, and water temperature are summarized in this chapter, but their potential impacts are described in other resource chapters. These include, but are not limited to the following.

- Potential effects associated with changes in river flow are discussed in Chapter 6, *Flooding, Sediment, and Erosion*; Chapter 7, *Aquatic Biological Resources*; Chapter 8, *Terrestrial Biological Resources*; Chapter 10, *Recreational Resources and Aesthetics*; and Chapter 12, *Cultural Resources*.
- Potential effects associated with changes in diversions from the rivers and the southern Delta are discussed in Chapter 7, *Aquatic Biological Resources*; Chapter 9, *Groundwater Resources*; Chapter 11, *Agricultural Resources*; Chapter 13, *Service Providers*; and Chapter 14, *Energy and Greenhouse Gases*.
- Potential effects associated with changes in reservoir storage are discussed in Chapter 7, *Aquatic Biological Resources*; Chapter 8, *Terrestrial Biological Resources*; Chapter 10, *Recreational Resources and Aesthetics*; and Chapter 12, *Cultural Resources.* The changes in reservoir elevation described here also can produce impacts associated with changes in hydropower, which are discussed in Chapter 14, *Energy and Greenhouse Gases*.
- Potential effects associated with changes in water temperature are discussed in Chapter 7, *Aquatic Biological Resources*.

In addition, a description of potential aquatic resource benefits associated with modeled changes are described in Chapter 19, *Analyses of Benefits to Native Fish Populations from Increased Flow Between February 1 and June 30,* and a description of potential economic effects associated with the modeled changes are described in Chapter 20, *Economic Analyses.*

Presentation of Results

The WSE model was used to simulate monthly hydrologic parameters for baseline and each LSJR alternative. A time series of the New Melones Reservoir storage (Figure 5-7) is shown as an example of the monthly model output of storage generated for the 82-year modeling period. The annual February–June flow at Ripon is shown in Figure 5-8, and annual diversions from the Stanislaus River in Figure 5-9. Similar results for the Tuolumne and Merced Rivers and for the SJR at Vernalis are shown in Appendix F.1, *Hydrologic and Water Quality Modeling*.

The evaluation of change in hydrologic parameters in this chapter and other chapters of this SED was based on the monthly cumulative distribution of values rather than individual changes in monthly values. As discussed previously in Section 5.2.2, *Upper San Joaquin River*, the cumulative distribution of monthly values is a better metric to describe the overall effects of the LSJR alternatives.

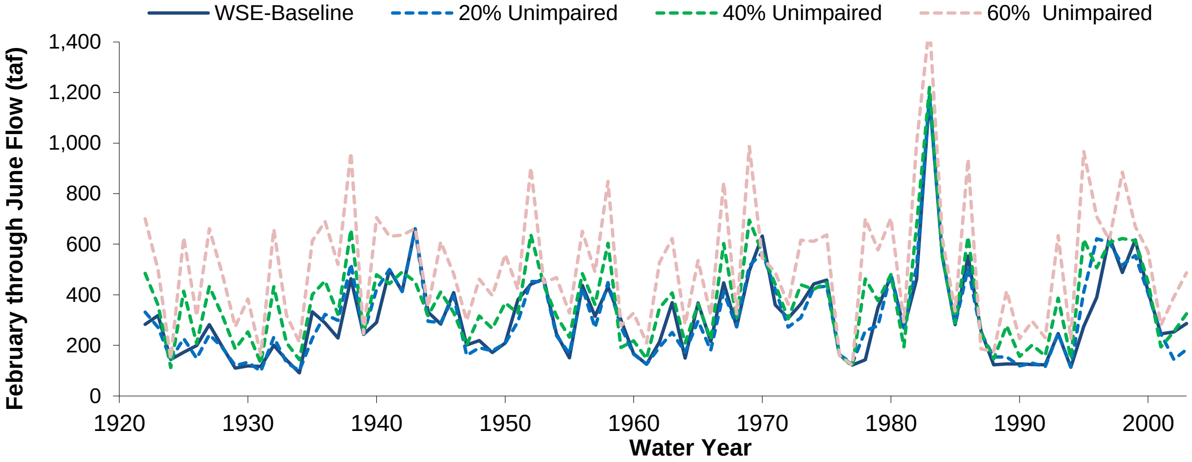

Figure 5-8. Comparison of WSE Model Results for Baseline and LSJR Alternatives: Stanislaus River Total February–June Flows for 1922–2003

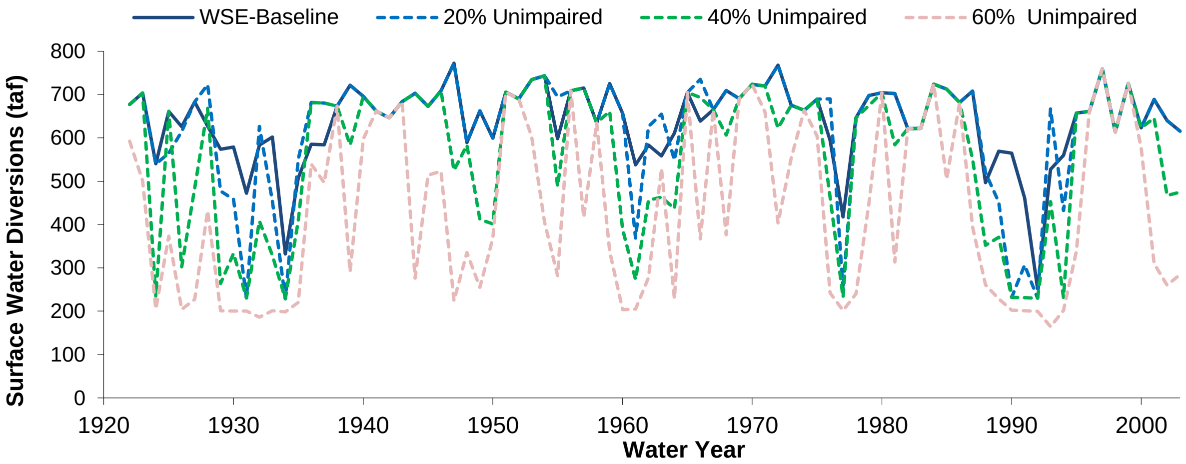

Figure 5-9. Comparison of WSE Model Results for Baseline and LSJR Alternatives: Stanislaus River Diversions for 1922–2003 (TAF = thousand acre-feet)

River Flow

As a general comparison of the LSJR alternatives, the baseline February–June flow volumes (TAF) and average changes to the February–June flow volumes are presented in Table 5-16 for the three eastside tributaries at their confluence with the LSJR and SJR at Vernalis. Average February – June flows increased under each of the LSJR alternatives for all rivers, with the exception of the Stanislaus River under LSJR Alternative 2, which experienced a decrease of 1 percent relative to baseline.

Table 5-16. Average February–June Baseline Flow and Differences from Baseline in the Eastside Tributaries and the SJR at Vernalis for the LSJR Alternatives for the 82-year Modeling Period

	Stanislaus River at Ripon TAF/ (%)	Tuolumne River at Modesto TAF / (%)	Merced River at Stevinson TAF / (%)	SJR at Vernalis TAF/ (%)
Baseline	312 / (100)	562/ (100)	242/ (100)	1,742/ (100)
LSJR Alternative 2 Difference from Baseline	-3 / (-1)	32 / (6)	27 / (11)	56 / (3)
LSJR Alternative 3 Difference from Baseline	62 / (20)	135 / (24)	91 / (38)	288 / (17)
LSJR Alternative 4 Difference from Baseline	203 / (65)	332 / (59)	193 / (80)	728 / (42)

Note: Resulting flow effects on the tributaries are as calculated near the confluence with the LSJR, specifically at Ripon, Modesto, and Stevinson.
TAF = thousand acre-feet

Tables 5-17a through 5-17d show the 10, 50, and 90 percent cumulative distributions (i.e., 10th, 50th, 90th percentiles) under the LSJR alternatives. These tables summarize the modeled effects of the LSJR alternatives at low, median, and high flows and show the variations from month-to-month and the magnitude of some of the largest percent increases. In general, during the objective months of February–June, the LSJR alternatives caused an increase in flows on all the rivers. There were also smaller changes to flow outside of these months on all the rivers, especially under LSJR Alternatives 3 and 4. Some river specific changes under the LSJR alternatives are noted below.

- On the Merced River, the percent increases in flow from the LSJR alternatives were smaller in February–March than in April–June (Table 5-17a). This occurred because from February–March, under baseline conditions, often there was already a relatively high percent of unimpaired flow released. The largest percent increase in both low and median flows was for the Merced River in May and June under LSJR Alternative 4. Under low (10th percentile) flow conditions in May, modeled flow for LSJR Alternative 4 were more than seven times the baseline flow. Large percent increases at low flow can be helpful to biological resources during periods of water stress. Percent increases in the median flows indicate a substantial change in the frequency of higher flows.
- On the Tuolumne River, the percent increases in flow from the LSJR alternatives were smaller in February–April than in May and June (Table 5-17b). This occurred because from February–April, under baseline conditions, often there was already a relatively high percent of unimpaired flow released.
- On the Stanislaus River (Table 5-17c), LSJR Alternative 2 had little effect on river flow, whereas LSJR Alternatives 3 and 4 generally produced increases in flow. The percentages of increase from April–June on the Stanislaus River were generally less than the percentages of increase on the Merced and Tuolumne Rivers because the baseline releases were already relatively high.

As shown in Tables 5-17a through 5-17d, the LSJR alternatives can also affect flows from July–January. This is due to changes in the flow requirements and diversions, which in turn affect reservoir storage relative to baseline. Two specific reasons for changes in July–January flow under the LSJR alternatives are: (1) changes to the flood control releases, and (2) adaptive implementation to shift some of the additional February–June flow to later in the year.

First, when the LSJR flow alternatives require more flow to be released February–June, in many years the storage by the end of June may end up lower than it did under baseline. If this occurs, the potential for flood control releases from July–January is also reduced, especially for the reservoirs that are small relative to watershed runoff volume (i.e., Lake McClure and New Don Pedro Reservoir), and thus flow in July through the following January can be reduced relative to baseline. In the modeling results, this occurred many times during years of high inflows and led to a change in the cumulative distribution during these months. For example, under LSJR Alternative 4, increased flood control space caused a 57 percent reduction in the 90th percentile flows in the Merced River in December and July, and a 64 percent reduction in the 90th percentile flows in the Tuolumne River in July. The reduced flood control releases can also occur during February–June if carryover storage has been reduced relative to baseline, leaving more space to retain flood waters.

Second, as described in the program of implementation, with adaptive implementation, some of the February–June flow can be retained in storage and released later in the year to reduce potential increases in river temperature. This typically occurs under LSJR Alternatives 3 and 4 and was modeled by shifting a portion of the additional February–June water to be released from July–November in wet years for all three rivers, from July–September in above normal years in the Merced River only, and during October for all year types in the Stanislaus River (for more specific details regarding flow shifting, see Appendix F.1, *Hydrologic and Water Quality Modeling,* Section F.1.2.7, *Calculation of River and Reservoir Water Balance*). This adaptive implementation maintains the colder temperatures generally experienced in wet water years due to flood control releases and maintains similar temperatures as baseline conditions for these year types by increasing flow during these months. Due to the increased flows of LSJR Alternatives 3 and 4, there is a reduced potential for flood control releases that causes flows to occasionally be reduced relative to baseline. Without adaptive implementation, these two alternatives may otherwise reduce the flows, resulting in temperature increases relative to baseline. The adaptive implementation, in part, leads to the changes in the cumulative distributions of flow from July–January, with increases in flows most apparent in September–November.

- There are several additional reasons why the LSJR alternatives may cause flow to change on the Stanislaus River, which explain some of the results presented in Table 5-17c.VAMP—Under baseline conditions, VAMP pulse flow requirements at Vernalis for April 15–May 15 resulted in additional releases from the rivers; however, VAMP is not part of the LSJR alternatives.
- D-1641 flow requirements—Under baseline conditions, water from the Stanislaus River was used to meet D-1641 flow requirements for flow at Vernalis from February 1–April 14 and May 16–June 30; however, these flow requirements are not part of the LSJR alternatives.
- Vernalis EC objectives—The Vernalis EC objectives are met under baseline conditions and in all LSJR alternatives. Water from the Stanislaus River is sometimes released to attain the Vernalis EC objective. The need for this release is dependent on flows from the other rivers, which varies with the alternatives.
- NMFS BO flows—Under baseline conditions and the LSJR alternatives, flows in the Stanislaus River must be at least as high as the NMFS BO flows. However, the NMFS BO flows vary depending on reservoir storage, so the baseline and alternative NMFS BO flows are not always the same.

Table 5-17a. Flow Summary for the Merced River at Stevinson—Monthly Cumulative Distributions of Baseline Flow and Differences from Baseline for the LSJR Alternatives for the 82-year Modeling Period

cfs = cubic feet per second

Adaptive implementation method 4 would allow an adjustment of the Vernalis February–June minimum flow requirement. Table 5-18 provides an evaluation of the Vernalis flow requirement using the WSE model. It indicates that changes due to method 4 under all alternatives would rarely alter the flows in the three eastside tributaries or the LSJR. The 1,000 cfs requirement is included in the WSE model simulations of the LSJR alternatives as evaluated in the SED. Increasing this requirement to 1,200 cfs or reducing it to 800 cfs would affect very few months because the Vernalis flows under the LSJR alternatives are generally greater than 1,200 cfs during February–June. For example, under LSJR Alternative 4, if the minimum Vernalis flow requirement were increased as part of adaptive implementation from 1,000 cfs to 1,200 cfs, then the number of months affected by the Vernalis flow requirement would increase from 1 month to 3 months out of the 410 that were simulated.

Table 5-18. Number and Percent of Months Affected by February–June Minimum Vernalis Flow Requirements Based on the 82 Years Simulated by the WSE Model

	800 cfs		1,000 cfs		1,200 cfs

LSJR Alternative 4	0	0.0	1	0.2	3	0.7

cfs = cubic feet per second

Water Diversions

The LSJR alternatives could require higher river flows in the three eastside tributaries and would potentially result in a change in surface water diversions. The runoff to the eastside tributary reservoirs is determined by rainfall and snowmelt conditions and the reservoir storage capacity is fixed. Accordingly, there is no possibility of increasing the total surface water supply to provide more water for surface water diversions. More water released to the rivers under the LSJR alternatives means, generally, there would be less water available for water supply diversions. The WSE model was used to predict the change in annual surface water diversions expected under each LSJR alternative and the results are presented here to provide a description of the magnitude of change under each of the alternatives.

Additionally, as discussed above in Section 5.4.2, *Methods and Approach*, the CVP and SWP exports could be modified based on the inflow from the LSJR. Because the WSE model does not simulate Delta exports, changes in exports were estimated from changes in flow at Vernalis and the Delta regulations that affect exports for each month. These changes were compared to the average historic exports for 1995–2013 (years since the Bay-Delta Plan was introduced).

Table 5-19a shows the simulated average differences in water supply diversions between baseline and the LSJR alternatives. The results indicate that there would be small reductions in water supply under LSJR Alternative 2, moderate water supply reductions under LSJR Alternative 3, and greater water supply reductions under LSJR Alternative 4. Table 5-19b shows the percentiles of these diversions in baseline and the LSJR alternatives, showing that the differences are greatest in drought years, e.g., 10th percentile.

Table 5-19a. Average Annual Baseline Water Supply and Differences from Baseline (Changes in Diversions) in the Eastside Tributaries and Plan Area for the LSJR Alternatives for 1922–2003

Tables 5-20a and 5-20b show the annual cumulative distribution for the WSE model simulated water supply diversions and the percentage of full demand for diversion that is met for the Stanislaus, Tuolumne, and Merced Rivers. These cumulative distribution values are based on the 82-years simulated by the WSE model and capture the historic range of hydrologic conditions. The annual values are calculated by irrigation year, which runs from March–February. Shortages typically are greater during drier conditions and are represented by low values for the percentage of demand for diversion that is met.

Diversions are reduced in dry years when the reservoir storage is not sufficient to supply the total demands. On the Stanislaus River, the baseline average annual diversion of 637 TAF was reduced by 12 TAF/y (2 percent), 79 TAF/y (12 percent), and 206 TAF/y (32 percent) for LSJR Alternative 2, LSJR Alternative 3, and LSJR Alternative 4, respectively. On the Tuolumne River, the baseline average annual diversion of 851 TAF was reduced by 20 TAF/y (2 percent), 119 TAF/y (14 percent), and 298 TAF/y (35 percent) for LSJR Alternative 2, LSJR Alternative 3, and LSJR Alternative 4, respectively.

On the Merced River, the baseline average annual diversion of 580 TAF was reduced by 33 TAF/y (6 percent), 95 TAF/y (16 percent), and 185 TAF/y (32 percent) for LSJR Alternative 2, LSJR Alternative 3, and LSJR Alternative 4, respectively. The percent change in diversions associated with each alternative was similar for all three rivers, with the biggest difference only being 4 percent.

Reductions in diversions were mirrored by decreases in the ability to meet full demands. For all three rivers, baseline demand for diversion was fully met in more than half the years and, on average, more than 90 percent of the demand for diversion was met, with the Stanislaus River meeting full demands less often than the Merced River, and the Merced River meeting full demands less often than the Tuolumne River. Under LSJR Alternative 2, there were slight (2–5 percent) decreases in the average percentage of demand that was met. Under LSJR Alternative 3, the average percentage of demand met decreased to approximately 80 percent for all three rivers, and under LSJR Alternative 4, the average percentage of demand met decreased further to 62 percent, 63 percent, and 64 percent for the Stanislaus, Tuolumne, and Merced Rivers, respectively.

Table 5-20a. Annual Cumulative Distributions of Unimpaired Runoff and Water Supply Diversions[14] for Baseline and LSJR Alternatives 2, 3, and 4 (20, 40, and 60 Percent Unimpaired Flow) for Irrigation Years 1922–2003 (TAF)

Average	5,185	1,525	18	16	76	67	194	211

TAF = thousand acre-feet

[a] based on DAYFLOW data

The calculated annual changes in CVP and SWP southern Delta exports were minimal. The estimated average annual change for Alternative 2 was an increase of 18 TAF/y and the estimated average annual change for LSJR Alternative 3 was an increase of 76 TAF/y. Both of these numbers are small compared to the historic annual average export of 5,185 TAF (data for water years 1995–2013).

The estimated annual changes in CVP and SWP southern Delta exports for LSJR Alternative 4 averaged 194 TAF/y. This small increase is approximately 4 percent of the historic average annual export of 5,185 TAF/y. On a year-by-year basis, the changes compared to baseline were often larger than the average change, but still small compared to total exports, and years with decreases in exports were balanced by years with increases in exports.

Reservoir Storage

In many years, modeling results showed storage in New Melones, New Don Pedro, and Lake McClure reservoirs was altered when compared to baseline. Reasons why reservoir storage changed include the following.

- Under the LSJR alternatives, the combination of higher river flows and demand for diversions sometimes resulted in lower carryover storage compared to baseline.
- The LSJR alternatives have minimum carryover storage guidelines to avoid adverse temperature impacts on fish and wildlife beneficial uses, and thus there were some dry years when the carryover storage was larger than under baseline conditions.
- The LSJR alternatives (particularly LSJR Alternatives 3 and 4) may retain water in the reservoirs beyond June for adaptive implementation purposes; this was modeled to occur during wet years and, for the Merced River, in above normal years.
- The LSJR alternatives caused variations in the frequency and timing of flood control releases (particularly for New Don Pedro Reservoir and Lake McClure).

Reservoir storage is of most concern during the fall when storage is at its lowest point. Table 5-22a shows average carryover storage (end of September) for each reservoir and alternative. The changes in average carryover storage were 13 percent or less. Under LSJR Alternative 2, all three reservoirs had an increase or no change in average carryover storage relative to baseline. Average carryover storage under LSJR Alternative 3 was less than for LSJR Alternative 2, and average carryover storage under LSJR Alternative 4 was less than for LSJR Alternative 3.

During critical years, LSJR alternative carryover storage was greater than baseline carryover storage under all LSJR alternatives for all reservoirs (Table 5-22b) because the carryover storage targets are part of the LSJR alternatives and not baseline. For both New Melones Reservoir and Lake McClure, the increase in critical-year carryover storage was substantial (47–113 percent)

Table 5-22a. Average Carryover Storage and Differences from Baseline in the Eastside Tributary Reservoirs for the LSJR Alternatives for the 82-Year Modeling Period

	New Melones TAF / (%)	New Don Pedro TAF / (%)	Lake McClure TAF / (%)

TAF = thousand acre-feet			

Hydropower

The rim dams release water through the hydroelectric turbines at their maximum efficiency capacity in order to generate energy. Typically, water is released for a specified number of hours each day. The number of hours of releases is a function of daily average release flow and the turbine capacity flow.

Downstream of the rim dams are regulating reservoirs on each of the three eastside tributaries (e.g., McSwain Dam on the Merced River; the hydroelectric power plant at TID canal on the Tuolumne River; and Tulloch Dam on the Stanislaus River). These regulating reservoirs operate with a seasonal storage elevation and a daily fluctuating elevation that depends on the number of peaking hours to flatten the peaking from the hydropower facilities and release more steady flows downstream.

The normal peaking-energy operation of the rim dams would continue under the LSJR alternatives. The only changes to the peaking energy operation would be slightly different hours with peaking energy releases each day during the month according to the monthly changes in the simulated WSE model river flows and diversion flows under the LSJR alternatives.

Because hydropower generation is dependent on reservoir elevation (head), a reduction in storage has the potential to affect hydropower generation. In addition, there is the potential for hydropower generation to be reduced as a result of the extent to which reservoir releases exceed the capacity of the hydropower turbines. The economic value of hydropower generation is somewhat dependent on time of year, with a greater demand for electricity in the summer than in the winter and spring. The change in reservoir releases associated with the LSJR alternatives affects the distribution of power generation between these seasons.

Water Temperature

A summary of modeled water temperature results for baseline and under each LSJR alternative are presented below for each tributary (Tables 5-23a through 5-23c). These temperature results are fully described in Appendix F.1, *Hydrologic and Water Quality Modeling*.

Due to the dynamics of heat exchange, river temperatures generally increase if river flow is reduced and decrease if river flow is increased. A change in flow can cause a corresponding change in the water temperature downstream. However, if the existing flow is relatively high, a change in flow would likely cause a smaller change in temperature than would the same change in flow if the existing flows were lower. Furthermore, a change in flow during colder months causes a smaller change in water temperature than during warmer months. This is because during colder months the reservoir release temperatures are more similar to the average ambient air temperatures. Appendix F.1 provides more detail about the relationship between flow and water temperature.

Changes in relatively low flows during warm months are likely to have a substantial effect on water temperatures. The biggest changes in water temperature are expected to occur from April–June. The LSJR alternatives also affected water temperature from February–March, but to a lesser degree than during the warmer months.

Although the LSJR alternatives apply to February–June, there are several reasons why modeled results show water temperatures changing outside of this period. One reason temperatures could change relative to baseline from July–January is that there are occasionally changes in flow during these months due to reduced spills in wet years, and shifting of flows to the fall as a part of adaptive implementation (for more specific details regarding flow shifting, see Appendix F.1, Section F.1.2.7, *Calculation of River and Reservoir Water Balance*). Water temperatures also are affected by changes in reservoir storage, which could occur during any month, but low storage in the fall is of most concern because the cold water at the bottom of the reservoirs could be depleted in the fall. Appendix F.1 provides more detail about the relationship between reservoir storage and water temperature.

The average monthly temperatures were compared between baseline and the LSJR alternatives (Table 5-23a through 5-23c). This temperature evaluation was performed at a single location for each tributary: at RM 27.1 on the Merced River; at RM 28.1 on the Tuolumne River; and at RM 28.2 on the Stanislaus River (Appendix F.1). These are approximately the halfway points between the river mouths and the upstream regulating reservoirs and were selected because they are good locations for capturing the effect of flow on water temperature. Water temperature effects at Lake McClure, New Don Pedro Reservoir, and New Melones Reservoir releases are driven only by changes in the storage.

The 10th, 50th (median), and 90th percentiles show the general range of temperatures modeled for baseline conditions and the LSJR alternatives. Baseline temperatures are shown followed by the differences between the LSJR alternatives and baseline. The 90th percentile results present the warmest temperatures, which generally are of more concern to the harming of fish and wildlife than cooler temperatures.

At the halfway locations, the baseline January to July seasonal warming of median temperatures ranged from 27°F on the Merced River to 19°F on the Stanislaus and Tuolumne Rivers (Table 5-23a through 5-23c). The spread of temperatures for any given month (90th percentile minus 10th percentile) varies by month, with June or July generally having the largest spread. The largest spread occurred on the Tuolumne River (23°F in July).

On the Merced River (Table 5-23a), LSJR Alternatives 2, 3, and 4 produced progressively cooler water temperatures in many months, with the effect being largest in May or June. Median June temperatures were 6.0°F cooler for LSJR Alternative 2, 8.7°F cooler for LSJR Alternative 3, and 10.3°F cooler for LSJR Alternative 4. Temperature reductions for the June 90th percentile values were 5-6°F smaller than the reduction in median temperatures.

Similarly, on the Tuolumne River (Table 5-23b), LSJR Alternatives 2, 3, and 4 produced progressively cooler water temperatures in many months, with the effect being largest in June. However, temperature reductions in the Tuolumne River were larger than on the Merced or Stanislaus Rivers. Median June temperatures were 8.3°F cooler for LSJR Alternative 2, 11.4°F cooler for LSJR Alternative 3, and 12.5°F cooler for LSJR Alternative 4. Temperature reductions for the June 90th percentile values were 1-6°F smaller than the reductions in median temperatures.

On the Stanislaus River (Table 5-23c), temperature effects for LSJR Alternative 2 were relatively small, with some values being a little higher than baseline and some being a little lower. This is a reflection of the effect of LSJR Alternative 2 on Stanislaus River flows, the effect of which was relatively small and variable relative to baseline. On the Stanislaus River, LSJR Alternatives 3 and 4 produced cooler water temperatures in many months, but the effect was smaller than on the

Tuolumne or Merced Rivers. Median June temperatures were 1.1°F cooler for LSJR Alternative 3 and 3.0°F cooler for LSJR Alternative 4.

5.4.3 Impacts and Mitigation Measures

Impact WQ-1: Violate water quality standards by increasing the number of months with EC above the water quality objectives for salinity at Vernalis or southern Delta compliance stations

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

The impact associated with each LSJR alternative was assessed using the existing water quality objectives. The impact WQ-1 analysis focuses on the objectives at the southern Delta compliance stations because these objectives are the most likely to be exceeded as a result of changes in LSJR flows. Water quality at locations farther downstream is less affected by changes in LSJR flow and is more likely to be affected by the presence of relatively clean water from the Sacramento River.

The monthly EC values at Vernalis, corresponding to the monthly flows and assumed LSJR salt loads, were calculated for the 1922–2003 time period with the WSE model. The modeling incorporated additional releases from New Melones Reservoir in some months to satisfy the baseline Vernalis EC objectives because USBR is required to maintain salinity at Vernalis in accordance with its water rights. Under the LSJR alternatives, the Vernalis objectives would be the same as the baseline objectives. Under the SDWQ alternatives, the Vernalis objectives would change, but the program of implementation would still require that USBR ensure the Vernalis EC values remain less than or equal to 0.700 dS/m for April–August and 1.000 dS/m for September–March as a 30-day running average.

The number of months when the estimated EC at the southern Delta compliance stations would exceed the existing water quality objectives for each LSJR alternative was compared to the number of months that the estimated EC would exceed the existing water quality objectives under baseline flow and EC conditions. The impact associated with each SDWQ alternative was assessed by evaluating how the number of months with EC greater than the objectives would change in response to the change in objectives under the SDWQ alternatives. The number of months the EC exceeded the existing EC objective was compared to the number of months the EC exceeded the objectives for each of the SDWQ alternatives.

Described below are baseline conditions at the Vernalis and the southern Delta compliance stations. Note that the baseline EC values described here are different from the historic measured EC values described in the environmental setting section above; the baseline values cover a longer period of record as simulated by the WSE model and they represent recent operating procedures unlike the historic values, which represent variable regulations for system operations. The baseline EC values are a better representation of EC under existing regulations than the historical EC values. The calculated monthly EC values for the SJR at Vernalis, SJR at Brandt Bridge, and Old River at Tracy

Boulevard for baseline are given in Appendix F.1, *Hydrologic and Water Quality Modeling,* (Tables F.1-14b, e, and g).

Table 5-24a shows a summary of monthly Vernalis EC values for baseline as simulated with the WSE model for 1922–2003, sorted by the number of years with values greater than 0.400–1.200 dS/m (400 µS/cm–1,200 µS/cm) in 0.100 dS/m (100 µS/cm) increments.[15] The table indicates the number of years with a calculated monthly EC value greater than the EC values given in the first column. For example, the Vernalis EC values in October for baseline were above 0.400 dS/m (400 µS/cm) in 78 years (out of 82 years); above 0.500 dS/m (500 µS/cm) in 36 years; and above 0.600 dS/m (600 µS/cm) in 0 years. Other months with an EC objective of 1.000 dS/m (1,000 µS/cm) show no violations at Vernalis. There were 20 years with an EC of greater than 0.900 dS/m (900 µS/cm) in February and 16 years with a March EC of greater than 0.900 dS/m (900 µS/cm), suggesting that the EC values for baseline were often approaching the EC objective in these months. Many of the simulated Vernalis EC values in April–August were above 0.600 dS/m (600 µS/cm), suggesting that EC was approaching the EC objectives in many years during this period.

Table 5-24a. Monthly Distribution of SJR at Vernalis EC Values (100 µS/cm increments) for Baseline for 1922–2003

EC Value	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Average
400	78	80	79	73	62	51	45	39	66	78	77	79	77
500	36	75	78	69	56	47	28	21	43	69	57	55	56
600	0	46	74	64	49	43	15	12	22	40	21	7	34
700	0	5	67	54	37	28	0	0	0	0	0	0	13
800	0	0	54	23	31	22	0	0	0	0	0	0	0

1,200	0	0	0	0	0	0	0	0	0	0	0	0	0

1000 µS/cm = 1 deciSiemen per meter (1 dS/m)
µS/cm = microSiemens per centimeter

Table 5-24b shows the baseline monthly distribution of calculated EC values at Brandt Bridge. There were 16 years in February and 15 years in March that exceeded the 1.000 dS/m (1,000 µS/cm) objective (a total of 31 months out of 574). There were 12 years in April, 8 years in May, 17 years in June, 26 years in July, and 16 years in August that exceeded the 0.700 dS/m (700 µS/cm) objective (a total of 79 months out of 410). The baseline EC values at Brandt Bridge exceeded the EC objectives in a total of 110 months out of the 984 months from 1922–2003.

---

[15] These EC objective values have a line under them in the table; the number of months with calculated EC above the EC objective is in this row.

Table 5-24b. Monthly Distribution of SJR at Brandt Bridge EC Values (100 µS/cm increments) for Baseline for 1922–2003

EC Value	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Average
400	80	80	79	73	62	52	47	40	67	78	79	79	80

1000 µS/cm = 1 deciSiemen per meter (1 dS/m)
µS/cm = microSiemens per centimeter

Table 5-24c shows the baseline monthly distribution of calculated EC in Old River at Tracy Boulevard. There was a total of 81 months with EC values higher than the EC objective of 1.000 dS/m (1,000 µS/cm) (September–March) and a total of 186 months with EC values higher than the EC objective of 0.700 dS/m (700 µS/cm) (April–August). The baseline EC values at Tracy Boulevard exceeded the existing EC objectives in a total of 267 months (out of 984), approximately 27 percent of the months in the 82-year modeled simulation. This percent of time with exceedances is greater than the percent of time of measured EC exceedances reported at Old River at Tracy during the past 25 years.[16]

Table 5-24c. Monthly Distribution of Old River at Tracy Boulevard EC Values (100 µS/cm Increments) for Baseline for 1922–2003

EC Value	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Average
400	80	80	79	74	62	55	57	58	71	78	79	79	81

1,200	0	0	0	0	0	6	0	0	0	2	1	0	0

1000 µS/cm = 1 deciSiemen per meter (1 dS/m)
µS/cm = microSiemens per centimeter

---

[16] The values predicted by the modeled simulation are more than the actual measured data because the method used to calculate the EC increment between Vernalis and Old River at Tracy Boulevard provides a conservative estimate of the effect of any potential decreases in flow at Vernalis on the EC increment (Appendix F.1, *Hydrologic and Water Quality Modeling*).

Table 5-25 summarizes the number of months with EC higher than the objectives at the two representative compliance stations for baseline and for each LSJR alternative. As described in Section 5.2.7, *Southern Delta*, Union Island (Old River near Middle River) has EC similar to Brandt Bridge. The number of months with EC higher than the objectives would be reduced for SDWQ Alternatives 2 and 3.

Table 5-25. Number of Months when Estimated EC Values would be Greater than EC Objectives at Southern Delta Compliance Stations 1922–2003 (984 months)

Compliance Station	Baseline	LSJR Alternative 2	LSJR Alternative 3	LSJR Alternative 4
Baseline EC Objectives (700 µS/cm April–August and 1,000 µS/cm September–March)				
Brandt Bridge	110	93	74	68
Tracy Boulevard	267	248	202	196
SDWQ Alternative 2 (1,000 µS/cm January–December)				
Brandt Bridge	31	40	28	17
Tracy Boulevard	101	107	95	86
SDWQ Alternative 3 (1,400 µS/cm January–December)				
Brandt Bridge	0	0	0	0
Tracy Boulevard	0	0	0	0

Note: The WSE modeling includes releases of additional water from New Melones Reservoir necessary to meet the existing Vernalis EC objectives of 0.700 dS/m (700 µS/cm) for April–August and 1.000 dS/m (1000 µS/cm) for September–March, which would be required as part of the program of implementation.

1000 µS/cm = 1 deciSiemen per meter (1 dS/m)

µS/cm = microSiemens per centimeter

LSJR Alternative 2 (Less than significant/Less than significant with adaptive implementation)

The calculated monthly EC values for the SJR at Vernalis, SJR at Brandt Bridge, and Old River at Tracy Boulevard for LSJR Alternative 2 are given in Appendix F.1, *Hydrologic and Water Quality Modeling* (Tables F.1-15a through 15c). Table 5-26a shows the monthly Vernalis EC values for LSJR Alternative 2. There were no months with EC values greater than the objectives at Vernalis because the WSE modeling for the LSJR alternatives included the requirement from the program of implementation that USBR continue to meet the existing Vernalis EC objectives by releasing water from the New Melones Reservoir.

Table 5-26b shows that Brandt Bridge EC values for LSJR Alternative 2 were higher than the 1.000 dS/m (1,000 µS/cm) objective in the months of September–March in a total of 40 months (out of 574 months) and were higher than the 0.700 (700 µS/cm) objective in the months of April–August in a total of 53 months (out of 410 months), for a total of 93 exceedances of the existing objectives. The EC was higher than the EC objective for LSJR Alternative 2 in 17 months fewer than for baseline because some of the estimated Vernalis flows were higher compared to baseline, and the corresponding Vernalis EC values were slightly lower. The calculated EC values in Old River at Middle River (Union Island) are assumed to be the same as at Brandt Bridge. Because of the overall reduced incidence of EC values that would be above the EC objective (93 months for LSJR Alternative 2 versus 110 months for baseline), impacts would be less than significant at Brandt Bridge and Union Island.

Table 5-26a. Monthly Distribution of SJR at Vernalis EC Values (100 µS/cm increments) for LSJR Alternative 2 for 1922–2003

EC Value	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Average

1,200	0	0	0	0	0	6	0	0	0	2	1	0	0

1000 µS/cm = 1 deciSiemen per meter (1 dS/m)
µS/cm = microSiemens per centimeter

Adaptive Implementation

Based on best available scientific information indicating that a change in the percent of unimpaired flow is needed to reasonably protect fish and wildlife, adaptive implementation method 1 would allow an increase of up to 10 percent over the 20-percent February–June unimpaired flow requirement (to a maximum of 30 percent of unimpaired flow). A change to the percent of unimpaired flow would take place based on required evaluation of current scientific information and would need to be approved as described in Appendix K, *Revised Water Quality Control Plan*. Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time. However, an increase of up to 30 percent of unimpaired flow would potentially result in different effects as compared to 20-percent unimpaired flow, depending upon flow conditions and frequency of the adjustment. Under LSJR Alternative 2, this adaptive implementation approach would increase flows in the three eastside tributaries. As a result, it is anticipated the EC values presented above for SJR at Vernalis, SJR at Brandt Bridge, and Old River at Tracy Boulevard would not be substantially different or would actually be reduced because any additional flow in the LSJR potentially required under adaptive implementation would likely result in a decrease in EC in the southern Delta and at compliance points because increases in flow from the relatively low salinity eastside tributaries would dilute salt load. Therefore, method 1 would not result in an increase in EC.

Based on best available scientific information indicating that a change in the timing or rate of unimpaired flow is needed to reasonably protect fish and wildlife, adaptive implementation method 2 would allow changing the timing of the release of the volume of water within the February–June time frame. While the total volume of water released February–June would be the same as LSJR Alternative 2 without adaptive implementation, the rate could vary from the actual (7-day running average) unimpaired flow rate. Method 2 would not authorize a reduction in flows required by other agencies or through other processes, which are incorporated in the modeling of baseline conditions. During February–June, method 2 could potentially cause temporary increases in EC associated with flow dropping below 20 percent of the unimpaired flow, but increases in EC would be limited by the salinity requirements for Vernalis as specified in the program of implementation and would be offset by reductions in EC associated with flow increasing above 20 percent unimpaired flow at other times during February–June. Although changes in the timing of flows released from February–June under adaptive implementation method 2 would cause flow to temporarily go below 20 percent of the unimpaired flow, EC at Vernalis would still be maintained at or below a running 30-day average of 0.7 dS/m April–August and 1.0 dS/m September–March through the program of implementation, as it is under the current objectives and, furthermore, flows would not be permitted to go below what is required by other agencies and processes. As such, it is unlikely that there would be more exceedances than would occur under baseline. Method 3 would not be authorized under LSJR Alternative 2 since the unimpaired flow percentage would not exceed 30 percent; therefore, method 3 would not affect EC.

Adaptive implementation method 4 would allow an adjustment of the Vernalis February–June flow requirement. WSE model results show that under LSJR Alternative 2 the 1,200-cfs February–June base flow requirement at Vernalis would require a flow augmentation in the three eastside tributaries and LSJR only 2.7 percent of the time in the 82-year record analyzed. Similarly, flow augmentation would be required 0.7 percent of the time to meet a 1,000-cfs requirement and 0.5 percent of the time for an 800-cfs Vernalis base flow requirement. These results indicate that changes due to method 4 under this alternative would rarely alter the flows in the three eastside tributaries or the LSJR.

Impacts associated with adaptive implementation method 1 may be slightly different from those associated with methods 2 and 3. With method 1, if the specified percent of unimpaired flow were changed from 20 percent to 30 percent on a long-term basis, the conditions and impacts could become more similar to those described under LSJR Alternative 3. It is anticipated that over time the unimpaired flow requirement could increase or not change at all within a year or between years, depending on fish and wildlife conditions and hydrology. If method 2 is implemented, the total annual volume of water associated with LJSR Alternative 2 (i.e., 20 percent of the February–June unimpaired flow) would not change, but the timing or magnitude of flows might change. Implementing method 4 would have little effect on conditions in the three eastside tributary rivers and LSJR because it rarely would cause a change in flow and the volume of water involved would be relatively small. As described above, adaptive implementation method 1 could cause a reduction in EC and methods 2 and 4 would cause little to no change in EC. Consequently, adaptive implementation would not affect the impact determination for the potential effect of LSJR Alternative 2 on attainment of EC objectives at Vernalis and southern Delta compliance locations, and impacts would be less than significant.

LSJR Alternative 3 (Less than significant/Less than significant with adaptive implementation)

The calculated monthly EC values for the SJR at Vernalis, SJR at Brandt Bridge, and Old River at Tracy Boulevard for LSJR Alternative 3 are given in Appendix F.1, *Hydrologic and Water Quality Modeling,* (Tables F.1-16a through 16c). Table 5-27a shows the monthly Vernalis EC values for LSJR Alternative 3, with adjusted Stanislaus River flows to meet the Vernalis EC objectives. There were no months with EC violations at Vernalis. Table 5-27b shows that Brandt Bridge EC values for LSJR Alternative 3 were higher than the 1.000 dS/m (1,000 µS/cm) objective in the months of September–March in a total of 28 months. The Brandt Bridge EC values were higher than the EC objective of 0.700 dS/m (700 µS/cm) in a total of 46 months during the April–August period. In total, at Brandt Bridge there were fewer months with EC values greater than the objective under

LSJR Alternative 3 than there were for baseline (74 months for LSJR Alternative 3 versus 110 months for baseline). As described in Section 5.2.7, *Southern Delta*, Union Island (Old River near Middle River) has EC similar to Brandt Bridge.

Table 5-27c shows that the Old River at Tracy Boulevard EC values for LSJR Alternative 3 were higher than the 1.000 dS/m (1,000 µS/cm) objective in the months of September–March in a total of 83 months.[17] The Tracy Boulevard calculated EC values for LSJR Alternative 3 were higher than the EC objective of 0.700 dS/m (700 µS/cm) in a total of 119 months during the April–August period. The total number of months with EC values above the EC objective for Old River at Tracy Boulevard would be reduced compared to baseline (202 months for LSJR Alternative 3 versus 267 months for baseline). Because LSJR Alternative 3 would likely reduce the number of months with EC above the existing EC objectives at Brandt Bridge, Union Island, and Tracy Boulevard, impacts would be less than significant.

1000 µS/cm = 1 deciSiemen per meter (1 dS/m)
µS/cm = microSiemens per centimeter

Adaptive Implementation

Under LSJR Alternative 3, impacts associated with adaptive implementation method 1 may be slightly different from those associated with adaptive implementation methods 2 and 3.

Implementing method 1 would allow an increase or decrease of up to 10 percent in the February–June, 40-percent unimpaired flow requirement (with a minimum of 30 percent and maximum of 50 percent). Adaptive implementation must be approved using the process described in Appendix K, *Revised Water Quality Control Plan*. Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time. Adaptive implementation method 1 could affect the amount of water available for water supply and the volume of water and level of flow in the LSJR and its tributaries. However, the frequency and duration of such a change is unknown. If the specified percent of unimpaired flow were changed from 40 percent to 30 percent or 40 percent to 50 percent on a long-term basis, the conditions and impacts could become more similar to LSJR Alternatives 2 or 4, respectively. It is anticipated that over time the unimpaired flow requirement could increase, decrease, or not change at all within a year or between years, depending on fish and wildlife conditions and hydrology. If February–June flow is reduced as a

---

[17] As described above, the calculated EC values in Old River at Tracy Boulevard are generally greater than the EC values measured during the past 25 years.

result of adaptive implementation method 1, the reduction could cause an increase in EC relative to LSJR Alternative 3 without adaptive implementation. However, flow would not be reduced below 30 percent of unimpaired flow. Because LSJR Alternative 2 at 20 percent of unimpaired flow would not significantly impact the attainment of EC objectives in the southern Delta, 30 percent of unimpaired flow, as allowed by adaptive implementation method 1, would also not significantly impact the attainment of EC objectives.

Under adaptive implementation methods 2 or 3, the overall volume of water from the February–June time period or after June would be the same as LSJR Alternative 3 without adaptive implementation, but the volume within each month could vary. These two methods would not allow flows to go below what is required by existing requirements on the three tributaries and the SJR. EC, which can be dependent on the timing or magnitude of flow, could potentially be affected by method 2 or 3. Under adaptive implementation methods 2 or 3, flows could temporarily be reduced and EC increased in comparison to the 40 percent unimpaired flows. However, flows would be unlikely to go below baseline flows and flow reductions would be offset by increases in flows during other months.

Implementing method 4 would have little effect on conditions in the three eastside tributary rivers. WSE model results show that under Alternative 3 the 1,200-cfs February–June base flow requirement at Vernalis would require a flow augmentation in the three eastside tributaries and LSJR only 1.2 percent of the time in the 82-year record analyzed. Similarly, flow augmentation would be required only 0.2 percent of the time to meet either a 1,000-cfs or 800-cfs Vernalis base flow requirement. These results indicate that method 4 would rarely alter the flows in the three eastside tributaries or the LSJR under this alternative and, thus, would not influence EC.

Because adaptive implementation method 1 would not allow flows to go below those of LSJR Alternative 2 and because increases in EC resulting from methods 2–4 would cause little to no change in EC, adaptive implementation would not affect the impact determination for the effect of LSJR Alternative 3 on attainment of EC objectives at Vernalis and southern Delta compliance locations. Impacts would remain less than significant.

LSJR Alternative 4 (Less than significant/Less than significant with adaptive implementation)

Table 5-28a shows the monthly Vernalis EC values for LSJR Alternative 4, with adjusted Stanislaus River flows to meet the Vernalis EC objectives. There were no months with EC violations at Vernalis. Table 5-28b shows that Brandt Bridge, EC values for LSJR Alternative 4 were higher than the 1.000 dS/m (1,000 μS/cm) objective in the months of September–March in a total of 17 months. The Brandt Bridge EC values were higher than the EC objective of 0.700 dS/cm (700 μS/cm) in a total of 51 months during the April–August period. In total, there were fewer months with Brandt Bridge and Union Island EC values greater than the EC objective under LSJR Alternative 4 (68 months for LSJR Alternative 4 versus 110 months for baseline).

1000 µS/cm = 1 deciSiemen per meter (1 dS/m)
µS/cm = microSiemens per centimeter

Adaptive Implementation

As discussed under LSJR Alternatives 2 and 3, adaptive implementation methods 2, 3, and 4 would not result in substantial increases in EC. Adaptive implementation method 1 would allow a decrease of up to 10 percent in the February–June, 60-percent unimpaired flow requirement (to 50 percent). Adaptive implementation must be approved using the process described in Appendix K, *Revised Water Quality Control Plan*. Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time. If the specified percent of unimpaired flow were changed from 60 percent to 50 percent on a long-term basis, the conditions and impacts could become more similar to LSJR Alternative 3, with adaptive implementation. Because LSJR Alternative 3 would have a less-than-significant effect on attainment of EC objectives, the impact of LSJR Alternative 4 with adaptive implementation would also be less than significant.

SDWQ Alternatives

SDWQ Alternative 2 (Less than significant)

Under SDWQ Alternative 2, the Vernalis and southern Delta salinity objectives would be changed to a year-round value of 1.0 dS/m. However, EC at Vernalis would be maintained at or below 0.7 dS/m April – August and 1.0 dS/m September–March through the program of implementation, as it is under the current objectives. This would provide some assimilative capacity downstream of Vernalis and protect beneficial agricultural uses. Because EC at Vernalis would be maintained under the program of implementation, as it is under the current objectives, SDWQ Alternative 2 would not change the Vernalis flow or EC values, regardless of whether the baseline flows or one of the LSJR alternatives were selected and implemented. SDWQ Alternative 2 would not lead to a deterioration of water quality at either Vernalis or the southern Delta.

The number of months with calculated EC values above the SDWQ Alternative 2 EC objective (1.0 dS/m in all months) would be different because most EC violations in the months of April–August at Brandt Bridge and Tracy Boulevard would be eliminated with the higher EC objective, but the calculated number of months with EC violations in the months of September–March would remain the same (because the EC objective would be the same). SDWQ Alternative 2 would generally reduce the number of months with EC values above the existing EC objectives (baseline) for the baseline flows and all LSJR alternatives (flows) in the following manner and as shown in Table 5-25.

- If SDWQ Alternative 2 is adopted, the number of calculated EC exceedances at Brandt Bridge would decrease from 110 months (out of 984) to 31 months if the flow and EC at Vernalis remain at baseline levels. The number of calculated EC violations at Tracy Boulevard would decrease from 267 months to 101 months. This reduces the incidence of EC values that were above the EC objective when compared to baseline.
- If LSJR Alternative 2 is implemented and SDWQ Alternative 2 is adopted, the number of EC violations at Brandt Bridge would decrease from a baseline of 110 months to 40 months. The Tracy Boulevard EC exceedance would decrease from 267 to 107.
- If LSJR Alternative 3 is implemented and SDWQ Alternative 2 is adopted, the number of EC violations at Brandt Bridge would decrease from a baseline of 110 months to 28 months. The number of EC violations at Tracy Boulevard would decrease from 267 months for existing EC objectives to 95 months with SDWQ Alternative 2.
- If LSJR Alternative 4 is implemented and SDWQ Alternative 2 is adopted, the number of EC violations at Brandt Bridge would decrease from a baseline of 110 months to 17 months. The number of EC violations at Tracy Boulevard would decrease from 267 months to 86 months.

Under SDWQ Alternative 2, the water quality objectives would be met in more months when compared to baseline conditions. Impacts would be less than significant.

SDWQ Alternative 3 (Less than significant)

Under SDWQ Alternative 3, the Vernalis and southern Delta salinity objectives would be changed to a year-round value of 1.4 dS/m. However, EC at Vernalis would be maintained at or below 0.7 dS/m April–August and 1.0 dS/m September–March through the program of implementation, as it is under the current objectives. This would provide some assimilative capacity downstream of Vernalis and protect beneficial agricultural uses.

SDWQ Alternative 3 would not change the Vernalis flow or EC values, regardless of whether the baseline flows or one of the LSJR alternatives were selected and implemented. The number of months with calculated EC values above the SDWQ Alternative 3 EC objectives (1.4 dS/m in all months) would be reduced to 0 months because there are no calculated EC values of greater than 1.4 dS/m for baseline or for any of the LSJR alternatives. The reduced incidence of EC values that were above the EC objective is considered beneficial, and because there has never been a calculated EC value greater than 1.4 dS/m for the southern Delta, impacts would be less than significant.

Impact WQ-2: Substantially degrade water quality by increasing Vernalis or southern Delta EC such that agricultural beneficial uses are impaired

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the*

No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1), for the No Project Alternative technical analysis.

LSJR Alternatives

The EC objectives are established to protect the beneficial use for agricultural water supply. The calculated monthly EC values were used to evaluate possible degradation of water quality through a substantial increase in salinity for agricultural beneficial uses at Vernalis or in the southern Delta channels when compared to baseline conditions. The approach for determining whether the LSJR alternatives could lead to an overall impact of increased salinity considers the long term cumulative distribution for EC during the irrigation season (April–September[18]).

The baseline monthly cumulative distributions of EC values at SJR at Vernalis, SJR at Brandt Bridge, and Old River at Tracy Boulevard are given in Appendix F.1, *Hydrologic and Water Quality Modeling,* (Tables F.1-14b, e, and g). The monthly cumulative distributions of EC values at SJR at Vernalis, SJR at Brandt Bridge, and Old River at Tracy Boulevard for the LSJR alternatives are also given in Appendix F.1 (Tables F.1-15a through 15c for LSJR Alternative 2, Tables F.1-16a through 16c for LSJR Alternative 3, and Tables F.1-17a through 17c for LSJR Alternative 4). The average April–September EC values for baseline at Vernalis ranged from 198 μS/cm to 678 μS/cm, with an average of 497 μS/cm. The calculated April–September average EC values for baseline at Brandt Bridge ranged from 205 μS/cm to 791 μS/cm, with an average of 545 μS/cm (48 μS/cm higher than Vernalis EC). The calculated April–September average EC values for baseline at Tracy Boulevard ranged from 218 μS/cm to 1,038 μS/cm, with an average of 640 μS/cm (143 μS/cm higher than Vernalis EC).

Tables 5-29a through 5-29c show the average April-September EC values expected under LSJR Alternatives 2, 3, and 4.

---

[18] September is included in the analysis because most agriculture still needs irrigation due to high air temperatures, high solar radiation, and little to no rain.

1000 µS/cm = 1 deciSiemen per meter (1 dS/m)
µS/cm = microSiemens per centimeter

Table 5-29c. Cumulative Distributions of April–September Average EC values at Old River at Tracy Boulevard for Baseline and LSJR Alternatives for 1922–2003

Percentile	Baseline	LSJR Alternative 2		LSJR Alternative 3		LSJR Alternative 4	
		Results	Change	Results	Change	Results	Change
April–September Average EC (µS/cm) at Tracy Boulevard for Baseline and LSJR Alternatives							
Minimum	218	218	0	220	2	239	21
10	400	398	-2	373	-27	383	-17
20	513	514	1	445	-68	423	-90
30	555	542	-14	476	-79	445	-110
40	580	570	-10	510	-70	474	-106
50	630	605	-25	530	-99	491	-139
60	677	646	-31	561	-116	521	-156
70	707	680	-27	598	-109	544	-163
80	794	720	-74	632	-162	573	-221
90	907	814	-92	710	-197	650	-257
Maximum	1,038	977	-62	923	-116	833	-205
Average	640	607	-34	540	-100	504	-137

1000 µS/cm = 1 deciSiemen per meter (1 dS/m)
µS/cm = microSiemens per centimeter

LSJR Alternative 2 (Less than significant/Less than significant with adaptive implementation)

Table 5-29a indicates that the average April–September EC values at Vernalis ranged from 0.198 dS/m (198 µS/cm) to 0.658 dS/m (658 µS/cm), with an average of 0.471 dS/m (471 µS/cm) under LSJR Alternative 2. The decrease in the distribution of EC at Vernalis was greater at the higher EC values, with an average reduction of 0.025 dS/m (25 µS/cm). This slight decrease in Vernalis EC was caused by the general increase in the monthly flows compared to the baseline flows at Vernalis. Because the baseline EC objectives at Vernalis are also expected to be met under the LSJR alternatives (due to the continuing responsibility of USBR to meet Delta water quality objectives identified in their water rights), the maximum EC values at Vernalis did not increase above the objectives under LSJR Alternative 2.

Table 5-29b indicates that the average April–September EC values at Brandt Bridge ranged from 0.205 dS/m (205 µS/cm) to 0.755 dS/m (755 µS/cm), with an average EC of 0.516 dS/m (516 µS/cm) under LSJR Alternative 2. The decrease in the distribution of EC at Brandt Bridge relative to baseline was greater at the higher EC values, with an average reduction of 0.028 dS/m (28 µS/cm).

Table 5-29c indicates that the average April–September EC values at Tracy Boulevard ranged from 0.218 dS/m (218 µS/cm) to 977 dS/m (977 µS/cm), with an average of 0.607 dS/m (607 µS/cm). The decrease in the distribution of EC at Tracy Boulevard was greater at the higher EC values, with an average reduction of 0.034 dS/m (34 µS/cm).

Although the monthly EC values might increase or decrease slightly, depending on the changes in the monthly flows, the range of salinity during the irrigation season of April–September in the SJR at

Vernalis and in the southern Delta channels under LSJR Alternative 2 would generally be reduced or remain very similar to baseline. Impacts would be less than significant.

Adaptive Implementation

As described under Impact WQ-1 for LSJR Alternative 2, adaptive implementation method 1 could only increase flow relative to LSJR Alternative 2; method 2 could cause temporary reductions in flow relative to LSJR Alternative 2, but these reductions would be offset by increases in flow at other times and flow could not go below what is required by other agencies or processes; method 3 is not applicable to LSJR Alternative 2; and method 4 would rarely affect flows. Because of the limited effect of adaptive implementation on flow, and, therefore EC, it is anticipated that adaptive implementation would not change the impact determination for the effects of LSJR Alternative 2 on EC for agricultural beneficial uses described above. Impacts would be less than significant.

LSJR Alternative 3 (Less than significant/Less than significant with adaptive implementation)

Table 5-29a indicates that the average April–September EC values at Vernalis ranged from 0.200 dS/m (200 µS/cm) to 0.608 dS/m (608 µS/cm), with an average of 0.418 dS/m (418 µS/cm) under LSJR Alternative 3. The decrease in the distribution of EC at Vernalis relative to baseline was greater at the higher EC values, with an average reduction of 0.078 dS/m (78 µS/cm). This reduction in Vernalis EC was caused by the general increase in the monthly flows compared to the baseline flows at Vernalis.

Table 5-29b indicates the average April–September EC values at Brandt Bridge ranged from 0.206 dS/m (206 µS/cm) to 0.713 dS/m (713 µS/cm), with an average EC of 0.459 dS/m (459 µS/cm) under LSJR Alternative 3. The decrease in the distribution of EC at Brandt Bridge relative to baseline was greater at the higher EC values, with an average reduction of 0.086 dS/m (86 µS/cm). Table 5-29c indicates that the average April–September EC values at Tracy Boulevard ranged from 0.220 dS/m (220 µS/cm) to 0.923 dS/m (923 µS/cm), with an average of 0.540 dS/m (540 µS/cm). The change in the distribution of EC at Tracy Boulevard for LSJR Alternative 3 was greatest for the higher EC values, with an average reduction of 0.100 dS/m (100 µS/cm) relative to baseline.

The range of salinity during the irrigation season of April–September in the SJR at Vernalis and in the southern Delta channels under LSJR Alternative 3 would generally be reduced when compared to baseline. Therefore, agricultural beneficial uses would not be impaired because crops are not harmed by application of water with lower salinity. Impacts would be less than significant.

Adaptive Implementation

As described under Impact WQ-1 for LSJR Alternative 3, adaptive implementation method 1 would not allow flow to go below that of LSJR Alternative 2; methods 2 and 3 could cause temporary reductions in flow relative to LSJR Alternative 2, but these reductions would be offset by increases in flow at other times and flow could not go below what is required by other agencies or processes; and method 4 would rarely affect flows. Because of the limited effect of adaptive implementation on flow, and, therefore EC, it is anticipated that adaptive implementation would not change the impact determination for the effects of LSJR Alternative 3 on EC for agricultural beneficial uses described above. Impacts would be less than significant.

LSJR Alternative 4 (Less than significant/Less than significant with adaptive implementation)

Table 5-29a indicates that the average April–September EC values at Vernalis ranged from 0.217 dS/m (217 µS/cm) to 0.545 dS/m (545 µS/cm), with an average of 0.389 dS/m (389 µS/cm) under LSJR Alternative 4. The reductions in EC at Vernalis for LSJR Alternative 4 were greatest for the higher EC values, with an average reduction of 0.108 dS/m (108 µS/cm). This reduction in Vernalis EC was caused by the general increase in the monthly flows compared to the baseline flows at Vernalis.

Table 5-29b indicates that the average April–September EC values at Brandt Bridge ranged from 0.224 dS/m (224 µS/cm) to 0.641 dS/m (641 µS/cm), with an average EC of 0.427 dS/m (427 µS/cm) under LSJR Alternative 4. The change in the EC at Brandt Bridge relative to baseline was greatest for the higher EC values, with an average reduction of 0.117 dS/m (117 µS/cm). Table 5-29c indicates that the average April–September EC values at Tracy Boulevard ranged from 0.239 dS/m (239 µS/cm) to 0.833 dS/m (833 µS/cm), with an average of 0.504 dS/m (504 µS/cm). The change in the distribution of EC at Tracy Boulevard for LSJR 4 was greatest for the higher EC values, with an average reduction of 0.137 dS/m (137 µS/cm) relative to baseline.

The range of salinity during the irrigation season of April–September in the SJR at Vernalis and in the southern Delta channels under LSJR Alternative 4 would generally be reduced when compared to baseline. Therefore, agricultural beneficial uses would not be impaired because crops are not harmed by application of water with lower salinity. Impacts would be less than significant.

Adaptive Implementation

As described under Impact WQ-1 for LSJR Alternative 4, adaptive implementation method 1 would not allow flow to go below that of LSJR Alternative 3; methods 2 and 3 could cause temporary reductions in flow relative to LSJR Alternative 2, but these reductions would be offset by increases in flow at other times and flow could not go below what is required by other agencies or processes; and method 4 would rarely affect flows. Because of the limited effect of adaptive implementation on flow, and, therefore EC, it is anticipated that adaptive implementation would not change the impact determination for the effects of LSJR Alternative 4 on EC for agricultural beneficial uses described above. Impacts would be less than significant.

SDWQ Alternatives

SDWQ Alternatives 2 and 3 (No impact)

Under SDWQ Alternatives 2 and 3, the Vernalis and southern Delta salinity objectives would be changed to a year-round value of 1.0 dS/m and 1.4 dS/m, respectively. However, under SDWQ 2 and 3, it is expected the program of implementation would maintain EC at Vernalis at or below 0.7 dS/m April-August and 1.0 dS/m September-March as a running 30-day average, similar to current conditions, through actions undertaken by USBR in accordance with its water rights. Changes in EC that may occur downstream of Vernalis are dependent on conditions at Vernalis and within the southern Delta. As modeled for baseline and the LSJR alternatives, additional water is not released from upstream reservoirs to meet EC objectives farther downstream in the southern Delta for the SJR at Brandt Bridge and Old River at Tracy Boulevard.

As explained above, under SDWQ Alternatives 2 and 3, there would be no change in operations affecting southern Delta salinity relative to baseline, and water quality at Vernalis would be unaffected. Merely changing the water quality objectives would not affect water quality in the southern Delta relative to baseline. Therefore, the historical range of salinity (between 0.2 and 1.2 dS/m [200 and 1,200 µS/cm]) is expected to remain unchanged under SDWQ Alternatives 2 and 3. It is not anticipated that agricultural beneficial uses would be impaired with SDWQ Alternatives 2 or 3 because salinity would not change as a result of implementing SDWQ Alternatives 2 or 3. Therefore, there would be no impacts, and implementation of SDWQ Alternatives 2 or 3 would not affect impacts associated with LSJR Alternatives 2, 3, or 4.

Impact WQ-3: Substantially degrade water quality by increasing pollutant concentrations caused by reduced river flows

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

There are multiple water quality constituents that are of concern within the study area. Impact WQ-3 focuses on water quality constituents that are not covered in other locations within this document. Chemicals that are of concern for drinking water quality, such as bromide and salinity are discussed in more detail in Chapter 13, *Service Providers*. A detailed discussion of the impact of potential changes in water temperature and other water quality indicators associated with the LSJR and SDWQ alternatives on fisheries resources can be found in Chapter 7, *Aquatic Biological Resources*. In addition, potential effects on turbidity, erosion, and siltation are discussed in Chapter 6, *Flooding, Sediment, and Erosion*, and Chapter 7, *Aquatic Biological Resources.* Impacts WQ-1 and WQ-2, above, emphasize potential salinity effects because agricultural beneficial uses would be sensitive to changes in salinity extensive EC data are available, and salinity has specific water quality objectives. Potential changes in salinity indicate how other water quality constituents would change. Impact WQ-3 focuses on other water quality constituents that may be affected by changes in flow.

Changing the baseline monthly flows would change the dilution of any pollutants (e.g., 303(d) pollutants listed in Table 5-4) that enter the LSJR or its tributaries or the southern Delta as a point source or non-point source. The source loading of 303(d) pollutants would either remain constant or be caused by storm water runoff or agricultural drainage, and would be independent of the reservoir releases occurring under baseline conditions and the LSJR alternatives. Therefore, the change in concentration would be the inverse of the change in flow (flow ratio). In other words, it is reasonable to assume the concentration of a 303(d) pollutant would increase with a decrease in flow. DO is not considered to be pollutants per se, but it is a water quality indicator that can also be improved by increased flow.

Implementation of the LSJR and SDWQ alternatives would not lead to changes in the Upper SJR flow or pollutant concentrations upstream of the confluence of the LSJR with the Merced River.

Changes in flow in the Merced River associated with the LSJR alternatives would change the dilution of pollutants in the Merced River and would change flows and dilution in the LSJR downstream of the Merced River. The changes downstream would be smaller than in the tributary river because the LSJR baseline flows are greater than the flows in the tributary river. Changes in the Tuolumne River flow would change the dilution and concentrations of pollutants in the Tuolumne River, with smaller changes in the LSJR downstream of the Tuolumne. Changes in the Stanislaus River flows would change the dilution of pollutants in the Stanislaus River and in the LSJR downstream of the Stanislaus (e.g., at Vernalis).

Changes in flow at Vernalis can change water quality through many parts of the southern Delta. In general, increases in flow at Vernalis would improve water quality in the southern Delta by diluting pollutant concentrations with the addition of relatively clean water from the Stanislaus, Tuolumne, and Merced Rivers. DO within the Stockton DWSC is also generally improved (increased) by increases in flow through several different mechanisms including a reduction in the concentration of algae from reduced travel time for algal growth (Central Valley Water Board 2014; ICF International 2010). Potential effects on southern Delta EC are discussed specifically above in Impacts WQ-1 and WQ-2. However, potential effects of changes in flow on other water quality constituents in the southern Delta are captured here under Impact WQ-3.

Changes in flow at Vernalis could also affect other portions of the Delta. Increases in flow at Vernalis could either contribute to increased Delta exports or to increased Delta outflows. Delta outflow helps to prevent salinity intrusion, so increases in Vernalis flow could potentially help to prevent salinity intrusion, although the effect of the LSJR alternatives on Delta outflow are generally relatively small compared to total Delta outflow, because the SJR Watershed only contributes approximately 13 percent to total Delta inflow (based on DAYFLOW data for water years 1995–2013).

The impact assessment is based on the comparison of the baseline flows to the LSJR Alternative flows. Because water quality is generally poorest at low flows, changes in the cumulative flow distribution at the low end of the distribution are most likely to affect water quality. For this reason, the potential effect of changes in flow on changes in water quality were evaluated primarily by looking at changes in the 10th percentile, but changes in median flows were also considered.

In general the LSJR Alternatives would cause flows to increase, which would reduce pollutant concentrations and improve any chronic water quality problems. However, it is possible that in some years, some months will experience flow reductions. These flow reductions would be unlikely to be detrimental because they would be of short duration. Furthermore, flows could not be reduced below levels required by other agencies or through other processes. Because a short-term reduction in flow would need to be relatively large to potentially cause water pollution problems, a threshold of a 50 percent increase in pollutant concentration was used. A 50 percent increase in pollutant concentration would occur if there was a one-third reduction in flow. Therefore, a reduction in 10th percentile or median flows of more than 33 percent for a particular month was considered to be potentially significant and subject to further evaluation. In addition, smaller reductions in flow (10 percent) would also be considered to be potentially significant if they occurred for multiple months.

LSJR Alternative 2 (Less than significant/Less than significant with adaptive implementation)

For each of the three eastside tributaries and the LSJR, flows generally stayed about the same (for the Stanislaus River) or increased with LSJR Alternative 2 (Tables 5-17a through 5-17d). While only a few months showed decreases in flows on all rivers, median flows on the Stanislaus River decreased by more than 10 percent during March. However, because baseline median flows in March on the Stanislaus River were moderately high (which would generally be associated with low pollutant concentrations), this decrease in flow is unlikely to cause an exceedance of a water quality objective. None of the monthly 10th percentile or median flows decreased by more than 33 percent relative to baseline. Impacts would be less than significant.

Adaptive Implementation

As described under Impact WQ-1 for LSJR Alternative 2, adaptive implementation method 1 could only increase flow relative to LSJR Alternative 2; method 2 could cause temporary reductions in flow relative to LSJR Alternative 2, but these reductions would be offset by increases in flow at other times and flow could not go below what is required by other agencies or processes; method 3 is not applicable to LSJR Alternative 2; and method 4 would rarely affect flows. Because of the limited effect of adaptive implementation on flow, and, therefore water quality, it is anticipated that adaptive implementation would not change the impact determination for the effects of LSJR Alternative 2 on pollutant concentrations as described above. Impacts would be less than significant.

LSJR Alternative 3 (Less than significant/Less than significant with adaptive implementation)

For each of the three eastside tributaries and the LSJR, low and median flows generally increased with LSJR Alternative 3 (Tables 5-17a through 5-17d). Few months showed decreases in flows and no months had 10th percentile or median flows that decreased by more than 33 percent. There were two instances of median flows decreasing by more than 10 percent (March on the Tuolumne River and February on the SJR at Vernalis). In these instances, because baseline median flows were moderately high, it is reasonable to assume that these decreases would not cause water quality problems because there would still be sufficient flow in the river to reduce concentrations of pollutants (flow would still be much higher than baseline summer median flows). Impacts would be less than significant.

Adaptive Implementation

As described under Impact WQ-1 for LSJR Alternative 3, adaptive implementation method 1 would not allow flow to go below that of LSJR Alternative 2; methods 2 and 3 could cause temporary reductions in flow relative to LSJR Alternative 2, but these reductions would be offset by increases in flow at other times and flow could not go below what is required by other agencies or processes; and method 4 would rarely affect flows. Because of the limited effect of adaptive implementation on flow, and, therefore water quality, it is anticipated that adaptive implementation would not change the impact determination for the effects of LSJR Alternative 3 on pollutant concentrations as described above. Impacts would be less than significant.

LSJR Alternative 4 (Less than significant/Less than significant with adaptive implementation)

For each of the three eastside tributaries and the LSJR, low and median flows generally increased with LSJR Alternative 4 (Tables 5-17a through 5-17d). Few months showed decreases in flows and none of the monthly 10th percentile or median flow decreased by more than 10 percent. Impacts would be less than significant.

Adaptive Implementation

As described under Impact WQ-1 for LSJR Alternative 4, adaptive implementation method 1 would not allow flow to go below that of LSJR Alternative 3; methods 2 and 3 could cause temporary reductions in flow relative to LSJR Alternative 2, but these reductions would be offset by increases in flow at other times and flow could not go below what is required by other agencies or processes; and method 4 would rarely affect flows. Because of the limited effect of adaptive implementation on flow, and, therefore water quality, it is anticipated that adaptive implementation would not change the impact determination for the effects of LSJR Alternative 4 on pollutant concentrations as described above. Impacts would be less than significant.

SDWQ Alternatives

SDWQ Alternatives 2 and 3 (No impact)

SDWQ Alternatives 2 and 3 would not result in an increase in pollutant concentrations because the SJR at Vernalis EC would continue to be maintained as it is under baseline conditions. As a result, SDWQ Alternatives 2 and 3 would not cause a change in flow. Therefore, WQ-3 impacts would not occur.

5.4.4 Impacts and Mitigation Measures: Extended Plan Area

Similar to the plan area, changing the flows in the rivers in the extended plan area would change the dilution of any water quality constituent of concern (e.g., 303(d) pollutants identified in Section 5.2.1, *San Joaquin River Basin and Southern Delta Hydrology and Water Quality)* that enter the rivers as a point source or non-point source. The source loading would either remain constant or be caused by storm water runoff or drainage, and would be independent of the reservoir releases occurring under baseline conditions or the LSJR alternatives with or without adaptive implementation. Therefore, the change in concentration would be the inverse of the change in flow. In other words, it is reasonable to assume the concentration would decrease with an increase in flow. There is a relatively small volume of water that could be affected by the flow requirements in the extended plan area on the three rivers. In general the LSJR alternatives with or without adaptive implementation would cause flows to increase, which would reduce concentrations and improve any chronic water quality problems. Furthermore, the water quality on the rivers in the extended plan area is generally high quality (Kennedy-Jenks Consultants 2013, 2014). As such, it is expected that additional water in the rivers would not degrade the existing water quality under LSJR Alternatives 2, 3, or 4 with or without adaptive implementation. Impacts would be less than significant.

Water quality could be affected by changes in reservoir elevation (storage levels) under the LSJR alternatives with or without adaptive implementation on the Stanislaus and Tuolumne Rivers. There are no substantial reservoirs on the Merced River in the extended plan area. The frequency with which reservoirs in the extended plan area are drawn down to lower storage levels would depend on the seniority of water rights, how water rights are conditioned to implement the flow objectives, and the duration and frequency of bypass flows. While the changes in storage levels may be greatest in critically dry and dry years, particularly under LSJR Alternatives 3 and 4 with or without adaptive implementation, there may be some changes in above normal years and wet years. To the extent that water in the extended plan area is bypassed to meet the unimpaired flow requirement, instead of being diverted to storage, reservoir levels in the extended plan area would decline. Water quality in upstream reservoirs in the Stanislaus and Tuolumne Watersheds is generally high quality (Kennedy-Jenks Consultants 2013). Furthermore, reservoir volume reductions would have minimal effects on most water quality constituents (e.g., mercury) because the reduction in storage would result from water (and the constituent) flowing out of the reservoir. In other words, the concentrations of water quality constituents would not change or increase relative to baseline and it is unlikely that the water quality would be degraded. Impacts would be less than significant under LSJR Alternatives 2, 3, or 4 with or without adaptive implementation.

5.5 Cumulative Impacts

For the cumulative impact analysis, refer to Chapter 17, *Cumulative Impacts, Growth-Inducing Effects, and Irreversible Commitment of Resources.*

Chapter 6
Flooding, Sediment, and Erosion

6.1 Introduction

This chapter describes the environmental setting for flooding, sediment (including gravel, sand, and silt), and erosion and the regulatory background associated with flooding, sediment, and erosion. It also evaluates environmental impacts on river channel flooding, erosion, and sediment transport that could result from the Lower San Joaquin River (LSJR) alternatives, the significance of any impacts, and, if applicable, proposes mitigation measures that would reduce significant impacts.

As described in Chapter 1, *Introduction*, the plan area generally includes those portions of the San Joaquin River (SJR) Basin that divert water from or otherwise support beneficial use (e.g., surface water supplies) from the three eastside tributaries[1] of the LSJR. These include the Stanislaus River from and including New Melones Dam and Reservoir to its confluence with the LSJR; the Tuolumne River from and including New Don Pedro Dam and Reservoir to its confluence with the LSJR; the Merced River from and including New Exchequer Dam and Lake McClure to its confluence with the LSJR; and, the SJR between its confluence with the Merced River and downstream to Vernalis (i.e., LSJR). The flow in the three eastside tributaries is primarily controlled by the three rim dams[2]; consequently, in this chapter, the rivers are only evaluated below these dams.

The extended plan area, also described in Chapter 1, *Introduction,* generally includes the area upstream of the rim dams. The area of potential effects for this area is similar to that of the plan area and includes the zone of fluctuation around the numerous reservoirs that store water on the Stanislaus and Tuolumne Rivers. (Merced River does not have substantial upstream reservoirs that would be affected.) It also includes the upper reaches of the Stanislaus, Tuolumne, and Merced Rivers. Unless otherwise noted, all discussion in this chapter refers to the plan area. Where appropriate, the extended plan area is specifically identified.

In Appendix B, *State Water Board's Environmental Checklist*, the State Water Board determined whether the plan amendment would cause any adverse impact for each environmental category in the checklist and provided a brief explanation for its determination. Impacts that are listed as "Potentially Significant Impacts" are discussed in detail in this chapter. Appendix B, Section IX, identified the LSJR alternatives as having a potentially significant impact by (1) substantially altering the existing drainage pattern, including through the alteration of the course of a stream or river, in a manner that would result in substantial erosion or siltation on- or off-site, and (2) substantially altering the existing drainage pattern, including through the alteration of the course of a stream or river, or substantially increasing the rate or amount of surface runoff in a manner that would result in flooding on- or offsite. In addition, whether or not people or structures

---

[1] In this document, the term *three eastside tributaries* refers to the Stanislaus, Tuolumne, and Merced Rivers.

[2] In this document, the term *rim dams* is used when referencing the three major dams and reservoirs on each of the eastside tributaries: New Melones Dam and Reservoir on the Stanislaus River; New Don Pedro Dam and Reservoir on the Tuolumne River; and New Exchequer Dam and Lake McClure on the Merced River.

are exposed to a significant risk of loss, injury or death involving flooding is addressed. Accordingly, this chapter evaluates these potential impacts of the LSJR alternatives on the alteration of the existing streams or rivers in the plan area. Impacts were assessed using results from the State Water Board's Water Supply Effects (WSE) monthly model to compare the changes in flows to channel capacities for each alternative and, specifically, to assess how frequently the channel capacities were exceeded, which could result in flooding, sediment, and erosion.

Table 6-1 summarizes the potential impacts of the LSJR alternatives. As described in Chapter 3, *Alternatives Description*, LSJR Alternatives 2, 3, and 4 each include four methods of adaptive implementation. The substitute environmental document (SED) provides an analysis with and without adaptive implementation because the frequency, duration, and extent to which each adaptive implementation method would be used, if at all, within a year or between years under each LSJR alternative is unknown. The analysis, therefore, discloses the full range of impacts that could occur under an LSJR alternative, from no adaptive implementation to full adaptive implementation. As such, Table 6-1 summarizes impact determinations with and without adaptive implementation.

Any change in salinity in the southern Delta as a result of southern Delta water quality (SDWQ) Alternatives 2 or 3 is expected to be similar to that of the historic range of salinity because Vernalis water quality would be maintained under the SDWQ alternatives through the program of implementation. Furthermore, change in water quality does not affect flooding, sedimentation, or erosion. Therefore, the SDWQ alternatives are not discussed in this chapter. To comply with specific water quality objectives or the program of implementation under SDWQ Alternatives 2 or 3, construction and operation of different facilities in the southern Delta could occur, which could involve impacts on flooding, sediment, and erosion. These impacts are evaluated in Chapter 16, *Evaluation of Other Indirect and Additional Actions.*

Impacts related to the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) are presented in Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* and the supporting technical analysis is presented in Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1).* Chapter 16, *Evaluation of Other Indirect and Additional Actions,* includes discussion of impacts related to actions and methods of compliance.

Table 6-1. Summary of Flooding, Sediment, and Erosion Impact Determinations

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
Impact FLO-1: Substantially alter the existing drainage pattern of the site or area, including through the alteration of the course of a stream or river, in a manner that would result in substantial erosion or siltation on- or off-site			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note.[b]	Less than significant	NA
LSJR Alternative 2	Substantial erosion is caused by high flow events resulting from flood control releases of peak flows. These flows would not increase under LSJR Alternative 2. On average, the occurrence of monthly flows greater than	Less than significant	Less than significant

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
	1,500 cfs on the Stanislaus River would be similar to baseline and would not influence stream bank erosion. Therefore, substantial alterations of the existing drainage patterns would not occur and would not result in an increase in substantial erosion or siltation.		
LSJR Alternative 3	Very occasional gravel transport and bank erosion would occur in the upper gravel-bedded reaches of the three eastside tributaries. The amount of bank erosion is limited by flood stage action levels, which is the river stage at which actions are presumed to occur to reduce flood risk, and existing bank armoring. Flows greater than 1,500 cfs on the Stanislaus River would occur with greater frequency than baseline, particularly during April to June; however, these flows are not sufficiently high to increase stream bank erosion. Therefore, substantial alterations of the existing drainage patterns would not occur and would not result in an increase in substantial erosion or siltation.	Less than significant	Less than significant
LSJR Alternative 4	Similar to Alternative 3, there would be occasional gravel transport and bank erosion in the upper gravel-bedded reaches of the three eastside tributaries. The amount of bank erosion is limited by the action stage, which is the river stage at which actions are presumed to occur to reduce flood risk, and existing bank armoring. Flows greater than 1,500 cfs on Stanislaus River would occur with greater frequency than baseline, particularly during April to June; however, these flows are not sufficiently high to increase stream bank erosion. Therefore, substantial alterations of the existing drainage patterns would not occur and would not result in an increase in substantial erosion or siltation.	Less than significant	Less than significant
Impact FLO-2: Substantially alter the existing drainage pattern of the site or area, including through the alteration of the course of a stream or river, or substantially increase the rate or amount of surface runoff in a manner that would result in flooding on- or offsite			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note.[b]	Less than significant	NA

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
LSJR Alternative 2	Controlled reservoir releases would be much lower than channel capacities and no significant flooding would occur outside of floodway. LSJR Alternative 2 would not change reservoir flood storage capacity and would not violate USACE flood reservation so there would be no changes in flood control operation procedures during major flood events. Therefore, substantial alterations of the existing drainage patterns would not occur and would not result in flooding. Consequently, people or structures would not be exposed to a significant risk of loss, injury or death involving flooding.	Less than significant	Less than significant
LSJR Alternative 3	Similar to Alternative 2 with respect to flood control operations. Substantial alterations of the existing drainage patterns would not occur and would not result in flooding. Consequently, people or structures would not be exposed to a significant risk of loss, injury or death involving flooding.	Less than significant	Less than significant
LSJR Alternative 4	Similar to Alternative 2, with respect to flood control operations. Substantial alterations of the existing drainage patterns would not occur and would not result in flooding. Consequently, people or structures would not be exposed to a significant risk of loss, injury or death involving flooding.	Less than significant	Less than significant

cfs = cubic feet per second

[a] Four adaptive implementation methods could occur under the LSJR alternatives, as described in Chapter 3, *Alternatives Description* and summarized in Section 6.4.2, *Methods and Approach*, of this chapter.

[b] The No Project Alternative (LSJR/SDWQ Alternative 1) would result in the continued implementation of flow objectives and salinity objectives established in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

6.2 Environmental Setting

The information in this section provides context for the impacts evaluation of the LSJR alternatives within the plan area. The LSJR alternatives neither involve ground-disturbing activities nor do they increase the potential for high peak flows that could result in substantial sediment transport of gravels and sands that would cause substantial erosion of stream banks or stream levees. The LSJR alternatives would alter the timing of flows in the three eastside tributaries and the LSJR but would not significantly change peak flow rates or the rates of bank erosion or sedimentation within the plan area. Potential impacts associated with sediment transport that are expected to occur under the

LSJR alternatives in relation to fisheries habitat are discussed in Chapter 7, *Aquatic Biological Resources*. Consequently, this section does not provide information on overall basin erosion and sedimentation.

6.2.1 Overview of the Bay-Delta and Central Valley Basin

Chapter 2, *Water Resources*, describes in detail the hydrology, dams, water diversions, operating agreements, and flow requirements of the plan area. The present chapter provides additional information on the channel geomorphology and channel capacities relevant to evaluating the potentials for flooding, and sedimentation, and erosion impacts as described in Sections 6.4.2, *Methods and Approach*, and 6.4.3, *Impacts and Mitigation Measures*, of this chapter.

The Central Valley is a low-lying basin that receives water and sediment from the surrounding highlands of the Sierra Nevada to the east and the Coast Ranges to the west. The Sacramento River drains the north end of the Central Valley while the SJR drains the south end. The Sacramento River and SJR flow along the lowest elevation portions of the Central Valley as low gradient rivers. The two rivers meet in the Delta and flow to the Pacific Ocean through Carquinez Strait and San Francisco Bay.

Streams entering the SJR from both the Sierra Nevada and the Coast Ranges have steeper gradients as they exit their respective mountain front and then become progressively lower gradient as they reach the lowermost SJR Basin and join the LSJR. In their upper portions, the Sierra Nevada tributaries are incised into bedrock, and the larger dams are placed in these bedrock reaches. Further downstream, the streams leave the bedrock and begin flowing within channels formed of the sediment they transport (i.e., they become alluvial channels). The upper river reaches are steeper and gravel dominated (and are considered transport reaches) while the lower reaches are lower gradient and sand dominated (and are considered response reaches, constantly adjusting their channel bed to the available sediment, and water supply).

The Sierra Nevada streams generally have more water discharge and are lower gradient than the streams that drain the Coast Range. The Sierra Nevada tributaries have also been modified by gold dredging in their upper gravel-bedded reaches as well as within-stream and stream adjacent gravel mining for aggregate (Kondolf et al. 1996, 2001; McBain and Trush 2000; Weissmann et al. 2005). The LSJR and the three eastside tributaries are described in the following sections.

6.2.2 Lower San Joaquin River, Delta, and Tributaries

The LSJR is a very low gradient river throughout the plan area and generally has a meandering pattern. The three eastside tributaries are generally steeper, confined gravel-bedded channels in their upper portion. The reservoirs on the tributaries control and maintain flows in the rivers. They transition to low gradient, sand-bedded meandering channels in their middle to lower reaches. The three eastside tributaries and the LSJR are constrained by channel modifications, development encroachment, agricultural encroachment and levees that limit their ability to flood the adjacent landscape or to have excessive channel erosion. The LSJR is further constrained by the alluvial fan sediment deposition of all tributary streams from both the Sierra Nevada and the Coast Ranges.

Reservoirs

Flood control operations for Lake McClure, New Don Pedro Reservoir, and New Melones Reservoir are developed as part of the Water Control Plans by the USACE Sacramento District, according to national flood control regulations. (33 C.F.R. § 208.11.) Based on hydrologic engineering studies of rainfall and snowmelt floods, standard project floods and reservoir design floods are identified for the reservoir. The seasonal rainfall and snowmelt flood control curves (i.e., empty storage space) are based on these design storms. For example, the rainfall flood control storage for Lake McClure increases linearly from 0 thousand acre-feet (TAF) at the end of August to 175 TAF at the end of September to 350 TAF at the end of October. The flood control space remains at 350 TAF until March 15, and is reduced linearly to 0 TAF on June 15. Flood control releases are made whenever the reservoir storage goes above the maximum flood control storage during rainfall runoff events, with a maximum flood control release flow of 6,000 cubic feet per second (cfs) at Stevinson. If necessary, additional storage space is reserved from the beginning of March to the end of July to prevent uncontrolled spilling. A constant supplemental river release is computed, based on snowpack and snowmelt forecasts. The maximum snowmelt storage space is 400 TAF from April 1 to May 15. Emergency spillway releases are regulated with a similar process that requires higher releases during very high inflow events once the Lake McClure elevation is above the spillway crest at 837 feet (ft) (30-ft spillway gates). New Don Pedro and New Melones Reservoirs have similar flood control and flood control operating rules.

Lower San Joaquin River and Delta

The SJR flows from high in the Sierra Nevada, drains west into the SJR Basin, turns north and drains to the Delta, a distance of approximately 180 miles below Friant Dam. Below Friant Dam, the river has deposited a wide alluvial fan that it now flows across (McBain and Trush 2002; Weissmann et al. 2005). At the bottom of this alluvial fan, the river turns north and flows towards the Delta. Figure 6-1 shows the SJR longitudinal profile from Friant Dam downstream to the Delta. Table 6-2 describes the eight LSJR channel reaches from the Merced River north. The SJR channel reaches are divided based on differences in floodplain width, connectivity of the channel to the floodplain, and encroachment. The SJR is generally a meandering channel in its lower reach; however, the width of the meander belt is related to space constraints placed upon it by both the San Joaquin Valley width and its tributary river and creek alluvial fans (Weissmann et al. 2005). Upstream of the Merced River confluence the SJR meandering floodplain is several miles wide because the Valley itself is wide and the Sierra Nevada tributaries (Chowchilla and Kings Rivers) do not have sufficient water and sediment available to fill the central basin and constrain the SJR (Weissmann et al. 2005).

Near the Merced River (LSJR River Mile [RM] 119), the LSJR floodplain becomes narrower because the Valley itself narrows and the Merced River alluvial fan has sufficient sediment deposition to constrain the LSJR's ability to migrate east. At the Merced River confluence, the SJR floodplain narrows from more than 3 miles to less than 1 mile. The channel pattern and floodplain width is similar from this location for approximately 44 miles north, past the confluence with the Tuolumne River at RM 83.5 to the confluence with the Stanislaus River at RM 75. The LSJR floodplain is also constrained by stream alluvial fans from the Coast Ranges to the west. These alluvial fans include Orestimba Creek at RM 109 and Del Puerco Creek at RM 93. North of the Stanislaus River at RM 75, the Valley and LSJR floodplain again widens towards the southern Delta (Weissmann et al. 2005). The LSJR has a very low gradient along this entire reach ranging from 0.000036 to 0.000284 and is sand-bedded (USACE 2002).

The LSJR generally forms a meandering pattern with features shown in Figures 6-2a and 6-2b. Meanders form by water flow eroding the channel bottom, forming a deep pool that also undercuts and erodes the adjacent channel bank. That eroded sediment is transported downstream and deposited, forming a shallow spot or riffle in the channel, which is followed by another pool with

Meandering Channel Characteristics

an eroding channel bank and then another riffle. Sediment is also deposited on the inside bend in the vicinity of the pool forming a point bar. Point bar sediment is commonly deposited during high flows and often forms arcuate ridges (scroll ridges, scroll bars) along the point bar that are visible at lower flows.

This erosion-deposition pattern causes the river channel to progressively erode the banks and “migrate” downstream. As the channel configuration changes, individual meanders may be cut off producing an oxbow lake (Figure 6-2c). The cutoff may occur at the meander neck (neck cutoff) or by flows across the point bar surface that erode a sufficiently deep channel to capture stream flow (chute cutoff) (Figure 6-2c).

Erosion and sediment transport occur during higher or flood flows, which can mobilize the bed sediment and undercut stream banks; consequently, overall meander channel dimensions reflect the high flows associated with individual river systems (McBain and Trush 2002; Larsen et al. 2006; Michalkova et al. 2011). Many factors control the rate of meander movement. These factors include magnitude of the flow, bed sediment size, bank erosional resistance and meander geometry. Higher flows, often approaching channel capacity, are required to move larger amounts of coarser sediment. Bank resistance can be influenced by numerous factors such as levee construction to contain flood flows, placement of large rocks or physical structures to prevent bank erosion, presence of bridge abutments, and local variations of natural bank materials (e.g., sediment size and the presence of bedrock or cohesive soils).

Finer sediment (fine sand, silt, and clay) is transported in suspension and is a major source of water turbidity. The amount of suspended sediment transported at a given time is generally related to discharge; that is, higher discharges can carry larger amounts of suspended sediment (Wright and Schoellhamer 2005; Saleh et al. 2007; Figure 19D for the SJR at Vernalis). However, the amount of fine sediment that a given discharge can possibly carry varies widely. For example, Kratzer and Shelton (1998: Figure 33) show that at 10,000 cfs suspended sediment concentrations in the SJR at Vernalis can vary from approximately 60 to more than 540 milligrams per liter. On the LSJR, dams and increased water use have reduced river flow, which reduces sediment transport (McBain and Trush 2002). Combined with the effects of levees that have been constructed to contain peak flows, the meander migration rates on the LSJR have been minimized (McBain and Trush 2002).

Figure 6-3 and Tables 6-3, 6-4, and 6-5 show the channel capacities, National Weather Service (NWS) flood categories, and observations of channel conditions and local inundation of the LSJR and the three eastside tributaries, respectively. The levee system shown in Figure 6-3 is part of the State Plan of Flood Control, which is part of the combined state-federal flood management system (DWR 2010). It has undergone a system-wide evaluation and update to improve flood control and management as part of the Central Valley Flood Protection Plan (DWR 2011, 2012). Private levees that are not part of the State Plan of Flood Control occur on the Stanislaus, Tuolumne, and Merced Rivers are not shown in Figure 6-3.

Table 6-2. Lower San Joaquin River Channel Reaches

Reach	1	2	3	4	5	6	7	8
River Mile	0 – 53	53 – 73	73 – 83.5	83.5 – 90	90 – 95	95 – 108	108 – 116	116 – 118
Gradient (%)	0.000036	0.000057	0.000234	0.000032	0.00011	0.000146	0.000284	0.000086
Description	Distributary channels downstream of Old River flowing towards junction with Sacramento River. Flow generally constrained between levees which protect adjacent Delta islands.	Floodplain continues to widen to Old River cutoff. Channel begins to become distributary at Paradise Cut and then Old River; main San Joaquin channel continues around east side of Delta. Vernalis stream gage at RM 72.	Floodplain 2 miles wide below Tuolumne confluence; continues to widen downstream. Tight meanders, then meander height increases with floodplain width. Main channel generally isolated from adjacent floodplain. Stanislaus enters at RM 75. SJR National Wildlife Refuge between Tuolumne and Stanislaus River confluences.	Floodplain widens to more than 2 miles. Laird Slough flows north from north side of river. Tuolumne River enters at approximately RM 83 and floodplain narrows.	Channel constrained with narrow floodplain less than 0.6 mile wide.	Floodplain and abandoned channels are adjacent to main channel but not generally connected. Floodplain up to 2 miles wide. Downstream end of reach terminates at Sewage Disposal Ponds southwest of Modesto.	Channel somewhat constrained with floodplain less than 1 mile wide. Channel less connected to floodplain than Reach 8. Ends at Crows Landing Bridge.	Meander Channels connected to main channel. Merced River enters at RM 118.

Figure 6-3
Channel Capacities and Levees

The LSJR channel capacity increases downstream from an estimated 26,000 cfs just above the Merced River confluence, to a designed capacity of 45,000 cfs below that confluence and increases downstream of the Tuolumne and Stanislaus River confluences as well. Some flow is diverted at the Paradise Cut, and additional flow is diverted at Old River. Evaluations for the Central Valley Flood Protection Plan indicate that, in some cases, channel capacity may be higher or lower than the estimated or design capacities (Table 6-3). On the LSJR present channel capacities are uncertain downstream of the Merced River confluence, downstream of the Tuolumne River confluence, and from Old River to Burns Cutoff (Table 6-3). Additional evaluation is needed in these three reaches (DWR 2011).

The above capacities are mostly within the levee system, which protects the adjacent meander belt floodplain and agricultural land. The San Joaquin River National Wildlife Refuge, located approximately between the confluences of the Tuolumne and Stanislaus Rivers, can receive flood flows to reduce discharge downstream during floods (USFWS 2006; River Partners 2008).

The action stage for the SJR at Vernalis is 22,000 cfs, and the minor flooding level for the LSJR is 34,000 cfs (NWS n.d.). Action stage is the point on a rising stream (i.e., the water discharge is increasing and expected to continue to increase) at which some type of mitigation action should be taken in preparation for possible significant hydrologic activity (NWS n.d.). Minor flooding has minimal or no property damage but possibly some public threat. Table 6-4 shows various action stages. Table 6-5 shows some local effects that occur at various discharge levels as well as reservoir flow limits.

Table 6-3. River Channel Capacity

Note: Data from the NWS Advanced Hydrologic Prediction Service. See “Default Hydrograph” dropdown box for flood categories and flood impacts.

cfs = cubic feet per second

RM = River Mile

Recent floods were recorded in the region and on the LSJR in 1983, 1986, 1995, 1997, and 2006 (USACE 1999; Parrett and Hunrichs 2006). Generally these flood flows were contained by the LSJR levees, although there were several levee breaches during the 1997 flood (USACE 1999; DWR 2010, 2011, 2012).

The composite condition (i.e., considering all the evaluated risk factors) for the LSJR levees is primarily “higher concern” (i.e., the levees display more performance problems than those of lower concern), with stretches of “medium concern” and short stretches of “lower concern” (DWR 2012: Figure 1-7), based on detailed levee evaluations along the LSJR conducted for the Central Valley Flood Protection Plan (DWR 2010, 2011, 2012). The evaluations included numerous criteria that affect levee integrity including seepage, slope stability, erosion, and animal burrows (DWR 2011, 2012). Individual rating maps for each assessment criteria are also included (DWR 2011).

Stanislaus River

Similar to other Sierra Nevada tributaries, the Stanislaus River transitions from steeper, gravel-bedded reaches affected by gold dredging and aggregate mining, to areas where various activities encroached on the stream channel and then to a lower gradient predominantly sand-bedded reach. The upper gravel-bedded reach is confined within a bedrock canyon (Goodwin Canyon) and extends from RM 54.75 to RM 58.4. Below RM 54.75, the river exits the bedrock canyon, but the channel is incised below adjacent alluvial river terraces that constrain the channel. This reach is gravel-bedded and there are occasional dredger tailings and gravel mining on the adjacent floodplain. This reach continues downstream to Oakdale (RM 41) and Riverbank (RM 34). At Riverbank, the channel and floodplain begin to become less constrained, and channel meandering becomes prominent. As its gradient reduces and meandering increases, the channel becomes more sand dominated in this reach. The lower and upper reaches have gradients of approximately 0.0004 to 0.0047, and the lowermost channel is sand-bedded (USACE 2002). Figure 6-4 shows the Stanislaus River longitudinal profile. Table 6-6 describes the three channel reaches, divided based on characteristics of the river channel, floodplain morphology and alterations to the river channel and floodplain (Kondolf et al. 2001).

Under current conditions, gravel transport in the upper part of Reach 2 is estimated to begin in the range of 5,000 to 8,000 cfs based on observations and calculations in Kondolf et al. 2001. Kondolf et al. (2001) reports a post New Melones Dam high flow of 7,350 cfs in 1997. Figure 2-10 presents the monthly unimpaired and historical flows February–June for the Stanislaus River. This shows that flows of this level were not reached for water years 2000–2009.

The lower Stanislaus River is protected by levees to approximately RM 11 that allow a channel capacity of 8,000 cfs (Figure 6-3). These levees are not part of the State Plan of Flood Control but are called Stanislaus Local Interest Project Levees (DWR 2010, 2011, 2012). This channel capacity is the flood design flow for the entire river below Goodwin Dam (Kondolf et al. 2001). Evaluations for the Central Valley Flood Protection Plan indicate that the lower Stanislaus River channel capacity is higher than the values shown in Figure 6-3 and Table 6-3.

Table 6-4 shows that the action stage for the Stanislaus River is 8,500 cfs, and that the minor flooding level for the Stanislaus River is 12,500 cfs (NWS n.d.). Table 6-5 shows some local effects that occur at various discharge levels as well as reservoir flow limits for power generation.

Figure 6-4
Longitudinal Profiles for
Stanislaus, Tuolumne, and Merced Rivers

Table 6-6. Stanislaus River Channel Reaches

Reach	1	2	3
River Mile	0–34	34–54.75	54.75–58.4
Gradient (%)	0.0004	0.0008	0.0047
Description	Reach below Riverbank composed of Holocene river deposits. Channel meandering begins and becomes more prominent downstream. Sand bedded conditions probably begin below Ripon based on the lower channel gradient and increased meandering. Levees extend from RM 0 to about RM 11 Gravel mining adjacent to river upstream of Ripon (RM 19).	Channel is inset below and confined by older and higher river terraces. Occasional gravel mining and dredger tailings indicating gravel bed conditions. Knights Ferry at RM 54. Oakdale at RM 41. Riverbank at RM 34.	Channel is incised into bedrock and very confined and non-meandering. Gravel bedded. Begins to emerge from bedrock canyon at RM 54.75.

Source: Kondolf et al. 2001
RM = River Mile

Kondolf et al. (2001) also report active channel meandering and potential avulsion at Caswell State Park (approximately RM 4 to RM 9.5). Avulsion occurs when a stream channel leaves its initial channel, flows across the landscape and establishes a new channel position. Depending on landscape condition, the new channel may or may not reconnect with the original channel downstream. Avulsion only occurs during high flows.

The U. S. Fish and Wildlife Service (2012, 2013) is evaluating floodplain fish habitat in relationship to discharge in the Stanislaus River (see detailed discussion in Chapter 19, *Analysis of Benefits to Native Fish Populations from Increased Flow Between February 1 and June 30*, Section 19.3, *Floodplain Inundation*). Current USFWS results indicate that floodplain inundation began at 1,250 cfs in both the Ripon to Jacob Meyers and the Orange Blossom Bridge to Knight's Ferry reaches.

Recent floods were recorded in the region and on the Stanislaus River in 1983, 1986, 1995, 1997, and 2006 (USACE 1999; Parrett and Hunrichs 2006). Generally these flood flows were contained by the channel and adjacent floodplain within the floodway (USACE 1999; DWR 2010, 2011, 2012).

Although the channel capacity is 8,000 cfs, there is agriculture within the floodway that may be affected by seepage and high water tables at flows above 1,500 cfs (McAfee 2000; Kondolf et al. 2001). Concerns about seepage involve potentially adverse impacts that may occur to agricultural crops such as damage to the root systems of tree crops when the groundwater level rises due to high river flows. NMFS Biological Opinion RPA (NMFS 2011) limits spring pulse flow events to <10 days to reduce potential impacts of seepage to orchard crops. The RPA also includes channel forming and maintenance flows in the 3,000- to 5,000-cfs range in above normal and wet years to maintain spawning and rearing habitat quality. These flows are scheduled to occur after March 1 to protect incubating eggs and provide outmigration flow cues. These flows are high intensity, but limited in duration to avoid potential seepage issues that have been alleged under extended periods of flow greater than 1,500 cfs. New Melones flow releases continue to operate in line with these limits (Clinton pers. comm.); however, flows on the Stanislaus are often above 1,500 cfs. The 1,500 cfs restriction does not apply for flood control releases.

The composite condition for the Stanislaus River levees is "higher concern," i.e., the levees display more performance problems than those of lower concern (DWR 2012:Figure 1-7). Detailed levee evaluations for the Central Valley Flood Protection Plan only include the levees immediately upstream of the Stanislaus River–SJR confluence to about RM 2 (DWR 2010, 2011, 2012). The evaluations include numerous criteria that affect levee integrity including seepage, slope stability, erosion, and animal burrows (DWR 2011, 2012). DWR (2011) also includes individual rating maps for each assessment criteria.

Tuolumne River

Similar to other Sierra Nevada tributaries, the Tuolumne River transitions from steeper, gravel-bedded reaches that have been affected by gold dredging and aggregate mining activities to areas where various activities have encroached on the stream channel, and then to a lower gradient sand-bedded reach. The upper gravel-bedded reaches are from RM 24 to RM 52 while the lower sand-bedded reaches are from RM 0 to RM 24. The lower and upper reaches have gradients of approximately 0.0003 to 0.0015, and the lowermost channel is sand-bedded (USACE 2002). Figure 6-4 shows the Tuolumne River longitudinal profile and Table 6-7 describes the seven channel reaches, divided based on characteristics of the river channel, floodplain morphology and alterations to the river channel and floodplain (McBain and Trush 2000).

Under current conditions, gravel transport in the upper reaches are estimated to begin at discharges of 7,050 cfs to 9,800 cfs based on observations and calculations presented in McBain and Trush 2000. USFWS (2010) reports a 1995 Tuolumne River flow of 8,400 cfs. Figure 2-9 (*Monthly Unimpaired and Historical Tuolumne River Flows February–June*) shows that in water years 2000–2009, flows of this level were reached only in water year 2006.

Private levees occur intermittently along the lower ten miles of the Tuolumne River (DWR 2010: Appendix A, Figure 7). The lower Tuolumne River has an estimated channel capacity of approximately 15,000 cfs, which is also the design channel capacity for the entire river (Figure 6-3; Table 6-3).

Table 6-4 shows that the action stage for the Tuolumne River is 6,600 cfs and that the minor flooding level for the Tuolumne River is 10,400 cfs (NWS n.d.). Table 6-5 shows some of the local effects that occur at various discharge levels as well as reservoir flow limits for power generation.

Overbank flow begins at river discharges of 1,100 cfs to 3,200 cfs, based on a USFWS flow-overbank inundation evaluation of the Tuolumne River from RM 21.5 (just upstream of the Santa Fe Bridge near the town of Empire) to the La Grange Dam at RM 52 (USFWS 2010) using river channel aerial photographs from various years with river flows of 100–8,400 cfs, and then plotting river acres inundated versus river flow. These "overbank" flows are not flood flows that inundate the entire floodway capacity; instead they are flows that inundate the adjacent point bars and varying portions of the floodplain (see discussion in Chapter 19, *Analysis of Benefits to Native Fish Populations from Increased Flow Between February 1 and June 30*, Section 19.3, *Floodplain Inundation*). The channel capacity for the Tuolumne River is approximately 15,000 cfs (Figure 6-3 and Table 6-3).

Table 6-7. Tuolumne River Channel Reaches

Reach	1	2	3	4	5	6	7
River Mile	0.0–10.5	10.5–19.3	19.3–24.0	24.0–34.2	34.2–40.3	20.3–46.6	46.6–52.0
Gradient (%)	<0.0003	<0.0003	<0.0003	<0.0003 – 0.0015	0.0010 – 0.0015	0.0010 – 0.0015	0.0010 – 0.0015
Description	Sand-Bedded Agricultural encroachment. No valley confinement during high flow.	Sand-Bedded Agricultural and urban encroachment. Moderate valley confinement. City of Modesto is in reach center. Dry Creek enters about midway.	Sand-Bedded Agricultural and rural encroachment. Low valley confinement. Upstream end is transition to gravel-bedded channel.	Gravel-Bedded In-channel gravel mining occurs with dike encroachments. Agricultural encroachment. Low valley confinement downstream of Waterford.	Gravel-Bedded Extensive off-channel gravel mining pits. Dikes to isolate pits from river. Agricultural encroachment. Low valley confinement.	Gravel-Bedded Remnant gold dredge tailings on floodplain. Fragmented channel with multiple backwaters. Low valley confinement during high flow.	Gravel-Bedded Highest salmon spawning use. Agricultural land use. Low valley confinement during high flow. Single thread meandering low water channel with low bankfull confinement.

Source: McBain & Trush, Inc. 2000.

Recent floods were recorded in the region and on the Tuolumne River in 1983, 1986, 1995, 1997, and 2006 (USACE 1999; Parrett and Hunrichs 2006). Generally these flood flows were contained by the channel and adjacent floodplain within the floodway (USACE 1999). However, the 1997 flood resulted in bank overtopping near Modesto, Waterford, La Grange, and Roberts Ferry (USACE 1999).

Merced River

Similar to other Sierra Nevada tributaries, the Merced River transitions from steeper, gravel-bedded reaches affected by gold dredging and aggregate mining, to areas where various activities have encroached on the stream channel, and then to a lower gradient sand-bedded reach. The lower and upper reaches have gradients of approximately 0.00002 to 0.0023, and the lowermost channel is sand-bedded (USACE 2002). Figure 6-4 shows the Merced River longitudinal profile, and Table 6-8 describes the five channel reach divisions (Stillwater Sciences 2001). These channel reach divisions are based on characteristics of the river channel, floodplain morphology and alterations to the river channel and floodplain.

Table 6-8. Merced River Channel Reaches

Reach	1	2	3	4	5
River Mile	0.0–8.0	8.0–26.8	26.8–32.5	32.5–45.2	45.2–52.0
Gradient (%)	0.0002	0.0003	0.0008	0.0015	0.0023
Description	Confluence Reach Reach entirely sand bedded and subject to backwater effects from SJR. Some meanders are armored, others not.	Encroached Reach Channel bed transitions from gravel to sand. The transition zone extends from RM 25.5 to 16.5. Agricultural development on former floodplain confines the river area between private levees. Channel migration eliminated and channel simplified.	Gravel Mining Reach 2 Reach includes Dry Creek confluence. Channel bed of sand, gravel, and cobble. Channel is incised up to 5 feet. Aggregate mining in channel and on floodplain. Dry Creek contributes large amount of sand.	Gravel Mining Reach 2 Cobble and gravel bedded but subsurface contains significant sand. Channel converted to single-thread channel with floodplain sloughs converted to irrigation ditches and drains. Some remnant off-channel meander channel features remain.	Dredger Tailings Reach Channel and floodplain dredged for gold. Adjacent floodplain raised by dredge piles. Channel converted from complex multi-thread channel to single channel. Agricultural development on floodplain.

Source: Stillwater Sciences 2001.
RM = River Mile

Gravel transport (or bed mobilization) in the upper dredger tailings reach was estimated to occur when flow conditions were greater than 4,800 cfs (Stillwater Sciences, 2001) which was similar to values in Kondolf et al. (1996) for similar sized material. Stillwater Sciences (2004) reports localized and short distance gravel movement (tens of ft) at flows of 1,870 cfs. Recent observations of gravel sediment movement in a restoration reach just above RM 43 (below Snelling, RM 48) show movement at similar discharges.

Harrison et al. (2011) measured discharge, flow characteristics and channel characteristics including changes in bed topography as an indicator of gravel mobility. They found that most of the gravel movement was in the upper 2,625 ft of the 6,645-ft restoration reach. This gravel movement primarily occurred at higher discharges of 4,255 cfs–5,015 cfs. Albertson et al. (2011) estimated more gravel mobility at lower discharges but that mobility does not reflect the observed gravel movement in the restoration reach (Harrison et al. 2011). Figure 2-8 (*Monthly Unimpaired and Historical Merced River Flows February–June*) shows that in water year 2000–water year 2009, flows of this level were reached in water years 2000, 2005, and 2006.

Bank erosion has decreased throughout the Merced River because of reduced peak flows and because of bank protection. About four percent of the channel banks show evidence of erosion, and these tend to alternate with bank protection sites (Stillwater Sciences 2001, Table 12). However, Harrison et al. (2011) evaluated ten meander bends in a restoration reach just above RM 43 and reported average bank erosion rates of 2.3 ft to 8.5 ft per year for the periods of peak flow (water years 2005 and 2006). This bank erosion along the restored channel occurred in the broad dredger tailings area (Figure 6-4, Reach 5) and this bank-floodplain area was specifically designed to allow such bank erosion-channel migration.

Private levees locally reduce floodplain width in reaches 3 and 4, and reach 2 has levees along approximately 60 percent of its length (Stillwater Sciences 2001; DWR 2010, 2011). The Merced River has an estimated channel capacity of approximately 6,000 cfs (Figure 6-3; Table 6-3; Stillwater Sciences 2001).

Table 6-4 shows that the action stage for the Merced River is 3,200 cfs, and that the minor flooding level for the Merced River is 6,900 cfs (NWS n.d.). Table 6-5 shows the reservoir flow limits for power generation. Floodplain inundation on the Merced River is assumed to start at 1,000 cfs (see discussion in Chapter 19, *Analysis of Benefits to Native Fish Populations from Increased Flow Between February 1 and June 30*, Section 19.3, *Floodplain Inundation*).

Recent floods were recorded in the region, with high flows on the Merced River in 1983, 1986, 1995, 1997, 2005, and 2006 (USACE 1999; Parrett and Hunrichs 2006; Albertson et al. 2011; Harrison et al. 2011). These flood flows were contained by the channel and adjacent floodplain within the floodway (USACE 1999).

6.2.3 Extended Plan Area

The Stanislaus, Tuolumne, and Merced rivers originate in the uppermost Sierra Nevada Mountains. The uppermost reaches have been scoured by glaciations so there is abundant exposed bedrock (California Geological Survey 2002). Above the rim dams the rivers generally flow through confined bedrock valleys or steep bedrock gorges (Kondolf et al. 2001; California Geological Survey 2002; Stillwater Sciences 2002). The stream channels are commonly very coarse-grained, especially downstream of dams on the Stanislaus and Tuolumne rivers (e.g., Kondolf et al. 2001). The stream channels also tend to be relatively steep, although the Yosemite Valley floor is very flat (Minear and Wright 2013).

6.3 Regulatory Background

6.3.1 Federal

Relevant federal programs, policies, plans, or regulations related to flood control and geomorphic conditions are described below.

U.S. Army Corps of Engineers Flood Operations

USACE is responsible for prescribing regulations for the use of storage allocated for flood control at certain reservoirs in the plan area. USACE maintains flood operations plans and operating criteria for these reservoirs. Flow criteria are described in Chapter 2, *Water Resources*, in Section 2.4.3, *Flow Requirements*. As described in that section combined Merced River and Dry Creek flows must not exceed 6,000 cfs and Tuolumne River flood control releases cannot exceed 9,000 cfs below Dry Creek. The Stanislaus River cannot exceed 8,000 cfs and the LSJR flow at Vernalis cannot exceed 50,000 cfs.

U.S. Army Corps of Engineers Levee Safety Program

In 2006, the USACE implemented a new Levee Safety Program with a more comprehensive and rigorous levee inspection process to aid in communicating to local sponsors and the public the overall condition of levee systems and to recommend actions to reduce flood risk. The USACE Rehabilitation and Inspection Program provides for rehabilitation and/or repair of certain eligible (active status) levees that are damaged during flood events. This authority covers post flood repair of both federally authorized and/or constructed and non-federally constructed flood control works. Inspections of federal levees are funded and conducted under the Inspection of Completed Works (ICW) program. Inspection of non-federal levees are funded and conducted under the Rehabilitation and Inspection Program. As the subject levees in the LSJR and lowermost Stanislaus River that are within the plan area, are classified as federal levees, inspections are funded and conducted under the ICW program.

6.3.2 State

Relevant state programs, policies, plans, or regulations related to flood control and geomorphic conditions are described below.

Central Valley Flood Protection Board and Central Valley Flood Protection Plan

The California Central Valley Flood Protection Board (CVFPB) (formerly the California Reclamation Board) provides flood management for the Central Valley, including the Sacramento River and SJR and their tributaries. The CVFPB has established standards that apply to encroachments and work that affect authorized flood control projects, floodways, and any adopted plan of flood control. (Cal. Code Regs., tit. 23, §§ 111–138.)

The Central Valley Flood Protection Act of 2008 requires the California Department of Water Resources (DWR) to prepare, and the CVFPB to adopt, the Central Valley Flood Protection Plan (CVFPP) by 2012. The plan, which was adopted in June 2012, is intended to provide a system-wide approach to protecting areas currently protected by facilities of the State Plan of Flood Control. The regional and system improvements considered in the CVFPP are intended to address a number of potential physical threats to the existing flood management system. As described in the CVFPP, cities and counties within the Sacramento–San Joaquin Valley must update their general plans and zoning ordinances within 24 months to include information in the plan, and goals and measures consistent with the plan, to reduce the risk of flood damage.

6.3.3 Regional or Local

Local policies relevant to flood control and geomorphic condition within the three eastside tributaries, LSJR, and the Delta result from implementation of, or compliance with, federal and state requirements.

6.4 Impact Analysis

This section identifies the thresholds or significance criteria used to evaluate the potential impacts on flooding, sediment, and erosion. It further describes the methods of analysis used to determine significance. If any significant impacts are identified, measures to mitigate (i.e., avoid, minimize, rectify, reduce, eliminate, or compensate for) them are included in the impact discussion.

6.4.1 Thresholds of Significance

The thresholds for determining the significance of impacts for this analysis are based on the State Water Resources Control Board's (State Water Board's) Environmental Checklist in Appendix A of the Board's CEQA regulations. (Cal. Code Regs., tit. 23, §§ 3720–3781.) The thresholds derived from the checklist have been modified, as appropriate, to meet the circumstances of the alternatives. (Cal. Code Regs., tit. 23, § 3777, subd. (a)(2).) Certain flooding, sediment, and erosion impacts were determined to be potentially significant in the State Water Board's Environmental Checklist (see Appendix B, *State Water Board's Environmental Checklist*) and, therefore, are discussed in this analysis as to whether the alternatives could result in the following:

- Substantially alter the existing drainage pattern of the site or area, including through the alteration of the course of a stream or river, in a manner that would result in substantial erosion or siltation on- or off-site.
- Substantially alter the existing drainage pattern of the site or area, including through the alteration of the course of a stream or river, or substantially increase the rate or amount of surface runoff in a manner that would result in flooding on- or off-site.

In addition, if flooding on- or off-site would occur, the analysis identifies if people or structures would be exposed to a significant risk of loss, injury or death involving flooding. Where appropriate, specific quantitative or qualitative criteria are described in Section 6.4.2, *Methods and Approach*, for evaluating these thresholds.

As described in Appendix B, *State Water Board's Environmental Checklist,* the LSJR and SDWQ alternatives would result in either no impact or less-than-significant impacts on the following related to flooding, sediment, and erosion, and, therefore, are not discussed within this chapter.

- Place housing within a 100-year flood hazard area as mapped on a federal Flood Hazard Boundary or Flood Insurance Rate Map or other flood hazard delineation map.
- Place within a 100-year flood hazard area structures that would impede or redirect flood flows.
- Expose people or structures to a significant risk of loss, injury or death involving result of the failure of dam.
- Inundation by seiche, tsunami, or mudflow.

In addition, as described in Appendix B, *State Water Board's Environmental Checklist,* the alternatives would result in either no impact or less-than-significant impacts in the following categories related to geology and soils, and, therefore, the following areas are not discussed within this chapter.

- Expose people or structures to potential substantial adverse effects, including the risk of loss, injury, or death involving: rupture of a known earthquake fault, as delineated on the most recent Alquist-Priolo Earthquake Fault Zoning Map issued by the State Geologist for the area or based on other substantial evidence of a known fault; strong seismic ground shaking; seismic-related ground failure, including liquefaction; or landslides.
- Be located on expansive soil, as defined in Table 18-1-B of the Uniform Building Code (1994), creating substantial risks to life or property.
- Have soils incapable of adequately supporting the use of septic tanks or alternative waste water disposal systems where sewers are not available for the disposal of waste water.
- Be located on a geologic unit or soil that is unstable, or that would become unstable as a result of the project, and potentially result in an on- or off-site landslide, lateral spreading, subsidence, liquefaction or collapse.
- Result in substantial soil erosion or the loss of topsoil.

6.4.2 Methods and Approach

LSJR Alternatives

This chapter evaluates the potential flooding, sediment, and erosion impacts associated with the LSJR alternatives. Each LSJR alternative includes a February–June unimpaired flow[3] requirement (i.e., 20, 40, or 60 percent) and methods for adaptive implementation to reasonably protect fish and wildlife beneficial uses, as described in Chapter 3, *Alternatives Description*. In addition, a minimum base flow is required at Vernalis at all times during this period. The base flow may be adaptively implemented as described below and in Chapter 3. State Water Board approval is required before any method can be implemented, as described in Appendix K, *Revised Water Quality Control Plan*. All

---

[3] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.

methods may be implemented individually or in combination with other methods, may be applied differently to each tributary, and could be in effect for varying lengths of time, so long as the flows are coordinated to achieve beneficial results in the LSJR related to the protection of fish and wildlife beneficial uses.

The Stanislaus, Tuolumne, and Merced Working Group (STM Working Group) will assist with implementation, monitoring, and assessment activities for the flow objectives and with developing biological goals to help evaluate the effectiveness of the flow requirements and adaptive implementation actions. Further details describing the methods, the STM Working Group, and the approval process are included in Chapter 3 and Appendix K. Without adaptive implementation, flow must be managed such that it tracks the daily unimpaired flow percentage based on a running average of no more than 7 days. The four methods of adaptive implementation are described briefly below.

1. Based on best available scientific information indicating that more flow is needed or less flow is adequate to reasonably protect fish and wildlife beneficial uses, the specified annual February–June minimum unimpaired flow requirement may be increased or decreased to a percentage within the ranges listed below. For LSJR Alternative 2 (20 percent unimpaired flow), the percent of unimpaired flow may be increased to a maximum of 30 percent. For LSJR Alternative 3 (40 percent unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 30 percent or increased to a maximum of 50 percent. For LSJR Alternative 4 (60 percent unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 50 percent.
2. Based on best available scientific information indicating a flow pattern different from that which would occur by tracking the unimpaired flow percentage would better protect fish and wildlife beneficial uses, water may be released at varying rates during February–June. The total volume of water released under this adaptive method must be at least equal to the volume of water that would be released by tracking the unimpaired flow percentage from February–June.
3. Based on best available scientific information, release of a portion of the February–June unimpaired flow may be delayed until after June to prevent adverse effects on fisheries, including temperature, which would otherwise result from implementation of the February–June flow requirements. The ability to delay release of flow until after June is only allowed when the unimpaired flow requirement is greater than 30 percent. If the requirement is greater than 30 percent but less than 40 percent, the amount of flow that may be released after June is limited to the portion of the unimpaired flow requirement over 30 percent. For example, if the flow requirement is 35 percent, 5 percent may be released after June. If the requirement is 40 percent or greater, then 25 percent of the total volume of the flow requirement may be released after June. As an example, if the requirement is 50 percent, at least 37.5 percent unimpaired flow must be released in February–June and up to 12.5 percent unimpaired flow may be released after June. If after June the STM Working Group determines that conditions have changed such that water held for release after June should not be released by the fall of that year, the water may be held until the following year. See Chapter 3 and Appendix K for further details.
4. Based on best available scientific information indicating that more flow is needed or less flow is adequate to reasonably protect fish and wildlife beneficial uses, the February–June Vernalis base flow requirement of 1,000 cfs may be modified to a rate between 800 and 1,200 cfs.

The operational changes made using the adaptive implementation methods above may take place on either a short-term (for example monthly or annually) or longer-term basis. Adaptive implementation is intended to optimize flows to achieve the narrative objective, while allowing for consideration of other beneficial uses, provided that these other considerations do not reduce intended benefits to fish and wildlife.

The impact mechanisms for causing sediment transport or erosion and flooding include (1) increasing flows such that they cause substantial additional sediment (gravel and sand) transport or siltation and stream bank erosion (Impact FLO-1), and (2) increasing flows such that they exceed channel capacities and cause flooding outside the levees or floodway (Impact FLO-2). The impact analysis uses results from the State Water Board's WSE monthly model (presented in Chapter 5, *Surface Hydrology and Water Quality*, and Appendix F.1, *Hydrologic and Water Quality Modeling)*, to assess whether the LSJR alternatives would result in flooding, sediment transport, or erosion. Impacts were assessed by comparing the baseline flow results with the results for LSJR Alternatives 2, 3, and 4. The quantitative results included in the figures, tables, and text of this chapter present WSE modeling of the specified unimpaired flow requirement for each LSJR alternative (i.e., 20, 40, or 60 percent). The impact assessment addresses the expected changes in flows for the LSJR alternatives compared to channel capacities (as identified in Table 6-3). The entire set of WSE results for 1922–2003 was used to assess how frequently the channel capacities were exceeded (Table 6-9). Because exceedances were very rare, the wettest years were examined more thoroughly (Tables 6-10, 6-11, and 6-12).

Table 6-9. Percent of Months with WSE Model Results Greater than Capacity

cfs = cubic feet per second

[a] These are water years with the highest monthly modeled flow and highest unimpaired annual flow.

The LSJR alternatives do not involve physical changes to existing drainage patterns of the site or area, such as habitat restoration, dredging, or floodplain restoration, in a manner that would result in substantial erosion or siltation. The LSJR alternatives do not involve physical changes that substantially alter the existing drainage of the site or area, including through the alteration of the course of a stream or river, or substantially increase the rate or amount of surface runoff in a manner that would result in flooding on- or off-site. Accordingly, because the LSJR alternatives do not involve physical changes to the existing drainage or increases in surface runoff, there are no associated impacts and these issues are not addressed further.

This SED also evaluates whether the LSJR alternatives would substantially alter in-channel sediment transport (erosion) in a manner that would result in substantial erosion or siltation (FLO-1). The information in Tables 6-3 and 6-9 through 6-12 is used to determine if flows under the LSJR alternatives would cause excessive sediment transport and erosion. One intent of the LSJR alternatives is to increase within-channel sediment transport to enhance fish habitat, including spawning habitat. Consequently, some increased transport of gravel, sand and silt are likely to occur; the transport amount would be dependent on the expected flow under a specific alternative. Therefore, the analysis evaluates whether the LSJR alternatives are likely to have significant impacts by eroding stream banks and causing channel instability or levee collapse, or by moving so much sediment that excessive sedimentation (gravel and sand) or siltation (silt) is likely to occur (Impact

FLO-1). Excessive sedimentation is large amounts of sediment that contribute to channel instability or bury aquatic habitat.

This SED also evaluates whether the LSJR alternatives would substantially alter in-channel patterns and sediment transport in a manner that would result in flooding on- or off-site (FLO-2). Flooding is considered to occur at discharges greater than the channel capacities (Table 6-3), since flows greater than the channel capacities would inundate areas outside the levees or floodway (DWR 2010, 2011, 2012). As described in Chapter 3, *Alternatives Description*, the specified minimum unimpaired flow requirement for a particular LSJR alternative would cease to apply when flows would exceed levels that would cause or contribute to flooding or other related public safety concerns. The State Water Board would consult with appropriate federal, state and local agencies, including the reservoir operators, USBR, and USACE, in making its determination whether the specified minimum unimpaired flow requirements would apply. The NWS action stage of the rivers, i.e., the point on a rising stream at which some type of action should be taken in preparation for possible significant hydrologic activity (e.g., preventing access to or evacuating low-lying areas adjacent to a river), is a reasonable proxy for the purposes of this SED analysis to describe the flows above which the unimpaired flow requirements may not apply as a result of public safety concerns (Impact FLO-2). Action stages for each river are identified in Table 6-4, and are generally considerably lower than the estimated channel capacity.

This chapter also incorporates a qualitative discussion of adaptive implementation under each of the LSJR alternatives that includes the potential environmental effects associated with adaptive implementation. To inform the qualitative discussion and account for the variability allowed by adaptive implementation, modeling was performed to predict conditions at 30 percent and 50 percent of unimpaired flow (as reported in Appendix F.1). The modeling also allows some inflows to be retained in the reservoirs until after June, as could occur under method 3, to prevent adverse temperature effects. This variety of modeling scenarios provides information to support the analysis and evaluation of the effects of the alternatives and adaptive implementation. This chapter incorporates a qualitative discussion of the potential flooding, sediment, and erosion impacts of adaptive implementation under each of the LSJR alternatives. For more information regarding the modeling methodology and quantitative flow and temperature modeling results, see Appendix F.1, *Hydrologic and Water Quality Modeling*.

The Stanislaus River has experienced seepage in some locations where agricultural production occurs at flows greater than 1,500 cfs. Therefore, the WSE model was used to calculate the percentage of monthly flows greater than 1,500 cfs under baseline and compared to the LSJR alternatives. Tables 6-13 and 6-14 show that under baseline, flows greater than 1,500 cfs occur at Goodwin and Ripon 27 and 28 percent of the time, respectively, in March; 46 and 52 percent of the time, respectively, in April; and 40 and 43 percent of the time, respectively, in May. This information is used to evaluate effects on stream bank erosion on the Stanislaus River in Impact FLO-1. Note that this seepage has not resulted in surface inundation (flooding). The impacts associated with underseepage on agricultural production are addressed in Chapter 11, *Agricultural Resources*.

Table 6-13. Percentage of Monthly Flows Greater than 1,500 cfs, Stanislaus River at Goodwin

Month/ Alternative	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Average Percent
Baseline	1	2	2	6	7	29	43	40	5	1	2	4	11
LSJR Alternative 2	1	2	4	7	10	33	34	33	2	1	5	5	11
LSJR Alternative 3	0	2	2	6	10	26	41	57	13	1	1	2	13
LSJR Alternative 4	0	1	1	4	21	29	65	76	39	1	0	1	19

cfs = cubic feet per second

Table 6-14. Percentage of Monthly Flows Greater Than 1,500 cfs, Stanislaus River at Ripon

Month/ Alternative	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Average Percent

LSJR Alternative 4	1	1	1	4	22	29	73	83	51	2	1	1	22

cfs = cubic feet per second

Flood Control Operations at the Reservoirs

The same flood control curves and daily operations would be used for actual operations of the three reservoirs under the LSJR alternatives as under the baseline. Although the monthly reservoir operations during the February–June period would be slightly different under the LSJR alternatives, the same end of month flood control storage space rules would apply and the same need for daily flood control releases would apply during major rainfall runoff events. Some of the LSJR alternatives would release more water than the baseline earlier in the year, and the storage would be reduced so that flood control releases that might have occurred under baseline conditions would be delayed and/or reduced. The daily releases could vary between the LSJR alternatives, but in general the maximum flood control release would not be increased. Therefore, periodic high flood flows during major storms on each of the three eastside tributaries would be nearly the same as the flood control releases under baseline.

Extended Plan Area

The analysis of the extended plan area generally identifies how the impacts may be similar to or different from the impacts in the plan area (i.e., downstream of the rim dams) depending on the similarity of the impact mechanism (e.g., changes in reservoir levels, reduced water diversions, and additional flow in the rivers) or location of potential impacts in the extended plan area. Where appropriate, the program of implementation is discussed to help contextualize the potential impacts in the extended plan area.

SDWQ Alternatives

As discussed in Chapter 5, *Surface Hydrology and Water Quality*, and Appendix B, *State Water Board's Environmental Checklist*, the baseline water quality in the southern Delta generally ranges from 0.2 dS/m and 1.2 dS/m during all months of the year. There is a strong relationship between salinity at Vernalis and salinity in the southern Delta, which generally increases by a maximum of 0.2 dS/m above the Vernalis salinity. Seasonal and inter-annual fluctuations in salinity in the southern Delta as a result of SDWQ Alternatives 2 or 3 are expected to be similar to historic fluctuations because the USBR's water rights would continue to be conditioned to meet the existing Vernalis electrical conductivity (EC)[4] requirement in through the program of implementation, thereby maintaining flows. Therefore, they are not discussed further in this chapter. To comply with specific water quality objectives or the program of implementation under SDWQ Alternatives 2 or 3, construction and operation of different facilities in the southern Delta could occur, which could involve impacts on biological resources. These impacts are evaluated in Chapter 16, *Evaluation of Other Indirect and Additional Actions.*

6.4.3 Impacts and Mitigation Measures

Impact FLO-1: Substantially alter the existing drainage pattern of the site or area, including through the alteration of the course of a stream or river, in a manner that would result in substantial erosion or siltation on- or off-site

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 *Water Quality Control Plan for the San Francisco Bay/Sacramento-San Joaquin Delta Estuary* (2006 Bay-Delta Plan). See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

---

[4] In this document, EC is *electrical conductivity*, which is generally expressed in deciSiemens per meter (dS/m). Measurement of EC is a widely accepted indirect method to determine the salinity of water, which is the concentration of dissolved salts (often expressed in parts per thousand or parts per million). EC and salinity are therefore used interchangeably in this document.

LSJR Alternatives

Sediment (gravel and sand) transport can undermine stream banks or levees, thus potentially altering the existing drainage patterns. The transport of gravel and sand and the effect on stream bank or levee stability typically occur at higher flows generally either near channel capacities or exceeding channel capacities; therefore, they are discussed together in the impact analysis below. Silt materials are more easily transported than gravel and sand and silt transport does not influence stream bank or levee stability. However, excessive silt erosion and transport could alter the existing drainage pattern of a site by causing excessive siltation within fish spawning gravels or elsewhere; therefore, it is discussed separately from gravel and sand transport in the impact analysis below.

LSJR Alternative 2 (Less than significant/Less than significant with adaptive implementation)

Gravel and Sand Erosion

The amount of sediment transport and bank erosion under LSJR Alternative 2 would be similar to existing conditions. Sediment transport and erosion would be restricted by flood control activities, existing action stages, and existing bank armoring on the rivers. Consequently, no significant impact would occur with respect to the amount of sand and gravel transported, or bank erosion. Similarly, although there are identified levee stability issues along the LSJR and within the Delta (DWR 2010, 2011, 2012), the expected amount of gravel and sand transported under LSJR Alternative 2 would not be large enough to contribute to levee instability.

The existing stream channels transport the coarsest sediment at flows near channel capacities or exceeding channel capacities. The flows associated with LSJR Alternative 2, even when cumulated downstream from each of the eastside tributaries, are almost always substantially lower than the channel capacities in these river reaches and the Delta (Table 6-3 and Figure 6-3). Therefore, the amount of coarse sediment transported at higher flows would be limited under LSJR Alternative 2.

The range of flows associated with LSJR Alternative 2 is similar to flows that occur under baseline conditions. Only two of the water years simulated by the WSE model, 1983 and 1997, had monthly flows that exceeded channel capacities on the Stanislaus, Tuolumne, or Merced Rivers or the SJR (Table 6-9). These exceedances, which resulted from large storm events that led to flood control releases, also occurred under baseline conditions. Therefore, the amount of coarse sediment transported at higher flows under LSJR Alternative 2 is expected to be similar to baseline conditions.

Tables 6-10, 6-11, and 6-12 show the monthly peak flows from the WSE modeling results for the three eastside tributaries during the wettest years and the percent of channel capacity for each flow based on Table 6-3 and Figure 6-3. These peak flood control flows are the flows that are most likely to transport coarse sediment and cause substantial erosion. Under LSJR Alternative 2, peak monthly flows in the three eastside tributaries would be similar to baseline peak flows because they result from flood control actions. Therefore, the monthly releases simulated by the WSE model for meeting the unimpaired flow objectives generally equaled or remained below the baseline peak monthly flood control releases and would not transport any more gravel and sand than is currently transported. The cumulative flow additions from the three eastside tributaries to the LSJR are substantially below its channel capacity, which ranges between 37,000 cfs and 52,000 cfs (Figure 6-3; Tables 6-10, 6-11, 6-12). These small flow additions would not increase coarse sediment transport in the LSJR.

The monthly peak flows from the WSE model would not exceed the action stage, which is lower than the channel capacity (Table 6-4), further restricting sediment transport and erosion under LSJR Alternative 2. There may be circumstances in which the specified minimum unimpaired flow requirement would not apply when flows would exceed levels that would cause or contribute to flooding or other related public safety concerns; however, the decisions regarding these flow levels would vary by river and would involve consultation between the State Water Board and appropriate federal, state, and local agencies as described in Section 6.4.2, *Methods and Approach*.

Varying amounts of bank armoring to reduce stream bank erodibility also occur along the three eastside tributaries (McBain and Trush 2000; Kondolf et al. 2001; Stillwater Sciences 2001). This bank armoring further limits the potential bank erosion under higher baseline flows and flows under LSJR Alternative 2.

Excessive seepage could undermine the riverbank, which has the potential to cause localized stream bank erosion. However, this type of seepage would not result in surface inundation. There have been documented seepage concerns on the Stanislaus River. On the Stanislaus River for flows greater than 1,500 cfs, Tables 6-13 and 6-14 show little change under LSJR Alternative 2, both on a month-by-month and overall average basis. The volume and rate of the resulting seepage would not be sufficient to transport sediment or particles; hence, would not have any effect on stream bank erosion. Furthermore, the flows themselves are not sufficient to cause additional erosion (i.e., flows that cause erosion are known to occur above 3,000 or 4,000 cfs).

Given the range of flows expected under LSJR Alternative 2, existing channel capacities, action stages, and bank armoring, impacts related to sediment transport or bank erosion would be less than significant.

Siltation

With respect to siltation (the deposition of suspended sediment or turbidity), the effects of LSJR Alternative 2 would be generally similar to those discussed above for gravel and sand erosion and be similar to baseline conditions. Higher flows, when they do occur, would transport larger amounts of fine sediment in suspension. Under LSJR Alternative 2, peak flows in the three eastside tributaries would be similar to baseline peak flows because those peak flows result from flood control actions. Therefore, LSJR Alternative 2 would not cause substantial siltation within the eastside tributaries or the LSJR. Consequently, impacts would be less than significant.

Adaptive Implementation

Based on best available scientific information indicating that a change in the percent of unimpaired flow is needed to reasonably protect fish and wildlife, adaptive implementation method 1 would allow an increase of up to 10 percent over the 20 percent February–June unimpaired flow requirement (to a maximum of 30 percent of unimpaired flow). A change to the percent of unimpaired flow would take place based on required evaluation of current scientific information and would need to be approved as described in Appendix K. Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time. However, an increase of up to 30 percent of unimpaired flow would potentially result in different effects as compared to 20 percent unimpaired flow, depending upon flow conditions and frequency of the adjustment. For example, an increase of up to 30 percent unimpaired flow would generally result in an increase in the volume of water in the rivers than would occur under 20 percent of unimpaired flow at those times of increased releases/flows. But as discussed above, peak flows are associated with flood control releases, not releases to meet LSJR Alternative 2 requirements, and are not expected to substantially change. In addition, it is expected flows would remain in channel capacities with a potential increase in the specified unimpaired flow requirement from 20 percent to 30 percent. Thus, adaptive implementation method 1 would not result in a substantial increase in erosion or siltation.

Based on best available scientific information indicating that a change in the timing or rate of unimpaired flow is needed to reasonably protect fish and wildlife, adaptive implementation method 2 would allow changing the timing of the release of the volume of water within the February–June time frame. While the total volume of water released February–June would be the same as LSJR Alternative 2 without adaptive implementation, the rate could vary from the actual (7-day running average) unimpaired flow rate. Method 2 would not authorize a reduction in flows required by other agencies or through other processes, which are incorporated in the modeling of baseline conditions. Changes in the timing of flows released from February–June adaptive implementation method 2 would not exceed peak flows experienced under baseline conditions, and therefore would not substantially result in increased erosion or siltation compared to baseline. In addition, during big storm events, the full specified percent unimpaired flow would not apply when projected flows under LSJR Alternative 2 would exceed levels that would cause or contribute to flooding or other related public safety concerns and therefore a substantial increase erosion or siltation would not occur relative to baseline.

Method 3 would not be authorized under LSJR Alternative 2 since the unimpaired flow percentage would not exceed 30 percent; therefore, adaptive implementation method 3 would not affect erosion or siltation.

Adaptive implementation method 4 would allow an adjustment of the Vernalis February–June flow requirement. The WSE model results show that under LSJR Alternative 2 the 1,200-cfs February–June base flow requirement at Vernalis would require a flow augmentation in the three eastside tributaries and LSJR only 2.7 percent of the time in the 82-year record analyzed. Similarly, flow augmentation would be required 0.7 percent of the time to meet a 1,000-cfs requirement and 0.5 percent of the time for an 800-cfs Vernalis base flow requirement. These results indicate that changes due to adaptive implementation method 4 under this alternative would rarely alter the flows in the three eastside tributaries or the LSJR.

Impacts associated with adaptive implementation method 1 may be slightly different from those associated with methods 2 and 3. With method 1, if the specified percent of unimpaired flow were changed from 20 percent to 30 percent on a long-term basis, the conditions and impacts could become more similar to those described under LSJR Alternative 3. It is anticipated that over time the unimpaired flow requirement could increase or not change at all within a year or between years, depending on fish and wildlife conditions and hydrology. If adaptive implementation method 2 is implemented, the total annual volume of water associated with LJSR Alternative 2 (i.e., 20 percent of the February–June unimpaired flow) would not change, but the timing or magnitude of flows might change. However, since monthly peak flows would not be substantially different than baseline, and flows would remain within channel capacities, the potential for additional erosion or siltation effects is similar to the results presented above for LSJR Alternative 2 without adaptive implementation. Implementing method 4 is expected to have little effect on conditions in the three eastside tributary rivers and LSJR because it rarely would cause a change in flow and the volume of water involved would be relatively small. Consequently the impact determination of LSJR Alternative 2 with adaptive implementation would be the same as described for LSJR Alternative 2 without adaptive implementation for erosion and siltation. Impacts would be less than significant.

LSJR Alternative 3 (Less than significant/Less than significant with adaptive implementation)

Gravel and Sand Erosion

The range of flows associated with LSJR Alternative 3 is similar to flows that occur under baseline conditions. Sediment transport and erosion would be restricted by flood control activities, existing action stages, and existing bank armoring on the rivers. Consequently, no significant impact would occur with respect to sediment transport or bank erosion. Similarly, although there are a variety of levee stability issues identified along the LSJR and Delta (DWR 2010, 2011, 2012), the expected amount of gravel and sand transported is not large enough to contribute to levee instability.

The existing stream channels transport the most coarse sediment) at higher flows. The flows associated with LSJR Alternative 3, even when cumulated downstream from each of the three eastside tributaries, are almost always substantially lower than the channel capacities in these river reaches and the southern Delta (Table 6-3 and Figure 6-3). This result applies even considering the lower channel capacity estimates from DWR for some reaches (2011, Table 6-3). Therefore, the amount of coarse sediment transported at higher flows would generally be limited under LSJR Alternative 3.

The range of flows associated with LSJR Alternative 3 would be similar to flows that occur under baseline conditions. Only two of the water years simulated by the WSE model, 1983 and 1997, had monthly flows that exceeded channel capacities on the Stanislaus, Tuolumne, and Merced Rivers or the SJR (Table 6-9). These exceedances, which resulted from large storm events that led to flood control releases, also occurred under baseline conditions. Therefore, the amount of gravel transported at higher flows under LSJR Alternative 3 is expected to be similar to baseline conditions.

Tables 6-10, 6-11, and 6-12 show the monthly peak flows from the WSE model results for the three eastside tributaries during the wettest years and show the percent of channel capacity for each flow based on Table 6-3 and Figure 6-3. The cumulative flow additions from the three eastside tributaries to the LSJR are substantially below its channel capacity, which ranges between 37,000 cfs and 52,000 cfs (Figure 6-3; Tables 6-10, 6-11, 6-12). These small flow additions would not increase coarse sediment transport in the LSJR. Under LSJR Alternative 3 peak monthly flows in the three eastside tributaries would seldom be sufficient to cause gravel transport in the upper gravel-bedded reaches (i.e., minimum flows in the range of 5,000–8,000 cfs [Stanislaus River], 7,000–9,800 cfs [Tuolumne River], and 4,800 cfs [Merced River]) and in-stream bank erosion. Additionally, the action stage is lower than the gravel transport flow levels in the Tuolumne River (6,600 cfs) and Merced River (3,200 cfs), thus actions to reduce flood risk under high flow conditions would also limit potential gravel transport. For the Stanislaus River the action stage coincides with flow levels that would allow gravel transport to occur. These high flow levels on the three eastside rivers would primarily be associated with peak flows during storm events under LSJR Alternative 3; therefore, they would generate a relatively small amount of stream bank erosion due to their low frequency of occurrence. Furthermore, any gravel movement that would occur is known to be beneficial for aquatic habitat enhancement (McBain and Trush 2000; Kondolf et al. 2001; Stillwater Sciences 2001, 2004). Chapter 7, *Aquatic Biological Resources*, includes a discussion of the importance of gravel transport for fish habitat maintenance.

As discussed under LSJR Alternative 2, varying amounts of bank armoring also occur along the three eastside tributaries. This further limits the potential for bank erosion to occur (McBain and Trush 2000; Kondolf et al. 2001; Stillwater Sciences 2001).

Sand transport begins at relatively low flows so that in the mid- to lower sand-bedded portions of the three eastside tributaries, flows greater than 2,000–3,000 cfs would increase sand movement (Hickin n.d.). However, the largest total amount of sand transport is associated with moderate to peak flows (Wolman and Leopold 1960), and the LSJR Alternative 3 flows would generate a small amount of total additional sand movement, which would be considered less than significant. Furthermore, any sand movement that would occur is known to be a contributing factor to the amount and diversity of aquatic habitat in these reaches and would be considered an enhancement to the aquatic habitat environment (Chapter 7, *Aquatic Biological Resources*).

Excessive seepage could undermine the riverbank, which has the potential causing localized stream bank erosion. This type of seepage would not result in surface inundation. There have been documented seepage concerns on the Stanislaus River. On the Stanislaus River for flows greater than 1,500 cfs, Tables 6-13 and 6-14 show that under LSJR Alternative 3, some months would have decreases in the frequency of flows above 1,500 cfs and some would have increases compared to baseline, but on average there would be moderate increases. As simulated by the WSE model, the overall average percent of months with flow greater than 1,500 cfs would increase by 1 percent at Goodwin and 2 percent at Ripon under LSJR Alternative 3, with the largest increases occurring May–June. These flows may cause localized underseepage to adjacent agricultural lands based on historical accounts. The associated seepage would not have an effect on stream bank erosion because the expected volume and rate of the seepage would not be sufficient to transport sediment or particles. Furthermore, the flows themselves are not sufficient to cause additional erosion (i.e., flows that cause erosion are known to occur above 3,000 or 4,000 cfs).

Given the range of flows expected under LSJR Alternative 3, existing channel capacities, action stages, and bank armoring, impacts related to sediment transport or bank erosion would be less than significant.

Siltation

With respect to siltation (deposition of suspended sediment or turbidity) the effects of LSJR Alternative 3 would be generally similar to those discussed above for gravel and sand transport and erosion. Peak monthly flows are not expected to change significantly compared to baseline conditions. Infrequent high flows would transport larger amounts of fine sediment in suspension than under lower flows. Therefore, LSJR Alternative 3 would not result in substantial siltation within the three eastside tributaries or the SJR. Consequently, impacts would be less than significant.

Adaptive Implementation

Under LSJR Alternative 3, impacts associated with adaptive implementation method 1 may be slightly different from those associated with adaptive implementation methods 2 and 3.

Implementing method 1 would allow an increase or decrease of up to 10 percent in the February–June, 40 percent unimpaired flow requirement (with a minimum of 30 percent and maximum of 50 percent) to optimize implementation measures to meet the narrative objective, while considering other beneficial uses, provided that these other considerations do not reduce intended benefits to fish and wildlife. Adaptive implementation must be approved using the process described in Appendix K. Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time. Adaptive implementation method 1 could affect the amount of water available for water supply and the volume of water and level of flow in the LSJR and its tributaries. However, the frequency and duration of such a change is unknown. If the specified percent of unimpaired flow were changed from 40 percent to 30 percent or 40 percent to 50 percent on a long-term basis, the conditions and impacts could become more similar to LSJR Alternatives 2 or 4, respectively. It is anticipated that over time the unimpaired flow requirement could increase, decrease, or not change at all within a year or between years, depending on fish and wildlife conditions and hydrology. As described in LSJR Alternatives 2 and 3, a change to the percent of unimpaired flow could affect the volume of water and level of flow in the LSJR and its tributaries; however, peak flows and flood control actions are not expected to change substantially under this range of unimpaired flows.

Under adaptive implementation methods 2 or 3, the overall volume of water from the February–June time period or after June would be the same as LSJR Alternative 3 without adaptive implementation, but the volume within each month could vary. Impacts associated with the total volume of water would not be affected by method 2 or 3, but sediment and erosion, which can be dependent on the timing or magnitude of flow, could potentially be affected. Although, the volume of water would be substantially greater in the eastside tributary rivers when compared to baseline conditions, the peak monthly flows would not be substantially different compared to baseline. Similarly, the water volumes that might be shifted under adaptive implementation methods 2 and 3 are small in comparison to peak monthly flows and the effects on sediment and erosion would be small. In addition, adaptive implementation method 3, which allows flow shifting from the February–June time frame to other times of year is incorporated into the modeling; thus, the range of erosion and siltation effects is reflected in the results presented above for LSJR Alternative 3. Finally, given that these two methods would not allow flows to go below what is required by existing requirements on the three eastside tributaries and the SJR, impacts would be similar to those described for LSJR Alternative 3 without adaptive implementation.

Implementing method 4 is expected to have little effect on conditions in the three eastside tributary rivers. The WSE model results show that under Alternative 3 the 1,200-cfs February–June base flow requirement at Vernalis would require a flow augmentation in the three eastside tributaries and LSJR only 1.2 percent of the time in the 82-year record analyzed. Similarly, flow augmentation would be required only 0.2 percent of the time to meet either a 1,000-cfs or 800-cfs Vernalis base flow requirement. These results indicate that method 4 would rarely alter the flows in the three eastside tributaries or the LSJR under this alternative.

Consequently the impact determination of LSJR Alternative 3 with adaptive implementation would be the same as described for LSJR Alternative 3 without adaptive implementation, for erosion and siltation. Impacts would be less than significant.

LSJR Alternative 4 (Less than significant/Less than significant with adaptive implementation)

Gravel and Sand Erosion

The range of flows associated with LSJR Alternative 4 is similar to flows that occur under baseline conditions. Sediment transport and erosion would be restricted by flood control activities, existing action stages, and existing bank armoring on the rivers. Consequently, no significant impact would occur with respect to sediment transport or bank erosion-. Similarly, although there are a variety of levee stability issues identified along the LSJR and Delta (DWR 2010, 2011, 2012), the expected amount of gravel transport is not large enough to contribute to levee instability.

The existing stream channels transport the coarsest sediment at higher flows. The flows associated with LSJR Alternative 4, even when cumulated downstream from each of the eastside tributaries, are almost always substantially lower than the channel capacities in these river reaches and the southern Delta (Table 6-3 and Figure 6-3). This result applies even considering the lower channel capacity estimates from DWR for some reaches (2011, Table 6-3). Therefore, the amount of coarse sediment transported at higher flows would generally be limited under LSJR Alternative 4.

The range of flows associated with LSJR Alternative 4 would be similar to flows that occur under baseline conditions. Only two of the water years simulated by the WSE model, 1983 and 1997, had monthly peak flows that exceeded channel capacities on the Stanislaus, Tuolumne or Merced Rivers or the SJR (Table 6-9). These exceedances, which resulted from large storm events that led to flood control releases, also occurred under baseline conditions as well as under LSJR Alternative 4, with the exception of the January 1997 exceedance on the Stanislaus River. This exceedance occurred only in the baseline modeling results and not the LSJR Alternative 4 results, due to lower reservoir storage in LSJR Alternative 4, which led to lower required flow releases at the time.

Tables 6-10, 6-11, and 6-12 show the monthly peak flows from the WSE model results for the three eastside tributaries during the wettest years and show the percent of channel capacity for each flow based on Table 6-3 and Figure 6-3. The cumulative flow additions from the three eastside tributaries to the LSJR are substantially below its channel capacity, which ranges between 37,000 cfs and 52,000 cfs (Figure 6-3; Tables 6-10, 6-11, 6-12). These small flow additions would not increase coarse sediment transport in the LSJR. The peak flows in the three eastside tributaries would occasionally be sufficient to cause gravel transport in the upper gravel-bedded reaches (i.e., minimum flows in the range of 5,000–8,000 cfs [Stanislaus River], 7,000–9,800 cfs [Tuolumne River] and 4,800 cfs [Merced River]) and some in-stream bank erosion. Additionally, the stage actions are lower than the gravel transport flow levels in the Tuolumne River (6,600 cfs) and Merced River (3,200 cfs). Thus actions to reduce flood risk under high flow conditions would also limit potential gravel transport. For the Stanislaus River the action stage would allow gravel transport to occur. These high flow levels on the three eastside tributaries would primarily be associated with peak flows during storm events under LSJR Alternative 4; therefore, they would generate a relatively small amount of stream bank erosion due to their low frequency of occurrence. Furthermore, any gravel movement that would occur is known to be beneficial for aquatic habitat enhancement (Chapter 7, *Aquatic Biological Resources*; McBain and Trush 2000; Kondolf et al. 2001; Stillwater Sciences 2001, 2004).

As discussed under LSJR Alternative 2, varying amounts of bank armoring also occur along the three eastside tributaries. This further limits the potential for bank erosion to occur (McBain and Trush 2000; Kondolf et al. 2001; Stillwater Sciences 2001).

Sand transport begins at relatively low flows so that in the mid- to lower sand-bedded portions of the three eastside tributaries, flows greater than 2,000–3,000 cfs would increase sand movement (Hickin n.d.). However, the largest total amount of sand transport is associated with moderate to peak flows (Wolman and Miller 1960), and the LSJR Alternative 2 flows would generate a small amount of total additional sand movement, which would be considered less than significant. Furthermore, this movement is known to be a contributing factor to the amount and diversity of aquatic habitat in these reaches and would be considered an enhancement to the aquatic habitat environment (Chapter 7, *Aquatic Biological Resources*).

Excessive seepage could undermine the riverbank, which has the potential causing localized stream bank erosion. This type of seepage does not result in surface inundation. There have been documented seepage concerns on the Stanislaus River. On the Stanislaus River for flows greater than 1,500 cfs, Tables 6-13 and 6-14 show that under LSJR Alternative 4, some months would have decreases in the frequency of flows above 1,500 cfs and some would have increases compared to baseline, but on average there would be moderate increases. As simulated by the WSE model, the overall average percent of months with flow greater than 1,500 cfs would increase by 7 percent at Goodwin and 8 percent at Ripon under LSJR Alternative 4, with the largest increases occurring April–June. These flows may cause localized underseepage to adjacent agricultural lands. The associated seepage would not have an effect on stream bank erosion because the volume and rate of water expected would not be sufficient to transport sediment or particles. Furthermore, the flows themselves are not sufficient to cause additional erosion (i.e., flows that cause erosion are known to occur above 3,000 or 4,000 cfs).

Given the range of flows expected under LSJR Alternative 4, existing channel capacities, action stages, and bank armoring, impacts related to sediment transport or bank erosion would be less than significant.

Siltation

With respect to siltation (desposition of suspended sediment or turbidity), the effects of LSJR Alternative 4 would be generally similar to those discussed above for gravel and sand transport or erosion Peak monthly flows are not expected to change significantly compared to baseline conditions. Infrequent high flows would transport larger amounts of fine sediment in suspension than under lower flow conditions. Therefore, LSJR Alternative 4 would not result in substantial siltation within the three eastside tributaries or the SJR. Consequently, impacts would be less than significant.

Adaptive Implementation

Under LSJR Alternative 4, impacts associated with adaptive implementation method 1 may be slightly different from those associated with methods 2 and 3. Adaptive implementation method 1 would allow a decrease of up to 10 percent in the annual February–June 60 percent unimpaired flow (to 50 percent) to optimize implementation measures to meet the narrative objective, while considering other beneficial uses, provided that these other considerations do not reduce intended benefits to fish and wildlife. Adaptive implementation must be approved using the process described in Appendix K. Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time. If the specified percent unimpaired flow were changed from 60 percent to 50 percent on a long-term basis, the conditions and impacts could become more similar to LSJR Alternative 3. It is anticipated that over time the unimpaired flow requirement could decrease or not change at all within a year or between years, depending on fish and wildlife conditions and hydrology.

Adaptive implementation method 2 or 3 would shift the timing of the river flows within the February–June time frame or after June. This adaptive implementation method would not affect the total volume of water, but as described above for LSJR Alternative 3, adjustments in the timing or magnitude of the flows could affect erosion and sedimentation. Although the volume of water would be substantially greater in the eastside tributary rivers when compared to baseline conditions, the peak monthly flows would not be substantially different compared to baseline. In addition, given that these two methods would not allow flows to go below what is required by existing requirements on the three eastside tributaries and the SJR, impacts would be similar to those described for LSJR Alternative 3 without adaptive implementation.

Implementing method 4 is expected to have little effect on conditions in the three eastside tributary rivers and LSJR. The WSE model results show that under Alternative 4 the 1,200-cfs February–June base flow requirement at Vernalis would require a flow augmentation in the three eastside tributaries and LSJR only 0.7 percent of the time in the 82-year record analyzed. Similarly, flow augmentation would be required only 0.2 percent of the time to meet a 1,000-cfs requirement and is not affected at all for an 800-cfs requirement. These results indicate that method 4 would rarely alter the flows in the three eastside tributaries or the LSJR under this alternative.

Consequently the impact determination of LSJR Alternative 4 with adaptive implementation would be the same as described for LSJR Alternative 4 without adaptive implementation for erosion and siltation. Impacts would be less than significant.

Impact FLO-2: Substantially alter the existing drainage pattern of the site or area, including through the alteration of the course of a stream or river, or substantially increase the rate or amount of surface runoff in a manner that would result in flooding on- or off-site

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

LSJR Alternative 2 (Less than significant/Less than significant with adaptive implementation)

LSJR Alternative 2 has the potential to affect the management of reservoir releases from the rim dams into the three eastside tributaries. Peak monthly flows are not expected to change substantially under LSJR Alternative 2. Only two of the water years simulated by the WSE model, 1983 and 1997, had monthly flows that exceeded channel capacities on the Stanislaus, Tuolumne or Merced Rivers or the LSJR (Table 6-9). These exceedances, which resulted from flood control releases due to large storm events, occurred under baseline conditions as well as under LSJR Alternative 2. Tables 6-10, 6-11, and 6-12 show the monthly peak flows from the WSE modeling results for the three eastside tributaries during the wettest years. These tables also show the percent of channel capacity for each flow based on Table 6-3 and Figure 6-3. Peak monthly flows under LSJR Alternative 2 are not expected to change, and generally remain within the channel capacity for the three eastside tributaries.

Since the flow objectives would generally not affect flood control storage capacity, as flood flow releases would still be made, and would not affect the USACE flood reservation, there would not be any changes in flood control operation procedures during major flood events. Under LSJR

Alternative 2, for most months, monthly median flows for the Stanislaus, Tuolumne, and Merced Rivers and the LSJR do not vary substantially from the modeled baseline median monthly flows (Tables 5-17a). Additionally, the peak monthly flow resulted from the WSE model would not exceed the action stage (Table 6-4) and would not apply when flows would exceed levels that would cause or contribute to flooding or other related public safety concerns as described in Section 6.4.2, *Methods and Approach*. This would further limit flooding under LSJR Alternative 2. LSJR Alternative 2 would not substantially alter existing drainage patterns or substantially increase the rate or amount of surface runoff in a manner that would result in flooding. Consequently, LSJR Alternative 2 would not expose people or structures to a significant risk of loss, injury or death involving flooding as noted in Section 6.4.1, *Thresholds of Significance*.

Adaptive Implementation

Adaptive implementation methods 1, 2, and 4 are not anticipated to substantially alter existing drainage patterns or substantially increase the rate or amount of surface runoff in a manner that would result in flooding. As described in Impact FLO-1, peak flows associated with flood control are not expected to substantially change. Thus, with a potential increase in the specified unimpaired flow requirement from 20 percent to 30 percent (i.e., method 1), it is expected flows would remain in channel capacities. A shift in timing or magnitude of flows under methods 2 is not expected to alter existing drainage patterns or substantially increase the rate or amount of surface runoff because the water volumes that might be shifted under these methods are small in comparison to peak monthly flows and the effects on sediment and erosion would be small. Therefore, impacts would be less than significant.

LSJR Alternative 3 (Less than significant/Less than significant with adaptive implementation)

LSJR Alternative 3 has the potential to affect management of reservoir releases from the rim dams into the three eastside tributaries. Peak monthly flows are not expected to change substantially under LSJR Alternative 3. Only two of the water years simulated by the WSE model, 1983 and 1997, had monthly flows that exceeded channel capacities on the Stanislaus, Tuolumne and Merced Rivers or the SJR (Table 6-9). These exceedances, which resulted from flood control releases due to large storm events, occurred under baseline conditions as well as under LSJR Alternative 3. Tables 6-10, 6-11, and 6-12 show the monthly peak flows from the WSE modeling results for the three eastside tributaries during the wettest years. These tables also show the percent of channel capacity for each flow based on Table 6-3 and Figure 6-3.

For the LSJR, the Delta, and the three eastside tributaries, the LSJR Alternative 3 flows are almost always substantially lower than the channel capacities in these river reaches and the southern Delta (Table 6-3 and Figure 6-3, and Tables 6-10, 6-11, and 6-12), even when considering the lower channel capacity estimates from DWR for some reaches (2011, Table 6-3). Since these channels are capable of carrying much higher flows, these flows would be contained within the existing floodway, and no significant impact would occur with respect to flooding. Furthermore, because the flow objectives would generally not affect flood control storage capacity, since flood flow releases would still be made, and would not affect the USACE flood reservation, there would not be any changes in flood control operation procedures during major flood events. Additionally, the peak monthly flows would not exceed the action stage (Table 6-4)and would not apply when flows would exceed levels that would cause or contribute to flooding or other related public safety concerns, as described in Section 6.4.2, *Methods and Approach*. This would further limit flooding under LSJR Alternative 3.

LSJR Alternative 3 would not substantially alter existing drainage patterns or substantially increase the rate or amount of surface runoff in a manner that would result in flooding. Consequently, LSJR Alternative 3 would not expose people or structures to a significant risk of loss, injury or death involving flooding as noted in Section 6.4.1, *Thresholds of Significance*.

Adaptive Implementation

Adaptive implementation methods 1, 2, 3, and 4 are not anticipated to substantially alter the existing drainage pattern or increase the rate of surface runoff in a manner that would result in flooding. As described in Impact FLO-1, peak flows associated with flood control are not expected to substantially change. Thus, with a potential increase or decrease in the specified unimpaired flow requirement from 40 percent to either 30 percent or 50 percent (i.e., method 1), it is expected flows would remain in channel capacities. Similarly, a shift in timing or magnitude of flows under methods 2 or 3 is not expected to alter existing drainage patterns or substantially increase the rate or amount of surface runoff because the water volumes that might be shifted under these methods are small in comparison to peak monthly flows and the effects on sediment and erosion would be small. Therefore, impacts would be less than significant.

LSJR Alternative 4 (Less than significant/Less than significant with adaptive implementation)

LSJR Alternative 4 has the potential to affect management of reservoir releases from the rim dams into the three eastside tributaries. Peak monthly flows are not expected to change under LSJR Alternative 4. Only two of the water years simulated by the WSE model, 1983 and 1997, had monthly flows that exceeded channel capacities on the Stanislaus, Tuolumne or Merced Rivers or the SJR (Table 6-9). These exceedances, which resulted from flood control releases during large storm events, occurred under baseline conditions as well as under LSJR Alternative 4, with the exception of the January 1997 exceedance on the Stanislaus River. This exceedance occurred only in the baseline modeling results and not the LSJR Alternative 4 results (due to lower reservoir storage in LSJR Alternative 4). Tables 6-10, 6-11, and 6-12 show the monthly peak flows from the WSE modeling results for the three eastside tributaries during the wettest years. These tables also show the percent of channel capacity for each flow based on Table 6-3 and Figure 6-3.

For the LSJR, the southern Delta, and the three eastside tributaries, the LSJR Alternative 4 flows are almost always substantially lower than the channel capacities in these river reaches and the southern Delta (Table 6-3, Figure 6-3, and Tables 6-10, 6-11, and 6-12), even considering the lower channel capacity estimates from DWR for some reaches (2011, Table 6-3). Since these channels are capable of carrying much higher flows, these flows would be contained within the existing floodway, and no significant impact would occur with respect to flooding. Furthermore, because the flow objectives would cause minimal changes to storage, and would maintain the USACE flood reservation, there would not be any changes in flood control operation procedures during major flood events. Additionally, the peak monthly flow resulted from the WSE model would not exceed the action stage (Table 6-4) and would not apply when flows would exceed levels that would cause or contribute to flooding or other related public safety concerns, as described in Section 6.4.2, *Methods and Approach*. This would further limit flooding under LSJR Alternative 4. LSJR Alternative 4 would not substantially alter existing drainage patterns or substantially increase the rate of surface runoff in a manner that would directly result in flooding. Consequently, LSJR Alternative 4 would not expose people or structures to a significant risk of loss, injury or death involving flooding as noted in Section 6.4.1, *Thresholds of Significance*.

Adaptive Implementation

Adaptive implementation methods 1, 2, 3, and 4 are not anticipated to result in flooding. As described in Impact FLO-1, peak flows associated with flood control are not expected to substantially change. Thus, with a potential decrease in the specified minimum unimpaired flow requirement from 60 percent to 50 percent (i.e., method 1), it is expected flows would remain in channel capacities. A shift in timing or magnitude of flows under methods 2 or 3 is not expected to alter existing drainage patterns or substantially increase the rate or amount of surface runoff because the water volumes that might be shifted under these methods are small in comparison to peak monthly flows and the effects on sediment and erosion would be small. Therefore, impacts would be less than significant.

6.4.4 Impacts and Mitigation Measures: Extended Plan Area

The types of impacts that could occur in the extended plan area with respect to flooding, sediment, and erosion are similar to those described and discussed for the plan area. In general, upstream reservoirs would have more storage capacity under LSJR Alternatives 2, 3, or 4 with or without adaptive implementation because flows would be bypassed so there would be no change in flooding, sediment, or erosion when compared to baseline conditions in the extended plan area for the Stanislaus and Tuolumne Rivers. Flood control releases from the upstream reservoirs on the Stanislaus and Tuolumne Rivers would not increase and peak flows would be similar to baseline because storage in the upstream reservoirs would generally remain the same or be lower than under baseline. Additionally, bypass flows would not be required if they would result in flood control releases from the rim reservoirs. Consequently, there would be no impacts on flooding, sediment, or erosion compared to baseline conditions due to an inability to store water.

The nature of the river channels (predominantly contained in bedrock with very coarse-grained sediment) in the extended plan area means there would be minimal potential for increased sediment transport, erosion, or flooding under LSJR Alternatives 2, 3, or 4 with or without adaptive implementation on the Stanislaus, Tuolumne, and Merced Rivers. Additionally, peak flows would be no higher than under baseline. While higher flows, particularly under LSJR Alternatives 3 and 4 with or without adaptive implementation, might cause more frequent inundation of shallow point bars and occasional low elevation areas along the river channels, this would not be significant because such inundation occurs under baseline conditions and the inundation would not cause channel changes. Consequently, impacts associated with flooding, sediment, and erosion would be less than significant in the extended plan area under LSJR Alternatives 2, 3, and 4 with or without adaptive implementation.

6.5 Cumulative Impacts

For the cumulative impact analysis, refer to Chapter 17, *Cumulative Impacts, Growth-Inducing Effects, and Irreversible Commitment of Resources.*

Chapter 7
Aquatic Biological Resources

7.1 Introduction

This chapter describes the environmental setting for aquatic biological resources and the regulatory background associated with this resource area. It also evaluates environmental impacts on aquatic biological resources that could result from the Lower San Joaquin River (LSJR) alternatives, the significance of any impacts, and, if applicable, the mitigation measures that would reduce significant impacts.

The Southern Delta Water Quality (SDWQ) alternatives would not affect aquatic biological resources. As summarized in Section 7.4.2, *Methods and Approach*, the SDWQ alternatives would not result in a change in the water quality at Vernalis and, therefore, would not result in a change from baseline conditions. As discussed in Chapter 5, *Surface Hydrology and Water Quality,* and Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta,* it is not expected that salinity within the southern Delta would exceed historical monthly salinity levels, which generally range between 0.2 deciSiemens per meter (dS/m) (0.134 parts per thousand [ppt]) and 1.2 dS/m, (0.768 ppt), which are levels that indicator species can tolerate. Therefore, the SDWQ alternatives are not analyzed in detail in this chapter.

As described in Chapter 1, *Introduction*, the plan area generally includes those portions of the San Joaquin River (SJR) Basin that drain to, divert water from, or otherwise obtain beneficial use (e.g., surface water supplies) from the three eastside tributaries[1] of the LSJR. These include the Stanislaus River from and including New Melones Dam and Reservoir to its confluence with the LSJR; the Tuolumne River from and including New Don Pedro Dam and Reservoir to its confluence with the LSJR; the Merced River from and including New Exchequer Dam and Lake McClure to its confluence with the LSJR; and, the SJR between its confluence with the Merced River and downstream to Vernalis (i.e., LSJR). The evaluation of impacts in this chapter focuses on these water resources within the plan area that comprise the ecosystem for aquatic species. This chapter also evaluates other areas outside of the LSJR and the three eastside tributaries (i.e., the greater San Francisco Bay/Sacramento-San Joaquin Delta [Bay-Delta]), to the extent that environmental impacts from the LSJR and SDWQ alternatives may affect aquatic resources in these areas.

The extended plan area, also described in Chapter 1, *Introduction,* generally includes the area upstream of the rim dams[2]. The area of potential effects for this area is similar to that of the plan area and includes the zone of fluctuation around the numerous reservoirs that store water on the Stanislaus and Tuolumne Rivers. (The Merced River does not have substantial upstream reservoirs that would be affected.) It also includes the upper reaches of the Stanislaus, Tuolumne, and Merced Rivers. Unless otherwise noted, all discussion in this chapter refers to the plan area. Where appropriate, the extended plan area is specifically identified.

---

[1] In this document, the term *three eastside tributaries* refers to the Stanislaus, Tuolumne, and Merced Rivers.

[2] In this document, the term *rim dams* is used when referencing the three major dams and reservoirs on each of the eastside tributaries: New Melones Dam and Reservoir on the Stanislaus River; New Don Pedro Dam and Reservoir on the Tuolumne River; and New Exchequer Dam and Lake McClure on the Merced River.

This chapter evaluates the potential for impacts on aquatic resources as a result of the LSJR and SDWQ alternatives within the plan area. Chapter 19, *Analyses of Benefits to Native Fish Populations from Increased Flow Between February 1 and June 30,* evaluates the various benefits for native fishes potentially resulting from the LSJR alternatives. Chapter 19 focuses on the benefits of temperature and floodplain inundation to Central Valley fall-run Chinook salmon (*Oncorhynchus tshawytscha*) and Central Valley steelhead (*Oncorhynchus mykiss*) as a result of the LSJR alternatives (including the adaptive implementation approaches describe in the program of implementation). Chapter 19 quantitatively evaluates temperature and floodplain inundation during February–June and compares conditions between baseline and the various LSJR alternatives on the three eastside tributaries and the LSJR.

In Appendix B, *State Water Board's Environmental Checklist*, the State Water Board determined whether the plan amendments[3] would cause any adverse impact on resources in each of the listed environmental categories and provided a brief explanation for its determination. Impacts in the checklist that are identified as "Potentially Significant Impacts" are discussed in detail in the resource chapters.

This chapter addresses Appendix B, Section IV, *Biological Resources*, and the potential for the plan amendments to have a substantial adverse impact on sensitive or special status aquatic species, either directly or through habitat modification, including interference with migratory movement or reproductive sites. Potential impacts on terrestrial species are analyzed in Chapter 8, *Terrestrial Biological Resources.* Due to the complexity of aquatic resources, review in this chapter is accomplished through analyzing specific potential impacts, described as Impacts AQUA-1 through AQUA-12 (Table 7-1). Accordingly, this chapter evaluates potential impacts in greater detail than those directly specified in Appendix B so as to thoroughly analyze the project on aquatic resources.

The LSJR alternatives could affect reservoir operations in the Stanislaus, Tuolumne, and Merced Rivers, flows in each of these tributaries, and flows in the LSJR and Delta, resulting in potential impacts on aquatic habitat and aquatic biological communities, including native and nonnative fish species. The following analysis evaluates the impacts on aquatic resources that are expected to result from the LSJR alternatives based on the predicted responses of indicator species to the frequency and magnitude of flows, water temperature, and other habitat metrics relative to baseline conditions.

The potential impacts of the LSJR alternatives on aquatic resources are summarized in Table 7-1 as Impacts AQUA-1 through AQUA-12. As described in Chapter 3, *Alternatives Description*, LSJR Alternatives 2, 3, and 4 each includes four methods of adaptive implementation. The recirculated substitute environmental document (SED) provides an analysis with and without adaptive implementation because the frequency, duration, and extent to which each adaptive implementation method would be used, if at all, within a year or between years under each LSJR alternative, is unknown. The analysis, therefore, discloses the full range of impacts that could occur under an LSJR alternative, from no adaptive implementation to full adaptive implementation. As such, Table 7-1 summarizes impact determinations with and without adaptive implementation.

Impacts related to the No Project Alternative (LSJR/SDWQ Alternative 1), are presented in Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* and the supporting technical analysis is presented in Appendix D, *Evaluation of the No Project Alternative (LSJR*

---

[3] These plan amendments are the *project* as defined in State CEQA Guidelines, Section 15378.

Alternative 1 and SDWQ Alternative 1). Chapter 16, *Evaluation of Other Indirect and Additional Actions,* includes discussion of impacts related to actions and methods of compliance.

The indicator species, or key evaluation species, used to determine impacts of the LSJR alternatives on aquatic resources include anadromous[4] fish (fall-run Chinook salmon and steelhead), coldwater reservoir fish (e.g., rainbow trout[5]), and warmwater reservoir fish (e.g., largemouth bass). Indicator species were selected based on their sensitivity to expected changes in environmental conditions in the plan area and their utility in evaluating broader ecosystem and community-level responses to environmental change. In particular, the responses of Central Valley fall-run Chinook salmon to changes in flow, water temperature, and other flow-related variables have been well studied and provide a general indication of the overall response of the ecosystem to hydrologic change.

Table 7-1. Summary of Aquatic Resources Impact Determinations

Alternative	Summary of Impact (s)	Impact Determination with or without Adaptive Implementation
Impact AQUA-1: Changes in spawning success and habitat availability for warmwater species resulting from changes in reservoir water levels		
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [a]	Significant[c]
LSJR Alternatives 2, 3, and 4	The frequency of 15-foot fluctuations in reservoir levels would not change or would be reduced relative to baseline conditions; therefore, no significant reductions in spawning success and habitat availability for warmwater species would occur.	Less than significant
Impact AQUA-2: Changes in availability of coldwater species reservoir habitat resulting from changes in reservoir storage		
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [a]	Significant[c]
LSJR Alternatives 2, 3, and 4	Changes in average reservoir storage levels at the end-of-September would range from little or no change to substantial increases relative to baseline levels; therefore, no significant reductions in coldwater habitat availability would occur.	Less than significant
Impact AQUA-3: Changes in quantity/quality of physical habitat for spawning and rearing resulting from changes in flow		
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [a]	Less than significant[c]
LSJR Alternative 2	Suitable spawning habitat on the three eastside	Less than significant

---

[4] *Anadromous* refers to fish that are born in freshwater then migrate to the ocean for feeding and growth, finally returning to freshwater to spawn.

[5] Rainbow trout and steelhead are the same species, *Oncorhynchus mykiss*, but distinguished taxonomically by their different forms. In this document *rainbow trout* refers to the form of this species that remains mostly or entirely in freshwater while *steelhead* refers to the anadromous form. It should be recognized that both forms exist in populations with access to the ocean, including populations within the plan area.

Alternative	Summary of Impact (s)	Impact Determination with or without Adaptive Implementation
	tributaries would remain unchanged or increase. Therefore, no significant adverse impacts on the amount of spawning habitat for Chinook salmon and steelhead in the Stanislaus, Tuolumne, and Merced Rivers would occur. No reductions in Chinook salmon fry and juvenile rearing habitat are expected on the Stanislaus River or LSJR compared to baseline. In the Tuolumne and Merced Rivers, weighted usable area (WUA) for Chinook salmon fry and juvenile rearing would decrease, but floodplain habitat would increase in response to higher spring flows. No substantial differences would occur in WUA for steelhead fry and juvenile rearing compared to baseline conditions. No long-term reductions in habitat availability for other native fish species would occur. Therefore, no significant adverse impacts on the amount of habitat for Chinook salmon, steelhead, and other native fishes in the Stanislaus, Tuolumne and Merced Rivers and the LSJR would occur.	
LSJR Alternative 3	Reductions in WUA for Chinook salmon spawning would occur in the three eastside tributaries, but higher flows and lower temperatures are expected to improve attraction and migration and the longitudinal extent of suitable spawning habitat. SJR Alternative 3 would substantially improve rearing habitat conditions for Chinook salmon and steelhead in the three eastside streams and LSJR. Considering the overall beneficial effects of higher flows on rearing habitat availability, no significant adverse impacts on Chinook salmon and steelhead populations would occur. Higher spring flows under LSJR Alternative 3 would also benefit other native fish species.	Less than significant
LSJR Alternative 4	Under LSJR Alternative 4, predicted changes in WUA values for Chinook salmon and steelhead spawning in the Stanislaus, Tuolumne, and Merced Rivers would be similar in magnitude to those predicted under LSJR Alternative 3. LSJR Alternative 4 would further improve rearing habitat conditions for Chinook salmon and steelhead in the three eastside tributaries and LSJR. Higher spring flows under LSJR Alternative 4 would also further improve habitat conditions for other native fish species. Therefore, no significant adverse impacts would occur.	Less than significant

Alternative	Summary of Impact (s)	Impact Determination with or without Adaptive Implementation
Impact AQUA-4: Changes in exposure of fish to suboptimal water temperatures resulting from changes in reservoir storage and releases		
No Project Alternative (LSJR/SDWQ Alternative 1)	See note.[a]	Significant[c]
LSJR Alternative 2	No substantial changes would occur in exposure of Chinook salmon and steelhead adult migration, spawning and incubation, juvenile rearing, and smolt life stages to suboptimal water temperatures in the Stanislaus, Tuolumne, Merced, and LSJR. Therefore, no significant adverse impacts on Chinook salmon and steelhead populations would occur.	Less than significant
LSJR Alternative 3	Decreases in exposure of Chinook salmon and steelhead life stages to suboptimal water temperatures would occur for spawning/incubation in the Tuolumne River (March); spring rearing in the Tuolumne, Merced, and LSJR (April–May); and summer rearing (steelhead only) in the Stanislaus, Tuolumne, and Merced Rivers (July). Therefore, no significant adverse impacts would occur. LSJR Alternative 3 would have beneficial temperature effects on Chinook salmon and steelhead in the Stanislaus, Tuolumne, and Merced Rivers (including Chinook salmon reared at Merced River Hatchery), and the LSJR.	Less than significant
LSJR Alternative 4	Decreases in exposure of Chinook salmon and steelhead life stages to suboptimal water temperatures would occur for spawning/incubation in the Stanislaus, Tuolumne, and Merced Rivers (February–March); spring rearing in the Stanislaus, Tuolumne, Merced, and LSJR (March–May); spring outmigration in the Stanislaus, Tuolumne, and Merced Rivers (April–June); and summer rearing (steelhead only) in the Tuolumne River (July). Therefore, no significant adverse impacts would occur. Overall, LSJR Alternative 4 would have beneficial temperature effects on Chinook salmon and steelhead in the Stanislaus, Tuolumne, and Merced Rivers (including Chinook salmon reared at Merced River Hatchery), and the LSJR.	Less than significant

Alternative	Summary of Impact (s)	Impact Determination with or without Adaptive Implementation
Impact AQUA-5: Changes in exposure to pollutants resulting from changes in flow		
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [a]	Significant[c]
LSJR Alternative 2	Changes in the frequency and magnitude of flows would not be sufficient to result in long-term adverse changes in dilution effects and exposure of fish to potentially harmful contaminants.	Less than significant
LSJR Alternative 3	Similar or higher 10th and 50th (median) percentile flows in most months would result in similar or reduced long-term exposure of fish to potentially harmful pollutants. Decreases in exposure of Chinook salmon and steelhead life stages to suboptimal water temperatures would contribute to reductions in the potential for adverse effects associated with contaminant exposure.	Less than significant
LSJR Alternative 4	Dilution would potentially increase as a result of the increase in flows, and temperatures would either be maintained or reduced; thus, an increase in exposure to pollutants would not occur.	Less than significant
Impact AQUA-6: Changes in exposure to suspended sediment and turbidity resulting from changes in flow		
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [a]	Less than significant[c]
LSJR Alternatives 2, 3, and 4	Changes in the frequency, duration, and magnitude of increased suspended sediment and turbidity levels would be minor and within the range of historical levels experienced by native fishes and other aquatic species on the three eastside tributaries and the LSJR.	Less than significant
Impact AQUA-7: Changes in redd dewatering resulting from flow fluctuations		
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [a]	Less than significant[c]
LSJR Alternatives 2, 3, and 4	There would be no substantial changes on the three eastside tributaries or the LSJR in the frequency and magnitude of flow reductions associated with potential impacts on Chinook salmon and steelhead redd dewatering.	Less than significant
Impact AQUA-8: Changes in spawning and rearing habitat quality resulting from changes in peak flows		
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [a]	Less than significant[c]
LSJR Alternatives 2, 3, and 4	Modeled results indicate that changes in peak flows are not expected to affect the frequency and magnitude of gravel mobilization events in the Stanislaus, Tuolumne, and Merced Rivers. Therefore, no long-term changes in geomorphic conditions	Less than significant

Alternative	Summary of Impact (s)	Impact Determination with or without Adaptive Implementation
	significantly affecting spawning and rearing habitat quality would occur.	
Impact AQUA-9: Changes in food availability resulting from changes in flow and floodplain inundation		
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [a]	Less than significant[c]
LSJR Alternative 2	No substantial changes are likely to occur in frequency and magnitude of floodplain inundation and associated food web conditions in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR. Therefore, no significant impacts on food availability would occur.	Less than significant
LSJR Alternatives 3 and 4	Higher spring flows and associated increases in riparian and floodplain inundation in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would potentially increase food abundance and growth opportunities for fish on floodplains as well as contribute to downstream food web support. This represents a beneficial effect on aquatic biological resources in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR.	Less than significant
Impact AQUA-10: Changes in predation risk resulting from changes in flow and water temperature		
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [a]	Significant[c]
LSJR Alternative 2	No substantial changes are predicted to occur in habitat availability and water temperatures potentially affecting Chinook salmon and steelhead populations or conditions supporting predator populations.	Less than significant
LSJR Alternatives 3 and 4	Higher flows and cooler water temperatures in the three eastside tributaries would reduce predation impacts by improving growth opportunities and reducing temperature-related stress in juvenile Chinook salmon and steelhead and limiting the distribution and abundance of largemouth bass and other nonnative species that prey on juvenile salmonids.	Less than significant
Impact AQUA-11: Changes in disease risk resulting from changes in water temperature		
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [a]	Significant[c]
LSJR Alternatives 2, 3, and 4	The frequency of spring water temperatures associated with potential increases in disease risk would stay the same or decrease.	Less than significant

Alternative	Summary of Impact (s)	Impact Determination with or without Adaptive Implementation
Impact AQUA-12: Changes in southern Delta and estuarine habitat resulting from changes in SJR inflows and export effects		
No Project Alternative (LSJR/SDWQ Alternative 1)	See note.[a]	Less than significant[c]
LSJR Alternatives 2, 3, and 4	No substantial changes in southern Delta and estuarine habitat would occur. The combination of monthly changes in pumping rates, SJR flow, and Delta outflow would not have substantial long-term effects on flow patterns in the southern Delta. Furthermore, there would be little effect on Delta outflows and the position of X2;[b] Delta operations would continue to be governed by current restrictions on export pumping rates, inflow/export ratios, and Old Middle River flows to protect listed fish species from direct and indirect impacts of southern Delta operations.	Less than significant

[a] The No Project Alternative (LSJR/SDWQ Alternative 1) would result in the continued implementation of flow objectives and salinity objectives established in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* the No Project Alternative impact discussion, and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

[b] X2 is the location of the 2 parts per thousand (ppt) salinity contour (isohaline), 1 meter off the bottom of the estuary measured in kilometers upstream from the Golden Gate Bridge. The abundance of several estuarine species has been correlated with X2. In the 2006 Bay-Delta Plan, a salinity value—or electrical conductivity (EC) value—of 2.64 millimhos/centimeter (mmhos/cm) is used to represent the X2 location. Note, in this SED, EC is generally expressed in deciSiemens per meter (dS/m). The conversion is 1 mmhos/cm = 1 dS/cm.

[c] Adaptive implementation does not apply to the No Project Alternative.

7.2 Environmental Setting

This section describes the life history, habitat requirements, and factors that affect the abundance of aquatic biological resources, including special-status, recreational, and indicator species in the plan area, and reviews historical and current fish communities and environmental stressors in the LSJR, three eastside tributaries, and the southern Delta. Additional background information and technical support for Section 7.2, *Environmental Setting*, and Section 7.4, *Impact Analysis*, are presented in Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*. In particular, Appendix C, Chapter 3, *Scientific Basis for Developing Alternative San Joaquin River Flow Objectives*, provides additional information on the life history of the indicator species (Chinook salmon and steelhead), detailed descriptions of existing fish monitoring and research programs, and reviews of published and unpublished technical information supporting current scientific understanding of the roles of flow, water temperature, and other mechanisms affecting Chinook salmon and steelhead populations in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR.

7.2.1 Fish Species

The LSJR, the three eastside tributaries, and the southern Delta support a diverse assemblage of native and nonnative fishes. Historically, the SJR and the three eastside tributaries in the plan area supported a distinctive native fish fauna adapted to widely fluctuating riverine conditions ranging from large winter and spring floods to low summer flows. Prior to large-scale hydrologic and physical alteration of the basin and species introductions, these environmental conditions resulted in a rich and diverse native fish fauna characterized by four major fish assemblages. The rainbow trout assemblage occurred in high gradient, upper elevation portions of the SJR basin, and commonly included riffle sculpin (*Cottus gulosus*), Sacramento sucker (*Catostomus occidentalis*), and speckled dace (*Rhinichthys osculus*). The California roach assemblage occurred in small, warm tributaries at middle elevations, and may have seasonally included Sacramento sucker, Sacramento pikeminnow, Chinook salmon, and steelhead. The Pikeminnow-hardhead-sucker assemblage historically occurred in larger mainstem portions of the SJR and its tributaries and included speckled dace, California roach, riffle and prickly sculpin, threespine stickleback, and rainbow trout. Anadromous species, including Chinook salmon, steelhead (anadromous or sea-run rainbow trout), and Pacific lamprey, spawned and reared in this zone. The deep-bodied fish assemblage generally occurred in the low gradient, valley-bottom portions of the SJR, and included Sacramento perch (*Archoplites interruptus*), thicktail chub, tule perch, hitch, and blackfish. Chinook salmon, steelhead, and sturgeon occurred in this zone on their way upstream to spawn or on their way downstream toward the ocean (Moyle 2002).

The fish assemblages that currently occur in SJR and the three eastside tributaries are the result of substantial changes to the physical environment and a long history of species introductions. A number of the native species are now uncommon, rare, or extinct, and have been designated as special-status species (Table 7-2). Some of these special-status species (e.g., rainbow trout, fall-run Chinook salmon, and steelhead) are the indicator species mentioned in Section 7.1, *Introduction*. Other species, both native and nonnative, support important recreational fisheries in the plan area (Table 7-3).

Table 7-2. Special-Status Fish Species that Occur in the Plan Area

	Status[a]	Recreationally Important?			Critical Habitat Designated?
Species Name	Fed/State	Yes/No	Location	Habitat	
Central Valley fall-/late fall–run Chinook salmon[b] *Oncorhynchus tshawytscha*	SC/–	Yes	Pacific Ocean, San Francisco Bay-Sacramento-San Joaquin Delta (Bay-Delta), SJR and the three eastside tributaries, Sacramento River and major tributaries.	Prefer well-oxygenated, cool, riverine habitat with water temperatures 8.0°C–12.5°C (46.5°F–54.5°F). Habitat types are riffles, runs, and pools.	No

	Status[a]	Recreationally Important?			
Species Name	Fed/State	Yes/No	Location	Habitat	Critical Habitat Designated?
Central Valley spring-run Chinook salmon *Oncorhynchus tshawytscha*	T/CT	No	Pacific Ocean, Bay-Delta, Sacramento River and major tributaries.	Prefer well-oxygenated, cool, riverine habitat with water temperatures 8.0°C–12.5°C (46.5°F–54.5°F). Coldwater pools are needed for holding adults.	Yes, but not in the plan area.
Central Valley steelhead[b] *Oncorhynchus mykiss*	T/–	Yes	Pacific Ocean, Bay-Delta, SJR and three eastside tributaries, Sacramento River and major tributaries.	Prefer well-oxygenated, cool, riverine habitat with water temperatures 7.8°°C–18°C (46°F–64.4°F). (Moyle 2002). Habitat types are riffles, runs, and pools.	Yes, the LSJR from the Merced River confluence to Vernalis, including the three eastside tributaries, and the southern Delta.
Green sturgeon (southern DPS) *Acipenser medirostris*	T/CSC	No	Pacific Ocean, Bay-Delta, Sacramento River.	Occur in both freshwater and saltwater habitat. Spawn in deep pools or in turbulent areas in the mainstem of large rivers (Moyle 2002) with well-oxygenated water with temperatures 8°C–14°C (46.5°F–57.2°F). Salinity tolerance to 35 ppt for adults.	Yes, the Bay-Delta.
Delta smelt *Hypomesus transpacificus*	T/CE	No	Primarily in the Bay-Delta, but has been found as far upstream as the mouth of the American River, on the Sacramento River, and at Mossdale on the SJR; range extends downstream to San Pablo Bay.	Endemic to the Bay-Delta and generally spend entire lifecycle in the open surface waters of the Bay-Delta and Suisun Bay. Prefer areas where fresh and brackish water mix in the salinity range of 2–7 ppt. Salinity tolerance to 19 ppt, sometimes higher (Bennett 2005).	Yes, the legal Delta and Suisun Bay and Marsh.

Species Name	Status[a] Fed/State	Recreationally Important? Yes/No	Location	Habitat	Critical Habitat Designated?
Longfin smelt *Spirinchus thaleichthys*	–/CT	No	Primarily in the Bay-Delta, but also in Humboldt Bay, Eel River estuary, and Klamath River estuary.	Primary habitat is the open water of estuaries; can be found in both the seawater and freshwater areas, typically in the middle or deeper parts of the water column. Salinity tolerance to 35 ppt. Spawning takes place in salt or brackish estuary waters with freshwater inputs (Merz et al. 2013).	No
Sacramento splittail *Pogonichthys macrolepidotus*	–/CSC	No	Throughout the year in low-salinity waters and freshwater areas of the Bay-Delta, Yolo Bypass, Suisun Marsh, Napa River, and Petaluma River (Moyle 2002).	Utilize floodplain habitat for feeding and spawning. Spawn among submerged and flooded vegetation in sloughs and the lower reaches of rivers. Estuarine species found 10–18 ppt, can tolerate up to 29 ppt (Cech et al. 1990).	No
Kern brook lamprey *Lampetra hubbsi*	–/CSC	No	Lower Merced River, Kaweah River, Kings River, and SJR.	Silty and backwaters and stream margins of Sierra foothill rivers.	No
River lamprey *Lampetra ayresi*	–/CSC	No	Bay-Delta and SJR from Friant Dam to Merced River and the LSJR.	Has not been thoroughly studied in California but appears to be more abundant in the Lower Sacramento River and LSJR than in other streams in California.	No

	Status[a]	Recreationally Important?			
Species Name	Fed/State	Yes/No	Location	Habitat	Critical Habitat Designated?
California roach (Sacramento-San Joaquin roach and Red Hills roach) *Lavinia symmetricus ssp.*	–/CSC	No	Sacramento–San Joaquin Watersheds; Red Hills roach known to occur only in several small streams in Tuolumne River basin.	California roach generally occur in small, warm streams, and individuals frequent a wide variety of habitats, often isolated by downstream barriers. Tolerant of relatively high water temperatures 30°C–35°C (86°F–95°F) with low oxygen levels.	No
Pacific lamprey *Entosphenus tridentatus*	SC/–	No	Pacific Ocean, Bay-Delta, SJR and three eastside tributaries, Sacramento River.	Prefer well-oxygenated, cool, riverine habitat with water temperatures 12°C–18°C (53.5°F–64.5°F). Spawning habitats are similar to that of salmonids. They are anadromous.	No
Hardhead *Mylopharodon conocephalus*	–/CSC	No	SJR and the three eastside tributaries, Sacramento River and major tributaries.	Prefer low to mid-elevation environments with clear, deep pools and runs with sand-gravel-boulder substrates. Optimal water temperatures range from 24°C–28°C (75°F–82°F); however, most streams where these fish occur have temperatures over 20°C (68°F) (Moyle 2002).	No

[a] Status:

Federal

E = Listed as endangered under the federal Endangered Species Act (ESA).
T = Listed as threatened under ESA.
SC = Listed as a species of concern.
– = No federal status.

State

CE = Listed as endangered under the California Endangered Species Act (CESA).
CT = Listed as threatened under CESA.
CSC = California species of special concern.
– = No state status.

[b] Central Valley fall-run Chinook salmon and Central Valley steelhead are considered indicator species of coldwater communities.

Table 7-3. Recreationally Important Fish Species in the Plan Area

	Status	Recreationally Important?			
Species Name	Fed/State	Yes/No	Location	Habitat	Critical Habitat Designated?
Rainbow trout *Oncorhynchus mykiss*[a, b]	–/–	Yes	SJR and the three eastside tributaries, Sacramento River and major tributaries. Also stocked in reservoirs in the plan area.	Prefer well-oxygenated, cool, riverine habitat with water temperatures 7.8°C–18°C (46°F–64.4°F). Habitat types are riffles, runs, and pools.	No
Largemouth bass[b] *Micropterus salmoides*	–/–	Yes	Bay-Delta, SJR, Sacramento River, and tributaries. Also stocked in reservoirs in the plan area.	Found in warm, quiet water with low turbidity and aquatic plants, such as lakes, reservoirs, sloughs, and river backwaters. Constructs its nests for eggs in shallow water. Optimal temperatures range from 25°C–30°C (77°F–86°F) but can persist in temperatures that approach 36°C–37°C (97°F–99°F) (Moyle 2002).	Not applicable – nonnative introduced species

Species Name	Status Fed/State	Recreationally Important? Yes/No	Location	Habitat	Critical Habitat Designated?
Striped bass *Morone saxatilis*	–/–	Yes	Bay-Delta, SJR and three eastside tributaries, Sacramento River and major tributaries.	Found in lakes, ponds, streams, wetlands, and brackish and marine waters. Anadromous, they spawn in fresh water in the spring (April–May) when water temperatures are about 15.5°C (60°F).	Not applicable - nonnative introduced species
White sturgeon *Acipenser transmontanus*	–/–	Yes	Pacific Ocean, Bay-Delta.	Inhabits riverine, estuarine, and marine (35 ppt) habitats at various life stages (Moyle 2002). Greatest portion of the population occurs in the brackish portion of the estuary.	No
American shad *Alosa sapidissima*	–/–	Yes	Bay-Delta, Sacramento River, and SJR. Also stocked in reservoirs in the plan area.	Prefer well-oxygenated, cool, riverine habitat. Peak spawning occurs in mid-May to mid-June, with water temperatures of 11°C–17°C (51.8°F–62.6°F).	Not applicable – nonnative introduced species
Kokanee *Oncorhynchus nerka*	–/–	Yes	Reservoirs in the plan area.	Landlocked populations occur in well-oxygenated reservoirs on three eastside tributaries. Preferred water temperatures are 1°C–15°C (50°F–59°F).	Not applicable – nonnative introduced species

°F = degrees Fahrenheit

°C = degrees Celsius

[a] In this document, *rainbow trout* refers to non-anadromous forms of the species *O. mykiss* above impassable dams. However, it should be recognized that both anadromous (steelhead) and non-anadromous forms occur below these dams. The anadromous form is recognized by the National Marine Fisheries Service as a distinct population segment of *O. mykiss*, which is listed as threatened under the ESA (see Table 7-2).

[b] Largemouth bass are considered an indicator species of warmwater reservoir fish communities that include fishes such as sunfish and catfish. Rainbow trout are considered an indicator species of coldwater reservoir fish communities.

Chinook Salmon

Central Valley Fall-Run

The Central Valley fall-run Chinook salmon evolutionarily significant unit (ESU) is listed as a federal species of concern. Currently, fall-run Chinook salmon are the most abundant of the Central Valley races, contributing historically to large commercial and recreational fisheries in the ocean and popular sport fisheries in the freshwater streams. Fall-run Chinook are raised at five major Central Valley hatcheries that release more than 32 million smolts each year (CDFW 2016a). The federal status of fall-run Chinook salmon is due in part to concerns regarding hatchery influence.

Central Valley fall-run Chinook salmon historically spawned in all major Central Valley tributaries, as well as the mainstem of the Sacramento River and SJR (Moyle 2002). Because much of fall-run Chinook salmon historical spawning and rearing habitat included the reaches downstream of major dams, the fall runs in the Central Valley were not as severely affected by early water projects as were spring-run Chinook salmon and steelhead, which ascended to higher elevations to spawn (Reynolds et al. 1993; Yoshiyama et al. 1996; McEwan 2001). Changes in seasonal hydrologic patterns resulting from operation of upstream reservoirs for water supplies, flood control, and hydroelectric power generation have altered instream flows and habitat conditions for fall-run Chinook salmon and other species downstream of the dams (Williams 2006).

Trends in adult fall-run Chinook salmon escapement on the SJR and the three eastside tributaries have been relatively low since the 1950s, ranging from several hundred adults to approximately 100,000 adults. Results of escapement estimates have shown a relationship between adult escapement in one year and spring flows on the SJR 2.5 years earlier when the juveniles in the cohort were rearing and migrating downstream through the Sacramento-San Joaquin Delta (Delta). Adult escapement appears to be cyclical and may be related to hydrology during juvenile rearing and migration periods, among other factors (CDFG 2005; SJRTC 2008). Population trends for fall-run Chinook salmon are discussed in Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*.

SJR fall-run Chinook salmon migrate into natal streams from late October to early December, with peak migration typically occurring in November (Table 3.13 of Appendix C). SJR fall-run Chinook salmon typically begin spawning between November and January when temperatures in the rivers are lower than 55°F. The majority of redds (a gravel depression in the riverbed the adults make with their tails for spawning) are observed in the month of November (McBain and Trush 2002). Egg incubation typically occurs between November and March, lasting 40–60 days, but can vary depending on water temperatures and timing of spawning. Optimal water temperatures for egg incubation range from 41 degrees Fahrenheit (°F) to 55°F (Moyle 2002; USEPA 2003). Eggs that incubate at temperatures higher than 60°F and lower than 38°F have suffered high mortality rates (Boles et al. 1988).

Newly hatched salmon (alevins) remain in the gravel for about 4–6 weeks, depending on surrounding water temperatures, until the yolk sac has been absorbed (Moyle 2002; NMFS 2009a). Generally, alevins suffer low mortality when consistently incubated at water temperatures between 50°F and 55°F. However, if incubated at constant temperatures between 55°F and 57.5°F, mortality has been shown to increase in excess of 50 percent (Boles et al. 1988).

Most fall-run Chinook salmon fry (the life stage after alevins) emerge from the gravel between February and March (McBain and Trush 2002) and are immediately dispersed into downstream feeding areas. However, many juveniles may rear in the river for some length of time before migrating downstream (Moyle 2002). Rearing and outmigration of fall-run Chinook salmon typically occurs between February and June; however, rotary screw trap and trawl data from the LSJR and its tributaries indicate that peaks in fry outmigration occur in February and March, and peaks in smolt (> 75 mm) outmigration occur in April and May.

Preferred rearing temperatures for Chinook have been reported to occur within the range of 54°F–58.5°F (12.2°C–14.7°C) (Hicks 2002) with optimum temperatures for growth occurring at temperatures of 50°F–60°F (10°C–15.6°C) (McCullough et al. 2001). Chinook salmon exhibit positive growth at temperatures ranging from 46.4°F–77°F (8°C–25°C), with optimum growth rates occurring at about 66.2°F (19°C) when fed maximal rations (Myrick and Cech 2001).

Juvenile Central Valley fall-run Chinook salmon undergo a change known as *smoltification* when they reach 3–4 inches (75–100 millimeters [mm]) during outmigration. Smoltification involves physiological and morphological changes that prepare juveniles for ocean entry (CDFG 2010). Elevated stream temperatures during rearing or downstream smolt migration can inhibit smolt development in anadromous salmonids. Water temperatures that have been reported in the literature to impair smoltification range from approximately 53.6°F–59°F (12°C–15°C) (McCullough et al. 2001). Evidence of impaired smoltification in Central Valley fall-run Chinook salmon has been observed at water temperatures above approximately 60.8°F (16°C), with significant impairment occurring at water temperatures above approximately 68°F (20°C) (Marine and Cech 2004).

Central Valley Spring-Run

The Central Valley spring-run ESU is a special-status species currently listed as threatened under the Endangered Species Act (ESA) and the California Endangered Species Act (CESA).

Spring-run Chinook salmon once occupied all major river systems in California and were widely distributed in Central Valley rivers (Myers et al. 1998). Spring-run Chinook salmon were widely distributed in streams of the Sacramento River and SJR Basins, spawning and rearing over extensive areas in the upper and middle reaches (elevations ranging from 1,400 to 5,200 feet (ft) [450 to 1,600 meters (m)]) of the San Joaquin, American, Yuba, Feather, Sacramento, McCloud, and Pit Rivers (Myers et al. 1998). Run sizes in the nineteenth century were probably in the range of 1 million fish per year +/-500,000 (Yoshiyama et al. 1998; Moyle et al. 2008). From 1900 to 1948, hydroelectric development and irrigation projects truncated large portions of the headwaters of most Central Valley Rivers by dam construction and greatly reduced access of spring-run Chinook salmon to spawning habitat (Yoshiyama et al. 1996). The SJR population was essentially extirpated by the late 1940s. Populations in the Upper Sacramento, Feather, and Yuba Rivers were eliminated with the construction of major dams during the 1950s and 1960s. Naturally spawning populations of spring-run Chinook salmon are currently restricted to accessible reaches of the Sacramento River, Antelope Creek, Battle Creek, Beegum Creek, Big Chico Creek, Butte Creek, Clear Creek, Deer Creek, Mill Creek, Feather River, and Yuba River (CDFG 1998). Naturally-spawning populations of Central Valley spring-run Chinook salmon with consistent spawning returns use the Bay-Delta as a migration corridor and are currently restricted to Butte Creek, Deer Creek, and Mill Creek (Moyle 2002; Good et al. 2005).

Currently, no spring-run Chinook salmon populations are found in the tributaries of the SJR (NMFS 2014), although there are occasional observations of small numbers of Chinook salmon in the tributaries that display spring-run characteristics. It is not well understood if these fish are in fact spring-run Chinook salmon, and if they are, from which Sacramento River tributary they have strayed from. Spring-run Chinook salmon populations were extirpated from the SJR Basin after construction of Friant Dam, which was completed in 1948 (Moyle 2002). However, in 2006 parties agreed to a stipulated settlement that required the reintroduction of spring-run Chinook salmon to this section of the SJR and required minimum flows to sustain the reintroduced population. In 2009, through the San Joaquin River Restoration Program (SJRRP),[6] the first restoration flows were released from Friant Dam. In 2010, the SJR reconnected to the LSJR at the Merced River confluence. The major goal of the SJRRP is to establish a naturally self-sustaining population (see Chapter 17, *Cumulative Impacts, Growth-Inducing Effects, and Irreversible Commitment of Resources*, for a discussion of the program) (USBR 2011).

The Central Valley spring-run Chinook salmon ESU has displayed broad fluctuations in adult abundance between 1960 and 2009. Although recent population trends are negative, annual abundance estimates display a high level of variation. The overall number of spring-run Chinook salmon remains well below estimates of historical abundance. Central Valley spring-run Chinook salmon have some of the highest population growth rates in the Central Valley, but other than in Butte Creek and the hatchery-influenced Feather River, population sizes are very small relative to fall-run Chinook salmon populations (Good et al. 2005).

In general, physical parameters (e.g., temperature and salinity thresholds) for spring-run Chinook salmon are similar to that of fall-run Chinook salmon, although the timing of the freshwater lifecycle is different. Spring-run Chinook salmon enter freshwater in the winter and spring and spawn in the late summer. This life history requires that they migrate far enough upstream to find habitat that remains cool enough (less than 70°F) for the adults to survive (Williams 2006). Embryos are less tolerant of warm water than adults, and as with fall-run Chinook salmon, spawning begins when water cools below 57°F to 59°F. The spring-run Chinook salmon lifecycle is well adapted to streams with snowmelt runoff and access to high elevation holding and spawning habitat (Williams 2006).

Rainbow Trout and Central Valley Steelhead

Rainbow trout and steelhead are the same species, *O. mykiss*, but distinguished by their behavior. All forms of the species spend the first part of their lives in freshwater, but steelhead are anadromous, migrating to the ocean (35 ppt) after 1–3 years. Rainbow trout are the most abundant and wide-spread native salmonids in western North America and recreationally important species. Hatchery and naturally produced populations of rainbow trout occur in reservoirs, lakes, and streams above impassable dams throughout California, and are sustained by both stocking and natural reproduction. However, mixing of rainbow trout in hatcheries and indiscriminate stocking have blurred distinctions among populations (Moyle 2002). For the purposes of this document, rainbow trout is used to distinguish *O. mykiss* populations above impassable dams, while steelhead is used to distinguish populations below these dams. However, it should be recognized that both forms can occur in *O. mykiss* populations with access to the ocean.

The Central Valley steelhead, a distinct population segment (DPS) of West Coast steelhead, is a special-status species that is listed as threatened under ESA (Moyle 2002), but not under CESA. The general habitat requirements of Central Valley steelhead also apply to rainbow trout as defined here. Historically, Central Valley steelhead were widely distributed throughout the Sacramento River and SJR. Historical Central Valley steelhead run sizes are difficult to estimate given the paucity

---

[6] Implementation of the settlement and the Friant Dam release flows required by the San Joaquin River Restoration Program are expected to increase the existing SJR flows at Stevinson in the near future.

of data, but may have approached one to two million adults annually (McEwan 2001). Adult steelhead typically migrate upstream and spawn during the winter months when river flows are high and water clarity is low. Unlike Chinook salmon, adult steelhead may not die after spawning and can return to coastal waters. In addition, steelhead frequently inhabit streams and rivers that are difficult to access and survey. Thus, information on the trends in steelhead abundance in the Central Valley has primarily been limited to observations at fish ladders and weirs (McEwan 2001).

Until recently, Central Valley steelhead were thought to be extirpated from the SJR Basin. However, recent monitoring has detected small self-sustaining populations of steelhead in the Stanislaus, Mokelumne, and Calaveras Rivers and other streams previously thought to be devoid of steelhead (McEwan 2001; Zimmerman et al. 2008). Incidental catches and observations of steelhead juveniles also have occurred on the Tuolumne and Merced Rivers during fall-run Chinook salmon monitoring activities, indicating that steelhead are widespread throughout accessible streams and rivers in the Central Valley (Good et al. 2005). Non-hatchery stocks of rainbow trout that have anadromous components within them are found in the Upper Sacramento River and its tributaries: Mill, Deer, and Butte Creeks; and the Feather, Yuba, American, Mokelumne, and Calaveras Rivers (McEwan 2001).

The most recent status review of the Central Valley steelhead DPS (NMFS 2009a) found that the status of the population appears to have worsened since the 2005 status review (Good et al. 2005), when it was considered to be in danger of extinction. Analysis of data from the Chipps Island monitoring program indicates that natural steelhead production has continued to decline, and hatchery-origin fish represent an increasing fraction of the juvenile production in the Central Valley. In recent years, the proportion of hatchery-produced juvenile steelhead in the catch has exceeded 90 percent, and in 2010 it was 95 percent of the catch. This recent trend appears to be related to poor ocean conditions and dry hydrology in the Central Valley (NMFS 2009b). Population trends for Central Valley steelhead are discussed in Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*.

Central Valley steelhead in the plan area can begin upstream migration as early as July and continue through April, with upstream migration peaking between October and February. Central Valley steelhead spawn downstream of impassable dams on the three eastside tributaries and the LSJR, similar to SJR Basin fall-run Chinook salmon (NMFS 2009c). Spawning typically occurs from December through June and peaks between January and March (NMFS 2009a; Table 3.14 of Appendix C) where cool (30°F–52°F), well-oxygenated water is available year-round (McEwan and Jackson 1996). Once spawning is complete, adult Central Valley steelhead may return to the ocean in preparation for a subsequent year, while others may die after spawning.

Depending on water temperature, Central Valley steelhead eggs may incubate in redds from 4 weeks to 4 months before hatching as alevins (McEwan 2001; NMFS 2009c). When water temperatures are warmer, less incubation time is needed and, conversely, when water temperatures are cooler, more incubation time is needed. Central Valley steelhead eggs that typically incubate at 50°F–59°F hatch in about 4 weeks, and alevins emerge from the gravel 4–8 weeks after hatching (Shapovalov and Taft 1954; Reynolds et al. 1993). Juvenile Central Valley steelhead rear for 1–3 years (1 percent spend 3 years) in cool, clear, fast flowing, permanent freshwater streams and rivers where riffles predominate over pools (CDFG 2010). Some juveniles may utilize tidal marsh areas, nontidal freshwater marshes, and other shallow water areas in the Bay-Delta as rearing areas for short periods prior to their final emigration to sea (NMFS 2009a).

Juveniles are dependent on suitable rearing habitat for an extended amount of time prior to outmigration, especially during the summer when suitable conditions are most restricted due to a host of stressors such as temperature, water quality and quantity, and ability to access floodplains. Diversity and richness of habitat and food sources, particularly in shallow water habitats, allows juveniles to grow larger before ocean entry, thereby increasing their chances of survival in the marine environment. A longer rearing period for juvenile Central Valley steelhead allows for them to be considerably larger and have a greater swimming ability than Chinook salmon juveniles during outmigration (ICF International 2012).

Central Valley steelhead juveniles generally begin outmigration anywhere between late December and July, with peaks occurring between March and April (McBain and Trush 2002; Table 3.14 of Appendix C; USDOI 2008). As with Chinook salmon, juveniles undergo smoltification during outmigration. Central Valley steelhead smoltification has been reported to occur successfully at 44–52°F (Myrick and Cech 2001; USDOI 2008).

Green Sturgeon

The North American green sturgeon (southern DPS) is a special-status species listed under ESA as threatened and identified as a California species of special concern (Table 7-2).

North American green sturgeon range along the Pacific coast from Mexico to Alaska (Colway and Stevenson 2007; Moyle 2002). Spawning populations of green sturgeon are currently found in three river systems: the Sacramento and Klamath Rivers in California and the Rogue River in southern Oregon (NMFS 2009a). The southern DPS of green sturgeon includes all green sturgeon populations south of the Eel River, with the only known spawning population being in the Sacramento River (NMFS 2009a). Within the Central Valley, green sturgeon have been observed in San Francisco Bay, San Pablo Bay, Suisun Bay, the Delta, Sacramento River, Feather River, Yuba River, Sutter Bypass, and Yolo Bypass (74 FR 52300; Israel and Klimley 2008; Moyle 2002; Gleason et al. 2008; Dubois et al. 2009, 2010, 2011, 2012; NMFS 2005; NMFS 2010). Currently, spawning is limited to the Sacramento River below Shasta and Keswick Dams, which block passage of green sturgeon to historic spawning areas above the dams (NMFS 2005). It is suspected that green sturgeon once spawned in the SJR but have since been extirpated (Moyle 2002; Israel and Klimley 2008). Moyle (2002) suggested that reproduction may have taken place in the SJR because adults have been captured at Santa Clara Shoal and Brannan Island. Egg and larval green sturgeon are confined to freshwater portions of the Sacramento River, while juvenile and sub-adult green sturgeon occur in riverine, subtidal, and intertidal habitats in the Lower Sacramento River and Bay-Delta (Israel and Klimley 2008).

Musick et al. (2000) suggest that the abundance of North American green sturgeon populations has declined as much as 88 percent. Based on the incidental capture of green sturgeon during surveys for white sturgeon, CDFG (2002) estimated that green sturgeon abundance in the Bay-Delta estuary ranged from 175 (1993) to more than 8,400 (2001) adults between 1954 and 2001. However, these estimates are uncertain and subject to the inherent biases of the sampling methods (NMFS 2009a). A decline in abundance is indicated by reductions in the average number of juvenile green sturgeon salvaged at the state and federal pumping facilities in recent years compared with annual salvage estimates before the mid-1980s (NMFS 2009a). A decline in abundance of green and white sturgeon since the 1960s is also evident from a reduction in the number of green and white sturgeon salvaged per acre-foot (AF) of water exported (April 5, 2005, 70 FR 17386). A recent genetic analysis indicated that spawning populations above Red Bluff Diversion Dam ranged from 32 to 124 spawning pairs between 2003 and 2006 (Israel and May 2010).

Green sturgeon pass through the San Francisco Bay to the ocean (35 ppt), where they primarily move northward, spending much of their lives in the ocean or in Oregon and Washington estuaries (Kelley et al. 2007). Adult green sturgeon are marine dependent and spends less time in estuarine and freshwater environments. Typically, these fish spend 3–13 years in the ocean before returning to freshwater to spawn (Moyle 2002). The LSJR and Bay-Delta serve as a migratory corridor, feeding area, and juvenile rearing habitat (ICF International 2012). Adult green sturgeon begin their upstream spawning migration into the San Francisco Bay in March, reach Knights Landing during April, and spawn between March and July (Heublein et al. 2006). Spawning typically occurs at temperatures between 46°F and 66°F (8°C–19°C) (Moyle 2002). Maximum spawning occurs at 58°F (14.4°C) in the Sacramento River (Kohlhorst 1976). Preferred spawning habitats for green sturgeon are thought to contain large cobble in deep and cool pools with turbulent water (Adams et al. 2002; Moyle 2002).

Larval green sturgeon exhibit nocturnal activity patterns (Cech et al. 2000) and begin nocturnal downstream migrational movements approximately 10 days after hatching (Kynard et al. 2005). Young green sturgeon appear to rear for the first 1 to 2 months in the Upper Sacramento River between Keswick Dam and Hamilton City (CDFG 2002). Juveniles spend 1–4 years in freshwater and estuarine habitats before they enter the ocean (Nakamoto et al. 1995). Younger fish have a lower salinity tolerance than adults, something that develops at a certain age (Allen et al. 2009).

Delta Smelt

Delta smelt is listed as threatened under ESA and endangered under CESA, and the U.S. Fish and Wildlife Service (USFWS) has designated critical habitat for delta smelt that incorporates the Bay-Delta.

Delta smelt are small fish (55–70 mm), that rarely live more than 1–2 years, have low fecundity, and are not recreationally or commercially fished. Delta smelt is endemic to only the Bay-Delta, and individuals generally spend their entire lifecycles in the open surface waters of the Bay-Delta and Suisun Bay. The geographic distribution of delta smelt includes low salinity and freshwater zones of the Bay-Delta system, including the Sacramento River downstream of Isleton, the Cache Slough subregion (Cache Slough-Liberty Island and the Sacramento Deep Water Ship Channel), the SJR downstream of Mossdale, and Suisun Bay and Suisun Marsh (Moyle 2002). Delta smelt are a euryhaline fish (occurring over a wide range of salinities) that are rarely found in water more than 10–12 ppt salinity; therefore, its distribution is thought to be related largely to freshwater flows into the Bay-Delta (Bennett 2005; Moyle 2002).

Delta smelt typically migrate December–March in response to “first flush” events that increase flow and turbidity in the Delta (Sommer et al. 2011). However, there is evidence of year-round residence of delta smelt in the northwestern Delta (Cache Slough region) (Nobriga et al. 2008; Lehman et al. 2010), possibly because turbidity and prey abundance are sufficient to support them (Sommer et al. 2004; Lehman et al. 2010). Spawning does not begin until late February, with peaks from March–May (Bennett 2005). Embryonic development is reported to last 11–13 days at 57°F–61°F (Moyle 2002). Baskerville-Bridges et al. (2004) reported hatching of delta smelt eggs after 8–10 days at 59°–62.5°F. Although spawning may occur at up to 71.5°F, hatching success of the larvae is very low at that high of temperatures (Bennett 2005). Spawning occurs primarily in sloughs and shallow edge areas in the Sacramento and Mokelumne Rivers and the SJR, the western and southern Delta, Suisun Bay, Suisun Marsh, and occasionally, in wet years, the Napa River (Wang 2007). Delta smelt have been found on the Sacramento River as far upstream as the confluence with American River and as far downstream as Mossdale on the SJR (Moyle 2002; Hobbs et al. 2007).

Upon hatching, larvae are semi-buoyant, staying near the bottom (Bennett et al. 2002), and are transported downstream to the low salinity habitat. However, recent evidence of year-round residence of delta smelt in the areas around Cache Slough indicates that downstream transport is not necessary for successful rearing. Within a few weeks, larvae develop an air bladder and become pelagic (living or occurring in the open sea) (Moyle and Bennett et al. 2002). Young-of-the-year delta smelt (i.e., production from spawning in the current year) rear from late spring through fall and early winter. Once in the rearing stage, growth is rapid, and juvenile fish are commonly 40–50 mm total length (TL) by early August (Radtke 1966). They reach adult size by early fall. Delta smelt growth during the fall months slows considerably (only 3–9 mm total), presumably because most of the energy ingested is being directed towards gonadal development (Radtke 1966; Mager 2004). Delta smelt are visual feeders (Baskerville-Bridges et al. 2004), swimming near the water surface and feeding on zooplankton in the wild (USFWS 2008). Feeding is size-based, with first-feeding larvae (5–8 mm standard length [SL]) consuming sub-adult cyclopoid and calanoid copepods (Nobriga 2002) and older larvae (10–15 mm SL) consuming adult copepods (Nobriga 1998).

Delta smelt seem to prefer water with high turbidity, based on a negative correlation between water quality and the frequencies of delta smelt occurrence in survey trawls during summer, fall, and early winter. For example, the likelihood of delta smelt occurrence in trawls at a given sampling station decreases with increasing Secchi depth[7] (Feyrer et al. 2007; Nobriga et al. 2008). This is consistent with behavioral observations of captive delta smelt. Few daylight trawls catch delta smelt at Secchi depths over 0.5 m and capture probabilities are highest at 0.40 m depth or less. Delta smelt's preference for turbid water may be related to increased foraging efficiency and reduced risk of predation (NMFS 2009a).

Temperature and salinity also affect delta smelt distribution. Swanson et al. (2000) indicate delta smelt tolerate temperatures between 46.5°F and 77°F; however, warmer water temperatures of more than 77°F restrict their distribution more than colder water temperatures. Delta smelt of all sizes are found in the main channels of the Delta and Suisun Marsh and the open waters of Suisun Bay where the waters are well oxygenated and temperatures are usually less than 77°F in summer (Nobriga et al. 2008). Suisun Bay and Suisun Marsh may be beneficial habitat for delta smelt due to salinity, which ranges from 0.5–10 ppt, though recent evidence suggests their presence may be more due to the food web. Typically, delta smelt follow X2,[8] low salinity habitat <2ppt that has decreased considerably in recent years (Feyrer et al. 2011).

---

[7] Secchi depth is a measurement of water clarity. A small white Secchi disk is lowered into the water column until it is no longer visible. Increased Secchi depth is an indicator of clear or less turbid water.

[8] X2 is the location of the 2 parts per thousand salinity contour (isohaline), 1 meter off the bottom of the estuary measured in kilometers upstream from the Golden Gate Bridge. The abundance of several estuarine species has been correlated with X2. In the 2006 Bay-Delta Plan, a salinity value—or electrical conductivity (EC) value—of 2.64 millimhos/centimeter (mmhos/cm) is used to represent the X2 location. Note, in this SED, EC is generally expressed in deciSiemens per meter (dS/m). The conversion is 1 mmhos/cm = 1 dS/cm.

Longfin Smelt

Longfin smelt is a special-status species that is not listed under ESA, but is listed as threatened under CESA (Baxter et al. 2009; California Fish and Game Commission 2009)

Populations of longfin smelt in California historically have been known to occur from the Bay-Delta, Humboldt Bay, the Eel River estuary, and the Klamath River estuary (Emmett et al. 1991). Longfin smelt occur throughout the Bay-Delta, including the Cache Slough region and Yolo Bypass. Adults occur seasonally as far downstream as the South Bay, but they are concentrated in Suisun, San Pablo, and North San Francisco Bays (Baxter 1999). Longfin smelt generally have a 2-year lifecycle. During this second year, they primarily inhabit the San Francisco Bay, but are thought to be pelagic (ocean-going). Thus, they have a salinity tolerance up to 35 ppt, though this is lower in younger life stages.

Spawning typically takes place as early as November and may extend into June, peaking between February and April. Spawning occurs in fresh or slightly brackish water over aquatic vegetation or sandy-gravel substrates when temperatures drop roughly below 64.5°F (Baxter et al. 2009). Based on their distribution patterns during the spawning season, the main spawning area appears to be downstream of Rio Vista on the Sacramento River (ICF International 2012). Spawning probably also occurs in the eastern portion of Suisun Bay and, in some years, the larger sloughs of Suisun Marsh. (Hobbs. et al. 2010). Historically, spawning probably also occurred in the SJR. Recent catches of longfin smelt in the SJR have been extremely low, potentially as a result of low flows in the river, which contribute to habitat degradation, unsuitable water temperature, and poor water quality (Moyle 2002).

Longfin smelt eggs typically hatch in February and disperse downstream (Wang 2007). The principal nursery habitat for larvae is the Suisun and San Pablo Bays (Meng and Matern 2001). However, the distribution of eggs may be shifted upstream in years of low outflow (Moyle 2002). Mortality for longfin smelt is highest February–May when larvae complete fin development (Wang et al. 2007), begin feeding, and are more exposed to predators. A positive relationship is observed between longfin smelt abundance and Delta outflow during the designated critical outflow period for longfin smelt between December and May (Stevens and Miller 1983; Kimmerer 2002), also suggesting a relationship to estuarine salinity. Longfin smelt have salinity tolerance up to ocean salinities, but are generally found between 0–20 ppt. Like delta smelt, longfin smelt larvae, in particular, are mostly found at <10 ppt, focusing near X2 (Hobbs et al. 2010; Kimmerer 2002).

Sacramento Splittail

Sacramento splittail is a special-status species that is not listed as threatened or endangered under ESA or CESA but is a California species of special concern. Sacramento splittail support a seasonal recreational fishery.

Sacramento splittail was listed as a federally threatened species but was delisted September 22, 2003. It is a large minnow endemic to the Bay-Delta and is confined to the lower reaches of the Sacramento River and SJR, the Delta, Suisun and Napa Marshes, and tributaries of northern San Pablo Bay (Wang 1986; Moyle et al. 1995). Although the Sacramento splittail generally abides in freshwater, the adults and sub-adults have a moderate to high tolerance for saline waters (up to 10–18 ppt) and are therefore considered an estuarine species. The salt tolerance of Sacramento splittail larvae is unknown (Meng and Moyle 1995; Moyle et al. 2004).

The decline in abundance of Sacramento splittail is attributable to the loss or alteration of lowland habitats (Young and Cech Jr. 1996). Specifically, the decline in abundance has been attributed to the reduction of the Delta outflow as a result of dam construction and upstream diversions and the changes in hydrodynamics in the Delta as a result of Delta exports (CDFG 1992a; Moyle 2002). High salinities are thought to restrict the downstream range of Sacramento splittail, and without adequate Delta outflow, juveniles are not able to rear in appropriate nursery areas (Young and Cech Jr. 1996).

Sacramento splittail have a high reproductive capacity. Individuals live 5–7 years and generally begin spawning at 1–2 years. Spawning, which seems to be triggered by increasing water temperatures and hours of sunlight, occurs over beds of submerged vegetation in slow-moving stretches of water, such as flooded terrestrial areas and dead-end sloughs (Sommer et al. 1997). Large-scale spawning and juvenile recruitment occurs only in years with significant protracted (greater than or equal to 30 days) floodplain inundation (McBain and Trush 2002), particularly in the Sutter and Yolo Bypasses (Meng and Moyle 1995; Sommer et al. 1997). Spawning also occurs in perennial marshes and along vegetated edges of the Sacramento River and SJR (Moyle et al. 2004). Adults spawn from late February through early July, most frequently during March and April (Wang 1986), and occasionally as early as January (Feyrer 2004).

Hatched larvae remain in shallow, weedy areas until they move to deeper offshore habitat later in the summer (Wang 1986). Young Sacramento splittail may occur in shallow and open waters of the Bay-Delta and San Pablo Bay, but they are particularly abundant in the northern and western Delta.

The diet of Sacramento splittail larvae up to 15 mm in length is dominated by zooplankton, primarily cladocerans, with some copepods, rotifers, and chironomids present in small amounts; chironomids become important after splittail reach 15 mm in length (Kurth and Nobriga 2001; Moyle 2002). In the 1980s, the diet of splittail age 1 and above included the native mysid shrimp, *Neomysis*, amphipods, and harpacticoid copepods, with detritus accounting for more than half the diet (Feyrer et al. 2003). After the invasion of the overbite clam *Potamocorbula amurensis* in the 1980s and the crash of *Neomysis*, clams, especially *Potamocorbula*, became an important component of the diet (Feyrer et al. 2003).

Kern Brook Lamprey

Kern brook lamprey is not listed as threatened or endangered under ESA or CESA but is a California species of special concern.

This species was first discovered in the Friant-Kern Canal, but it has since been found in the lower reaches of the Merced River, Kaweah River, Kings River, and SJR downstream to Kerckhoff Dam (Wang 1986). Based on the life history of other non-parasitic brook lampreys, Kern brook lampreys are thought to live for 4–5 years as ammocoetes (larvae) before metamorphosing into adults. Principal habitats of Kern brook lamprey are silty backwaters of large rivers in the foothill regions (mean elevation = 440 ft; range = 100–1,100 ft). In summer, ammocoetes are usually found in shallow pools along the edges of runs with slight current, depths of 12–45 inches, and water temperatures rarely exceeding 25°C (77°F). Ammocoetes appear to prefer sand/mud substrate where they remain buried with the head protruding above the substrate and feed by filtering diatoms and other microorganisms from the water. Adults likely require coarser gravel-rubble substrate for spawning (Moyle et al. 1995).

River Lamprey

River lamprey is not listed as threatened or endangered under ESA or CESA but is a species of special concern in California.

The biology of the river lamprey has not been well studied in California. As a result, much of this discussion is derived from information known for river lamprey from British Columbia. Thus, timing and life history events may be dissimilar due to differences in abiotic factors that are unique to California river systems (e.g., temperature, hydrology). River lamprey appear to be more abundant in the Lower Sacramento River, LSJR, and Stanislaus and Tuolumne Rivers than in other streams in California (Moyle 2002) such as Mill Creek (Wang 1986).

River lamprey begin their migration into freshwater in the fall towards suitable spawning areas upstream. However, river lamprey can spend their entire lives in freshwater as adults (such as the land-locked population of Sonoma Creek) (Wang 1986). Spawning occurs February–May in gravelly riffles. The eggs hatch into ammocoetes that remain in fresh water for approximately 3–5 years in silty or sandy low-velocity backwaters or stream edges where they bury into the substrate and filter-feed on algae, detritus, and micro-organisms (Moyle et al. 1995; USBR 2011).

During summer, ammocoetes change into juveniles and then adults at approximately 12 centimeter (cm) TL. This process takes 9–10 months, during which individuals may shrink in length by up to 20 percent (Moyle 2002). Adults spend approximately 3–4 months in the ocean, where they grow rapidly to 25–31 cm TL. If the ammocoete stage is 3–5 years, the total life span of river lamprey is estimated to be 6–7 years (Moyle et al. 1995; Moyle 2002).

River lamprey adults are parasitic during both freshwater and saltwater phases (Wang 1986). Adults feed on a variety of host fish species that are small to intermediate size (4–12 inches TL) (Moyle et al. 1995).

California Roach

California roach are sub-divided into several subspecies, two of which occur in the Sacramento–San Joaquin River Basin: the Sacramento-San Joaquin roach and the Red Hills roach (Moyle 2002). The Sacramento–San Joaquin roach is widely distributed throughout Sacramento and SJR drainages, while the Red Hills roach is known to occur in Horton Creek and other small streams near Sonora, California, in the Tuolumne River drainage. This species is recognized as a California species of special concern.

California roach frequent a variety of habitats, are generally found in small, warm streams, and are most abundant in mid-elevation streams in the Sierra Nevada foothills. Roach are tolerant of relatively high temperatures (86°F–95°F) and low oxygen levels (1–2 parts per million [ppm]). They also thrive in cold, clear, well-aerated streams, in heavily modified habitats, and in the main channels of rivers (Brown and Moyle 1993), such as the Tuolumne River (Moyle 2002).

Roach are omnivorous and are largely benthic feeders. However, in the Tuolumne River (below Preston Falls), they feed in fairly fast current on drift organisms, such as terrestrial insects. In larger streams, such as the North Fork Stanislaus River, aquatic insects may dominate their diets year-round (Moyle 2002).

Roach usually mature after reaching 45–60 mm TL at 2–3 years of age. Spawning is from March through early July, depending on water temperature, usually occurring when temperatures exceed 16°C (60.8°F) (Moyle 2002).

Pacific Lamprey

Pacific lamprey is not listed as threated or endangered under ESA or CESA but is a federal species of concern.

In the Central Valley, Pacific lamprey occur in the Lower Sacramento River and SJR and many of their tributaries, including the three eastside tributaries (Brown and Moyle 1993). Similar to the river lamprey, the majority of Pacific lamprey spend the predatory phase of their lives in the ocean (35 ppt) (USBR 2011). Pacific lamprey begin their migration into freshwater towards upstream spawning areas primarily between early March and late June. Spawning habitat requirements are thought to be similar to those of salmonids (Moyle 2002).

Pacific lamprey construct nests in gravelly substrates at a depth of 30–150 cm with moderately swift currents and water temperatures of typically 12°C–18°C (53.5°F–64.5°F). The eggs hatch into ammocoetes after 19 days at 59°F and then drift downstream to suitable areas in sand or mud. Ammocoetes remain in fresh water for approximately 5–7 years, where they bury into silt and mud and feed on algae, organic material, and microorganisms in various locations. Ammocoetes change into juveniles when they reach 14–16 cm TL. Downstream migration begins when the change is complete and generally coincides with high flow events in winter and spring (Moyle 2002; USBR 2011).

Hardhead

Hardhead is a special-status species that is not listed as threated or endangered under ESA or CESA but is a California species of special concern.

Hardhead is widely distributed in low- to mid-elevation streams in the Sacramento River and SJR Basins, scattered in tributary streams, and absent from valley reaches of the LSJR (Brown and Moyle 1993). Hardhead is also abundant in a few mid-elevation reservoirs used largely for hydroelectric power generation, such as Redinger and Kerkhoff Reservoirs (Moyle 2002).

Optimal temperatures for hardhead are determined to be 75°F–83°F, and most streams where hardhead are present have summer temperatures in excess of 68°F. At higher temperatures, hardhead is relatively intolerant of low oxygen levels, a factor that may limit its distribution to well-oxygenated streams and reservoir surface waters (Moyle 2002). Hardhead prefers clear, deep (more than 80 cm) pools and runs with sand-gravel-boulder substrates and slow velocities (20–40 cm per second). These fish are primarily riverine or freshwater; hardhead are always found in association with Sacramento pikeminnow (*Ptychocheilus grandis*) and usually with Sacramento sucker (*Catostomus occidentalis*) (Moyle 2002). Hardhead tend to be absent from streams where introduced species, especially centrarchids, predominate (Brown and Moyle 1993).

Hardhead mature in their third year and spawn mainly in April and May (Grant and Maslin 1999). Juvenile recruitment patterns suggest that spawning may extend into August in some foothill streams. Hardhead from larger rivers or reservoirs may migrate 30–75 kilometers (km) or more upstream in April and May, usually into tributary streams (Moyle et al. 1995). In small streams, hardhead may move only a short distance from their home pools for spawning, either upstream or downstream (Grant and Maslin 1999).

Hardhead are omnivores that consume drifting insects and algae in the water column and forage for benthic invertebrates and aquatic plant material on the bottom of the river floor (Alley and Li 1977).

Largemouth Bass

Largemouth bass is not a special-status species. A nonnative, it was first introduced into California in 1874, it spread to suitable habitat throughout the state and has become an important warmwater game fish in the state (Dill and Cordone 1997; Moyle 2002).

Largemouth bass are found in warm, quiet water with low turbidity and aquatic plants, such as farm ponds, lakes, reservoirs, sloughs, and river backwaters. Adult bass remain close to shore and usually are abundant in water 1–3 m deep near submerged rocks or branches. Young-of-the-year largemouth bass also usually stay close to shore in schools but occasionally swim about in the open (Moyle 2002).

Many California reservoirs and farm ponds provide excellent largemouth bass fishing with sizable populations of large, fast-growing fish. In reservoirs, the manipulation of water levels for water supply or hydropower production influences bass populations by affecting food availability and spawning success (Moyle 2002). However, largemouth bass are largely more tolerant to environmental stressors, such as the change in water levels in reservoirs, than native special-status fishes (Schindler et al. 1997; Moyle 2002).

Largemouth bass tolerate extreme water quality conditions, such as temperatures of 96.8°F–98.6°F with dissolved oxygen (DO) concentrations as low as 1 milligram per liter. Water temperatures optimum for growth range from 77°F–86°F (Moyle 2002). Very little growth occurs at temperatures below 59°F or above 96.8°F (Stuber et al. 1982).

Optimal riverine habitat for largemouth bass consists of large, slow-moving rivers or pools with fine-grained (sand or mud) substrates, some aquatic vegetation, and relatively clear water. Optimal velocities are generally less than 0.2 feet/second (ft/s), and velocities more than 0.34 ft/s are avoided. Velocities of over 0.66 ft/s are believed to be unsuitable (Stuber et al. 1982).

Largemouth bass spawn for the first time during their second or third spring, when they are approximately 180–210 mm. Spawning begins in March or April when water temperatures reach 59°F–60.8°F and may continue through June when water temperatures up to 75.2°F (Moyle 2002; ICF International 2012). Males build nests in a wide variety of substrates, including sand, mud, cobble, and vegetation, and gravel. Gravel seems to be preferred, while silty substrates are unsuitable (Stuber et al. 1982). Rising waters in reservoirs may cause active nests to be located as deep as 4–5 m. The eggs adhere to the nest substrate and hatch in 2–5 days (Moyle 2002). They are brackish water tolerant but tend to stay in freshwater and can persist in waters with low DO content (Moyle 2002).

For the first month or two after hatching, the fry feed mainly on rotifers and small crustaceans, but by the time they are 50–60 mm, they feed largely on aquatic insects and fish fry, including those of their own species. Once largemouth bass exceed 100–125 mm, they feed principally on fishes; however, prey preferences can vary from year to year (Moyle 2002).

Striped Bass

Striped bass, an introduced species, is not a special-status species but supports a popular and economically important recreational fishery. It is considered one of the species affected by the Pelagic Organism Decline (Sommer et al. 2007).

Striped bass are native to the Atlantic Coast of North America and was introduced to California in 1879 (Dill and Cordone 1997; Moyle 2002). Since being introduced, striped bass have become widespread in the Bay-Delta as both juveniles and adults. The species can also be found in the larger river systems downstream of impassible dams and the LSJR (Baxter et al. 2008). Striped bass are anadromous, spending the majority of their lives in saltwater (35 ppt) and returning to freshwater to spawn. When not migrating, the population located in the Bay-Delta is concentrated in San Pablo Bay, San Francisco Bay, and the ocean, but only within approximately 40 miles of the Golden Gate Bridge (Moyle 2002). Striped bass spawn in the Bay-Delta and lower reaches of the Sacramento River and SJR, including their tributaries. Spawning usually begins in April or May when water temperatures reach 60°F and continues sporadically over 3–5 weeks. It peaks in May and June, depending on the interaction of three factors: temperature, flow, and salinity (Farley 1966). Optimum temperatures appear to be roughly between 59°F and 68°F. Successful spawning in the LSJR above Vernalis occurs mainly during years of high flow when the large volume of runoff dilutes salty irrigation wastewater that normally comprises much of the river flow. In years of lower flow, spawning occurs in the Bay-Delta itself. The interaction of these factors produces spawning habitat in the LSJR and the southern Delta from sloughs near Venice Island down to Antioch (Farley 1966; Moyle 2002).

Eggs hatch in approximately 2 days at 64.5°F–66°F, and the larvae stage lasts an additional 4–5 weeks. Embryos and larvae drift into the Bay-Delta[9] and disperse as they grow. Larvae and juveniles feed primarily on invertebrates but switch their diet mainly to fish when transitioning to sub-adulthood. Modeling studies indicate striped bass predation on salmonids has the potential to be high (Nobriga and Feyrer 2007; Lobonschefsky et al. 2012).

White Sturgeon

While not a special-status species, white sturgeon is a native and recreationally important species in the Bay-Delta that inhabits riverine, estuarine, and marine habitats.

Historically, white sturgeon ranged from Ensenada, Mexico, to the Gulf of Alaska. Currently, spawning populations are found in the Sacramento–San Joaquin, Columbia, Snake, and Fraser River systems (Moyle 2002). In California, white sturgeon are most abundant in the Bay-Delta and Sacramento River (Moyle 2002), but they have also been observed in the SJR system, particularly in wet years (CDFG 2002; Beamesderfer et al. 2004). Known spawning areas include the Sacramento River between the Red Bluff Diversion Dam and Jelly's Ferry Bridge (river mile [RM] 267) in areas characterized by swift currents and deep pools with gravel (CDFG 2002), and recent egg sampling surveys have detected spawning in the mainstem SJR as far upstream as Grayson (RM 142) (Jackson and Van Eenennaam 2013).

White sturgeon spend most of their lives in the brackish portions of the upper estuary, although small number of individuals move extensively in the ocean (35 ppt); they are thought to be anadromous (Moyle 2002; Welch et al. 2006). Individuals can live over 100 years and can grow to over 19.7 ft (6 m), but sturgeon greater than 27 years old and over 6.6 ft (2 m) are rare (Moyle 2002). Male white sturgeon reach sexual maturity at 10–12 years of age, and females reach sexual maturity at 12–16 years (Moyle 2002). White sturgeon can spawn multiple times throughout their lives. Males are believed to spawn every 1–2 years, whereas females spawn every 2–4 years (Moyle

---

[9] Larval striped bass are associated with X2.

2002). Spawning typically occurs between February and June, when temperatures are 46°F–66°F (8°C–19°C) (Moyle 2002). Maximum spawning occurs at 58°F (14.4°C) in the Sacramento River (Kohlhorst 1976). It is thought that adults broadcast spawn in the water column in areas with swift current.

Fertilized eggs sink and attach to the gravel bottom, where they hatch after 4 days at 61°F (16°C) (Beer 1981), though hatching may take up to 2 weeks at lower water temperatures. Temperatures suitable for incubation and hatching range from 46°F to 68°F (ICF International 2012). Newly hatched larvae generally remain in the gravel for 7–10 days before emergence into the water column (Moyle 2002). Larvae are yolk sac dependent for approximately 7–10 days until the yolk sac is absorbed, at which time they begin actively feeding on amphipods and other small benthic macroinvertebrates (Wang 1986). Juvenile white sturgeon feed primarily on algae, aquatic insects, small clams, fish eggs, and crustaceans, but their diet becomes more varied with age (Wang 1986; Moyle 2002). Since the invasion by the overbite clam in the western Delta and Suisun Bay during the late 1980s, the clam has become a major component of the diet of juvenile and adult white sturgeon.

Spawning success varies from year to year, but is most likely related to temperature and Delta outflow. Spring flows in wet years may be the single most significant factor for white sturgeon year class strength (Beamesderfer et al. 2005). Although the mechanism is unknown, it is hypothesized that higher flows may help disperse young sturgeon downstream, provide increased freshwater rearing habitat, increase spawning activity cued by higher upstream flows, increase nutrients in nursery areas, or increase downstream migration rate and survival through reduced exposure time to predators (USFWS 1995).

American Shad

American shad is not a special-status species. American shad was introduced into the Sacramento River in the late 1800s and supported a commercial fishery by 1879 (Reynolds et al. 1993). Once established, American shad quickly spread into other rivers along the West Coast, including the LSJR (Dill and Cordone 1997). American shad population abundance in the Central Valley has declined from historical levels. The decline is attributed to increased water diversions and changing ocean conditions. The limited population data available also appears to indicate that American shad recruitment is lower during drier years (when Delta outflow is low) (Moyle 2002). Drought conditions are often accompanied by increases of temperature, causing juveniles rearing in the Bay-Delta and LSJR to become stressed.

The geographic distribution of American shad includes the Delta and Sacramento River, American River, Feather River, Yuba River, and SJR. Mature American shad start appearing in the LSJR in late April, with increased recruitment occurring in wetter years. Peak spawning occurs from mid-May to mid-June at water temperatures of 51.8°F–62.6°F; however, some spawning can occur as late as early September. American shad spawn mostly in main channels of rivers over a wide variety of substrates, although sand and gravel are most commonly used. Depth of the water is usually less than 3 m but can range from 1–10m. Following their first spawning event, American shad will return annually to spawn until they are up to 7 years of age (Moyle 2002).

Depending on water temperatures, larvae hatch from eggs in 3–12 days. Larval American shad are planktonic for about 4 weeks and cannot survive in saltwater (Zydlewski and McCormick 1997). The first several months are usually spent in fresh water, but small shad can live in salinities of up to

20 ppt. American shad seem to prefer temperatures of 62.6°F–77°F during the rearing stage (Stier and Crance 1985; Moyle 2002).

While in the Bay-Delta, young American shad feed on zooplankton, especially mysid shrimp, copepods, and amphipods. Although they feed primarily in the water column, they are opportunistic and will also take abundant bottom organisms and surface insects. Entry into saltwater takes place in September, October, and November, but may start as early as June, especially in wet years when outflows are high. Peak salvage of juvenile shad at the southern Delta pumping plants generally occurs during this time (Moyle 2002).

Kokanee

Kokanee is not a special-status species. It was brought from Idaho to California in 1941 (Moyle 2002). Kokanee is the nonanadromous form of sockeye salmon; individuals mature in lakes and reservoirs rather than in the ocean. Kokanee prefer well-oxygenated, open waters of lakes and reservoirs, roughly 1–3 m from the water's surface where temperatures range between 50°F and 59°F. Most kokanee populations mature in 4 years; however, populations can mature in as little as 2 years or take as many as 7 years (Moyle 2002). Like other salmonid species, once kokanee mature, they typically return to the stream in which they were hatched as fry (Moyle 2002).

Spawning behavior of kokanee is similar to that of other salmonids (e.g., mate selection, redd construction, death after spawning). Typically, kokanee spawn between August and February; however, they have been observed to spawn as late as April in California. Most spawning takes place in the gravel riffles of small streams a short distance from a lake or reservoir where temperatures are roughly 43°F–55.5°F. Fry typically emerge from the redds in April and June and immediately move to downstream rearing habitat (Moyle 2002).

7.2.2 Reservoirs, Tributaries, and LSJR

This section describes the water bodies comprising the environmental setting for aquatic resources that may be affected by the LSJR alternatives. These water bodies are the major storage reservoirs on the Stanislaus, Tuolumne, and Merced Rivers; the downstream reaches of the Stanislaus, Tuolumne, and Merced Rivers below the rim dams; and the LSJR and southern Delta. For each water body, the indicator species and the baseline environmental stressors affecting aquatic resources are discussed. Table 7-4 summarizes the indicator species found in these geographic locations and their life stages.

Efforts to protect aquatic resources in the SJR Basin, outside the plan area, are currently underway. As discussed in Appendix K, *Revised Water Quality Control Plan*, SJRRP is currently undertaking the restoration of flow to the Upper SJR from Friant Dam to the confluence with the Merced River to restore a self-sustaining Chinook salmon fishery in the river, while reducing or avoiding adverse water supply impacts from restoration flows. Major planning and permitting activities are currently underway, as well as studies and monitoring activities to evaluate the current and future needs of fish in the river The State Water Resources Control Board (State Water Board) will continue to coordinate adaptive implementation and future changes to the 2006 *Water Quality Control Plan for the San Francisco Bay/Sacrament–San Joaquin Delta Estuary* (2006 Bay-Delta Plan) with the SJRRP to assure the protection of fish and wildlife in the SJR Basin. Following full implementation of the SJRRP, the State Water Board will also evaluate whether additional changes should be made to flow, water right, or other requirements to protect fish and wildlife in the SJR.

Stanislaus River

New Melones Reservoir

New Melones Reservoir supports sport fisheries for coldwater and warmwater species, including rainbow trout, brown trout, kokanee, largemouth bass, smallmouth bass, crappie (*Pomoxis* spp.), bluegill (*Lepomis macrochirus*) catfish, minnows, suckers, and carp. Rainbow and brown trout are generally restricted to colder, deeper water during summer, while most of the other species inhabit warmer surface and shallow inshore waters (USBR 2009).

Stanislaus River below New Melones Reservoir

Historically, spring-run Chinook salmon, fall-run Chinook salmon, Central Valley steelhead, and possibly late fall-run Chinook salmon occurred in the Stanislaus River (Yoshiyama et al. 1996, 1998). Salmon and steelhead were abundant in the Merced and Tuolumne Rivers and presumably the Stanislaus River before the Gold Rush began in 1849. Populations declined thereafter in response to dam construction, expansion of commercial fishing, and habitat degradation associated with early hydraulic mining, dredging, and water diversions. Spring-run Chinook salmon are thought to have been extirpated from the Stanislaus River after the construction of Melones Dam in 1926, which blocked access to their historical spawning habitat in the upper watershed (Yoshiyama et al. 1996, 1998). Goodwin Dam, completed in 1913, was passable but became a complete barrier to migration by 1940 and is now the upstream limit of migration for anadromous fish (Stanislaus River Fish Group 2003). These barriers likely had a similar effect on steelhead because of steelhead's dependence on higher elevation streams for holding, spawning, and early rearing.

Today, the only anadromous salmonids in the Lower Stanislaus River supports are fall-run Chinook salmon and steelhead, both of which are currently restricted to the lowermost 58 RMs below Goodwin Dam. Small numbers of adult salmon are observed in the summer, but these may be spring-run strays from the Sacramento River Basin based on the recovery of tagged adults originating from the Feather River Hatchery (Stanislaus River Fish Group 2003). Other anadromous fish species that occur in the Lower Stanislaus River include striped bass, American shad, Pacific lamprey, and river lamprey (Stanislaus River Fish Group et al. 2003). Striped bass and American shad were introduced into the Sacramento and SJR Basin in the late 1880s (Stanislaus River Fish Group et al. 2003).

Indicator Species

Fall-Run Chinook Salmon

The fall-run Chinook salmon population of the Stanislaus River is maintained by natural production and hatchery strays originating from the Merced River, Mokelumne River, and Sacramento River Basin hatcheries. The California Department of Fish and Wildlife (CDFW [formerly California Department of Fish and Game (CDFG)]) began estimating the number of fall-run Chinook salmon that returned to spawn each year (i.e., spawning escapement) in the Stanislaus River in 1947 (Stanislaus River Fish Group 2003). Since 1947, annual escapement to the Stanislaus River has fluctuated substantially with the highest returns generally occurring during wet periods or after years of relatively high spring flows and the lowest returns generally occurring during dry periods or after years of relatively low flows (Figure 7-1).

Annual escapement of fall-run Chinook salmon was minimally estimated at 4,000–35,000 spawners (average about 11,100) from 1946–1959 before the construction of Tulloch Dam in 1959. In the following 12-year period (1960–1971), the average run size was about 6,000 fish. Fall-run abundances during the 1970s and 1980s ranged up to 13,600 (average about 4,300) spawners annually (CDFG unpublished data). The numbers of spawners returning to the Stanislaus River have been especially low during most of the 1990s—<500 fish annually in 1990–1993, 600–800 fish in 1994–1995, and <200 fish in 1996—but there was a modest increase to 1,500 spawners in 1997 and 2,200 spawners in 1998 (CDFG unpublished data) (Figure 7-1). Estimation of the proportion of hatchery- and natural-origin fall-run Chinook salmon returning to the Central Valley in recent years indicates that returns to the Stanislaus River are dominated by hatchery-origin fish. In 2011, an estimated 83 percent of the run were hatchery-produced fish originating primarily from Mokelumne River Hatchery, Coleman National Fish Hatchery, and Merced River Hatchery (Palmer-Zwahlen and Kormos 2013). Juvenile salmon may occur throughout the Stanislaus River below Goodwin Dam during the primary rearing and emigration period (February–May). Monitoring of downstream movements of juvenile Chinook salmon at Oakdale and Caswell from 1996–2005 revealed a consistent migration pattern characterized by downstream dispersal of newly emerged fry from late January through early March, followed by the emigration of smaller numbers of parr and smolts through mid-June. Peak movements of juveniles generally coincided with rapid increases or peaks in flow (i.e., flow pulses), especially during the fry emigration period (Pyper and Justice 2006).

Steelhead

Steelhead were thought to have been extirpated from their entire historical range in the San Joaquin Valley, but current populations consisting of anadromous and non-anadromous forms survive in the Stanislaus, Tuolumne, and Merced Rivers (NMFS 2009a). Information regarding steelhead numbers on the Stanislaus River is scarce and has typically been gathered incidental to existing monitoring activities for fall-run Chinook salmon. For example, in 2006–2007, 12 steelhead were observed passing through the counting weir (NMFS 2009c). Steelhead smolts have been captured in rotary screw traps at Oakdale and Caswell State Park since 1995 (S. P. Cramer and Associates Inc. 2000, 2001), but the numbers are very low, ranging from 10–30 annually. Most of the steelhead smolts are captured from January to mid-April at a size of 175–300 mm fork length. The distribution and habitat preferences of spawning adults in the Stanislaus River are unknown, but it is presumed that the majority of spawning occurs between Goodwin Dam and Orange Blossom Bridge.

Graphics…00427.11 (8-13-2014)

Figure 7-1
Estimates of Annual Escapement of Fall-run Chinook Salmon in the Stanislaus River from 1952 to 2011

Most of the environmental factors that potentially limit survival and production of fall-run Chinook salmon in the Stanislaus River likely apply to steelhead to some degree. However, because juvenile steelhead rear in the river for 1 or more years before migrating to the ocean, steelhead also require suitable flows and temperatures during the summer months.

Environmental Stressors

Baseline stressors that affect aquatic resources in the Stanislaus River include impassable dams and alteration of the natural flow regime, loss of natural riverine function and morphology, agricultural and urban land uses, gravel mining, predation, and water quality (e.g., contaminants and suspended sediment) (NMFS 2009c).

Flow Regulation

Flow releases for fishery purposes in the Lower Stanislaus River are designated in a 1987 agreement, the New Melones Interim Plan of Operations (IPO) between the U.S. Bureau of Reclamation (USBR) and CDFG. The IPO specifies interim annual flow allocations for fisheries 98,300–302,100 AF, depending on carryover storage at New Melones Reservoir and inflow. Additional flow regulation efforts exist for the Stanislaus River, including D-1422,[10] which imposes flow requirements to provide water quality control and maintain monthly total dissolved solids (TDS) concentration. The Anadromous Fish Restoration Program (AFRP) recommended a instream flow schedule that increased flows during the spring outmigration period (February–May) and was expected to double salmon production for the SJR Basin. The National Marine Fisheries Service (NMFS) biological opinion (BO) Stanislaus River reasonable and prudent alternative, including Action 3.1.3 (NMFS BO) provides a minimum flow schedule measured at Goodwin Dam; and the U.S. Army Corps of Engineers (USACE) provides flood control release limits. (For a discussion of the flows, see Chapter 2, *Water Resources*; Chapter 5, *Surface Hydrology and Water Quality*; and Chapter 3 of Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*).

The historical relationship between spring flows during the Chinook salmon rearing and emigration period and subsequent adult abundance has been the basis for a number of analyses and experimental investigations aimed at understanding the factors influencing the population dynamics of Chinook salmon populations in the Stanislaus, Tuolumne, and Merced Rivers (see Appendix C, Chapter 3, *Scientific Basis for Developing Alternative San Joaquin River Flow Objectives*). These investigations suggest that flow in the SJR and the three eastside tributaries has a major influence on juvenile salmon survival between March and June as individuals complete the freshwater rearing, smoltification, and migration stages of their lifecycles.

Habitat Alteration

Since New Melones Dam was constructed in 1979, the quantity and quality of spawning and rearing habitat has also been adversely affected by reductions in the frequency of bed-mobilizing and channel forming flows. The effects include encroachment of riparian vegetation, increased channel

---

[10] State Water Board's Water Right Decision 1422 (D-1422) approved the permits for USBR's New Melones Reservoir on the Stanislaus River and conditioned the permits on meeting total dissolved solids of 500 parts per million (ppm) (833 mmhos/cm electrical conductivity [EC]) on the SJR at Vernalis.

incision and bed armoring, and reductions in recruitment of spawning gravel to the active channel (Kondolf et al. 2001).

Impaired geomorphic processes associated with gravel mining and controlled flow releases as a result of dam operations are considered a major stressor on aquatic resources in the Stanislaus River. Historical gravel mining (dredged river channels and mine pits) and the cessation of gravel recruitment from upstream sources have reduced the availability of spawning gravel in the Stanislaus River below Goodwin Dam. Currently, fall-run Chinook salmon are known to spawn in a 23-mile stretch of the Stanislaus River downstream of Goodwin Dam, but most spawning occurs in the first 10 miles below New Melones Dam (USBR 2011). Since 1997, gravel replenishment projects have increased the amount of spawning habitat, but redd superimposition continues to be a problem and may limit the number of adult salmon that can successfully spawn in the Stanislaus River (Stanislaus River Fish Group 2003). Gravel replenishment projects have offset some habitat loss, but the rate of replenishment is neither sufficient to offset ongoing loss rates nor to offset losses from past years of operations (NMFS 2009c).

Flood attenuation, channel incision, and agricultural and urban encroachment have also reduced the frequency of overbank flows and the availability of floodplain habitat for salmon rearing and other ecosystem functions on the Stanislaus River (NMFS 2009c). Losses and degradation of riparian and floodplain habitat and reductions in natural hydrologic variability that connect rivers to their floodplains has been identified as a major stressor on native Central Valley fish populations through direct impacts on spawning and rearing habitat availability and indirect impacts on aquatic productivity and food web support provided by seasonal floodplain inundation (see Appendix C, *Technical Report on the Scientific Basis for Alternatives San Joaquin River Flow and Southern Delta Salinity Objectives*). Although specific food web studies have not been conducted on the Stanislaus River, current research indicates that regulated flows downstream of dams and losses of overbank flooding have likely contributed to historical declines and current limitations on native fish populations through reductions in primary and secondary production (phytoplankton and invertebrate production) associated with seasonal floodplain inundation (Sommer et al. 2004; Ahearn et al. 2006).

Water Quality

Land uses adjacent to the Stanislaus River and within its watershed influence the water quality of the river and the types and quantities of pollutants found in the water. Poor water quality associated with agricultural runoff (i.e., pesticides) and increasing urbanization has been identified as a potential stressor on steelhead and other aquatic resources in the Lower Stanislaus River. Common pollutants include nutrients from agricultural and livestock operations; pesticides, herbicides, and fungicides applied to crops and orchards; sediment and soil from runoff of agricultural operations; oil or grease from junkyards along the river; and trace metals, heavy metals, and sediment from historical and current mining or gravel extraction operations (NMFS 2009a). Water quality impairments for the Stanislaus River below New Melones Reservoir include diazinon, group A pesticides,[11] and mercury. Additionally, chlorpyrifos and water temperature may also be added to

---

[11] Group A pesticides include one or more of the following compounds: Aldrin, Dieldrin, Endrin, Chlordane, Lindane, Heptachlor, Heptachlorepoxide, and Endosulfan and Toxaphene.

the impaired water bodies 303(d) list[12] (see Section 7.3.2, *State [Regulatory Background]*) as water quality impairments in the future.

Introduced Species and Predation

The establishment and expansion of nonnative species in the Stanislaus River, and the SJR Basin in general, has contributed to increases in potential predation-related mortality of native species such as fall-run Chinook salmon and steelhead. Striped bass, smallmouth bass, and largemouth bass are only a few of the introduced species that prey on salmonids, but they may be responsible for much of the increased predation pressure on special-status fish species compared to historical conditions (USDOI 2008). Alteration of the stream channel by the creation of ditch-like channels from historical gravel mining has also improved habitat conditions and predation opportunities for striped bass, largemouth bass, and other predatory fishes that might contribute to low survival of juvenile salmon as they migrate downstream through the lower reaches of the Stanislaus River (Grossman et al. 2013). However, exact estimates in this system need further study, and approximately 9 percent of winter-run Chinook salmon in the Central Valley are thought to be predated depending on time of migration (Loboschefsky et al. 2012; Grossman et al. 2013).

Disease

Diseased fish are present and have been caught in the Stanislaus River. Naturally produced Chinook salmon juveniles caught in rotary screw traps were diagnosed with the causative agent of bacterial kidney disease (BKD), *Renibacterium salmoninarum.* Additionally, columnaris disease, caused by the bacterium *Flexibacter columnaris*, was observed in juvenile Chinook salmon in 2007. This disease can rapidly increase in the population as water temperatures reach a mean daily temperature of 68°F–69.8°F (Nichols and Foott 2002).

Tuolumne River

New Don Pedro Reservoir

New Don Pedro Reservoir provides a warmwater and coldwater sport fishery. A variety of game fish are stocked in the reservoir. Warmwater game fish in the reservoir are a Florida strain of largemouth bass, smallmouth and spotted bass, channel catfish, crappie, sunfish, blue gill, and carp. Coldwater game fish in the reservoir are kokanee; Chinook salmon; and brown, brook, and rainbow trout (Don Pedro Lake 2012).

Tuolumne River below New Don Pedro Reservoir

Historically, the Tuolumne River had 99 miles of anadromous fish habitat, and currently there is approximately 47 miles of accessible habitat (USFWS 2008). La Grange Dam is the upstream extent of accessible anadromous fish habitat. Historically, the Tuolumne River supported abundant populations of Central Valley steelhead and fall-run and spring- run Chinook salmon (Yoshiyama et al. 1996) and now supports smaller populations of steelhead and fall-run Chinook salmon (NMFS 2009c). Spring-run Chinook salmon were extirpated from the Tuolumne River Watershed when dam construction eliminated access to upstream habitats (Stillwater Sciences n.d.). Central Valley steelhead were thought to have been extirpated from the Tuolumne River, but fisheries monitoring

---

[12] Clean Water Act section 303(d) requires states, territories, and authorized tribes to develop a ranked list of water quality limited segments of rivers that do not meet water quality standards.

for the New Don Pedro Federal Energy Regulatory Commission (FERC) relicensing project have documented the presence of *O. mykiss* in the Lower Tuolumne River (TID and MID 2012).

The mainstem Tuolumne supports both nonnative and native fish species. Nonnative fish species important for sport fisheries include American shad, catfish species, largemouth, smallmouth and striped bass, and sunfish species. Native fish species include Pacific and river lamprey, hardhead, Sacramento pikeminnow, Sacramento blackfish, and Sacramento sucker (TID and MID 2012).

Indicator Species

Fall-Run Chinook Salmon

The fall-run Chinook salmon population is maintained by natural production and hatchery strays from the Merced River and other basin hatcheries. Since 1960, annual escapement to the Tuolumne River has fluctuated substantially, with the highest returns generally occurring during wet periods or after years of relatively high spring flows and the lowest returns generally occurring during dry periods or after years of relatively low flows (Figure 7-2). Tuolumne River Chinook salmon estimates have ranged from a high of 45,900 fish in 1959 to a low of 77 in 1991. The population estimate for 2011 was 893 fish (CDFG unpublished data). Estimation of the proportion of hatchery- and natural-origin fall-run Chinook salmon returning to the Central Valley in recent years indicates that returns to the Tuolumne River are dominated by hatchery-origin fish. In 2011, an estimated 73 percent of the run consisted of hatchery-produced fish that originated primarily from the Merced River Hatchery, Mokelumne River Hatchery, and Feather River Hatchery (Palmer-Zwahlen and Kormos 2013).

Spawning in the Tuolumne River has been observed mainly upstream of Hickman Bridge. Spawning is most heavily concentrated in the reach between RM 51.5 (upstream of Old La Grange Bridge) and Basso Bridge. Adult Chinook salmon in the Tuolumne River generally spawn September–December, but some later-arriving fish have been observed. Recent observations of fry emergence in late May suggest that adults spawn as late as February. Also, in 2000, adults were observed in the river during summer (Stillwater Sciences n.d.). Fry emergence extends primarily from January–March (McBain & Trush 2000). Juvenile Chinook salmon leave the river as fry, juveniles, smolts (subyearlings), or yearlings. Large numbers of fry leave the river particularly during wet years. Smolts emigrate February–June. A few salmon spend summer in the river and emigrate during the fall and early winter as yearlings (Stillwater Sciences n.d.).

Steelhead

The historical distribution of steelhead in the SJR Basin, including the Tuolumne River, is poorly known, but steelhead were recorded by CDFG in counts conducted at Dennett Dam (RM 16.2) in 1940 and 1942 (CDFG unpublished data). O. mykiss population estimate snorkeling surveys started in July 2008, pursuant to an April 2008 FERC order, and ended September, 2011. The estimated population results are shown in Table 7-5 (TID and MID 2012).

Note: 2008-2011 data are preliminary

Graphics…00427.11 (8-13-2014)

Figure 7-2
Estimates of Annual Escapement of Fall-run Chinook Salmon in the Tuolumne River from 1952 to 2011

Table 7-5. Estimated Population of *O. Mykiss* from Turlock Irrigation District and Modesto Irrigation District (2012) Snorkel Surveys

Date	Number of Juveniles	Number of Adults
July 2008	2,472	643
March 2009	63	170
July 2009	3,475	963
March 2010	0	109
August 2010	2,405	2,139
September 2011	47,432	9,541

An acoustic tag and tracking survey was done pursuant to a May 2010 FERC Order. *O. mykiss* were tagged with acoustic tags and tracked to determine spawning locations, migration patterns, and potential habitat use of restored river reaches. Tracking began in 2010 and continued into 2011. No other fish were tagged in 2011. All tagged fish remained in the river. Two tagged fish moved up- and downstream as far as 6.8 miles, and all other fish remained near their release locations (TID and MID 2012).

Environmental Stressors

Anthropogenic factors have affected salmonid habitat on the Tuolumne River. Water supply development, flood control, gold dredging, aggregate mining, and hatchery operations have all affected salmonid populations (Stillwater 2002).

Flow Regulation

Available fish habitat on the Tuolumne River is primarily controlled by established flows. Flow requirements for the Lower Tuolumne River are specified in the *New Don Pedro Proceeding Settlement Agreement* and the *FERC License Amendment for the New Don Pedro Project*. These flows are provided to protect fall-run Chinook salmon spawning below La Grange Dam. (For a discussion of the flows, see Chapter 2, *Water Resources*; Chapter 5, *Surface Hydrology and Water Quality*; and Appendix C, Chapter 3, *Scientific Basis for Developing Alternative San Joaquin River Flow Objectives*).

The historical relationship between spring flows during the juvenile emigration period and subsequent adult abundance has been the basis for a number of analyses and experimental investigations aimed at understanding the factors influencing salmon survival and population dynamics under historical and recent water management operations in the SJR and Delta (see Appendix C, Chapter 3, *Scientific Basis for Developing Alternate San Joaquin River Flow Objectives*). These investigations suggest that flow in the SJR and the three eastside tributaries has a major influence on juvenile salmon survival between March and June as individuals complete the freshwater rearing, smoltification, and migration stage of their lifecycles.

Habitat Alteration

Habitats in the Tuolumne River downstream from LaGrange Dam have been influenced and altered by former gold mining activities and gravel mining (USBR 2011). As a result, there is limited spawning habitat in upstream areas, and this results in redd superimposition and egg mortality (Stillwater Sciences n.d.; Moyle 2002). During the early twentieth century, the Tuolumne River channel and floodplain were dredged for gold. The gold dredges excavated channel and floodplain deposits to the depth of bedrock (approximately 25 ft [7.6 m]) and often realigned the river channel. Due to gravel mining activities, the channel has become constrained by dredge tailings, which restricts channel meander and reduces delivery of gravel to the river. Riparian vegetation is also scarce due to dredge tailings. By the end of the gold mining era, the floodplain adjacent to 12.5 miles (20 km) of the river (RM 50.5–38) had been converted to tailings deposits. Tailings remain in the reach from RM 45.4–40.3 (Stillwater Sciences n.d.). Additionally, pits were made in the channel that provide habitat for largemouth bass and other predatory fish species.

Land clearing for gold dredging, aggregate mining, and agricultural and urban development has resulted in the loss of 85 percent of the Tuolumne River's historical riparian forest. Vegetation that once extended from bluff to bluff prior to the Gold Rush is now confined to a narrow band along the active channel margins in many areas, or is nonexistent. Nearly all of the areas in the gravel-bedded zone that historically supported riparian forests have been mined, grazed, or farmed (Stillwater Sciences n.d.).

Under the FERC settlement agreement, habitat restoration has begun on the Lower Tuolumne River. A total of 14 channel restoration projects have been identified in the *Habitat Restoration Plan for the Lower Tuolumne River Corridor* (McBain and Trush 1999). From reach RM 0–52, which is below La Grange Dam, general restoration components include restoring floodplain habitat, planting riparian vegetation along the banks, and adding spawning gravel to reaches of the river that are conducive to spawning (USFWS 1999). Between 1994 and 2003, 19,250 cubic yards of gravel were added to enhance spawning and rearing habitats in the Tuolumne River (Table 7-6).

Table 7-6. Tuolumne River Gravel Augmentation Projects

Tuolumne River Projects	Gravel Volume Added (yard^3)	Year Construction Completed
La Grange Gravel Addition Project, early	6,750	1994
La Grange Gravel Addition Project, Phases I and II	12,500	1999–2003

Source: Mesick and Marston 2007.

Reductions of the magnitude, frequency, and duration of flood flows and confinement of the natural floodway of the Tuolumne River has disrupted the natural processes creating high-quality salmon spawning and rearing habitat, including shallow, slow-water river margins and floodplain habitat supporting rearing juveniles and other native fishes (McBain and Trush 2000). Losses and degradation of floodplain habitat and reductions in natural hydrologic variability that connect rivers to their floodplains has been identified as a major stressor on native Central Valley fish populations through direct impacts on spawning and rearing habitat availability and indirect impacts on aquatic productivity and food web support provided by seasonal floodplain inundation (see Appendix C, *Technical Report on the Scientific Basis for Alternatives San Joaquin River Flow and Southern Delta Salinity Objectives*). Although specific food web studies have not been conducted in the Tuolumne River, current research indicates that regulated flows downstream of dams and losses of overbank flooding have likely contributed to historical declines and current limitations on native fish populations through reductions in primary and secondary production (phytoplankton and invertebrate production) associated with seasonal floodplain inundation (Sommer et al. 2004; Ahearn et al. 2006).

Water Quality

As discussed for the Stanislaus River, land uses adjacent to and within the watershed influence the water quality of the river and the types and quantities of pollutants found in the water. Poor water quality associated with agricultural runoff and increasing urbanization has been identified as a potential stressor on steelhead and other aquatic resources in the Lower Tuolumne River. Common pollutants include nutrients from agricultural and livestock operations; pesticides, herbicides, and fungicides applied to crops and orchards; sediment and soil from runoff of agricultural operations; oil or grease from junkyards along the river; and trace metals, heavy metals, and sediment from historical and current mining or gravel extraction operations (NMFS 2009a).

Introduced Species and Predation

Studies of predator abundance, habitat use, and predation rates on juvenile Chinook salmon in the Tuolumne River indicate that predation by largemouth bass, smallmouth bass, and other nonnative fishes may be a limiting factor for Chinook salmon outmigrant survival and may be a source of mortality under low flow conditions (EA 1992; TID and MID 1992; FishBio 2013). In general, reduced spring flows, elevated water temperatures, and the presence of low-velocity habitats (including former in-channel aggregate mining pits) in the lower reaches of the Tuolumne River favor fish communities dominated by nonnative, warmwater species such as largemouth bass and other potential predators on native salmonids (EA 1992; McBain and Trush 2000; Brown and Ford 2002). For example, Brown and Ford (2002) found that the spawning success of nonnative species, as measured by the proportion of nonnative juveniles (consisting predominantly of bass and sunfish species) in winter and spring samples, was inversely related to spring discharge the previous year (Brown and Ford 2002). The response of nonnative warmwater fish species to high spring flows also included a downstream shift in distribution consistent with the hypothesized effect of higher flows and lower water temperatures on spawning success (Stillwater Sciences et al. 2006).

Hatchery Operations

As discussed above, large numbers of unmarked hatchery salmon are released into the Merced River each year and may stray into the Tuolumne River. In recent years, up to 200,000 hatchery-origin salmon from the Merced River Hatchery have been released annually in the Tuolumne River. As a result, a significant number of hatchery-origin Merced River salmon return to the Tuolumne River each year. Fish produced by the hatcheries have the potential to negatively affect natural fall-run Chinook salmon by displacing wild salmonid juveniles through competition and predation, competing with natural adults for limited resources, and hybridizing Central Valley Chinook salmon with fish from outside the SJR Basin (CDFG 2011a).

Disease

Fish species on the Tuolumne River are susceptible to similar diseases as those discussed for fish in the Stanislaus River. The causative agent of BKD was detected in naturally produced juveniles caught in rotary screw traps from Tuolumne River (Nichols and Foott 2002).

Merced River

Lake McClure and Lake McSwain

Lake McClure, which is impounded by New Exchequer Dam, and Lake McSwain, which is impounded by McSwain Dam, both support warmwater and coldwater sport fish species. Lake McClure contains a variety of sport fish species, such as largemouth bass, spotted bass, bluegill, green sunfish, kokanee, rainbow trout, and Chinook salmon. Common carp and catfish are also in the reservoir (Merced ID 2011). CDFW annually stocks rainbow trout, kokanee, and Chinook salmon. Spawning habitat for warmwater fish species is available in low gradient areas in Lake McClure. Spawning gravels in six tributaries surrounding the reservoir could provide spawning habitat for both warmwater and coldwater species. Lake McSwain has the same fish species, but also contains brook and brown trout (Merced ID 2011).

Merced River below Crocker-Huffman Dam

As with the Stanislaus and the Tuolumne Rivers, the Merced River historically supported abundant populations of coldwater fish species, such as Central Valley steelhead and spring- and fall-run Chinook salmon. Chinook salmon may have occurred up to an elevation of 2,000 ft near El Portal. By 1925, Crocker-Huffman, Merced Falls, and New Exchequer Dams had blocked anadromous fish passage (Stillwater Sciences 2002). Crocker-Huffman and Merced Falls dams have fish ladders, but they were shut down when the Merced River Hatchery was constructed at the base of Crocker-Huffman Dam. These barriers likely had a similar effect on steelhead because of their dependence on higher elevation streams for holding, spawning, and early rearing (Stillwater Sciences 2002).

Today, the river supports only fall-run Chinook salmon and a small population of wild and hatchery steelhead. Currently, the Merced River is accessible to anadromous fishes for the first 51 RMs, with access terminating at Crocker-Huffman Dam (USBR 2011). There are also limited numbers of hatchery-reared, late-fall-run Chinook that have strayed from their natal streams. The Merced River Hatchery, which has been operated by CDFW since 1971, produces fall-run Chinook salmon that are released into the Merced River and used for studies throughout the SJR Basin (Stillwater Sciences 2002).

There is a variety of introduced fish species in the mainstem Merced River, including catfish, several species of bass, sunfish, American shad, threadfin shad, and carp. Native fish species include Sacramento sucker, prickly sculpin, Sacramento blackfish, Sacramento pikeminnow, Pacific and Kern Brook lamprey, hardhead, and Sacramento splittail (Stillwater Sciences 2002).

Indicator Species

Fall-Run Chinook Salmon

Since the 1940s, CDFW has conducted escapement surveys to document the number and timing of adult Chinook salmon returning to the Merced River to spawn. Since 1998, CDFW, with funding from the Central Valley Project Improvement Act–Comprehensive Monitoring and Assessment Program, also operated a rotary screw trap near the mouth of the river to document juvenile salmon outmigration and abundance (Stillwater Sciences 2002).

Annual escapement for fall-run fish has fluctuated from a high of 29,749 in 1984 to 82 adults in 1990. Before 1966, the population was less than 500 fish until minimum instream flows were established under the Davis-Grunsky Act in October of 1966 and the Merced River Hatchery opened in 1970 (Mesick 2010a). Escapement from 2007 to 2009 declined to an average of about 500 fish, presumably because of poor ocean conditions (Lindley et al. 2009). The population estimate in 2011 was 1,942 fish. Figure 7-3 shows the annual escapement of fall-run Chinook salmon from 1952 to 2011 (CDFG unpublished data). Estimation of the proportion of hatchery- and natural-origin fall-run Chinook salmon returning to the Central Valley in recent years indicates that returns to the Merced River are dominated by hatchery-origin fish. In 2011, an estimated 88–89 percent of the returns to the Merced River and Merced River Hatchery were hatchery-produced fish originating primarily from Merced River Hatchery, Mokelumne River Hatchery, and Coleman National Fish Hatchery (Palmer-Zwahlen and Kormos 2013).

Merced River fall-run Chinook salmon migrate upstream October–December and spawn through January (Stillwater Sciences 2002). Most spawning habitat is within the 24-mile reach of the Merced River between the Crocker-Huffman Dam and the town of Cressy, with rearing habitat extending downstream to the SJR confluence (USBR 2011). The majority of spawning occurs upstream of State Route 59 bridge (RM 42) (Yoshiyama et al. 2000).

Juvenile Chinook salmon rear in the river mainly between February and May, but some fish stay year-round (Yoshiyama et al. 2000). Outmigration of juveniles 0+ age (fry) occurs from January through the beginning of June. Outmigration of 1+ age fish (smolts) occurs November–February.

Steelhead

Steelhead have been captured in the rotary screw traps (Stillwater Sciences 2002), but no population estimates have been done on the Merced River. The distribution and habitat preferences of spawning adults in the Merced River is unknown, but it is presumed that the majority of spawning occurs between Crocker-Huffman Dam and the town of Cressey. Timing of adult and juvenile migration is unknown.

Most of the environmental factors that potentially limit survival and production of fall-run Chinook salmon in the Merced River likely apply to steelhead to some degree. However, because juveniles rear in the river for 1 or more years before migrating to the ocean, steelhead also require suitable flows and temperatures during the critical summer months.

Environmental Stressors

Anthropogenic factors have affected salmonid habitat on the Merced River. Water supply development, flood control, gold dredging, aggregate mining, bank stabilization, and hatchery operations have all affected salmonid populations (Stillwater 2002).

Flow Regulation

Available fish habitat on the Merced River is primarily controlled by established flows. FERC License No. 2179 for the New Exchequer project and the Davis-Grunsky Contract No. D-GG417 mandate streamflows for fishery purposes in the Lower Merced River. (For a discussion of the flows, see Chapter 2, *Water Resources*; Chapter 5, *Surface Hydrology and Water Quality*; and Appendix C, T*echnical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*). Several dams and reservoirs control flows on the mainstem Merced River, two of which are Lake McClure (impounded by New Exchequer Dam) and Lake McSwain (impounded by McSwain Dam). Lake McClure is regulated by USACE to maintain space in Lake McClure for incoming flood flows and limit the amount of water that can be released to the lower river (Stillwater 2002). Also, USACE influences flows by establishing flood control release limits for the Merced River not to exceed 6,000 cubic feet per second (cfs) downstream of Dry Creek.

The historical relationship between spring flows during the juvenile emigration period and subsequent adult abundance has been the basis for a number of analyses and experimental investigations aimed at understanding the factors influencing salmon survival and population dynamics under historical and recent water management operations in the SJR and Delta (see Appendix C, Chapter 3, *Scientific Basis for Developing Alternate San Joaquin River Flow Objectives*). These investigations suggest that flow in the SJR and the three eastside tributaries has a major influence on juvenile salmon survival between March and June as individuals complete the freshwater rearing, smoltification, and migration stages of their lifecycles (Moyle 2002; Merced ID 2011).

Habitat Alteration

Gold and aggregate mining have reduced spawning and rearing habitat for Chinook salmon and steelhead. Both gold and aggregate mining have removed gravel from the river, which is used as spawning substrate for adults (Stillwater Sciences 2002). From 1907–1952, the Lower Merced River channel and floodplain were dredged for gold. After extracting the gold, the tailings were placed in rows on the floodplain. The tailings prevent riparian vegetation from establishing and confine the river channel to a narrow corridor. Because of the dredging and the lack of sediment supply from upstream, the dredged reach is characterized by long, deep pools. Both Chinook salmon and steelhead need shallow, riffle habitat with gravel for successful spawning (Stillwater 2002). Aggregate mining, which began in the 1940s and continues today, excavates floodplain habitat important for rearing Chinook salmon and spawning Sacramento splittail.

Inundation of floodplains is also important for establishing and maintaining a healthy riparian vegetation community (Stillwater Sciences 2002). Aggregate mining also creates pits that provide habitat for largemouth bass, which prey on native fish, including outmigrating juvenile Chinook salmon. In-channel mining has been discontinued, but floodplain and terrace mining continues today (Stillwater 2002). Bank stabilization has been used throughout the Merced River to prevent bank erosion.

The riprap, concrete rubble, and gabions that have been used limit channel migration and native riparian vegetation establishment (Stillwater Sciences 2002). Channel migration is important to allow different instream habitat types to form (pools, riffles, runs), which support different life stages of salmon and other fish species. Riparian vegetation along the river banks provides food and cover and controls water temperatures for juvenile salmonids. Rock stabilization along the banks prevents riparian vegetation from establishing and is typically associated with nonnative, invasive plant species such as giant reed (*Arundo donax*) (Stillwater Sciences 2002).

Flood regulation, levee construction, and floodplain alteration have reduced the extent and frequency of floodplain inundation on the Merced River (Stillwater Sciences 2002). Losses and degradation of riparian and floodplain habitat and reductions in natural hydrologic variability that connect rivers to their floodplains has been identified as a major stressor on native Central Valley fish populations through direct impacts on spawning and rearing habitat availability and indirect impacts on aquatic productivity and food web support provided by seasonal floodplain inundation (see Appendix C, *Technical Report on the Scientific Basis for Alternatives San Joaquin River Flow and Southern Delta Salinity Objectives*). Although specific food web studies have not been conducted in the Merced River, current research indicates that regulated flows downstream of dams and losses of overbank flooding have likely contributed to historical declines and current limitations on native fish populations through reductions in primary and secondary production (phytoplankton and

invertebrate production) associated with seasonal floodplain inundation (Sommer et al. 2004; Ahearn et al. 2006).

Water Quality

As discussed for the Stanislaus and Tuolumne Rivers, pollutants from agriculture and increasing urbanization have been identified as potential stressors on steelhead and other aquatic resources in the Merced River. Unsuitable water temperatures for Chinook salmon and Central Valley steelhead have been identified in the Merced River. Elevated water temperatures have been recorded in the lower reach, some portions of the spawning reach, and at the Merced River Hatchery in October and November. In late April and May, water temperatures exceed limits for emigrating smolts. Elevated spring water temperatures are more prevalent on the Merced River than in the Stanislaus or Tuolumne Rivers due to the Merced River's southerly location and higher air temperatures (Stillwater Sciences 2002).

Introduced Species and Predation

Predation is a possible source limiting survival of juvenile Chinook salmon in the Merced River. As discussed previously, some hot-spots exists, such as in-river mining pits provide habitat for largemouth bass and other nonnative predatory fish species (Grossman et al. 2013).

Hatchery Operations

The Merced River has one hatchery, the Merced River Hatchery, located below the Crocker-Huffman Dam. It is the only hatchery in the SJR Basin (Stillwater Sciences 2002). In recent years, the percentage of hatchery-reared fall-run Chinook salmon returning to the LSJR and the three eastside tributaries has been high (Greene 2009) even though hatchery fish are typically less productive and have higher straying rates than wild fish. A study by Mesick (2009) found that up to 58 percent of Merced River Hatchery fall-run Chinook salmon strayed to the Sacramento River Basin when flows in the SJR were less than 3,500 cfs for 10 days in late October, but stray rates were less than 6 percent when flows were at least 3,500 cfs (CSPA and CWIN 2010; Mesick 2010b). This report indicated that providing 1,200 cfs flows from the three eastside tributaries to the LSJR for 10 days in late October increases escapement by an average of 10 percent (CSPA and CWIN 2010).

The average estimated returns of hatchery Chinook salmon to the Merced River from 1998–2007 was 72.8 percent. Because of the high numbers of hatchery fish returning to the Merced River and the low numbers of salmon returning every year, this creates a high risk of extinction for the Merced River fall-run population (Mesick 2010a). Hatchery production has been shown to negatively affect the genetic diversity and fitness of wild salmonid populations. Impacts can be genetic, ecological, or behavioral. Fish produced in the Merced River Hatchery can displace wild salmonid juveniles through competition and predation, competition with wild adults for limited resources, and introgression with other runs of Chinook salmon outside of the SJR Basin (Moyle 2002). However, a large portion of the existing genetic diversity for Central Valley Chinook salmon are contained in hatchery origin stocks, so hatchery stocks may be important contributors to overall stock recovery, including natural and hatchery origin fish.

Disease

Between 2000 and 2002, BKD was been detected in both natural and hatchery fall-run Chinook salmon juveniles in the Merced River (Nichols and Foott 2002). Occurrence of the parasite that causes BKD in samples of fish kidneys generally increased from 2 percent of the juvenile samples in 2000 to 90–100 percent of the 2001 samples. It then decreased to only 51 percent of the 2002 samples. Heavy infections were observed in 22 percent of the samples in 2002 (Nichols and Foott 2002). Proliferative Kidney Disease (PKD), caused by the myxosporean *Tetracapsuloides bryosalmonae*, has been diagnosed in Merced River Hatchery juvenile Chinook salmon for several decades, and is a currently considered a significant mortality factor for hatchery smolts during their early seaward entry phase (Foott et al. 2007).

LSJR

The LSJR between the Merced River and the Delta historically supported a distinctive native fish fauna adapted to widely fluctuating riverine conditions ranging from large winter and spring floods to low summer flows. Prior to large-scale hydrologic and physical alteration of the SJR, the fish community in this reach was dominated by fishes adapted to warmwater habitats of the valley floor, including deep, slow river channels, oxbow and floodplain lakes, swamps, and sloughs. These fishes included Sacramento perch, thicktail chub, tule perch, hitch, Sacramento blackfish (*Orthodon microlepidotus*), Sacramento splittail, Sacramento pikeminnow, and suckers. Anadromous species, including spring-run Chinook salmon, fall-run Chinook salmon, and sturgeon occurred seasonally in these reaches during their upstream and downstream migrations. Key habitats that contributed substantially to the productivity of native fishes on the valley floor were the floodplains, riparian forests, and wetlands that were inundated by winter and spring floods (Moyle 2002).

Currently, the SJR from the Merced River to the Delta provides migration habitat for fall-run Chinook salmon and steelhead as they migrate upstream to spawning tributaries and downstream toward the Delta. The seasonal timing of adults and juveniles in this reach generally corresponds to that described for each of the tributaries. Other native species that occur in this reach include Sacramento sucker, Sacramento pikeminnow, Sacramento splittail, tule perch, prickly sculpin (*Cottus asper*), Sacramento blackfish, and hardhead (Brown and May 2006).

Many of the species that were present historically in the LSJR have been replaced by nonnative fish species that are better adapted to the disturbed habitat conditions (Moyle 2002). Most notably, the deep-bodied fish assemblage of the valley floor and lower portions of the three eastside tributaries has been largely replaced by largemouth bass, sunfish species, and other nonnative warmwater species that likely prey on or compete with the native species (Moyle 2002). Nonnative fishes reported to occur in the LSJR include red shiner (*Cyprinella lutrensis*), inland silverside (*Menidia beryllina*), threadfin shad, western mosquito fish (*Gambusia affinis*), fathead minnow (*Pimephales promelas*), largemouth bass, bigscale logperch (*Percina macrolepida*), bluegill, white crappie (*Promoxis annularis*), striped bass, redear sunfish (*Lepomis microlophus*), common carp (*Cyprinus carpio*), goldfish (*Carassius auratus*), black bullhead (*Ameiurus melas*), channel catfish, and green sunfish (Brown and May 2006).

Environmental Stressors

Baseline stressors that affect aquatic resources in the LSJR include alteration of the natural flow regime, loss of natural riverine function and morphology due to habitat modification and flood control activities, predation, water quality (e.g., temperature and pollutants), and disease.

Flow Regulation

The natural hydrologic regime and geomorphic processes of the LSJR have been substantially altered by upstream dams, diversions, and agricultural drainage. Analyses of the historical relationship between spring flows during the juvenile Chinook salmon emigration period and subsequent adult abundance indicate that flow in the three eastside tributaries and LSJR has a substantial influence on juvenile salmon survival between March and June as they complete their freshwater rearing, smoltification, and migration stages. Flow in the three eastside tributaries and LSJR may affect survival through a number of mechanisms, including effects on water temperature, predation, habitat availability (e.g., access to floodplain habitat), water quality (e.g., contaminants), and entrainment in diversions (see Appendix C, Chapter 3, *Scientific Basis for Developing Alternate San Joaquin River Flow Objectives*).

Habitat Alteration

Clearing of land for agriculture and flood control activities have resulted in loss or disconnection of the river from historical wetland, riparian, and floodplain areas (Brown 2000). The loss of habitat connectivity between the river and riparian areas in the LSJR has greatly affected salmonids (McBain and Trush 2002). Riparian forests that historically surrounded river and estuarine channels had an important role in minimizing stressors related to habitat availability, water temperature, and water quality. However, riparian forests have generally been converted to agricultural uses, reducing the amount of floodplains and other habitat and increasing surface water temperatures.

Flood control levees closely border much of the river but are set back in places, creating some off-channel aquatic habitat areas when inundated. However, the levees and dikes have acted to isolate historical riparian land and floodplains from the channel. The bank protection along channel margins, coupled with a reduced flow regime, has stabilized the channel, reducing bank erosion, lateral migration, and greatly reducing the processes that create complex side channels and high flow scour channels (McBain and Trush 2002). This has led to a reduction of various types of habitat (e.g., refuge, rearing, and spawning) for steelhead, Chinook salmon, and other native fish species.

Flood regulation, channel confinement, and disconnection of historical wetland, riparian, and floodplain habitat have greatly decreased the frequency and extent of floodplain inundation and the quantity and quality of existing habitat for juvenile salmonids and other native fishes in the LSJR (McBain and Trush 2002). Losses and degradation of riparian and floodplain habitat and reductions in natural hydrologic variability that connect rivers to their floodplains has been identified as major stressors on native Central Valley fish populations. These factors directly impact spawning and rearing habitat availability and indirectly impact aquatic productivity and food web support provided by seasonal floodplain inundation (see Appendix C, *Technical Report on the Scientific Basis for Alternatives San Joaquin River Flow and Southern Delta Salinity Objectives*). Recent modeling of the potential ecological benefits associated with floodplain restoration in the LSJR and southern Delta indicates that the frequency and duration of floodplain inundation events sufficient to meet the habitat requirements of Chinook salmon, Sacramento splittail, and their food resources (phytoplankton and zooplankton), are limited under current and potential future hydrological conditions (Matella and Merenlender 2014). However, the frequency and duration of floodplain inundation events can be increased through floodplain restoration and the restoration of a more natural flow regime to achieve the desired levels of hydrologic connectivity (Matella and Merenlender 2014).

Water Quality

Water temperatures in the LSJR reflect those of the three eastside tributaries and are generally within a range considered to be suitable (< 68°F) for rearing and outmigrating Chinook salmon smolts during April and May (SJRGA 2011). However, in certain water year types, elevated water temperature can be a major stressor on fish, especially salmonids, during months when juveniles are rearing and outmigrating. All of the tributaries generally experience an increase in water temperatures in the late spring and summer, which then contributes to increases in water temperature in the LSJR. Summer water temperatures in many Central Valley streams regularly exceed 77°F (Moyle 2002). These sustained periods of increased water temperature are known to affect behavioral and biological functions of all fishes in the LSJR, notably salmonids and Central Valley steelhead.

The LSJR is generally considered to have poor water quality in part due to agricultural drainage, which is a major source of salts and pollutants (e.g., boron, selenium, pesticides). Discharges from the existing wastewater treatment plants (WWTP) also reduce water quality in the LSJR (State Water Board 2006). However, water quality is known to improve during periods of high flow due to dilution effects.

Introduced Species and Predation

Nonnative fish species prey on Central Valley steelhead and fall-run Chinook salmon in the LSJR. The most prevalent nonnative predators in the LSJR are: striped bass (Moyle 2002); smallmouth bass; and largemouth bass. Although bass are only one of the introduced species that prey on salmonids, they probably represent the most change in predation experienced compared to historical conditions (USDOI 2008), in part due to their salt tolerance to polluted agricultural runoff especially during spawning (Moyle 2002).

Disease

Diseases have been identified in LSJR fish populations. Samples from Chinook salmon juveniles caught with a Kodiak trawl at Mossdale were positive for the causative agent of BKD (Nichols and Foott 2002). Additionally, BKD was detected in both natural and hatchery juveniles from the LSJR in both 2000 and 2001 *Ceratomyxa shasta*, a myxosporean parasite, is also a pathogen present in the Central Valley, and they are of particular concern on the LSJR (Nichols and Foott 2002).

7.2.3 Extended Plan Area

The native fish communities of the extended plan area have changed substantially beginning with gold rush immigration and subsequent landscape modification (Moyle et al. 1996). Native fishes include rainbow trout *(Oncorhynchus mykiss)*, Sacramento hitch *(Lavinia exilicauda exilicauda)*, and hardhead minnow *(Mylopharodon conocephalus)* (Moyle et al.1996). Many nonnative fish were introduced to the rivers, as well as upper watershed lakes, that had previously been fishless (Moyle et al. 1996). These species include brown trout *(Salmo trutta)* and eastern brook trout *(Salvelinus fontinalis)* (Moyle et al. 1996). The rim dams blocked upstream migration of anadromous species. The recreational fishery in the rivers and reservoirs in the extended plan area includes rainbow trout, eastern brook trout, and brown trout, including some hatchery-stocked species (Moyle et a Central California roach 1996; National Wild and Scenic River Systems 2016). There are no federal or state endangered or threatened fish species associated with the reservoirs in the extended plan area (i.e., above the rim dams) (CDFW 2016b). There are four fish species of special concern (CSC) associated with these reservoirs: hardhead minnow; Central California roach *(Lavinia symmetricus symmetricus)*; Sacramento hitch; and riffle sculpin *(Cottus gulosus)* (CDFW 2016b).

7.2.4 Southern Delta

The southern Delta is part of the larger Bay-Delta system and provides habitat for resident and migratory fish species. Essential habitats for salmonids and other fish species consist of suitable water quality and water quantity conditions. For salmonids, these conditions must support juvenile and adult physiological transitions between fresh water and saltwater (NMFS 2009b). Changes to estuarine habitat that degrade any of these conditions can have a negative effect on aquatic resources. Therefore, similar stressors influence the abundance and presence of fish in the southern Delta and Bay-Delta as described above for the three eastside tributaries and LSJR. However, conditions in the southern Delta are also influenced by river inflow, tidal action, water export facilities and local pump diversions, and agricultural and municipal return flows (Moyle 2002).

Environmental Stressors

The distribution of fish in the southern Delta is determined by tidal flows, tidally averaged (nontidal) net flows, and directed swimming of the fish. The largest flows in the southern Delta are tidal flows, which far exceed other flows in most Delta channels. The tidal flows tend to move small, weak-swimming fish, such as fish larvae, upstream and downstream, dispersing them into neighboring channels without imparting any net directional movement (Kimmerer and Nobriga 2008). Nontidal flows determine the net direction of water movement (i.e., net flows) and of fish larvae and other weak swimmers suspended in the water (Kimmerer 2008; Kimmerer and Nobriga 2008; Monsen et al. 2007). Baseline stressors that affect aquatic resources in the southern Delta include alteration of the natural Delta inflows and hydrodynamics, habitat alteration due to channelization, diversions and entrainment, water quality (e.g., temperature and pollutants) and predation.

Delta Inflows and Hydrodynamics

Recent fisheries investigations in the southern Delta (e.g., Vernalis Adaptive Management Program [VAMP]) have focused on the survival of Chinook salmon smolts in relation to SJR inflows, Delta exports, and barrier installation at the head of Old River (HORB). A review of the VAMP studies and other investigations and their findings is presented in Appendix C, Chapter 3, *Scientific Basis for Developing Alternate San Joaquin River Flow Objectives.*

Changes in delta smelt habitat quality in the San Francisco estuary can be indexed by changes in X2. The abundance of many local species has tended to increase in years when flows into the estuary are high and the 2 ppt isohaline is pushed seaward (Jassby et al. 1995), implying that over the range of historical experience, the quantity or suitability of estuarine habitat increases when outflows are high (USBR 2008). Because large volumes of water are drawn from the estuary, water exports and inadvertent fish entrainment at the CVP and SWP export facilities are among the best studied top-down effects in the San Francisco estuary (Sommer et al. 2007). The export facilities are known to entrain most species of fish inhabiting the Delta (Brown et al. 1996) and are of particular concern in dry years, when the distributions of delta smelt and longfin smelt shift upstream, closer to the diversions (Stevens et al. 1985; Sommer et al. 1997).

Habitat Alteration

Prior to development and channelization, the Bay-Delta provided hospitable habitat for rearing and migrating salmonids. Historical floodplain areas were dynamic areas that generally contained complex, heterogeneous habitat types (e.g., grassland, riparian, tidal and nontidal marsh, and agriculture). Inundation of surrounding floodplains provided refuge, warmer temperatures, and abundant food supplies for rearing juvenile Chinook salmon, enabling them to grow faster than by solely migrating through riverine and southern Delta corridors. These smolts grew quickly and migrated out to the ocean sooner, ultimately resulting in higher survival rates in the ocean (Stillwater Sciences 2003).

Currently, the LSJR flow into the southern Delta is influenced by existing channels. From Vernalis, the Old River channel diverges from the LSJR downstream of Mossdale and connects with Middle River and Grant Line Canal. About 50 percent of the LSJR flow splits into the Old River channel, and the other 50 percent continues down the LSJR channel toward Stockton. Channel pathways affect migration of juvenile Chinook salmon. Temporary barriers or agricultural barriers in the Middle River, Grant Line Canal, and Old River can block access, restrict passage to rearing habitat, or redirect migration for adult and juvenile fall-run Chinook salmon. Specifically, the HORB has been installed in April and May of many years (not in years with flows above 7,000 cfs) to improve juvenile Chinook fish migration from the SJR Basin.

The current channelization and other southern Delta developments make the Bay-Delta less hospitable for Chinook salmon as compared to the historical Bay-Delta conditions. Central Valley salmonids and other native fishes use tidal marsh directly or indirectly for at least one if not several of their life stages. Tidal marsh provides spawning and rearing areas for Sacramento splittail and rearing habitat for salmonids. However, much of the historical riparian forests that support suitable habitat for these species has been converted to agricultural uses (Moyle 2002). This conversion has reduced the amount of floodplains and habitat and increased surface water temperatures.

Diversions and Entrainment

The two major water diversions in the southern Delta are the SWP (Banks Pumping Plant) and the CVP (Jones Pumping Plant). The Contra Costa Water District also diverts water from the southern Delta. Many small agricultural diversions (siphons and pumps) divert water from throughout the Delta during the spring and summer irrigation season. These diversions affect fish species by physically entraining them and altering flow such that migration cues are modified.

CVP and SWP export pumping is controlled under the 2006 Bay-Delta Plan objectives (State Water Board's Water Right Decision 1641 [D-1641]). Both the CVP and the SWP have maximum permitted pumping (or diversion) rates. Delta outflow requirements may limit pumping if the combined Delta inflow is not enough to satisfy the in-Delta agricultural diversions and the full capacity CVP and SWP pumping. When pumping is limited, the cooperative operating agreement (COA) governs the CVP and SWP share in reservoir releases and Delta pumping. The CVP and SWP typically increase their rate of pumping approximately 10–40 percent during April and May.

Changes in the direction of channel flows, due to export pumping at the CVP and SWP pumping plants, strongly affect net flow patterns in the southern Delta. These altered flow patterns also influence how fish are distributed in the southern and interior Delta and how long the fish remain there (NMFS 2009a; Kimmerer and Nobriga 2008; Monsen et al. 2007). These flows can lead to increased straying away from the main channel of the SJR and towards the southern Delta via reverse OMR flows (USDOI 2008; Kimmerer and Nobriga 2008; Mesick 2001). Reverse OMR flows occur because the major freshwater source, the Sacramento River, enters on the northern side of the Bay-Delta while the two major pumping facilities, the CVP and SWP, are located in the south. This results in a net water movement across the Delta in a north to south direction along a network of channels, including OMR (see Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*).

Water is drawn from the central Delta through lower OMR to the pumps in the southern Delta when combined pumping exceeds the incoming flow from the LSJR. This situation causes reverse flows in OMR. Reverse flows in the southern Delta make fish more vulnerable to entrainment at the pumps and delay migrations through or from the southern Delta. However, SJR inflow generally counteracts the effects of reverse OMR flows by providing higher inflows, which tend to result in movement of fish and larvae away from the southern Delta. In addition to the pumps, there are hundreds of agricultural diversions throughout the southern Delta that entrain small fish. These diversions not only entrain fish, but also affect them indirectly by altering flow patterns, food supply, and habitat.

The CVP and SWP pumping facilities are known to entrain various fish species in the southern Delta nearly year-round. The CVP and SWP fish facilities report entrainment of adult delta smelt during spawning migration December–April (USFWS 2008) while juveniles are entrained primarily April–June. Longfin smelt are primarily observed in the salvage operations during the spring (March–May) as juveniles, although larger subadult longfin smelt are also observed in the salvage operations during early winter. Young-of-year splittail are entrained April–August when fish are moving downstream into the Bay-Delta (Meng and Moyle 1995). Juvenile Chinook salmon are entrained in all months but primarily November–June when juveniles are migrating downstream. Green sturgeon are rarely entrained at the CVP and SWP fish facilities (probably due to low abundance in the southern Delta); however, entrainment has occurred in every month, indicating the presence of green sturgeon year-round (USBR 2009). Juvenile Central Valley steelhead from the SJR Basin are vulnerable to entrainment and salvage operations at the CVP and SWP export facilities, primarily March–May (Kimmerer 2008).

Pumping in the southern Delta may disorient salmonids and cause delayed outmigration of salmonids. While recent studies (Newman and Brandes 2010) indicate that spring water exports are not significantly impacting SJR outmigrating smolts under certain export conditions, there could be significant impacts on salmonids if exports are outside of the range tested. For example, in addition to creating false migration pathway, as discussed previously, strong negative flows in OMR can confuse outmigrating and rearing salmonids. Pumping-related impacts could affect salmonids between March and June but could vary with water year type. When exports are high relative to SJR flows, it is likely that little, if any, SJR Basin water reaches the San Francisco Bay. It is necessary for the scent of the SJR Basin to enter the bay in order for adult salmonids to find their way back to their natal streams. Specifically, Mesick (2001) observed that reduction, or even the elimination, of this scent trail is likely to increase the likelihood for fall-run Chinook salmon to stray from the SJR Basin and into the adjacent Mokelumne River or Sacramento River Basins.

There are over 2,200 small water diversions within the Delta, the majority of which are unscreened (Herren and Kawasaki 2001). These unscreened diversions have the potential to directly remove fish from the channels and alter local movement patterns (Kimmerer and Nobriga 2008; CDFG 2011a). Removal of fish and alteration of movement patterns take place throughout the year and are highest during fall, winter, and spring (CDFG 2011a). April–September is the high irrigation season and diversion period. Agricultural diversions have the limited potential to remove spring-run and winter-run Chinook salmon adults, juveniles, or fry, or any life stage of Central Valley steelhead from the Bay-Delta. It is undocumented how many juvenile Central Valley steelhead are entrained at the unscreened small water diversions in the Bay-Delta. However, because Central Valley steelhead are moderately large (more than 200 mm fork length), typically older, and relatively strong swimmers when outmigrating, the effects of small in-Delta agricultural water diversions on steelhead are thought to be lower than those on Central Valley Chinook salmon. Longfin smelt and delta smelt are typically present in the Delta primarily November–June. Since exports are typically greater when inflows from the Sacramento River and LSJR are greater in spring and summer, longfin smelt and delta smelt are expected to be affected by diversions.

Other smaller diversions, such as drawing cooling water for power generation plants and small agricultural diversions, also affect migrating Chinook salmon, but not to the extent of the CVP and SWP pumping facilities. Drawing cooling water from the Bay-Delta through power generation plants can remove fish and kill them due to mechanical and thermal trauma. These effects are potentially greatest on pelagic larvae of longfin smelt and delta smelt, one or both of which could be adjacent to the power plants in the western Delta during late December through July. Fall-run Chinook salmon fry may also be present and somewhat vulnerable late December through February during high-outflow years. Juvenile and adult smelt are present also during all other times of year but are less vulnerable because of greater mobility. The western Delta power plants are called to operate during times of high power demand, which are most apt to occur during peak summer temperatures July–September.

Water Quality

Because the southern Delta receives a substantial portion of its water from the LSJR, the influence of the relatively poor LSJR water quality is greatest in the southern Delta channels. Currently, the LSJR, Delta, and San Francisco Bay are listed under Section 303(d) of the federal Clean Water Act (CWA) as impaired for a variety of toxic contaminants that may contribute to reduced population abundance of important fishes and invertebrates.

Agricultural and urban runoff and domestic WWTP discharges in the southern Delta can cause direct and chronic toxicity to eggs, larvae, and adults of pelagic fish species. Some other contaminants that can affect pelagic fishes (delta smelt and longfin smelt) in the southern Delta are mercury, copper, oil and grease, selenium, pesticides, herbicides, and ammonia. These contaminants have the potential to affect fish or the food webs that support them and typically result from in-river activities (mining and dredging), urban runoff, urban sewage, municipal and industrial discharges, and agricultural drain water.

In addition, turbidity in the southern Delta is low, which may reduce habitat for delta smelt and other species (Feyrer 2004; Feyrer and Healey 2003; Feyrer et al. 2007; Monsen et al. 2007; Nobriga et al. 2008). Therefore, flow patterns that cause delta smelt to move into the southern Delta could negatively affect the population. During the fall adult salmon migration season, when LSJR inflows to the Bay-Delta are less than 1,500 cfs, low DO levels in the SJR at the Stockton Deep Water Ship Channel (e.g., less than 6 ppm) create a chemical migration barrier to upstream migrating adult salmon. Failure of SJR Basin salmon to reach the spawning grounds results in negative spawning impacts on the SJR fall-run Chinook salmon population (CDFG 2011a).

Unsuitable salinity gradients can cause physiological stress for many aquatic species in the Bay-Delta. Inflow from the LSJR to the Bay-Delta helps to establish the location in the Bay-Delta of the low salinity zone (LSZ), an area often referenced by X2 that historically has had high prey densities and other favorable habitat conditions for rearing juvenile delta smelt, striped bass, and other fish species (USBR 2008). However, changes in Delta inflows from the LSJR have the potential to alter LSZ salinity gradients and the location of X2, which can influence temperature, turbidity, and other habitat characteristics (Moyle et al. 2010). These alterations can potentially create an environment that is physiologically stressful to most organisms that utilize the Bay-Delta and X2, including Chinook salmon and Central Valley steelhead.

Agricultural diversions also influence the typical salinity gradients that migrating smolts encounter. Typically, outmigrating smolts would perceive a steadily increasing salinity gradient as the ocean grew closer. However, today, outmigrating fall-run Chinook salmon smolts encounter agricultural return flows that are of elevated temperature, nutrient and pesticide load, and salinity concentration (State Water Board 1999) in the Bay-Delta. As juveniles enter the southern Delta, the salinity (or electrical conductivity [EC][13]) at the three southern Delta compliance stations downstream of Vernalis (SJR at Brandt Bridge [P-12], Old River at Middle River [C-8], and Old River at Tracy Boulevard [C-6]) is generally slightly higher than the Vernalis EC. This is largely due to agricultural drainage and municipal discharges. As juveniles orient themselves and begin the last leg of their outmigration, they encounter a plume of low salinity Sacramento River water from the Delta Cross Channel, which is shuttled across the interior Bay-Delta.

Water temperature is determined by a number of factors, such as quantity and quality of water, channel geometry, and ambient air temperatures (TBI 2010). In general, the special-status fish species listed in Table 7-2 require lower water temperatures than the recreationally important fish species listed in Table 7-3. Water temperatures in the southern Delta show temperatures generally increase as a function of distance downstream within the mainstem of the LSJR (SJRGA 2010). Sites sampled on the mainstem of the LSJR as it enters the southern Delta (e.g., Durham Ferry, Mossdale, and Old River at HORB) were within a range considered to be suitable during April and May (typically < 68°F) for emigrating juvenile Chinook salmon (SJRGA 2010). Temperatures are slightly higher, but generally under 68°F further downstream within the southern Delta (e.g., Old River-Indian Slough Confluence) during this time (SJRGA 2010). However, water temperatures during early June were within the range (> 68°F) considered to be stressful for juvenile Chinook salmon (SJRGA 2010). Lethal temperatures for Chinook salmon and Central Valley steelhead juveniles are not reached under baseline conditions at Vernalis until August, and at that time these fishes typically are not present in the Bay-Delta.

Introduced Species and Predation

Predation rates in the southern Delta are believed to be higher than in other parts of the Bay-Delta. This is due to a variety of reasons, including: (1) turbidity is generally lower in the southern Delta, which increases visibility for predators (Nobriga et al. 2008; Feyrer et al. 2007); (2) many of the structures and facilities in the southern Delta support excellent conditions for predators by providing suitable habitat and flows, especially the Clifton Court Forebay and fish louver screens at the CVP and SWP facilities; and (3) recent invasions by the submerged plant, Brazilian water weed *Egeria densa* (Nobriga et al. 2008; Feyrer et al. 2007). The Brazilian water weed is an invasive, nonnative freshwater species that grows in denser stands than native submerged aquatic

---

[13] In this document, EC is *electrical conductivity*, which is generally expressed in deciSiemens per meter (dS/m). Measurement of EC is a widely accepted indirect method to determine the salinity of water, which is the concentration of dissolved salts (often expressed in parts per thousand or parts per million). EC and salinity are therefore used interchangeably in this document.

vegetation, providing rearing habitat for nonnative fish species, including bass. Brazillian water weed filters sediment and nutrients from the water column resulting in decreased turbidity in the southern Delta, which historically provided cover and habitat for outmigrating smolts but now provides cover for larger predatory fishes (Ferrari et al. 2013).

Based on their review of the VAMP studies, Dauble et al. (2010) concluded that predation appears to be having a variable effect on survival of smolts moving through the Delta (Grossman et al. 2013), which may in part account for the low survival of tagged fish in recent years as measured in the SJR at Vernalis (Dauble et al. 2010).

7.3 Regulatory Background

For a broad summary of relevant statutory and regulatory provisions, see Chapter 1, *Introduction*. For a more specific description of regulatory requirements set as existing and historical instream flow prescriptions on the LSJR and the three eastside tributaries, see Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*.

7.3.1 Federal

Relevant federal programs, policies, plans, or regulations related to aquatic resources are described below.

Clean Water Act

The CWA generally applies to all navigable waters of the United States and is discussed in Chapter 5, *Surface Hydrology and Water Quality.*

Central Valley Project Improvement Act

The Central Valley Project Improvement Act (CVPIA) was enacted in 1992 to balance the needs of fish and wildlife resources with other uses of CVP water. The purposes of the CVPIA are as follows.

- Protect, restore, and enhance fish, wildlife, and associated habitats in the Central Valley and Trinity River Basins of California.
- Address impacts of the CVP on fish, wildlife, and associated habitats.
- Improve the operational flexibility of the CVP.
- Increase water-related benefits provided by CVP to the State of California through expanded use of voluntary water transfers and improved water conservation.
- Contribute to California's interim and long-term efforts to protect the Bay-Delta Estuary.
- Achieve a reasonable balance among competing demands for use of CVP water, including the requirements of fish and wildlife, agricultural, municipal and industrial, and power contractors.

The CVPIA added mitigation, protection, and restoration of fish and wildlife to the purposes of the CVP, dedicated 800,000 AF of CVP yield for the primary purpose of implementing fish, wildlife, and habitat restoration, and created a Central Valley Project Restoration Fund to carry out CVPIA programs, projects, plans, and habitat restoration, improvement, and acquisition provisions. Among the CVPIA programs that benefit salmonids and other fish species is the AFRP, the Anadromous Fish

Screen Program (AFSP), and the Water Acquisition Program (WAP). The AFRP conducts monitoring, education, and restoration projects directed toward recovery of anadromous fish species in the Central Valley. Restoration projects funded through the AFRP include fish passage, fish screening, riparian easement and land acquisition, development of watershed planning groups, instream and riparian habitat improvement, and gravel replenishment. The AFSP combines federal funding with state and private funds to prioritize and construct fish screens on major water diversions mainly in the Upper Sacramento River. The goal of the WAP is to acquire water supplies to meet the habitat restoration and enhancement goals of the CVPIA and to improve the DOI's ability to meet regulatory water quality requirements.

Endangered Species Act

The purpose of the ESA is to protect and recover imperiled species and the ecosystems upon which they depend. ESA is administered by USFWS and NMFS. In general, NMFS is responsible for protecting ESA-listed threatened or endangered marine species and anadromous fishes, while other listed species (e.g., freshwater and terrestrial species) are under USFWS jurisdiction. An *endangered species* is defined as "… any species which is in danger of extinction throughout all or a significant portion of its range." (16 U.S.C., § 1532, subd. (6).) A *threatened species* is defined as "… any species that is likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range." (16 U.S.C., § 1532, subd. (20).) ESA Section 9 makes it illegal to *take* (i.e., harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, or collect, or attempt to engage in such conduct) any endangered fish or wildlife species. (16 U.S.C., §§ 1538; 1532, subd. (19).)
For threatened fish and wildlife species, ESA Section 4(d) allows for the adoption of protective regulations, including provisions extending the Section 9 take prohibition to that species. (16 U.S.C., § 1538, subd. (d).)

ESA also requires the designation of critical habitat for listed species. *Critical habitat* is defined as: (1) specific areas within the geographical area occupied by the species at the time of listing, if they contain physical or biological features essential to a species' conservation, and those features may require special management considerations or protection; and (2) specific areas outside the geographical area occupied by the species if the agency determines that the area itself is essential for conservation (NMFS 2011; NMFS 2009a; ICF International 2012).

If a federal agency believes that its action will jeopardize a listed species or destroy or adversely modify critical habitat, the agency must request formal consultation with USFWS or NMFS, as appropriate, under Section 7 of the ESA. (16 U.S.C., § 1536.) The USFWS or NMFS then issues a BO as to whether the action is likely to jeopardize a listed species or to destroy or adversely modify its critical habitat. If an action will result in jeopardy, the USFWS or NMFS will provide the consulting federal agency with reasonable and prudent alternative actions to avoid jeopardy. For any non-federal action otherwise prohibited by Section 9, the applicant must apply to the Secretaries for an incidental take permit under ESA Section 10 (16 U.S.C., § 1539.) Species that are candidates for listing are not protected under ESA; however, USFWS advises that a candidate species could be elevated to listed status at any time, and, therefore applicants should regard these species with special consideration.

Long-Term Central Valley Project Operations Criteria and Plan and Biological Opinions

The *Long-Term Central Valley Project – Operations Criteria and Plan* (OCAP) is a baseline description of the facilities and operating environment of the CVP and SWP and identifies the many factors influencing the physical and institutional conditions and decision-making processes under which the USBR and the California Department of Water Resources (DWR) operate the integrated SWP and CVP system, including how the CVP and the SWP divert, store, and convey water consistent with applicable law (USBR 2008).

U.S. Fish and Wildlife Service Biological Opinion

Pursuant to the ESA, USBR requested a biological opinion from the USFWS as to whether its operations, as described in the OCAP, would jeopardize listed species. The 2008 USFWS BO concurred with USBR's determination that the coordinated operations of the SWP and CVP are not likely to adversely affect listed species, with the exception of delta smelt (USFWS 2008). The USFWS concluded that the coordinated operations of the SWP and CVP, as proposed, were likely to jeopardize the continued existence of delta smelt and adversely modify delta smelt critical habitat. Consequently, USFWS developed a reasonable and prudent alternative (RPA) to the project as described in the OCAP, consisting of a number of operational changes and other actions to avoid the likelihood of jeopardizing the continued existence of delta smelt or destroying or adversely modifying delta smelt critical habitat. These actions include: (1) preventing/reducing entrainment of delta smelt at the Jones and Banks Pumping Plants, (2) providing adequate habitat conditions that will allow adult delta smelt to successfully migrate and spawn in the Bay-Delta, (3) providing adequate habitat conditions that will allow larvae and juvenile delta smelt to rear, and (4) providing suitable habitat conditions that will allow successful recruitment of juvenile delta smelt to adulthood. In addition, USFWS specified that it is essential to monitor delta smelt abundance and distribution through continued sampling programs through the Interagency Ecological Program (IEP). The RPA restricted pump operations and limited deliveries of water to SWP and CVP contractors south of the Delta.

Various parties, including SWP and CVP contractors, brought suit in federal court challenging the USFWS 2008 BO. Years of litigation followed, and in March 2014, the United States Court of Appeals, Ninth Circuit, upheld the biological opinion and concluded that USBR must comply with the National Environmental Policy Act to evaluate the effects of the USBR's adoption and implementation of the 2008 BO.

National Marine Fisheries Service Biological Opinion

The NMFS BO (NMFS 2009a) concluded that the joint operations of the CVP and SWP, as described in the OCAP, were likely to jeopardize the continued existence of the following species.

- Sacramento River winter-run Chinook salmon.
- Central Valley spring-run Chinook salmon.
- Central Valley steelhead.
- Southern DPS of North American green sturgeon.
- Southern resident killer whale.

NMFS (2009a) also concluded that CVP and SWP operations, as described in the OCAP, were likely to destroy or adversely modify the designated critical habitats of Sacramento River winter-run Chinook salmon, Central Valley spring-run Chinook salmon, Central Valley steelhead, and green sturgeon. The actions included in the RPA to USBR's proposed action are summarized below relevant to the plan area (NMFS 2009a).

- New OMR reverse flow levels to limit the strength of reverse flows and reduce entrainment at the SWP and CVP facilities.
- Additional technological measures at the SWP and CVP facilities to enhance screening and increase survival of fish.
- Additional measures to improve survival of steelhead smolts, including increased SJR flows and export curtailments, and a new study of acoustic tagged fish in the SJR Basin to evaluate and refine these measures.
- A year-round minimum flow regime on the Stanislaus River necessary to minimize project effects on each life stage of steelhead, including new springtime flows that will support rearing habitat formation and inundation, and create pulses that allow salmon to outmigrate successfully.

Various parties challenged the 2009 BO in federal court. In December 2014, the United States Court of Appeals, Ninth Circuit, upheld the BO in its entirety.

Recovery Plan for Sacramento–San Joaquin Delta Native Fish Species

The *Recovery Plan for the Sacramento–San Joaquin Delta Native Fishes* was released in 1996 by USFWS with the basic goal of establishing self-sustaining populations of species of concern. The plan specifically focused on delta smelt, longfin smelt, Sacramento splittail, and Sacramento perch.

National Wildlife Refuge System Improvement Act of 1997

Comprehensive conservation plans (CCPs) are prepared by USFWS and are required under the National Wildlife Refuge System Improvement Act of 1997. In 2006 the USFWS prepared a final CCP for the San Joaquin River National Wildlife Refuge to guide the management of the refuge for the next 15 years. The primary goals of the refuge are to accomplish the following: conserve and protect the natural diversity of migratory birds, resident wildlife, fish, and plants through restoration and management of riparian, upland, and wetland habitats on refuge lands; contribute to the recovery of threatened and endangered species, as well as the protection of populations of special-status wildlife and plant species and their habitats; provide optimum wintering habitat for Aleutian Canada geese to ensure the continued recovery from threatened and endangered species status; coordinate the natural resource management of the San Joaquin River National Wildlife Refuge in the context of the larger Central Valley-San Francisco ecoregion; and provide the public with opportunities for compatible, wildlife-dependent visitor services to enhance understanding, appreciation, and enjoyment of natural resources at the San Joaquin River National Wildlife Refuge (USBR 2011).

Federal Power Act

Under the Federal Power Act (FPA), the FERC is responsible for determining under what conditions to issue licenses, or relicense, non-federal hydroelectric projects. Under the provisions of Section 10(j) of the FPA, each hydroelectric license issued by FERC is required to include conditions for the protection, mitigation, or enhancement of fish and wildlife resources affected by the project. These required conditions are to be based on recommendations of federal and state fish and wildlife agencies. FERC may reject or alter the recommendations on several grounds, including if FERC determines they are inconsistent with the purposes and requirements of the FPA or other applicable law. The State Water Board exercises authority over hydropower projects through Section 401 of the Clean Water Act, which requires an applicant for a federal license or permit that conducts an activity that results in a discharge into the navigable waters of the United States to apply for a certification from the state that the discharge will comply with state and federal water quality standards. The certification will include conditions requiring compliance with the Bay-Delta Plan's water quality objectives, including the LSJR flow requirements. FERC does not have authority to review or set aside the water quality certification.

7.3.2 State

Relevant state programs, policies, plans, or regulations related to aquatic resources are described below. Descriptions of the *2006 San Francisco Bay/Sacramento-San Joaquin Delta Estuary Water Quality Control Plan* (Bay-Delta Plan), Porter-Cologne Act, California's water rights system, and State Water Board authorities are described in Chapter 1, *Introduction*.

California Endangered Species Act of 1970

CESA (Fish & G. Code, § 2050 et seq.), expresses state policy to conserve, protect, restore, and enhance any endangered or threatened species or its habitat. The Act generally prohibits the take (hunt, pursue, catch, capture, or kill) of listed species, although it may allow for take incidental to otherwise lawful activities. (Fish & G. Code, § 2080 et seq.) Under CESA, the California Fish and Game Commission has the responsibility for maintaining a list of threatened and endangered species (Fish & G. Code, § 2070), and CDFW may authorize take that is otherwise prohibited (by permits, agreements, etc.) or pursue enforcement actions for unauthorized take.

California Department of Fish and Wildlife Species Designations

CDFW maintains an informal list of "species of special concern." The intent of the designation is to focus on plant and wildlife species that are at conservation risk, stimulate research on poorly known species, and achieve conservation and recovery of species before they are listed under CESA. Species of special concern have factors in common such as small isolated populations, marked population decline, fragmented habitat, and association with habitats that are declining in California.

Salmon, Central Valley Steelhead Trout, and Anadromous Fisheries Program Act

The 1988 Salmon, Central Valley Steelhead Trout, and Anadromous Fisheries Program Act was enacted in response to reports that the natural production of salmon and steelhead in California had declined dramatically since the 1940s. The Act expressed the State's policy to significantly increase the natural production of salmon and steelhead trout by the end of the century. CDFW was charged with developing a plan and program that strives to double the then-current natural production of the fishery. (Fish & Game Code, § 6902, subd. (c).)

7.3.3 Regional or Local

Relevant regional or local programs, policies, plans, or regulations related to aquatic resources are described below. Although local policies, plans, and regulations are not binding on the State of California, below is a description of relevant ones.

County General Plans

As required by state law, counties must develop their own general plans. Within the plan area, applicable general plans include the *Calaveras County General Plan* (1996), the *Tuolumne County General Plan* (1996), the *Mariposa County Wide General Plan* (2010), and the *San Joaquin County Wide General Plan* (2005). These plans have policies that can preserve and protect open space and natural resources, such as rivers and reservoirs and the lands adjacent to them.

San Joaquin County Multi-Species Habitat Conservation and Open Space Plan

The *San Joaquin County Multi-Species Habitat Conservation and Open Space Plan*, approved and adopted in November 2000, includes compensation measures to offset the effects of development on special-status plant, fish, and wildlife species throughout San Joaquin County, including the LSJR. The plan's purpose is to provide a strategy for balancing the need to conserve open space and the need to convert open space to non-open space uses while protecting the region's agricultural economy and preserving landowner property rights. The plan also is to provide for the long-term management of plant, fish, and wildlife species, especially those that are currently listed or may be listed in the future under ESA or CESA (County of San Joaquin 2012).

7.4 Impact Analysis

This section identifies the thresholds or significance criteria used to evaluate the potential impacts on aquatic resources. It further describes the methods of analysis used to evaluate the potential impacts and to determine the significance of those impacts. Measures to mitigate (i.e., avoid, minimize, rectify, reduce, eliminate, or compensate for) significant impacts accompany the impact discussion if any significant impacts are identified.

7.4.1 Thresholds of Significance

The thresholds for determining the significance of impacts for this analysis are based on the State Water Board's Environmental Checklist in Appendix A of the Board's CEQA regulations. (Cal. Code Regs., tit. 23, §§ 3720–3781.) The thresholds derived from the checklist(s) have been modified, as appropriate, to meet the circumstances of the alternatives. (Cal. Code Regs., tit. 23, § 3777, subd. (a)(2).) Impacts on aquatic biological resources were identified as potentially significant in the State Water Board's Environmental Checklist (see Appendix B, *State Water Board's Environmental Checklist*) and, therefore, are discussed in this analysis as to whether the alternatives could result in the following.

- Cause significant changes in spawning success and habitat availability for warmwater species resulting from changes in reservoir water levels.
- Cause significant changes in availability of coldwater species reservoir habitat resulting from changes in reservoir storage.
- Cause significant changes in quantity/quality of physical habitat for spawning and rearing resulting from changes in flow.
- Cause significant changes in exposure of fish to suboptimal water temperatures resulting from changes in reservoir storage and releases.
- Cause significant changes in exposure to pollutants resulting from changes in flow.
- Cause significant changes in exposure to suspended sediment and turbidity resulting from changes in flow.
- Cause significant changes in redd dewatering resulting from flow fluctuations.
- Cause significant changes in spawning and rearing habitat quality resulting from changes in peak flows.
- Cause significant changes in food availability resulting from changes in flow and floodplain inundation.
- Cause significant changes in predation risk resulting from changes in flow and water temperature.
- Cause significant changes in disease risk resulting from changes in water temperature.
- Cause significant changes in southern Delta and estuarine habitat resulting in changes in SJR inflows and export effects.

A significant impact under these thresholds would result in a significant impact on aquatic resources. Where appropriate, specific quantitative or qualitative criteria are described in Section 7.4.2, *Methods and Approach*, for evaluating these thresholds.

7.4.2 Methods and Approach

This section describes the methods and approach for analyzing the effects of the LSJR and SDWQ alternatives.

LSJR Alternatives

This chapter evaluates the potential aquatic resource impacts associated with the LSJR alternatives. Each LSJR alternative includes a February–June unimpaired flow[14] requirement and methods for adaptive implementation to reasonably protect fish and wildlife beneficial uses, as described in Chapter 3, *Alternatives Description*. The impact analysis for aquatic resources evaluates expected aquatic species responses to changes in environmental conditions under the LSJR alternatives.

---

[14] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.

Impacts were evaluated based on expected changes in the environment relative to the temporal and spatial occurrence of indicator species and applicable life stages for which impact mechanisms and environmental requirements, or tolerances, are sufficiently understood to support an analysis. In addition, a minimum base flow is required at Vernalis at all times during this period. The base flow may be adaptively implemented as described below and in Chapter 3. State Water Board approval is required before any method can be implemented, as described in Appendix K, *Revised Water Quality Control Plan*. All methods may be implemented individually or in combination with other methods, may be applied differently to each tributary, and could be in effect for varying lengths of time, so long as the flows are coordinated to achieve beneficial results in the LSJR related to the protection of fish and wildlife beneficial uses. The methods used in the analysis varied by geographic area, species life stages, and environmental conditions, and depended largely on the best available scientific information.

For purposes of impact assessment, the plan area has been divided into the following geographic areas.

- The major reservoirs: New Melones Reservoir, New Don Pedro Reservoir, and Lake McClure.
- The three eastside tributaries: Stanislaus, Tuolumne, and Merced Rivers.
- LSJR (Merced River confluence with the SJR downstream to Vernalis).
- The southern Delta.

Because impacts have been evaluated based on predicted effects on indicator species and their specific life stages, each impact discussion is organized by the relevant life stage of the indicator species in the three eastside tributaries and LSJR, as appropriate. These species include coldwater reservoir fish (i.e., rainbow trout[15]), anadromous fish (i.e., fall-run Chinook salmon and steelhead), and warmwater reservoir fish (i.e., largemouth bass). Specific indicator species were selected because they are either native species whose populations in California are declining and/or have received a special-status designation by federal or state resource agencies, or they are recreationally important game fish species. Additionally, these indicator species would be sensitive to the environmental changes expected to result from the LSJR alternatives in each of the geographic areas comprising the plan area. Furthermore, these species have utility in evaluating broader ecosystem and community-level effects of these changes on aquatic resources. For example, the results of the impact analysis on Chinook salmon and steelhead are considered indicative of effects on other native fishes because of the broad ecological benefits of natural flow variability restoration efforts aimed at anadromous salmonids on other native fish communities. A general discussion of the potential responses of, and impacts on, other fish species under the LSJR alternatives are qualitatively discussed where appropriate (i.e., Impacts AQUA-3, AQUA-4, and AQUA-10).

In order to analyze the potential impacts from the LSJR alternatives on indicator species relative to the thresholds discussed above, the impact analysis focuses on the effects of changes in flows and reservoir levels and resultant environmental conditions on indicator species. Changes in flow or reservoir levels directly relate to the quantity and quality of available habitat for various life stages of aquatic species and, therefore, also to population distribution, numbers, and dynamics (see Appendix C, *Technical Analysis on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*).

---

[15] For the purposes of this document, rainbow trout refers to *O. mykiss* populations above impassable dams while steelhead refers to *O. mykiss* populations below these dams.

Each LSJR alternative includes a February–June unimpaired flow requirement (i.e., 20, 40, or 60 percent) from February–June and adaptive implementation, as described in Chapter 3, *Alternatives Description*. Adaptive implementation could change the volume, rate, or timing of water released February–June. While the adaptive implementation approaches are common to all alternatives, the specific changes vary between the alternatives and may vary by the adaptive implementation approach being implemented, as described in Appendix K. As discussed in Chapter 3, the intent of adaptive implementation is to provide flexibility in meeting biological goals based on monitoring and data collection, to best support ecosystem functions from February–June, as well as support biological needs outside of that time frame. Quantitative or qualitative evaluations were performed in this chapter to evaluate the impacts of the LSJR alternatives. The evaluations used a variety of data sources, such as results from the Water Supply Effects (WSE) models of diversions, reservoir operations, streamflow, and results from the water temperature model. Details of the models and results are presented in Chapter 5, *Surface Hydrology and Water Quality*; Appendix F.1, *Hydrologic and Water Quality Modeling*; and Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta*.

In this chapter, hydrologic conditions related to aquatic resources are often described using cumulative distribution tables. The cumulative distribution of a particular variable (e.g., flow at a location or temperature at a location) provides a basic summary of the distribution of values. The percentile (i.e., percent cumulative distribution) associated with each value indicates the percent of time that the values were less than the specified value. For example, a 10th percentile value of 2 indicates that 10 percent of the time, the values were less than 2. The 0th percentile is the minimum value, the 50th percentile is the median value, and the 100th percentile is the maximum value. The 10th and 90th percentiles represent relatively low and relatively high values and are representative of multiple years rather than the 1 year with the highest value and the 1 year with the lowest value.

Impacts on indicator species were evaluated by applying one or more of the following general methods.

- Comparison of quantitative simulations: Quantitative output from modeling tools were used for direct comparisons between baseline conditions and the LSJR alternatives to identify effects on aquatic resources.
- Interpretation/extrapolation from quantitative simulations: Output of quantitative models were interpreted/extrapolated to describe effects on aquatic resources.
- Interpretation/extrapolation and qualitative assessment: Existing data and information from previous studies were used to interpret/extrapolate the effects on aquatic resources and to provide a qualitative assessment.

Table 7-7 summarizes the criteria that were evaluated and the habitat variables, biological criteria, and the modeling tools or data used.

Table 7-7. A Summary of the Impact Thresholds, Variables, Criteria, and Data or Methods Used (see also Table 7-1)

Impact Thresholds	Environmental or Habitat Variable	Impact Criteria	Data and Method Used
Impact AQUA-1: Changes in spawning success and habitat availability for warmwater species resulting from changes in reservoir water levels	• Frequency/magnitude of reservoir drawdowns during primary spawning and rearing periods	• Reservoir level fluctuations of 15 feet or more	• Hydrologic/reservoir operations model (Water Supply Effects [WSE] model) • Relationships between reservoir storage and water surface elevation
Impact AQUA-2: Changes in availability of coldwater species reservoir habitat resulting from changes in reservoir storage	• Reservoir storage (end-of-September)	• Storage (water volume) used as an indicator of changes in coldwater habitat availability	• Hydrologic/reservoir operations model (WSE model)
Impact AQUA-3 : Changes in quantity/quality of physical habitat for spawning and rearing resulting from changes in flow	• Frequency/magnitude of changes in spawning and rearing weighted usable area (WUA) • Frequency/magnitude of changes in floodplain inundation area	• WUA and floodplain inundation area	• WUA-discharge relationships • Floodplain inundation area-flow relationships
Impact AQUA-4: Changes in exposure of fish to suboptimal water temperatures resulting from changes in reservoir storage and releases	• Frequency of 7-day averages of the daily maximum water temperatures exceeding criteria	• Water temperature criteria (USEPA criteria)	• Hydrologic/reservoir operation model (WSE model) • River temperature model
Impact AQUA-5: Changes in exposure to pollutants resulting from changes in flow	• Dilution effect of flow on pollutant concentrations • Effect of water temperature on exposure/sensitivity of fish to pollutants	• 50% increase in baseline concentrations	• Published literature • Qualitative evaluation
Impact AQUA-6: Changes in exposure to suspended sediment and turbidity resulting from changes in flow	• Frequency of sediment-mobilizing flows	• Flow thresholds for mobilization of gravel and fine sediment	• Published literature • Qualitative evaluation

Impact Thresholds	Environmental or Habitat Variable	Impact Criteria	Data and Method Used
Impact AQUA-7: Changes in redd dewatering resulting from flow fluctuations	• Frequency/magnitude of flow reductions exceeding depth thresholds during primary spawning and incubation periods	• Habitat suitability criteria (spawning depth preferences and egg pocket depths)	• Hydrologic/reservoir operations model (WSE model) • Flow-depth relationships • Habitat suitability criteria
Impact AQUA-8: Changes in spawning and rearing habitat quality resulting from changes in peak flows	• Frequency/magnitude of gravel-mobilizing flows	• Flow thresholds for gravel mobilization	• Hydrologic/reservoir operations model (WSE model)
Impact AQUA-9: Changes in food availability resulting from changes in flow and floodplain inundation	• Frequency/magnitude of floodplain inundation	• Floodplain inundation area	• Published literature • Qualitative evaluation
Impact AQUA-10: Changes in predation risk resulting from changes in flow and water temperature	• Frequency/magnitude of habitat availability and suboptimal water temperatures	• WUA, floodplain inundation area, and USEPA water temperature criteria for juvenile rearing and outmigration life stages	• Impact AQUA-3 and Impact AQUA-4 results • Published literature • Qualitative evaluation
Impact AQUA-11: Changes in disease risk resulting from changes in water temperature	• Water temperatures associated with increased incidence of disease	• Temperature thresholds for disease incidence in indicator species	• Published literature • Qualitative evaluation • Impact AQUA-4 results
Impact AQUA-12: Changes in southern Delta and estuarine habitat resulting in changes in SJR inflows and export effects	• Change in magnitude of Delta exports in relation to SJR inflows	• Potential effect on fish distribution, entrainment risk, and estuarine habitat quality	• Hydrologic/reservoir operations model (WSE model) • Rules and objectives governing Delta operations • Qualitative evaluation

The Stanislaus, Tuolumne, and Merced Working Group (STM Working Group) will assist with implementation, monitoring, and assessment activities for the flow objectives and with developing biological goals to help evaluate the effectiveness of the flow requirements and adaptive implementation actions. The STM Working Group may recommend adjusting the flow requirements through adaptive implementation if scientific information supports such changes to reasonably protect fish and wildlife beneficial uses. Scientific research may also be conducted within the adaptive range to improve scientific understanding of measures needed to protect fish and wildlife and reduce scientific uncertainty through monitoring and evaluation. Further details describing the methods, the STM Working Group, and the approval process are included in Chapter 3 and Appendix K.

Without adaptive implementation, flow must be managed such that it tracks the daily unimpaired flow percentage based on a running average of no more than 7 days. The four methods of adaptive implementation are described briefly below.

1. Based on best available scientific information indicating that more flow is needed or less flow is adequate to reasonably protect fish and wildlife beneficial uses, the specified annual February–June minimum unimpaired flow requirement may be increased or decreased to a percentage within the ranges listed below. For LSJR Alternative 2 (20 percent unimpaired flow), the percent of unimpaired flow may be increased to a maximum of 30 percent. For LSJR Alternative 3 (40 percent unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 30 percent or increased to a maximum of 50 percent. For LSJR Alternative 4 (60 percent unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 50 percent.
2. Based on best available scientific information indicating a flow pattern different from that which would occur by tracking the unimpaired flow percentage would better protect fish and wildlife beneficial uses, water may be released at varying rates during February–June. The total volume of water released under this adaptive method must be at least equal to the volume of water that would be released by tracking the unimpaired flow percentage from February–June.
3. Based on best available scientific information, release of a portion of the February–June unimpaired flow may be delayed until after June to prevent adverse effects to fisheries, including temperature, which would otherwise result from implementation of the February–June flow requirements. The ability to delay release of flow until after June is only allowed when the unimpaired flow requirement is greater than 30 percent. If the requirement is greater than 30 percent but less than 40 percent, the amount of flow that may be released after June is limited to the portion of the unimpaired flow requirement over 30 percent. For example, if the flow requirement is 35 percent, 5 percent may be released after June. If the requirement is 40 percent or greater, then 25 percent of the total volume of the flow requirement may be released after June. As an example, if the requirement is 50 percent, at least 37.5 percent unimpaired flow must be released in February–June and up to 12.5 percent unimpaired flow may be released after June. If after June the STM Working Group determines that conditions have changed such that water held for release after June should not be released by the fall of that year, the water may be held until the following year. See Chapter 3 and Appendix K for further details.

4. Based on best available scientific information indicating that more flow is needed or less flow is adequate to reasonably protect fish and wildlife beneficial uses, the February–June Vernalis base flow requirement of 1,000 cfs may be modified to a rate between 800 and 1,200 cfs.

The operational changes made using the adaptive implementation methods above may be approved if the best available scientific information indicates that the changes will be sufficient to support and maintain the natural production of viable native SJR Watershed fish populations migrating through the Delta and meet any biological goals. The changes may take place on either a short-term (for example monthly or annually) or longer-term basis. Adaptive implementation is intended to foster coordinated and adaptive management of flows based on best available scientific information in order to protect fish and wildlife beneficial uses. Adaptive implementation could also optimize flows to achieve the objective, while allowing for consideration of other beneficial uses, provided that these other considerations do not reduce intended benefits to fish and wildlife. While the measures and processes used to decide upon adaptive implementation actions must achieve the narrative objective for the reasonable protection of fish and wildlife beneficial uses, adaptive implementation could result in flows that would benefit or reduce impacts on other beneficial uses that rely on water. For example, terrestrial riparian species could benefit by receiving additional flows during key germination times in the late spring.

The quantitative results included in the figures, tables, and text of this chapter present WSE modeling of the specified unimpaired flow requirement for each LSJR alternative (i.e., 20, 40, or 60 percent). The modeling results also reflect some adjustments in the allocation of flows (as might occur under adaptive implementation method 3 above) to prevent adverse temperature effects in years in which strict adherence to the unimpaired flow percentages results in predicted water temperatures that exceed the significance thresholds for sensitive life stages in the summer and fall (e.g., Chinook salmon spawning and incubation). In practice, such allocations would be implemented in accordance with the adaptive implementation process described above, which would consider a full range of potential flow management methods (methods 1, 2, 3, and 4 above) to maximize fisheries benefits while balancing the needs of other beneficial uses. For more information regarding the modeling methodology and quantitative flow and temperature modeling results, see Appendix F.1, *Hydrologic and Water Quality Modeling.*

The below subsections provide additional information regarding specific methodologies used for Impact AQUA-3 (changes in quantity/quality of physical habitat for spawning and rearing resulting from changes in flow) and Impact AQUA-4 and Impact AQUA-11 (changes in disease risk resulting from changes water temperature), as well as for Impact AQUA-6 and Impact AQUA-8 (changes in spawning and rearing habitat quality resulting from changes in peak flows).

Physical Habitat Availability

Changes in flow under the LSJR alternatives could affect the quantity and quality of Chinook salmon and steelhead spawning and rearing habitat through changes in the extent of suitable water depths, velocities, substrate types, and other physical attributes of the stream environment. The effects of flow on Chinook salmon and steelhead physical habitat availability were evaluated using two flow-based habitat indices: weighted usable area (WUA) and floodplain inundation area. Both indices were necessary to address changes in habitat availability for the juvenile rearing life stages over the full range of modeled flows.

WUA is a measure of the quantity and quality of habitat for a given species and life stage and is generally defined as the surface area of a stream having a certain combination of water depths, velocities, and other physical attributes that define suitable habitat for that species and life stage. The relationship between WUA and streamflow is a key element of the Instream Flow Incremental Methodology (IFIM) (Bovee et al. 1998). WUA is expressed in terms of square feet or square feet per unit distance (e.g., square feet per 1,000 linear feet of stream). WUA-discharge relationships were developed for Chinook salmon and steelhead spawning, fry rearing, and juvenile rearing life stages as part of a number of instream flow studies conducted on the Stanislaus, Tuolumne, and Merced Rivers (Bowen et al. 2012; MID 2013; Stillwater Sciences 2013). WUA-discharge relationships were available for all three Chinook salmon and steelhead life stages, except for the Stanislaus River, where a WUA-discharge relationship for steelhead spawning was not available. For Impact AQUA-3, existing WUA-discharge relationships were applied to the WSE modeling results to evaluate changes in the quantity and quality of Chinook salmon and steelhead spawning and rearing habitat in key months over the 82-year modeling period.

Since the WUA-discharge relationships are limited to the range of flows that generally fall within the bankfull width of the channel, the floodplain inundation-flow relationships were used to evaluate potential changes in juvenile rearing habitat within the upper range of flows that inundate adjacent floodplains. The primary sources for the floodplain inundation-flow relationships were USFWS 2008; USFWS 2011, 2012, 2013; and cbec 2010 (see Chapter 19, *Analyses of Benefits to Native Fish Populations from Increased Flow Between February 1 and June 30*, Section 19.3, *Floodplain Inundation*). These relationships define changes in wetted floodplain inundation area (above bankfull thresholds) as a function of flow.

Peak Flows

Potential effects of the LSJR alternatives on the frequency and magnitude of flow events capable of inducing sediment transport in the upper and lower reaches of the Stanislaus, Tuolumne, and Merced Rivers were evaluated to determine the potential for changes in exposure of fish to increases in suspended sediment concentrations and turbidity (Impact AQUA-6) and changes in spawning gravel quality resulting from gravel mobilization (Impact AQUA-8). Under baseline conditions, gravel transport is estimated to occur at flows between 5,000 and 8,000 cfs in the Stanislaus River (Kondolf et al. 2001), between 7,050 and 9,800 cfs in the upper reaches of the Tuolumne River (McBain and Trush 2000), and at flows greater than 4,800 cfs in the upper reaches of the Merced River (Stillwater Sciences 2001; Kondolf et al. 1996). Flows below these levels (above approximately 2,000–3,000 cfs) can mobilize finer sediment in the mid- to lower sand-bedded portions of these tributaries, potentially increasing suspended sediment and turbidity in the lower reaches of the three eastside tributaries and the LSJR. These flows served as thresholds for evaluating the potential for impacts on indicator species and aquatic habitat resulting from changes in the frequency and magnitude of bed-mobilizing flows in the Stanislaus, Tuolumne, and Merced Rivers.

Water Temperature and Dissolved Oxygen

Impacts of changes in water temperatures on indicator species were evaluated using the San Joaquin River Basin-Wide Water Temperature Model (temperature model) developed by Resource Management Associates for CALFED using the USACE HEC-5Q simulation model (CALFED 2009). The temperature model provides a basin-wide evaluation of temperature response at 6-hour intervals for alternative conditions. The geographic extent of the model includes the Stanislaus, Tuolumne, and Merced River systems from their confluences with the LSJR to upstream of the major reservoirs (New Melones Reservoir, New Don Pedro Reservoir, and Lake McClure, respectively). The downstream extent of the model is Mossdale on the LSJR. See Appendix F.1, *Hydrologic and Water Quality Modeling*, for a full discussion of this model and its application.

Daily water temperature model results of LSJR Alternatives 2, 3, and 4 were quantitatively assessed to determine the changes in the frequency of potentially stressful water temperatures at key locations and months during the 1970–2003 temperature modeling period. The months and locations generally coincide with the occurrence of each life stage and the maximum water temperatures potentially encountered by individual life stages within each geographic area. This information is incorporated into Impact AQUA-4.

Although water temperature can affect DO levels, and both factors are related to apparent blockage and delays in migration of adult salmon in the Delta (see Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*), adverse effects associated with low DO levels have not been documented in reaches of the SJR or the three eastside tributaries. Therefore, DO levels are expected to remain within acceptable levels and could potentially increase in response to higher flows and cooler temperatures under the LSJR alternatives, as discussed under Impact AQUA-4.

Extended Plan Area

The analysis of the extended plan area generally identifies how the impacts may be similar to or different from the impacts in the plan area (i.e., downstream of the rim dams) depending on the similarity of the impact mechanism (e.g., changes in reservoir levels, reduced water diversions, and additional flow in the rivers) or location of potential impacts in the extended plan area. Where appropriate, the program of implementation is discussed to help contextualize the potential impacts in the extended plan area.

SDWQ Alternatives

In general, most fish species identified in Table 7-2 spend the majority or a significant portion of their life history in the Bay-Delta and are accustomed to variations in salinity. Specific salinity information for fish species is presented in Section 7.2.1, *Fish Species*. Indicator species are able to tolerate salinity changes within the range of 0.2 dS/m (0.134 ppt) and 1.2 dS/m, (0.768 ppt), as these salinity levels are within the general historical salinity conditions of the southern Delta. As described in Chapter 5, *Surface Hydrology and Water Quality*, reservoir releases are currently increased in order to meet the existing salinity objectives of maintaining EC below 1.000 dS/m (1,000 μS/cm) (0.67 ppt) for September–March and below 0.700 dS/m (700 μS/cm) (0.37 ppt), for April–August in the SJR at Vernalis. Changes in EC that may occur downstream of Vernalis are dependent on conditions at Vernalis and within the Delta. Under the SDWQ alternatives, there would be no change in operations affecting Delta salinity relative to baseline. This is because EC at Vernalis would be maintained at or below 0.7 dS/m (0.37 ppt) April–August and 1.0 dS/m (0.67 ppt) September–March through the program of implementation, as it is under the current objectives. However, under the SDWQ alternatives, the Vernalis and southern Delta salinity objectives would be changed to a year-round value of either 1.0 dS/m (0.67 ppt) or 1.4 dS/m (0.94 ppt), under SDWQ Alternative 2 or 3, respectively. This would provide some assimilative capacity downstream of Vernalis and protect beneficial agricultural uses. Therefore, the general historic range of salinity (between 0.200 [0.134 ppt] and 1.200 dS/m [0.77 ppt]) would remain unchanged under SDWQ Alternatives 2 and 3. These changes are not expected to increase exposure of sensitive fish species to salinity levels that may adversely affect migration conditions or spawning habitat suitability in the LSJR due to their low levels of salinity. The modeling results indicated that under SDWQ Alternatives 2 or 3, exceedances (described in Section 7.3.2, *State [Regulatory Background]*) would not increase relative to baseline and the salinity in the LSJR and southern Delta would remain similar to baseline or be reduced (Appendix F.1, Section F.1.5.2, *Salinity Modeling Results*). Consequently, there would be little to no change from baseline; therefore, the SDWQ alternatives are not discussed further in this chapter.

7.4.3 Impacts and Mitigation Measures

Impact AQUA-1: Changes in spawning success and habitat availability for warmwater species resulting from changes in reservoir water levels

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

Reservoir water level changes associated with the flow releases under the LSJR alternatives could impact recreationally important warmwater reservoir species due to resultant changes in the availability of habitat. The three eastside tributary reservoirs (New Melones, New Don Pedro, and Lake McClure) support several warmwater species that inhabit surface waters and shallow areas near shore (the littoral zone) (USBR 2011). Water level fluctuations resulting from reservoir operations (for irrigation, power generation, reservoir recharge, flood control, downstream flow releases, etc.) can impact habitat quantity and quality, particularly in the shallow-water areas.

Water level fluctuations can have a direct effect on largemouth bass and other warmwater fish that construct their nests in shallow water habitat (USBR 2011). Nearshore spawning species can be affected when reservoir levels rise with snowmelt capture. Rising water levels result in increased water depth of largemouth bass nests, potentially exposing them to water temperatures that may be too cold for the developing eggs (USBR and DWR 2003). Cold water slows the development of the eggs and larvae and, because eggs and larvae are highly vulnerable to predation or infection by fungi, longer development times can substantially reduce survival (USBR 2011). Extensive drawdown of reservoir water levels can also result in declines in reservoir fish species populations through direct effects on spawning success (due to nest abandonment or stranding) and habitat availability for spawning and rearing life stages. Water level fluctuations also inhibit development of shoreline vegetation, which provides cover and feeding substrates for many warmwater fish species in reservoirs. Vegetation also stabilizes shoreline sediments, reducing erosion and sedimentation. Consequently, increases in water level fluctuations could affect reservoir fish species indirectly through effects on vegetation (USBR and DWR 2003).

To assess impacts on warmwater fish species due to changes in reservoir levels under the LSJR alternatives, changes in the frequency and magnitude of reservoir level fluctuations were evaluated during the months of April–September. This period corresponds to the primary spawning, incubation, and early rearing period for largemouth bass and other warmwater species and, thus, the period when these species are most sensitive to reservoir level fluctuations. During this period, a monthly drop in elevation of 15 ft or more was used to evaluate the frequency of events that could have adverse effects on warmwater fish species based on the spawning preferences of largemouth bass. Typical spawning depths for largemouth bass range from the surface to about 15 ft (PG&E 2000; USBR 2011). Therefore, a drop in elevation of 15 ft per month during the spawning season could result in substantial effects on spawning success. It was also assumed that fluctuations of this magnitude (increases or decreases in reservoir levels) could also adversely affect spawning and rearing success through effects on water temperature, vegetation success, and shallow water habitat availability. A 10 percent increase in the occurrence of 15 foot fluctuations compared to baseline conditions was considered to be significant. A decrease in the occurrence of water level fluctuations of this magnitude would result in a more stable environment for the spawning and rearing life stages of warmwater species and, consequently, would not be considered a significant impact.

LSJR Alternative 2 (Less than significant)

Under LSJR Alternative 2, the percentage of months in which water level fluctuations of 15 ft or more would occur at New Melones Reservoir, New Don Pedro Reservoir, and Lake McClure during April–September would be reduced compared to baseline conditions (Tables 7-8a, 7-8b, and 7-8c). These results generally reflect more stable habitat conditions during the largemouth bass spawning and rearing season (April–September), resulting in improved habitat conditions for largemouth bass and other warmwater species. Therefore, adverse impacts on warmwater reservoir species would be less than significant.

LSJR Alternative 3 (Less than significant)

Under LSJR Alternative 3, the percentage of months in which water level fluctuations of 15 ft or more would occur at New Melones Reservoir, New Don Pedro Reservoir, and Lake McClure during April–September would be further reduced compared to LSJR Alternative 2 (Tables 7-8a, 7-8b, and 7-8c). Overall, more stable reservoir levels through the spawning and rearing season for largemouth bass and other warmwater species would further improve habitat conditions and result in beneficial effects on these species. Therefore, adverse impacts on warmwater reservoir species would be less than significant.

LSJR Alternative 4 (Less than significant)

Under LSJR Alternative 4, the percentage of months in which water level fluctuations of 15 ft or more would occur at New Melones Reservoir, New Don Pedro Reservoir, and Lake McClure during April–September would be further reduced compared to LSJR Alternative 3 (Tables 7-8a, 7-8b, and 7-8c). Overall, spawning and rearing habitat conditions for largemouth bass and other warmwater species would be further improved, resulting in beneficial effects on these species. Therefore, adverse impacts on warmwater reservoir species would be less than significant.

Table 7-8a. Percent of Time Greater than or Equal to 15-foot Change in Elevation from Previous Month for New Melones Reservoir (Average)

	Apr	May	Jun	Jul	Aug	Sep
Baseline	13	27	12	17	7	1
LSJR Alternative 2	5	18	6	2	0	0
Change from Baseline	-8	-9	-6	-15	-7	-1
LSJR Alternative 3	2	9	4	4	1	0
Change from Baseline	-11	-18	-8	-13	-6	-1

Change from Baseline	-19	-28	-15	-20	-16	-15
LSJR Alternative 4	11	18	6	21	48	13
Change from Baseline	-31	-56	-16	-60	-45	-13

Note: Negative numbers indicate a reduction in 15-foot fluctuations.

Impact AQUA-2: Changes in availability of coldwater species reservoir habitat resulting from changes in reservoir storage

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

Changes in reservoir storage resulting from the LSJR alternatives could change the volume of cold water (hypolimnetic zone) in the reservoirs and the availability of coldwater habitat for recreationally important salmonids such as rainbow trout and kokanee. The hypolimnetic zone forms in the deepest levels of reservoirs during thermal stratification that occurs during spring, summer, and early fall months. Surface water warmed by the air and solar radiation during the spring and summer floats on top of the cooler, denser water of the hypolimnetic zone. The depth of the warmer surface water layer can vary but is generally 15–30 ft deep in most California reservoirs (including New Melones Reservoir, New Don Pedro Reservoir, and Lake McClure) (EA EST 1999). Thus, reservoir drawdown can affect the volume of cold water below this surface layer, potentially limiting the availability of usable habitat for coldwater reservoir fishes.

In order to evaluate impacts on coldwater storage and resulting habitat for coldwater fish species, end-of-September storage levels in New Melones Reservoir, New Don Pedro Reservoir, and Lake McClure were compared to baseline. The end-of-September storage was used as a basis for comparison because it typically represents the month at the end of the summer irrigation season when reservoir storage and coldwater habitat availability are at their lowest levels. While the amount of actual habitat cannot be quantified, the end-of-September storage levels are utilized as an indicator of the amount of summer habitat available to coldwater reservoir species. In the absence of quantitative information relating reservoir storage to effects on habitat availability for coldwater fish, the potential for significant impacts was assumed to exist if reservoir storage levels in September are reduced by 10 percent or more relative to baseline conditions. This is considered a reasonable criterion given the large seasonal and annual fluctuations in reservoir storage experienced by fish in reservoirs and the dependence of the reservoir fisheries on hatchery trout and salmon stocking programs. Tables 7-9a, 7-9b, and 7-9c show the changes in end-of-September elevation for the three reservoirs compared to baseline.

Table 7-9a. Percent Change in End-of-September Storage from Baseline for New Melones Reservoir

Percentile	LSJR Alternative 2	LSJR Alternative 3	LSJR Alternative 4
Minimum	-5	-23	-47
10	0	-16	-29
20	0	-9	-21
30	3	-3	-16
40	4	-1	-6
50	7	1	-2
60	12	5	3
70	18	17	13
80	27	33	37
90	81	84	92
Maximum	582	573	534
Average	42	39	33

Note: Negative percentages indicate a decrease in storage levels relative to baseline conditions.

Table 7-9b. Percent Change in End-of-September Storage from Baseline for New Don Pedro Reservoir

Percentile	LSJR Alternative 2	LSJR Alternative 3	LSJR Alternative 4
Minimum	-16	-29	-37
10	-5	-18	-26
20	-3	-15	-22
30	-2	-13	-18
40	-2	-11	-14
50	0	-5	-7
60	0	-1	-3
70	0	0	0
80	2	3	10
90	7	8	16
Maximum	33	30	44
Average	1	-6	-6

Note: Negative percentages indicate a decrease in storage levels relative to baseline conditions.

Table 7-9c. Percent Change in End-of-September Storage from Baseline for Lake McClure

Percentile	LSJR Alternative 2	LSJR Alternative 3	LSJR Alternative 4
Minimum	-12	-32	-39
10	-1	-21	-27
20	0	-14	-20
30	0	-3	-10
40	0	-1	-2
50	4	0	0
60	15	14	19
70	35	38	29
80	91	82	60
90	139	142	122
Maximum	157	206	181
Average	36	31	23

Note: Negative percentages indicate a decrease in storage levels relative to baseline conditions.

LSJR Alternative 2 (Less than significant)

Under LSJR Alternative 2, modeled September storage levels in New Melones Reservoir were equal to or higher than baseline levels in most years; average September storage is predicted to increase by 48 percent with annual levels ranging from little or no change to a 582-percent increase compared to baseline levels (Table 7-9a). In New Don Pedro Reservoir, modeled September storage levels differed only slightly from baseline levels in most years, averaging 1 percent over the 82-year modeling period (Table 7-9b). In Lake McClure, average September storage is predicted to increase by 36 percent with annual levels ranging from a 12 percent decrease to a 157 percent increase compared to baseline levels (Table 7-9c). Therefore, average summer storage levels in New Melones Reservoir, New Don Pedro Reservoir, and Lake McClure under LSJR Alternative 2 would be similar to or higher than baseline levels, resulting in no long-term adverse impacts on coldwater fish habitat. Negative impacts on coldwater fish species would be less than significant.

LSJR Alternative 3 (Less than significant)

Under LSJR Alternative 3, no substantial long-term impacts on the availability of coldwater fish habitat in New Melones Reservoir, New Don Pedro Reservoir, and Lake McClure are expected to occur. Differences in average September reservoir storage from baseline levels ranged from a 6 percent decrease in New Don Pedro Reservoir to a 39 percent increase in New Melones Reservoir (Tables 7-9a, 7-9b, and 7-9c). Adverse impacts on coldwater fish species would be less than significant.

LSJR Alternative 4 (Less than significant)

Under LSJR Alternative 4, no substantial long-term adverse impacts on the availability of coldwater fish habitat in New Melones Reservoir, New Don Pedro Reservoir, and Lake McClure are expected to occur. Differences in average September reservoir storage from baseline levels ranged from a 6 percent decrease in New Don Pedro Reservoir to a 33 percent increase in New Melones Reservoir

(Tables 7-9a, 7-9b, and 7-9c). Adverse impacts on coldwater fish species would be less than significant.

Impact AQUA-3: Changes in the quantity/quality of physical habitat for spawning and rearing resulting from changes in flow

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

The LSJR alternatives could affect the quantity and quality of Chinook salmon and steelhead spawning and rearing habitat through changes in the extent of suitable water depths, velocities, substrate types, and other physical attributes of the stream environment. The following assessment focuses on potential impacts of the alternatives on Chinook salmon and steelhead populations because of their sensitivity to flow and other flow-related variables (e.g., water temperature) and because of their utility as key indicators of the responses of other native fish species to altered flow regimes in regulated rivers. As previously discussed in Section 7.4.2, *Methods and Approach*, the results of this assessment are considered indicative of effects on other native fishes; however, a general qualitative discussion of the potential responses of other fish species to the proposed alternatives is provided below.

As described in Section 7.4.2, the effects of flow on Chinook salmon and steelhead physical habitat availability were evaluated using two flow-based habitat indices: WUA and floodplain inundation. The WUA-flow relationships were used to evaluate changes in spawning and rearing habitat within the lower range of flows that generally fall within the bankfull width of the channel while the floodplain inundation-flow relationships were used to evaluate potential changes in rearing habitat within the upper range of flows that inundate adjacent floodplains. Table 7-10 summarizes the flow ranges used to evaluate changes in spawning and rearing WUA and floodplain inundation for each of the three eastside tributaries.

Table 7-10. Flow Ranges used to Evaluate Changes in Weighted Usable Area (WUA) and Floodplain Inundation under the LSJR Alternatives for the Stanislaus, Tuolumne, and Merced Rivers

	WUA Flow Range (cfs)	WUA Flow Range (cfs)	Floodplain Inundation Flow Range (cfs)
Stanislaus River	Spawning	25–1,300	1,000–5,000
	Fry/juvenile rearing	250–1,500	
Tuolumne River	Spawning	50–1,200	1,100–5,000
	Fry/juvenile rearing	50–1,200	
Merced River	Spawning	75–1,250	
	Fry/juvenile rearing	75–1,250	1,000–5,000

Impacts on Chinook salmon and steelhead spawning and rearing habitat were evaluated by comparing the magnitude and frequency of WUA and floodplain inundation area under each of the LSJR alternatives to baseline conditions over the 82-year modeling period. The analysis first presents modeled baseline flows and associated habitat metrics for the indicator species, followed by conditions under each LSJR alternative. Reductions in average WUA of 10 percent or more were considered sufficient to result in a significant impact on fry and juvenile production. Because modeled winter and spring flows frequently exceeded the range of flows for which WUA values could be determined, impact determinations for effects on fry and juvenile rearing habitat also considered predicted changes in floodplain inundation and water temperatures (see Impact AQUA-4) associated with these higher flows. To address uncertainties in floodplain inundation duration associated with the use of monthly modeled flows, reductions of 10 percent or more in the frequency of floodplain inundation areas of 50 acres or more were considered sufficient to result in a significant impact on fry and juvenile production. A criterion of 10 percent change, in combination with professional judgment, is used to determine whether impacts are significant. Due to lack of quantitative relationships between a given change in environmental conditions and relevant population metrics (e.g., survival or abundance), 10 percent was selected because that value is assumed to be high enough to reveal significant change to a condition while a lessor amount of change could be due in error in the various analytical and modeling techniques. Therefore, 10 percent provides a conservative qualitative basis to evaluate whether adverse effects to sensitive species at the population level will occur.

Baseline

Modeled baseline flows and associated habitat conditions for the indicator species and their key life stages are summarized below. As described in Chapter 5, *Surface Hydrology and Water Quality*, modeled baseline flows reflect current flow management operations and regulatory requirements in each of three eastside tributaries. Tables 7-11a, 7-11b, and 7-16c summarize baseline habitat conditions as well as expected changes from baseline conditions under each of the LSJR alternatives (discussed in subsequent sections).

Spawning

Chinook Salmon Spawning

Under baseline conditions, WUA values for Chinook salmon spawning in the Stanislaus, Tuolumne, and Merced Rivers in October averaged 47 percent, 80 percent, and 87 percent, respectively, of maximum WUA (Tables 7-11a, 7-11b, and 7-11c). These values reflect current operations that include the release of pulse flows in October for adult salmon attraction. Following these attraction flows, flows are generally maintained near optimal levels for spawning; monthly WUA values in the Stanislaus, Tuolumne, and Merced Rivers averaged 82–94 percent of maximum WUA values in November and December (Tables 7-11a, 7-11b, and 7-11c).

Steelhead Spawning

WUA-discharge relationships for steelhead spawning are only available for the Tuolumne and Merced Rivers. Based on those years in which WUA values could be evaluated (approximately 50–80 percent of the years had modeled flows within the range of the WUA-discharge relationships), average WUA values in January-March were 77–80 percent of maximum WUA for the Tuolumne River and 90–95 percent of maximum WUA for the Merced River (Tables 7-12a and 7-12b).

Juvenile Rearing

Chinook Salmon Rearing

In the Stanislaus River, baseline WUA values during the primary Chinook salmon fry rearing period (January–March) could not be evaluated in most years because modeled flows were frequently lower than the lowest flow defined by the WUA-discharge relationship (250 cfs) (Table 7-13a). However, minimum modeled flows in these months were between 200 and 250 cfs, indicating that physical habitat for fry was near maximum WUA levels in most years. In the Tuolumne and Merced Rivers, average WUA values for fry rearing in January–March were 67–69 percent of maximum WUA in the Tuolumne River and 73–79 percent of maximum WUA in the Merced River (Tables 7-13b and 7-13c). During the spring (April–May), average WUA values for juvenile rearing were 93 percent of maximum in the Stanislaus River, 71–73 percent of maximum WUA in the Tuolumne River, and 77–79 percent of maximum WUA in the Merced River (Tables 7-14a, 7-14b, and 7-14c).

Based on floodplain inundation area-flow relationships, the frequency of floodplain inundation in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR generally peaks in spring. Under baseline conditions, floodplain inundation events of 50 acres occurred less than 10 percent (February) to 50 percent of the time (April) in the Stanislaus River, 20–50 percent of the time in the Tuolumne River, and less than 10 percent to 20 percent of the time in the Merced River (Tables 7-15a, 7-15b, and 7-15c). In the LSJR between the Stanislaus River and Mossdale, floodplain inundation events of 50 acres or more occurred approximately 50–70 percent of the time during the winter and spring months (Table 7-15d). Over the 82-year modeling period, average floodplain inundation areas ranged from 25–58 acres in the Stanislaus River, 140–288 acres, 11–61 acres in the Merced River, and 257–368 acres in the LSJR.

Steelhead Rearing

Under modeled baseline conditions, average WUA values for steelhead fry rearing in April–May were 79–80 percent of maximum WUA in the Stanislaus River, 60 percent of maximum WUA in the Tuolumne River, and 71 percent of maximum WUA in the Merced River (Tables 7-16a, 7-16b, and 7-16c). During summer (July–September), WUA values for juvenile rearing in the Stanislaus, Tuolumne, and Merced Rivers were near maximum WUA levels (88–99 percent) in the majority of years (Tables 7-17a, 7-17b, and 7-17c). Spring floodplain inundation, which serves as an indicator of floodplain habitat availability for Chinook salmon (as discussed previously), may also benefit juvenile steelhead.

LSJR Alternative 2 (Less than significant)

Spawning

Under LSJR Alternative 2, spawning habitat availability for Chinook salmon, steelhead, and other fish species on the Stanislaus, Tuolumne, and Merced Rivers would remain unchanged or increase compared to baseline conditions. Adverse impacts would be less than significant.

Chinook Salmon Spawning

Under LSJR Alternative 2, modeled flows and associated WUA values indicate that there would be little or no change in the availability of spawning habitat for Chinook salmon relative to baseline conditions on the three eastside tributaries (Tables 7-11a, 7-11b, and 7-11c). Therefore, adverse impacts would be less than significant.

Steelhead Spawning

In the Tuolumne River, average WUA values for steelhead spawning would remain unchanged in January and increase by 6 percent in February and 10 percent in March compared to baseline conditions (Table 7-12a). In the Merced River, little or no change in steelhead spawning habitat availability is predicted to occur (Table 7-12b). Therefore, adverse impacts would be less than significant.

Other Fish Species (Spawning)

Based on the relatively small changes in Chinook salmon and steelhead spawning habitat under LSJR Alternative 2, no major changes in habitat availability for other native and nonnative species in the Stanislaus, Tuolumne, and Merced Rivers are expected. Therefore, adverse impacts would be less than significant.

Juvenile Rearing

Under LSJR Alternative 2, no substantial changes are expected in the quantity and quality of Chinook salmon and steelhead fry and juvenile rearing in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR compared to baseline conditions. Fry and juvenile rearing habitat for Chinook salmon on the Stanislaus River or LSJR would remain unchanged. While WUA for Chinook salmon fry and juvenile rearing would decrease in the Tuolumne and Merced Rivers, floodplain habitat would increase and water temperatures would decrease in response to higher spring flows. Therefore, adverse impacts would be less than significant.

Chinook Salmon Rearing

Under LSJR Alternative 2, modeled Stanislaus River flows (i.e., Goodwin Dam releases) during the Chinook salmon fry and juvenile rearing period (January–May) frequently fell outside the range of flows that could be evaluated using the WUA-discharge relationship (250–1,500 cfs). However, for those years in which flows were within this range, no substantial changes were evident in the magnitude of WUA values compared to baseline conditions (Tables 7-13a and 7-14a). In the Tuolumne River, increases in flows would reduce average WUA for fry and juvenile rearing by 6–10 percent in February–May (Tables 7-13b and 7-14b) but would increase the frequency of floodplain inundation events of 50 acres or more by approximately 20 percent in May (Table 7-15b) and decrease average water temperatures at the confluence by 1.7°F in May (Table 7-22b in Impact

AQUA-4). In the Merced River, increases in flows would primarily affect juvenile rearing habitat in May by reducing average WUA by 18 percent (Table 7-14c). However, overall increases in flow in May were accompanied by an average decrease in water temperature of 2.1°F at the confluence of the Merced (Table 7-22c), representing an overall improvement in habitat quality throughout the river. In addition, higher flows in the LSJR in May would increase the frequency of floodplain inundation events of 50 acres by 10 percent (Table 7-15d). Overall, the quantity and quality of rearing habitat for Chinook salmon fry and juvenile salmon, as measured by WUA, floodplain inundation area, and water temperature, would not change substantially relative to baseline conditions. Therefore, flow-related impacts on the quantity and quality of Chinook salmon rearing habitat would be less than significant.

Steelhead Rearing

Under LSJR Alternative 2, no substantial differences were evident in the magnitude of WUA values for steelhead fry and juvenile rearing compared to baseline conditions (Tables 7-16a, 7-16b, 7-16c, and 7-17a, 7-17b, and 7-17c). Therefore, adverse impacts would be less than significant.

Other Fish Species (Rearing)

Based on the conclusions above for Chinook salmon and steelhead juvenile rearing habitat, no major changes in habitat availability for other native and nonnative species in the Stanislaus, Tuolumne, and Merced Rivers are expected. Therefore, adverse impacts would be less than significant.

LSJR Alternative 3 (Less than significant)

Spawning

Under LSJR Alternative 3, the quantity and/or quality of spawning habitat for Chinook salmon, steelhead, and other fish species in the Stanislaus, Tuolumne, and Merced Rivers would be improved relative to baseline conditions. Negative impacts on the quantity and quality of spawning habitat would be less than significant.

Chinook Salmon Spawning

Under LSJR Alternative 3, average WUA values for Chinook salmon spawning in the Stanislaus River would decrease by 37 percent in October and remain unchanged in November and December relative to baseline conditions (Table 7-11a). Reductions in average WUA of 8–14 percent are also predicted to occur in the Tuolumne and Merced Rivers in October and November (Tables 7-11b and 7-11c). However, these reductions are associated with higher flows, which are expected to improve flow and temperature conditions for attraction, migration, and spawning (see Impact AQUA-4, LSJR Alternative 3) and potentially increase the longitudinal extent of suitable spawning habitat below the dams. Additionally, it is important to note that WUA for this life-stage does not take into account a number of other benefits associated with higher flows, including improved substrate (e.g., mobilization of fine sediment) and hyporheic (e.g., DO in redds) conditions. Finally, analyses of juvenile and adult production in relation to fall flows suggest that spawning habitat is not a major limiting factor for Chinook salmon populations in the LSJR tributaries (Mesick et al. 2007). Therefore, flow-related impacts on Chinook salmon spawning habitat would not have a significant adverse impact on Chinook salmon populations in the Stanislaus, Tuolumne, and Merced Rivers.

Steelhead Spawning

Under LSJR Alternative 3, average WUA values for steelhead spawning in the Tuolumne River would decrease by 1 percent in January, 17 percent in February, and 24 percent in March (Table 7-12a). In the Merced River, only slight changes would occur in spawning WUA relative to baseline conditions (Table 7-12b). Therefore, flow-related impacts on steelhead spawning habitat availability in the Stanislaus, Tuolumne, and Merced Rivers would be less than significant.

Other Fish Species (Spawning)

Under LSJR Alternative 3, increases in magnitude of spring flows in the Stanislaus, Tuolumne, and Merced Rivers and associated increases in floodplain habitat availability and decreases in water temperatures would benefit other (non-salmonid) native species and negatively affect nonnative species such as largemouth bass and other warmwater species that prey on or compete with native fishes. Based on reported changes in the abundance and distribution of native and nonnative resident species in the Tuolumne River and other Central Valley streams, higher spring flows and cooler water temperatures that mimic the natural flow regime provide more appropriate spawning conditions for native species (Brown and Ford 2002). Potential mechanisms include increases in water velocity that benefit native resident species that spawn in high-velocity habitats (e.g., riffle spawners such as Sacramento sucker, Sacramento pikeminnow, and riffle sculpin) and negatively affect nonnative species that spawn in low-velocity habitats (e.g., largemouth bass) (Brown and Ford 2002; Kiernan et al. 2012).

Increases in spring flows will also improve spawning conditions for splittail, sturgeon, striped bass, and other fishes, as well as improve water quality (e.g., water temperature and salinity) in the Stanislaus, Tuolumne, and Merced Rivers and in the LSJR (see Impact AQUA-4, LSJR Alternative 3). Therefore, LSJR Alternative 3 would have beneficial effects on other native fishes in the Stanislaus, Tuolumne and Merced Rivers and LSJR.

Juvenile Rearing

Under LSJR Alternative 3, fry and juvenile rearing conditions for Chinook salmon, steelhead, and other fish species in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would be substantially improved compared to baseline conditions. Therefore, adverse impacts would be less than significant.

Chinook Salmon Rearing

Under LSJR Alternative 3, no substantial differences are evident in the magnitude of WUA values for Chinook salmon fry and juvenile rearing in the Stanislaus River compared to baseline conditions (Tables 7-13a and 7-14a). Flows exceeding the range of the WUA-discharge relationship (250–1,500 cfs) would increase in frequency, increasing potential floodplain rearing opportunities for juvenile salmon under this alternative. In April and May, floodplain inundation events of 50 acres or more in the Stanislaus River are predicted to increase by approximately 10–20, corresponding to average increases in floodplain inundation area of 6 acres in April and 56 acres in May (Table 7-15a).

In the Tuolumne River, average WUA values for Chinook salmon rearing are predicted to decrease by 17 percent in February and 25 percent in March (fry rearing) and by 14 percent in April and May (juvenile rearing) compared to baseline conditions (Tables 7-13b and 7-14b). During these months, floodplain inundation events of 50 acres or more are predicted to decrease in frequency by approximately 10 percent in March and increase in frequency by 30 percent in April and

60 percent in May (Table 7-15b). These changes correspond to a decrease in average floodplain inundation area of 60 acres in March and increases in average floodplain inundation areas of 57 acres in April and 269 acres in May. Although habitat availability for fry would decrease in March, the capacity of the river for juvenile rearing would increase in April and May in response to higher spring flows, cooler water temperatures, and greater floodplain rearing opportunities. Higher spring flows and associated reductions in water temperatures are expected to increase the downstream extent and duration of suitable rearing temperatures throughout the river in many years (see Impact AQUA-4, LSJR Alternative 3). Overall, improvements in water temperatures and floodplain habitat availability later in the season (April and May) would likely enhance juvenile growth and survival, potentially increasing the number of juveniles that successfully emigrate from the river as smolts.

In the Merced River, LSJR Alternative 3 would not substantially affect Chinook salmon fry habitat availability in January–March as measured by WUA (Table 7-13c). During the juvenile rearing season (April–May), average WUA values are predicted to decrease by 21 percent in April and 25 percent in May compared to baseline conditions (Table 7-14c). However, similar to the Tuolumne River, LSJR Alternative 3 would result in substantial increases in the frequency and magnitude of floodplain inundation in April and May. Over the 82-year modeling period, the frequency of floodplain inundation events of 50 acres or more would increase in frequency by 10 percent in April and 50 percent in May, corresponding to increases in average floodplain inundation areas of 11 acres in April and 71 acres in May (Table 7-15c). Increases in floodplain rearing opportunities in April and May would also be accompanied by reductions in water temperatures throughout the Merced River (see Impact AQUA-4, LSJR Alternative 3). Overall, this alternative is expected to increase juvenile salmon production in the Stanislaus, Tuolumne, and Merced Rivers.

Under LSJR Alternative 3, higher flow contributions from the tributaries are also expected to increase the availability of floodplain habitat in the LSJR for juvenile Chinook salmon that leave the tributaries as fry or juveniles. Over the 82-year modeling period, the frequency of floodplain inundation events of 50 acres or more would increase by approximately 20 percent in April and May, corresponding to increases in average floodplain inundation areas of 39 acres in April and 137 acres in May (Table 7-15d).

Steelhead Rearing

Under LSJR Alternative 3, no substantial changes would occur in steelhead fry and juvenile rearing habitat availability (as measured by WUA) in the Stanislaus, Tuolumne, and Merced Rivers during the spring and summer rearing periods (Tables 7-16a, 7-16b, 7-17a, and 7-17b). However, steelhead fry and juveniles would benefit from increases in floodplain habitat availability and decreases in water temperatures in April and May as described for Chinook salmon. Therefore, flow-related adverse impacts on steelhead rearing habitat availability in the Stanislaus, Tuolumne, and Merced Rivers would be less than significant.

Other Fish Species (Rearing)

As discussed above under spawning, increases in spring flows will also improve rearing conditions for splittail, sturgeon, striped bass, and other fishes, as well as improve water quality (e.g., water temperature and salinity) in the Stanislaus, Tuolumne, and Merced Rivers, and in the LSJR and the Delta (See Impact AQUA-4, LSJR Alternative 3). For example, increases in the frequency, magnitude, and duration of spring floodplain inundation could enhance spawning and rearing success of migratory species such as Sacramento splittail that depend on relatively long periods of seasonal floodplain inundation to achieve strong year classes (Sommer et al. 2001). Therefore, LSJR Alternative 3 would have beneficial effects on other native fishes in the Stanislaus, Tuolumne, and Merced Rivers.

LSJR Alternative 4 (Less than significant)

Spawning

Under LSJR Alternative 4, suitable spawning habitat for Chinook salmon, steelhead, and other fish species in the Stanislaus, Tuolumne, and Merced Rivers would substantially improve compared to baseline conditions. Adverse impacts would be less than significant.

Chinook Salmon and Steelhead Spawning

Under LSJR Alternative 4, predicted changes in WUA values for Chinook salmon and steelhead spawning in the Stanislaus, Tuolumne, and Merced Rivers would be similar in magnitude to those predicted under LSJR Alternative 3 (Tables 7-11a, 7-11b, and 7-11c and 7-12a, 7-12b, and 7-12c). Therefore, flow-related impacts on Chinook salmon spawning habitat would not have a significant negative impact on Chinook salmon populations in the Stanislaus, Tuolumne, and Merced Rivers.

Other Fish Species (Spawning)

Under LSJR Alternative 4, further increases in the frequency, magnitude, and duration of spring flows compared to those occurring under LSJR Alternative 3 are expected to further increase the quantity and quality of habitat for native fish species and result in long-term increases in spawning success of other native fish species in the Stanislaus, Tuolumne, and Merced Rivers. The proposed flow regime, which is characterized by further increases in monthly modeled flows relative to LSJR Alternative 3, would further improve spawning conditions for splittail, sturgeon, striped bass, and other fishes, as well as improve water quality (e.g., water temperature and salinity) in the Stanislaus, Tuolumne, and Merced Rivers and in the LSJR and the Delta. Associated increases in the frequency, magnitude, and duration of floodplain inundation would further increase aquatic productivity (see Impact AQUA-9, LSJR Alternative 4) and the quantity of suitable spawning and rearing habitat for floodplain-dependent species such as Sacramento splittail. Similar to LSJR Alternative 3, this flow regime would also be expected to reduce the distribution and abundance of nonnative fishes as well as their negative impacts (e.g., predation) on other native fishes (see Impact AQUA-10, LSJR Alternative 4). Therefore, LSJR Alternative 4 would have beneficial effects on other native fishes in the Stanislaus, Tuolumne, and Merced Rivers.

Juvenile Rearing

Under LSJR Alternative 4, fry and juvenile rearing conditions for Chinook salmon, steelhead, and other fish species in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would be substantially improved compared to baseline conditions. Therefore, adverse impacts would be less than significant.

Chinook Salmon and Steelhead Rearing

Under LSJR Alternative 4, predicted changes in average WUA values for Chinook salmon and steelhead fry and juvenile rearing in the Stanislaus, Tuolumne, and Merced Rivers would be similar to those predicted under LSJR Alternative 3 (Tables 7-13a, 7-13b, 7-13c; 7-14a, 7-14b, 1-14c; 7-16a, 7-16b, 7-16c; and 7-17a, 7-17b, 7-17c). However, higher spring flows under this alternative would further increase the rearing capacity of these rivers by expanding the area of inundated floodplain habitat and downstream extent of suitable water temperatures especially in April and May (see Impact AQUA-4, Alternative LSJR 4). Over the 82-year modeling period, the frequency of floodplain inundation events of 50 acres or more in the Stanislaus, Tuolumne, and Merced Rivers would increase by 20–50 percent in April and 40–70 percent in May, corresponding to increases in average floodplain inundation areas of 68–179 acres in April and 176–484 acres in May (Tables 7-15a, 7-15b, and 7-15c). Therefore, LSJR Alternative 4 would substantially improve rearing conditions for Chinook salmon and steelhead populations in the Stanislaus, Tuolumne, and Merced Rivers.

Under LSJR Alternative 4, higher spring flows in the LSJR relative to LSJR Alternative 3 would further increase the availability of floodplain habitat for juvenile Chinook salmon that leave the tributaries as fry or juveniles. Over the 82-year modeling period, floodplain inundation area under LSJR Alternative 4 would increase by 123 acres in April and 352 acres in May compared to baseline conditions (Table 7-16d).

Other Fish Species (Rearing)

As discussed for spawning, LSJR Alternative 4 would further increase the frequency, magnitude, and duration of spring flows compared to LSJR Alternative 3. The resulting increases in the quantity and quality of habitat for native fish species would result in long-term increases in rearing success of other native fish species in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR. Therefore, LSJR Alternative 4 would have beneficial effects on other native fishes in the three eastside tributaries and the LSJR.

Impact AQUA-4: Changes in exposure of fish to suboptimal water temperatures resulting from changes in reservoir storage and releases

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

The LSJR alternatives would affect river temperatures through changes in reservoir storage and flow on the three eastside tributaries and in the LSJR; this would affect the extent of suitable water temperatures for Chinook salmon and steelhead in the river environment below the dams.
The following assessment focuses on potential impacts of the alternatives on Chinook salmon and steelhead populations because of their sensitivity to water temperature, which is a flow-related variable, and their utility as key indicators of the responses of other native fish species to altered flow regimes in regulated rivers. Where appropriate, the Chinook salmon and steelhead analyses are combined. As previously discussed in Section 7.4.2, *Methods and Approach*, the results of this assessment are considered indicative of effects on other fish species; however, a general discussion of the potential responses of other fish species to the proposed alternatives is provided below.

The suitability of water temperatures for fish can generally be defined by optimal, suboptimal, and lethal ranges based on the chronic and acute responses of fish to thermal stress under laboratory and field conditions. Optimal water temperatures are those that cause no significant impacts, suboptimal temperatures are associated with chronic effects and cause increasing thermal stress as water temperatures approach lethal levels, and lethal temperatures are those that cause acute effects (e.g., severe impairment or death). The duration of exposure to suboptimal and lethal temperatures must also be considered in determining the potential for significant impacts.

Changes in water temperatures in the three eastside tributaries and mainstem LSJR associated with each of the LSJR alternatives were evaluated using the CALFED temperature model described in Section 7.4.2, *Methods and Approach* (CALFED 2009). The temperature thresholds used in this analysis are based on the U.S. Environmental Protection Agency's (USEPA's) recommended temperature criteria for protection of salmonids (USEPA 2003). The recommended metric for these criteria is the 7-day average of the daily maximum (7DADM). This metric is recommended because it describes maximum temperatures in a stream but is not overly influenced by the maximum temperature of a single day. Thus, it reflects an average of maximum temperatures that fish are exposed to over weekly periods. Since this metric is based on daily maximum temperatures, it can be used to protect against acute effects, such as lethality and migration blockage conditions, and can also be used to protect against sublethal or chronic effects such as temperature effects on growth, disease, smoltification, and competition (USEPA 2003).

USEPA's recommended criteria were used to define the upper limits of the optimal temperature ranges for adult migration, spawning and incubation, juvenile rearing, smolt outmigration, and summer rearing (Tables 7-18 and 7-19). These criteria serve as benchmarks to evaluate the frequency with which water temperatures exceed optimum water temperatures and potentially result in adverse chronic or acute effects on specific life stages. Predicted changes in exposure of Chinook salmon and steelhead to suboptimal water temperatures were evaluated by comparing the frequency and magnitude of 7DADM values (calculated as a running average of 7-day maximum daily temperatures during the modeled 1970–2003 period) under modeled baseline conditions and the LSJR alternatives. Significant impacts were identified based on changes of 10 percent or more in the frequency of water temperatures exceeding the USEPA criteria, and/or changes in average 7DADM water temperature of 1°F or more. These thresholds in combination with consideration of the potential exposure of Chinook and steelhead populations to suboptimal water temperatures at key locations and months (Tables 7-18 and 7-19) were used to determine whether impacts are significant. Due to lack of quantitative relationships between a given change in environmental conditions and relevant population metrics (e.g., survival or abundance), 10 percent was selected because that value is assumed to be high enough to reveal significant change to a condition while a lessor amount of change could be due to error in the various analytical and modeling techniques. Therefore, 10 percent provides a conservative qualitative basis to evaluate whether adverse effects to sensitive species at the population level will occur.

Table 7-18 and Table 7-19 summarize the water temperature criteria and the primary locations and months that were used to evaluate potential temperature impacts on Chinook salmon and steelhead life stages. The primary evaluation locations and months are based on the general distribution, abundance, and timing of each life stage in the eastside tributaries and LSJR. For example, water temperatures at locations approximately three-quarters of the distance from the mouth of each tributary to the first impassable dam were used to characterize water temperatures in the primary Chinook salmon and steelhead spawning reaches. This location was selected because it generally represents conditions in the majority of the spawning reaches and, therefore, reflects changes in both the downstream extent and quality of suitable water temperatures for spawning and incubation.

Table 7-18. Water Temperature Thresholds and Primary Locations and Months Used to Evaluate Potential Temperature Impacts on Chinook Salmon and Steelhead Life Stages in the Eastside Tributaries

Evaluation Time Period	Primary Life Stage (fall-run Chinook and steelhead)	Temperature Evaluation Thresholds (°C)	Temperature Evaluation Thresholds (°F)	Primary Evaluation Locations
September–October	Adult Migration	18 (7DADM)	64.4 (7DADM)	Confluence
October–March	Spawning and Incubation	13 (7DADM)	55.4 (7DADM)	¾ River
March–May	Juvenile Rearing (Chinook)	16 (7DADM)	60.8 (7DADM)	Confluence
April–June	Smoltification	14 (7DADM)	57.2 (7DADM)	Confluence
July–August	Summer Rearing (steelhead)	18 (7DADM)	64.4 (7DADM)	¾ River

Note: Each tributary was divided into quarters, with ¼, ½, and ¾ representing the fractional distances from the confluence to the first impassable dam.

Table 7-19. Water Temperature Thresholds and Primary Locations and Months Used to Evaluate Potential Temperature Impacts on Chinook Salmon and Steelhead Life Stages in the LSJR

Evaluation Time Period	Primary Life Stage (fall-run Chinook and steelhead composite)	Temperature Evaluation Thresholds (°C)	Temperature Evaluation Thresholds (°F)	Primary Evaluation Locations
September–October	Adult Migration	18 (7DADM)	64.4 (7DADM)	Vernalis
January–March	Juvenile Rearing	16 (7DADM)	60.8 (7DADM)	Vernalis
April–June	Smoltification	14 (7DADM)	57.2 (7DADM)	Vernalis

Although water temperature can affect DO levels, and both factors are related to apparent blockage and delays in migration of adult salmon in the Delta (see Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*), adverse effects associated with low DO levels have not been documented in other reaches of the SJR and its tributaries. Therefore, DO levels would remain within acceptable levels and potentially increase in response to higher flows and cooler temperatures under the LSJR alternatives.

Baseline

Water temperature is recognized as a primary stressor for Chinook salmon and steelhead in the SJR Basin. Exposure of these species to elevated water temperatures can cause thermal stress and lead to reductions in survival through a number of direct and indirect effects. These effects can be generally characterized as: (1) chronic effects related to changes in growth, disease resistance, swimming performance, and other biological functions over relatively long periods; and (2) acute effects related to the thermal tolerance of fish to lethal temperatures over relatively short periods (Sullivan et al. 2000). Water temperatures in the LSJR are typically in equilibrium with air temperatures during the hottest summer months. In the spring and fall, LSJR temperatures are influenced to some extent by inflows and water temperatures from the three eastside tributaries.

Reservoir operations can lead to elevated water temperatures in the spring, which have been identified as a major factor contributing to reduced survival and abundance of juveniles and subsequent returns of spawning adults to the LSJR and the three eastside tributaries. Excessively warm summer temperatures in the tributaries act to limit steelhead abundance by restricting suitable summer rearing habitat to the cooler uppermost reaches of accessible habitat immediately downstream of the rim dams. Consequently, the amount of suitable habitat may be insufficient to sustain healthy steelhead populations (CDFG 2007).

Modeled baseline temperatures and associated habitat conditions for the indicator species and their key life stages are summarized in text below. Modeled baseline temperature conditions are summarized in Tables 7-20a–7-20d through Tables 7-24a–7-24d for each river. These tables also provide a summary of expected temperatures under the LSJR alternatives.

Adult Migration

Potential exposure of adult salmon and steelhead to suboptimal water temperatures during their upstream migration was evaluated based on modeled September and October water temperatures in the SJR at Vernalis and at the mouths of the Stanislaus, Tuolumne, and Merced Rivers. Upstream migration of adult salmon into the SJR and its tributaries generally begins in September, although most of the run enters after September, with peak migration typically occurring in late October and early November following the onset of declining fall temperatures and managed pulse flows (CFS 2007a; CDFG 2001; CDFG 2002). It is assumed that adult steelhead also begin their upstream migration into the tributaries in early fall, with most migration occurring in late fall and winter. The USEPA criteria for salmon and trout migration (64.4°F 7DADM) was used to define the upper limit of the optimal temperature range for adult migration.

Under modeled baseline conditions, suitable water temperatures for adult migration in the SJR and eastside tributaries typically do not occur until October. In the Stanislaus River, 7DADM water temperatures exceeding 64.4°F at the mouth of the Stanislaus River occurred approximately 90 percent of the time in September and 20 percent of the time in October, and average 7DADM water temperatures were 69.6°F and 62.0°F, respectively (Table 7-20a). Water temperatures in the Tuolumne and Merced Rivers in September and October were generally warmer; 7DADM water temperatures exceeding 64.4°F at the mouths of the Tuolumne and Merced Rivers occurred approximately 90 percent of the time in September and 60-70 percent of the time in October (Tables 7-20b and 7-20c). Modeled 7DADM water temperatures in September and October averaged 75.5°F and 67.5°F in the Tuolumne River and 72.2°F and 65.9°F in the Merced River. At Vernalis, 7DADM water temperatures exceeding 64.4°F occurred approximately 90 percent of the time in September and 50 percent of the time in October (Table 7-20d). Average 7DADM temperatures were 72.4°F in September and 64.8°F in October.

Table 7-20a. Distribution of September–-October 7DADM Water Temperatures in Relation to USEPA Criteria for Salmon and Steelhead Adult Migration (64.4˚ F) at the Confluence of the Stanislaus River under Modeled Baseline Conditions and LSJR Alternatives 2, 3, and 4

▨ Gray shading indicates temperatures that exceed USEPA criteria.

Spawning and Incubation

Potential exposure of Chinook salmon and steelhead spawning and incubation life stages to suboptimal water temperatures was evaluated based on modeled water temperatures at RM 43.7 on the Stanislaus River, RM 38.3 on the Tuolumne River, and RM 37.8 on the Merced River. These stations are located approximately three-quarters of the distance from the mouth of each tributary to the first impassable dam, and generally characterize water temperatures in the primary Chinook salmon and steelhead spawning reaches. Chinook salmon spawning and incubation generally extends from October–March while steelhead spawning and incubation extends from January–March.

Under modeled baseline conditions, suitable water temperatures for Chinook salmon spawning and incubation in the Stanislaus, Tuolumne, and Merced Rivers generally do not occur until early to late November in most years. In the Stanislaus River, 7DADM temperatures exceeding the USEPA criterion for salmon and trout spawning (55.4°F) occurred approximately 80 percent of the time in October and over 50 percent of the time in November (Table 7-21a). Water temperatures generally decline in October and November, reach annual lows (typically less than 55.4°F) from December–February, and begin increasing in February and March. The same general pattern is observed in the Tuolumne and Merced Rivers although modeled water temperatures at comparable locations downstream of the dams are typically warmer than those on the Stanislaus River (Tables 7-21b and 7-21c).

Under modeled baseline conditions, water temperatures in the Stanislaus, Tuolumne, and Merced Rivers are nearly always suitable for steelhead spawning and incubation in January (Table 7-21a, 7-21b, and 7-21c). Water temperatures exceeding the USEPA spawning and incubation criterion (55.4°F) begin to increase in frequency in February and occur approximately 20 percent of the time in the Stanislaus River, 40 percent of the time in the Tuolumne River, and 70 percent of the time in the Merced River by March (Tables 7-21a, 7-21b, and 7-21c).

Juvenile Rearing

Potential exposure of Chinook salmon rearing life stages to suboptimal water temperatures was evaluated based on modeled water temperatures at the mouths of the Stanislaus, Tuolumne, and Merced Rivers. These stations were selected because juvenile salmon rearing in the tributaries may occur as far downstream as the tributary mouths following their emergence as fry in the winter and early spring (although some proportion of these fry migrate beyond the confluences to complete their freshwater rearing phases in the LSJR and/or Delta; see *LSJR* in Section 7.2.2. *Reservoirs, Tributaries, and LSJR*). Chinook salmon rearing in the tributaries generally occurs from January–May; however, the primary months of concern with respect to temperature are March–May. In contrast, the evaluation of potential water temperature effects on steelhead rearing focused on the summer months (July–August) at stations located three quarters of the distance from the confluence to the first impassable dam, which generally marks the downstream limit of summer rearing (CALFED 2009; NMFS 2009c).

Under modeled baseline conditions, exposure of juvenile salmon to suboptimal water temperatures (as defined by the USEPA criterion of 60.8°F) in the Stanislaus, Tuolumne, and Merced Rivers and LSJR increases through the spring. In the Stanislaus River, 7DADM water temperatures exceeding this threshold occurred 10 percent of the time in March, 20 percent of the time in April, and 40 percent of the time in May (Table 7-22a). Modeled 7DADM temperatures in these months averaged 56.5°F, 58.5°F, and 61.5°F, respectively. Higher water temperatures are predicted to occur in the Tuolumne and Merced Rivers. In the Tuolumne River, 7DADM water temperatures exceeding the USEPA criterion are predicted to occur approximately 30 percent of the time in March, 40 percent of the time in April, and 70 percent of the time in May (Table 7-22b). Modeled 7DADM water temperatures in these months averaged 58.5°F, 61.7°F, and 65.9°F. In the Merced River, 7DADM water temperatures exceeding the USEPA criterion are predicted to occur approximately 30 percent of the time in March, 70 percent of the time in April, and 90 percent of the time in May (Table 7-22c). Modeled 7DADM water temperatures in these months averaged 58.6°F, 64.0°F, and 68.2°F. In the SJR at Vernalis, 7DADM water temperatures exceeding the USEPA criterion are predicted to occur approximately 10 percent of the time in March, 50 percent of the time in April, and 90 percent of the time in May (Table 7-22d). Modeled 7DADM water temperatures in these months averaged 58.0°F, 61.6°F, and 65.7°F.

During the summer, juvenile steelhead frequently experience suboptimal water temperatures (as defined by the USEPA criterion of 64.4°F) in the Stanislaus, Tuolumne, and Merced Rivers under baseline conditions. In the Stanislaus River at RM 43.7, 7DADM water temperatures exceeding the USEPA criterion are predicted to occur approximately 50 percent of the time in July and August (Table 7-23a). Modeled 7DADM temperatures in these months averaged 64.8°F and 65.0°F, respectively. Higher water temperatures are predicted to occur at similar locations in the Tuolumne and Merced Rivers, exceeding the USEPA criterion 70 percent of the time in July and 80–90 percent of the time in August (Tables 7-23b and 7-23c). Modeled 7DADM temperatures in July and August averaged 69.8°F and 71.1°F in the Tuolumne River, and 73.3°F and 73.2°F in the Merced River.

Smoltification

Potential exposure of Chinook salmon and steelhead smolts to suboptimal water temperatures under baseline and alternative operational conditions was evaluated based on modeled water temperatures at the mouths of the Stanislaus, Tuolumne, and Merced Rivers and in the SJR at Vernalis during the spring outmigration period (April–June). These stations were selected because of the importance of suitable water temperatures for smolt development and health prior to their transition from fresh to saltwater. The following analysis examines differences in exposure of salmon and steelhead smolts to suboptimal water temperatures based on the frequency of modeled 7DADM temperatures that exceed the recommended USEPA criterion of 57.2°F for steelhead smoltification. Steelhead smolts are considered the most temperature-sensitive species and life stage during the spring outmigration period.

Under modeled baseline conditions, spring water temperatures frequently exceed the USEPA criterion for smoltification at the mouths of the Stanislaus, Tuolumne, and Merced Rivers and in the LSJR. Modeled 7DADM water temperatures exceeding the USEPA criterion are predicted to occur 60–90 percent of the time in April, 90 percent of the time in May, and nearly 100 percent of the time in June (Tables 7-24a, 7-24b, and 7-24c). Average 7DADM temperatures ranged from 58.5°F–64.0°F in April, 61.5°F–68.2°F in May, and 66.8°F–72.3°F in June.

Table 7-24a. Distribution of April–May 7DADM Water Temperatures in Relation to USEPA Criteria for Steelhead Smoltification (57.2˚F) at the Confluence of the Stanislaus River under Modeled Baseline Conditions and LSJR Alternatives 2, 3, and 4

Notes: Table shows the percent of time that a temperature of equal or lower value occurs. Gray shading indicates temperatures that exceed USEPA criteria.

LSJR Alternative 2 (Less than significant)

Under LSJR Alternative 2, exposure of Chinook salmon and steelhead to suboptimal water temperatures on the Stanislaus and LSJR would not substantially change compared to baseline conditions. No substantial changes would occur in the frequency of suboptimal water temperatures for migration, spawning, and incubation life stages in the three eastside tributaries although spring water temperatures would be improved for rearing and outmigrating salmon in the Tuolumne and Merced Rivers. Other native fishes would experience a similar range of seasonal water temperatures and therefore would not be substantially affected by implementation of this alternative. Impacts on Chinook salmon, steelhead, and other native fishes would not be adverse and would be less than significant.

Adult Migration

Under LSJR Alternative 2, the frequency of suboptimal water temperatures for Chinook salmon and steelhead adult migration (as defined by the USEPA criterion of 64.4°F) at the mouths of the Stanislaus, Tuolumne, and Merced Rivers and in the SJR at Vernalis is expected to remain largely unchanged from baseline conditions (Tables 7-20a, 7-20b, 7-20c, and 7-20d). Therefore, water temperature impacts on migrating adult salmon (including adults returning to Merced River Hatchery) and steelhead would be less than significant.

Spawning and Incubation

Under LSJR Alternative 2, the frequency of suboptimal water temperatures for Chinook salmon and steelhead spawning and incubation life stages (as defined by the USEPA criterion of 55.4°F) in the Stanislaus, Tuolumne, and Merced Rivers is not expected to change substantially relative to baseline conditions (Tables 7-21a, 7-21b, and 7-21c). Therefore, water temperature impacts on Chinook salmon and steelhead spawning and incubation life stages (including adult salmon and incubating eggs and fry in the Merced River Hatchery) would not be adverse and would be less than significant.

Juvenile Rearing

Under LSJR Alternative 2, exposure of juvenile salmon to suboptimal rearing temperatures (as defined by the USEPA criterion of 60.8°F) at the mouth of the Stanislaus River during the spring rearing period is not expected to change substantially relative to baseline conditions (Table 7-22a). In the Tuolumne and Merced Rivers, rearing temperatures under LSJR Alternative 2 are expected to improve based on reductions in average temperatures of 1.7°F to 2.1°F in May (Tables 7-22b and 7-22c). In the SJR at Vernalis, spring water temperatures under LSJR Alternative 2 are predicted to be similar to those under baseline conditions (Table 7-22d). Overall, changes in the exposure of juvenile salmon and steelhead during the spring rearing period are not expected to result in significant impacts on natural or hatchery production compared to baseline conditions.

Under LSJR Alternative 2, exposure of juvenile steelhead in the Stanislaus, Tuolumne, and Merced River to suboptimal rearing temperatures (as defined by the USEPA criterion of 64.4°F) in July and August is not expected to change substantially relative to baseline conditions (Tables 7-23a, 7-23b, and 7-23c). Therefore, water temperature impacts on summer rearing conditions for juvenile steelhead would not be adverse and would be less than significant.

Smoltification

Under LSJR Alternative 2, exposure of salmon and steelhead smolts to suboptimal temperatures (as defined by the USEPA criterion of 57.2°F) in the Stanislaus River and SJR at Vernalis is not expected to change substantially relative to baseline conditions (Table 7-24a and 7-24d). However, smolt outmigration conditions in the Tuolumne and Merced Rivers are expected to improve based on reductions in average temperatures of 1.7°F–2.1°F in May and 1.6°F–2.8°F in June over the 34-year modeling period (Tables 7-24b and 7-24c). This represents a beneficial effect on spring outmigration conditions for juvenile salmon and steelhead in the Tuolumne and Merced Rivers (including juvenile salmon reared at the Merced River Hatchery and released in the Merced River). Therefore, adverse impacts would be less than significant.

Other Fish Species

Higher spring flows and associated decreases in spring water temperatures under LSJR Alternative 2 are not expected to substantially affect the structure and composition of native and nonnative fish communities in the three eastside tributaries. The range of seasonal water temperatures predicted to occur under LSJR Alternative 2, including maximum water temperatures occurring in the summer, would remain within the ranges generally experienced by other fishes under baseline conditions. Therefore, adverse impacts would be less than significant.

LSJR Alternative 3 (Less than significant)

Under LSJR Alternative 3, Chinook salmon and steelhead populations in the Stanislaus, Tuolumne, and Merced Rivers and LSJR would experience improved water temperatures primarily during the spring rearing and outmigration months in response to higher flows in each of the tributaries (Tables 7-20a, 7-20b, 7-20c, and 7-20d through Tables 24a, Table 24b, Table 24c, and Table 7-24d). Water temperatures favoring native fish species over nonnative warmwater species would generally be improved relative to baseline conditions. Impacts on Chinook salmon, steelhead, and other native fishes would not be adverse and would be less than significant.

Adult Migration

Under LSJR Alternative 3, exposure of migrating Chinook salmon and steelhead adults to suboptimal water temperatures (as defined by the USEPA criterion of 64.4°F) in the Stanislaus, Tuolumne, Merced, and LSJR would be similar or slightly reduced relative to baseline conditions (Tables 7-20a, 7-20b, 7-20c, and 7-20d). Changes in water temperatures during the fall migration period ranged from little or no change at most locations to a 10 percent reduction in the frequency of suboptimal water temperatures and a 1.2°F reduction in average temperature in the Stanislaus River in October (Tables 7-20a). Therefore, water temperature impacts on migrating adult salmon (including adults returning to Merced River Hatchery) and steelhead would not be adverse and would be less than significant.

Spawning and Incubation

Under LSJR Alternative 3, the percent of time suboptimal water temperatures occur for Chinook salmon and steelhead spawning and incubation life stages (as defined by the USEPA criterion of 55.4°F) in the Stanislaus, Tuolumne, and Merced Rivers is not expected to change substantially relative to baseline conditions (Tables 7-21a, 7-21b, and 7-21c). Changes in the exposure of Chinook salmon and steelhead spawning and incubation life stages to suboptimal water temperatures (as defined by the USEPA criterion of 55.4°F) were characterized by little or no change at most locations. An exception is the 30 percent reduction in the frequency of suboptimal water temperatures and a 1.6°F reduction in average temperature in the Tuolumne River in March (Table 7-21b). Therefore, water temperature impacts on Chinook salmon and steelhead spawning and incubation conditions (including conditions at Merced River Hatchery) would not be adverse and would be less than significant.

Juvenile Rearing

Under LSJR Alternative 3, exposure of juvenile salmon to suboptimal water temperatures (as defined by the USEPA criterion of 60.8°F) during the spring rearing period is expected to decrease in the Stanislaus, Tuolumne and Merced Rivers and LSJR relative to baseline conditions. The largest changes are expected to occur in the Tuolumne River and Merced Rivers where 7DADM temperatures exceeding the USEPA criterion are predicted to decrease in frequency by 10–20 percent in March, 10–20 percent in April, and 10–30 percent in May, corresponding to reductions in average temperatures of 0.4°F–1.2°F in March, 2.2°F–2.5°F in April, and 4.3°F–4.8°F in May (Tables 7-22b and 7-22c). Therefore, implementation of LSJR Alternative 3 would have a beneficial effect on spring rearing conditions for Chinook salmon in the Stanislaus, Tuolumne, and Merced Rivers (including fish reared at the Merced River Hatchery and released upstream of Vernalis), and the LSJR. Adverse impacts would be less than significant.

Under LSJR Alternative 3, juvenile steelhead would experience lower summer water temperatures in the Stanislaus, Tuolumne, and Merced Rivers relative to baseline conditions (Tables 7-23a, 7-23b, and 7-23c). The largest change is expected to occur in the Tuolumne where 7DADM temperatures exceeding the USEPA criterion (64.4°F) in July are predicted to decrease in frequency by approximately 20 percent, corresponding to a reduction in average temperature of 2.0°F (Table 7-23b). Therefore, some improvement in summer rearing conditions for steelhead is expected in the Stanislaus, Tuolumne, and Merced Rivers. Adverse impacts would be less than significant.

Smoltification

Under LSJR Alternative 3, salmon and steelhead smolts would experience lower water temperatures during their outmigration in the Stanislaus, Tuolumne, and Merced Rivers and LSJR relative to baseline conditions (Tables 7-24a, 7-24b, 7-24c, and 7-24d). The largest changes are expected to occur in the Tuolumne River and Merced Rivers where 7DADM temperatures exceeding the USEPA criterion are predicted to decrease in magnitude by an average of 2.2°F–2.5°F in April, 4.3°F–4.8°F in May, and 3.3°F–6.0°F in June (Tables 7-24b and 7-24c). These changes represent improved conditions for smolt development and migration in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR (including juvenile salmon reared at the Merced River Hatchery and released upstream of Vernalis). Adverse impacts would be less than significant.

Other Fish Species

Under LSJR Alternative 3, higher spring flows and associated reductions in water temperature in the Stanislaus, Tuolumne, and Merced Rivers and LSJR could benefit other native species and adversely affect nonnative species, such as largemouth bass and other warmwater species, which prey on or compete with native fishes. Based on reported changes in the abundance and distribution of native and nonnative resident species in the Tuolumne River and other Central Valley streams, higher spring flows and cooler water temperatures that mimic conditions that occur under the natural flow regime provide more appropriate spawning and rearing conditions for native species (Brown and Ford 2002). Increases in spring flows would also improve migration, spawning, and rearing conditions for splittail, sturgeon, striped bass, and other fishes, as well as improve water quality (e.g., water temperature and salinity) in the Stanislaus, Tuolumne, and Merced Rivers and in the LSJR (see Impact AQUA-4, LSJR Alternative 3). Therefore, LSJR Alternative 3 would have beneficial effects on other native fishes in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR. Impacts on native fish species would not be adverse and would be less than significant.

LSJR Alternative 4 (Less than significant)

Under LSJR Alternative 4, Chinook salmon and steelhead populations in the Stanislaus, Tuolumne, and Merced Rivers and LSJR would experience improved water temperatures primarily during the spring rearing and outmigration months in response to higher flows in each of the tributaries (Tables 7-20a, 7-20b, 7-20c, and 7-20d through Tables 7-24a, 7-24, 7-24c, and 7-24d). Water temperatures favoring native fish species over nonnative warmwater species would be improved relative to baseline conditions. Impacts on Chinook salmon, steelhead, and other native fishes would not be adverse and would be less than significant.

Adult Migration

LSJR Alternative 4, water temperatures for migrating Chinook salmon and steelhead in the Stanislaus, Tuolumne, Merced, and LSJR would be similar or slightly improved relative to baseline conditions (Tables 7-20a, 7-20b, 7-20c, and 7-20d). Changes in average water temperature during the fall migration period ranged from little or no change at most locations to a 1.0°F reduction in average temperature in the Tuolumne River in September (Table 7-20b). Therefore, water temperature impacts on migrating adult salmon (including adults returning to Merced River Hatchery) and steelhead would not be adverse and would be less than significant.

Spawning and Incubation

Under LSJR Alternative 4, no substantial changes are predicted to occur in the frequency of suboptimal water temperatures for Chinook salmon and steelhead spawning and incubation life stages (as defined by the USEPA criterion of 55.4°F) in the Stanislaus, Tuolumne, and Merced Rivers (Tables 7-21a, 7-21b, and 7-21c). Some improvement in water temperatures would occur in February and March when the frequency of water temperatures exceeding the USEPA criterion are expected to decline by 10–40 percent, and average temperatures are expected to decline by up to 2.2°F. Adverse impacts would be less than significant.

Juvenile Rearing

Implementation of LSJR Alternative 4 would substantially reduce the exposure of juvenile salmon to suboptimal water temperatures during the spring rearing period in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR. Under this alternative, modeled 7DADM temperatures exceeding the USEPA criterion are predicted to decline in frequency by approximately 0–30 percent in March, 20–40 percent in April, and 10–30 percent in May, and to be reduced in magnitude by an average of 0.8°F–2.2°F in March, 1.1°F–3.8°F in April, and 2.1°F–5.7°F in May (Tables 7-22a, 7-22b, 7-22c, and 7-22d). These changes represent substantial increases in the frequency, duration, and longitudinal extent of suitable rearing temperatures for juvenile salmon in the LSJR and tributaries. Thus, implementation of LSJR Alternative 4 would have beneficial effects on spring rearing conditions for

Chinook salmon in the Stanislaus, Tuolumne, and Merced Rivers (including juvenile salmon reared at the Merced River Hatchery), and LSJR. Adverse impacts would be less than significant.

Under LSJR Alternative 4, substantial changes in the frequency of suboptimal water temperatures for juvenile steelhead (as defined by the USEPA criterion of 64.4°F) during the summer rearing months are only expected to occur in the Tuolumne River where 7DADM temperatures exceeding the USEPA criterion are predicted to decrease in frequency by 20 percent, and to decrease in magnitude by an average of 1.7°F (Table 7-23b). Adverse impacts would be less than significant.

Smoltification

Under LSJR Alternative 4, salmon and steelhead smolts would experience substantial reductions in exposure to suboptimal water temperatures (as defined by the USEPA criterion of 57.2°F) during the spring outmigration period in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR relative to baseline conditions (Tables 7-24a, 7-24b, 7-24c, and 7-24d). Modeled 7DADM temperatures exceeding the USEPA criterion at the mouths of the Stanislaus, Tuolumne, and Merced Rivers and in the SJR at Vernalis are predicted to decrease in frequency by 20 percent or less but decrease in magnitude by an average of 1.1°F–3.8°F in April, 2.1°F–5.7°F in May, and 2.4°F–7.3°F in June. These changes represent substantial improvement in conditions for smolt development and migration in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR (including juvenile salmon reared at the Merced River Hatchery and released). Adverse impacts would be less than significant.

Other Fish Species

Under LSJR Alternative 4, further increases in spring flows and associated reductions in water temperature (compared to those occurring under LSJR Alternative 3) are expected to further increase the quantity and quality of habitat for native fish species in the Stanislaus, Tuolumne, Merced, and LSJR. As discussed under LSJR Alternative 3, the predicted changes in flows and water temperatures would be expected to reduce the distribution and abundance of nonnative fishes and their negative impacts (e.g., predation) on native fishes (see Impact AQUA-10, LSJR Alternative 4). Therefore, LSJR Alternative 4 would have beneficial effects on native fishes in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR.

Impact AQUA-5: Changes in exposure to pollutants resulting from changes in flow

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

In general, surface water originating in the three eastside tributary watersheds is good quality and has low salinity concentrations. As increased flow due to precipitation or reservoir operations mobilizes sediment, pollutant levels in the water column have the potential to increase if present in the sediment. Certain land uses, such as abandoned mining operations, in the tributary watersheds have leached different pollutants into the rivers. These pollutants include toxic trace metals (e.g., copper, zinc, and cadmium) (Boles et al. 1988). This has increased known pollutant concentrations in river sediment, which can result in increased fish mortality.

Increased flows under the LSJR alternatives have the potential to increase mobilization and concentration of pollutants in surface waters in the three eastside tributaries and LSJR, potentially increasing exposure of aquatic organisms to toxic substances. While copper, zinc, and cadmium tolerance limits exist for juvenile Chinook salmon (Boles et al. 1988), direct effects on fish cannot be accurately or precisely quantified given the current understanding of the complex processes involved in mobilization and fate of sediment-linked toxins. The volume and concentrations of pollutants that could be mobilized into rivers are generally unknown, and site-specific analyses would be needed to confirm real-time concentrations. However, because pollutants attached to sediment enter the water column, the potential for increased toxins in the system can be linked to a change in suspended sediment and turbidity. An increased concentration of toxins as a result of increased flows could adversely impact indicator species. Alternatively, increased flows can also dilute existing pollutants in the water column and any other pollutants that may be mobilized from the sediment on the riverbed and along the river channel, thereby benefiting indicator species.

Decreased flows could increase concentrations of pollutants, adversely impacting indicator species. Decreased flows could also result in increased temperatures, which generally increase the toxic effects of metals and reduce the survival time of Chinook salmon if lethal levels of metals are present. Warming water temperatures can increase pollutant dose because fish respiration and feeding rates must increase to support the higher metabolic rates that result from warmer water temperatures (Myrick and Cech 2004). Additionally, warming water temperatures can reduce the energy reserves that fish utilize to lessen the effects of pollutants (Brooks et al. 2012). Consequently, lower flows and higher temperatures may exacerbate the effects of pollutants (Heugens et al. 2001).

This assessment is qualitative and based on the dilution effects of proposed changes in flows (see Chapter 5, *Surface Hydrology and Water Quality*, Impact WQ-3) and changes in exposure of fish to thermal stress that could increase their uptake and vulnerability to contaminants under each of the LSJR alternatives (see Impact AQUA-4). Potential water quality impacts under the following analysis assumes that dilution from increased flow would result in long-term reductions in contaminant concentrations and exposure of fish to potentially harmful concentrations in the plan area. However, it should be recognized there is uncertainty regarding the effects of flow in addressing contaminant loads because of concerns related to remobilization of pesticides, trace metals, and other contaminants in the sediment, and the need to implement point- and non-point source reduction actions as part of future restoration efforts (McBain and Trush 2002). For a description of expected changes to sediment and turbidity resulting from increased flows, see Impact AQUA-6.

Impact WQ-3 in Chapter 5 was evaluated based on the changes in the 10th percentile and median values of flow. A concentration ratio of more than 1.5 would represent an increase of 50 percent of the baseline concentration and would be expected to cause a significant increase in pollutants when baseline concentrations are approaching water quality objectives for water resources. As detailed in Chapter 5, a concentration ratio of 1.5 would occur if there was a one-third reduction in flow. Therefore, a reduction in 10th percentile or median flows of more than 33 percent for a particular month is considered to be potentially significant and subject to further evaluation.

LSJR Alternative 2 (Less than significant)

Under LSJR Alternative 2, Chinook salmon, steelhead, and other fish species would not experience an increased exposure or vulnerability to contaminants in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR. Flows were similar in most months and substantially higher in the spring (May and June primarily) compared to baseline conditions (Tables 5-17a, 5-17b, 5-17c, and 5-17d). Reductions in magnitude of the 10th to 90th percentile flows of 10 percent or more occurred in some months but these reductions were associated with the highest flow years (e.g., >50th percentile flows) or flows during the winter and early spring (December–March) when water temperatures are not a concern (see Impact AQUA-4, LSJR Alternative 2). Impacts on Chinook salmon, steelhead, and other fishes would not be adverse and would be less than significant.

LSJR Alternative 3 (Less than significant)

Under LSJR Alternative 3, Chinook salmon, steelhead, and other fish species would not experience an increased exposure or vulnerability to contaminants because of higher spring flows and substantial improvement in water temperatures for juvenile rearing and smolt outmigration in the Tuolumne River, the Merced River, and the LSJR (Tables 5-17a, 5-17b, 5-17c, and 5-17d). Reductions in magnitude of the 10th to 90th percentile flows of 10 percent or more occurred in some months but these reductions were associated with the highest flow years (e.g., upper 50th percentile flows) or flows during the winter and early spring (December–March) when water temperatures are not a concern (see Impact AQUA-4, LSJR Alternative 3). Impacts on Chinook salmon, steelhead, and other fishes would not be adverse and would be less than significant.

LSJR Alternative 4 (Less than significant)

Under LSJR Alternative 4, Chinook salmon, steelhead, and other fish species would not experience an increased exposure or vulnerability to contaminants because of higher spring flows and substantial improvement in water temperatures for juvenile rearing and smolt outmigration in the Tuolumne River, the Merced River, and the LSJR (Tables 5-17a, 5-17b, 5-17c, and 5-17d). Reductions in magnitude of the 10th to 90th percentile flows of 10 percent or more occurred in some months but these reductions were associated with the highest flow years (e.g., upper 50th percentile flows) or flows during the winter and early spring (December–March) when water temperatures are not a concern (see Impact AQUA-4, LSJR Alternative 4). Impacts on Chinook salmon, steelhead, and other fishes would not be adverse and would be less than significant.

Impact AQUA-6: Changes in exposure to suspended sediment and turbidity resulting from changes in flow

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

Higher flows generally have a higher capacity to mobilize and transport sediment in rivers, resulting in higher concentrations of suspended sediment and reduced water clarity (i.e., increased turbidity). Suspended sediments, such as clay, silt, organic matter, plankton, and other microscopic organisms cause turbidity in water that can affect primary productivity, water temperature, DO, and fish feeding. During high-flow events, high concentrations of suspended sediment can settle out and bury stream substrates that provide habitat for aquatic invertebrates and other important food sources for fish. Sediment that settles out of suspension may also reduce the quality of spawning substrates and entomb or suffocate salmonid eggs and alevins in stream gravels. Other effects of suspended sediment on fish include displacement from key habitats, physiological stress, respiratory impairment, damage to gills, reduced tolerance to disease and toxicants, and direct mortality at very high levels (Newcombe and Jensen 1996; Bash et al. 2001).

High turbidity levels generally reduce the efficiency of piscivorous (fish-eating) and planktivorous (plankton-eating) fish in finding and capturing their prey (Henley et al. 2000). Higher turbidity may favor the survival of young fish by protecting them from predators (De Robertis et al. 2003), but can also reduce the feeding rates of young fish that depend on sight to detect prey (Newcombe and Jensen 1996). Typically, when waters are turbid, predator success rate is less. Juvenile salmon losses to predators may be reduced by at least 45 percent in turbid stream reaches relative to clearer water reaches (Gregory and Levings 1998). Turbid water may also stimulate faster migration rates, which reduces the time young fish are exposed to freshwater mortality risks (USBR 2008). In the southern Delta, low turbidity contributes to poor feeding conditions and potentially higher predation rates on delta smelt and other pelagic species. For delta smelt, it appears that turbidity enhances visual contrast and detection of prey (Baskerville-Bridges et al. 2004). Feeding of other planktivorous species, such as longfin smelt, may also be similarly affected by turbidity (Nobriga et al. 2008; USBR 2011).

Potential effects of the LSJR alternatives on the frequency and magnitude of flow events capable of inducing sediment transport in the upper and lower reaches of the Stanislaus, Tuolumne, and Merced Rivers were evaluated to determine the potential for changes in exposure of fish to increases in suspended sediment concentrations and turbidity (Impact AQUA-6), and changes in channel complexity (habitat diversity) and spawning gravel quality resulting from gravel mobilization (Impact AQUA-8). Under baseline conditions, gravel transport is estimated to occur at flows between 5,000 and 8,000 cfs in the Stanislaus River (Kondolf et al. 2001), flows between 7,000 and 9,800 cfs in the upper reaches of the Tuolumne River (McBain and Trush 2000), and flows greater than 4,800 cfs in the upper reaches of the Merced River (Stillwater Sciences 2001; Kondolf et al. 1996). Flows below these levels (above approximately 2,000–3,000 cfs) can mobilize finer sediment in the mid- to lower sand-bedded portions of these tributaries, potentially increasing suspended sediment and turbidity in the lower reaches of these tributaries and the LSJR. These flows were used as thresholds to evaluate potential impacts on the indicator fish species and aquatic habitat resulting from changes in the frequency and magnitude of bed-mobilizing flows in the Stanislaus, Tuolumne, and Merced Rivers. This analysis is based on modeled peak monthly flows in the wettest years of the 1922–2003 modeling period (Chapter 6, *Flooding, Sediment, and Erosion*, Tables 6-10 through 6-12).

LSJR Alternative 2 (Less than significant)

Under LSJR Alternative 2, the modeling of peak flows during the wettest years of the 1922–2003 modeling period indicates that the frequency and magnitude of flows exceeding the thresholds associated with gravel mobilization in the upper reaches of the Stanislaus, Tuolumne, and Merced Rivers would be similar to that occurring under baseline conditions (Tables 6-9 through 6-12; Chapter 6, *Flooding, Sediment, and Erosion*, Impact FLO-1) In addition, no substantial changes would occur in the frequency of peak flows capable of inducing increased turbidity and suspended sediment in the lower portions of Stanislaus, Tuolumne, and Merced Rivers (>2,000 cfs). Therefore, no long-term changes in suspended sediment and turbidity affecting aquatic resources would occur. Adverse impacts would be less than significant.

LSJR Alternative 3 (Less than significant)

Under LSJR Alternative 3, peak flows associated with gravel mobilization in the Stanislaus, Tuolumne, and Merced Rivers would remain unchanged or decrease in frequency relative to baseline conditions (Tables 6-10 through 6-12; Chapter 6, *Flooding, Sediment, and Erosion*, Impact FLO-1). Peak flow events capable of transporting fine sediment in the lower sand-bedded reaches of these tributaries are predicted to increase in frequency in the Stanislaus River during the 82-year modeling period (15 years under LSJR Alternative 3 compared to 11 years under baseline conditions; see Table 6-10) but the magnitude of these events is expected to remain within the range of historical levels experienced by native fishes and other aquatic species. Furthermore, sediment carried into the southern Delta is generally considered beneficial to delta smelt and other pelagic fish species because of reductions in turbidity that have contributed to habitat degradation for pelagic fishes in the Bay-Delta estuary (Ferrari et al. 2013). Therefore, no long-term changes in suspended sediment and turbidity affecting aquatic resources would occur. Adverse impacts would be less than significant.

LSJR Alternative 4 (Less than significant)

Under LSJR Alternative 4, peak flows associated with gravel mobilization would increase in frequency in the Stanislaus River and decrease in frequency in the Tuolumne and Merced River (Tables 6-10 through 6-12; Chapter 6, *Flooding, Sediment, and Erosion*, Impact FLO-1). However, increases in the frequency of gravel-mobilization events are not expected to substantially affect native fish communities or aquatic habitat because of the low frequency of these events over the 82-year modeling period. Furthermore, such events are generally recognized as beneficial for aquatic habitat maintenance (McBain and Trush 2000; Kondolf et al. 2001; Stillwater Sciences 2001, 2004). Similar to LSJR Alternative 3, peak flow events capable of transporting fine sediment in the lower sand-bedded reaches of these tributaries could increase in frequency in the Stanislaus River (16 years under LSJR Alternative 4 compared to 11 years under baseline conditions; see Table 6-10) but the magnitude of these events is expected to remain within the range of historical levels experienced by native fishes and other aquatic species. Furthermore, sediment carried into the southern Delta is generally considered beneficial to delta smelt and other pelagic fish species because of reductions in turbidity that have contributed to habitat degradation for pelagic fishes in the Bay-Delta estuary. Therefore, no long-term changes in suspended sediment and turbidity affecting aquatic resources would occur. Adverse impacts would be less than significant.

Impact AQUA-7: Changes in redd dewatering resulting from flow fluctuations

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

Reservoir operations can result in fluctuations in river flows that can dewater Chinook salmon and steelhead redds. In general, redd dewatering depends on site conditions selected by females for spawning, the magnitude and duration of subsequent flow reductions during the incubation period, and the developmental stage of the embryos or fry at the time of the flow reductions. Spawning site selection depends on the presence of suitable water depths, velocities, and substrate sizes for adult spawning activities and redd construction. Suitable spawning sites are also characterized by bed topography that facilitates flow exchange through the gravel, as occurs in the transitional areas between pools and riffles (Shapovalov and Taft 1954) or where other channel features induce upwelling or downwelling (Geist et al. 2001). Following egg deposition and completion of redd construction, the survival of eggs and alevins (yolk-sac fry) depends on the maintenance of suitable hyporheic flow[16], water temperatures, and DO levels. Salmonid eggs can tolerate temporary (1–5 weeks) dewatering provided that the temperature remains suitable and the eggs remain moist (Becker et al. 1982; Reiser and White 1983; McMichael et al. 2005). Alevins are less tolerant of dewatering because of their dependence on hyporheic flow and relatively high concentrations of DO in the surrounding water (Becker et al. 1982).

Potential redd dewatering impacts were evaluated based on habitat suitability criteria (HSC) for Chinook salmon and steelhead spawning (water depths) and published data on egg burial depths. Depth HSCs and redd measurements for Chinook salmon and steelhead in the three eastside tributaries and other Central Valley rivers indicate that the shallowest depth utilized by spawning Chinook salmon and steelhead adults is approximately 0.5 ft (USFWS1993, 1997, 2010; MID 2013; Stillwater Sciences 2013). Redds become fully dewatered when the surface of the hyporheic zone drops below the elevation of the egg pocket. However, impacts may occur with reductions in surface flow depending on site conditions (e.g., intragravel permeability) and developmental stage of the embryos or fry (Reiser and White 1983). Published measurements of egg burial depths (excavation depth to top of main egg pocket) average 0.5–1.4 ft for Chinook salmon and 0.4–0.8 inches for steelhead (DeVries 1997). Because of variability in potential effects related to site conditions and developmental stage, the following analysis includes the assumption that embryos and fry in the shallowest redds begin to experience adverse intragravel conditions with flow reductions exceeding the minimum spawning depth (0.5 ft). Additionally, based on the range of egg burial depths cited above, complete dewatering of the shallowest redds is assumed to occur with flow reductions of approximately 1 foot. Therefore, significant adverse impacts could occur if the frequency of flow reduction of 1 foot or more increases by 10 percent or more under the alternatives.

---

[16] The *hyporheic zone* is the zone below and adjacent to the streambed where surface and subsurface water mix and are readily exchanged.

Table 7-25 summarizes the flow-depth relationships that were used to calculate average monthly changes in water depth over redds during the Chinook salmon and steelhead incubation periods. These relationships describe the average change in water depth as a function of flow based on a series of channel cross sections and flow-stage relationships within the principal spawning reaches of the Stanislaus, Tuolumne, and Merced Rivers.[17] Polynomial equations were fit to the average flow-depth relationships for each tributary and used to calculate the average monthly change in water depth during the Chinook salmon and steelhead incubation period based on monthly modeled reservoir releases at Goodwin Dam, La Grange Dam, and Crocker-Huffman Dam for the years 1922–2003. It should be recognized that monthly flow modeling provides only a coarse approximation of potential impacts associated with redd dewatering because such impacts are highly sensitive to daily variation in flows, spawning timings, and daily reservoir operational decisions and rules that govern the magnitude and rate of flow reductions during the Chinook salmon spawning and incubation season. Under current operations, redd dewatering has not been identified as a significant stressor on Chinook salmon and steelhead populations in the Stanislaus, Tuolumne, and Merced Rivers.

Table 7-25. Flow-Depth Relationships for the Principal Chinook Salmon and Steelhead Spawning Reaches in the Stanislaus, Tuolumne, and Merced Rivers

Stanislaus at Goodwin		Tuolumne at La Grange		Merced at Crocker Huffman	
flow (cfs)	depth (feet)	flow (cfs)	depth (feet)	flow (cfs)	depth (feet)
250	3.03	250	3.40	250	2.46
500	3.64	500	3.88	500	2.98
1,000	4.60	1,000	4.61	1,000	3.30
1,500	5.59	1,500	5.13	1,500	3.69
2,000	6.24	2,000	5.52	2,000	4.03
2,500	6.81	2,500	5.85	2,500	4.35
3,000	7.29	3,000	6.04	3,000	4.64
4,000	8.22	4,000	6.28	4,000	5.09
5,000	9.01	5,000	5.95	5,000	5.62

cfs = cubic feet per second

Tables 7-26a, 7-26b, and 7-26c summarize the frequency and magnitude of monthly changes in water depth during the primary Chinook salmon and steelhead incubation months (October–May) under baseline conditions and LSJR Alternatives 2, 3, and 4. The results are shown for 10th, 50th, 90th percentiles and averages for the years 1922–2003. A positive value for a given month indicates an increase in water depth from the previous month, while a negative value indicates a decrease in water depth from the previous month.

---

[17] These relationships were developed from 36 cross sections on the Stanislaus River between RM 33.3 and 58.5, 37 cross sections on the Tuolumne River between RM 29.2 and 53.1, and 45 cross sections on the Merced River between RM 27.4 and 52.2 (see AD Consultants et al. 2009).

Baseline

Seasonal flow fluctuations in the Stanislaus, Tuolumne, and Merced Rivers during the Chinook salmon and steelhead spawning and incubation seasons are generally characterized by flow reductions in the fall (following pulse flows typically in late October to attract Chinook salmon into the tributaries), relatively stable base flows through the winter (punctuated by storm-driven flow pulses), sustained higher flows in the late winter and spring, and a flow reduction to summer base flows in late spring or summer. Under modeled baseline conditions, reductions in monthly flows below Goodwin, La Grange, and Crocker-Huffman Dams typically occur between October and November, resulting in average changes in water depth of 3.7 ft in the Stanislaus River, 0.1 ft in the Tuolumne River, and 2.4 ft in the Merced River (Tables 7-26a, 7-26b, and 7-26c). Although the potential exists for redd dewatering in the Stanislaus and Merced Rivers, the incidence of redd dewatering is likely low because most adults do not spawn until after the fall attraction flow. Beginning in November, modeled baseline flows generally remain stable or increase during the Chinook salmon and steelhead spawning and incubation season.

LSJR Alternative 2 (Less than significant)

Under LSJR Alternative 2, no substantial changes would occur in the frequency and magnitude of flow reductions associated with potential Chinook salmon and steelhead redd dewatering impacts (decreases in water depth of greater than 0.5 ft) relative to baseline conditions (Tables 7-26a, 7-26b, and 7-26c). Therefore, redd dewatering impacts on Chinook salmon and steelhead populations in the Stanislaus, Tuolumne, and Merced Rivers would be less than significant.

LSJR Alternative 3 (Less than significant)

Under LSJR Alternative 3, no substantial changes would occur in the frequency and magnitude of flow reductions associated with potential Chinook salmon and steelhead redd dewatering impacts (decreases in water depth of greater than 0.5 ft) relative to baseline conditions (Tables 7-26a, 7-26b, and 7-26c). Therefore, redd dewatering impacts on Chinook salmon and steelhead populations in the Stanislaus, Tuolumne, and Merced Rivers would be less than significant.

LSJR Alternative 4 (Less than significant)

Under LSJR Alternative 4, no substantial changes would occur in the frequency and magnitude of flow reductions associated with potential Chinook salmon and steelhead redd dewatering impacts (decreases in water depth of greater than 0.5 ft) relative to baseline conditions (Tables 7-26a, 7-26b, and 7-26c). Therefore, redd dewatering impacts on Chinook salmon and steelhead populations in the Stanislaus, Tuolumne, and Merced Rivers would be less than significant.

Impact AQUA-8: Changes in spawning and rearing habitat quality resulting from changes in peak flows

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

In general, historical dam operations and mining operations in the Stanislaus, Tuolumne, and Merced Rivers have eliminated natural gravel sources and channel forming flows that maintain the geomorphic processes needed to maintain high-quality spawning and rearing habitat for native salmonids and other fishes (McBain and Trush 2002). As discussed for Impact AQUA-6, gravel transport is estimated to occur at flows between 5,000 and 8,000 cfs in the Stanislaus River (Kondolf et al. 2001), between 7,050 and 9,800 cfs in the upper reaches of the Tuolumne River (McBain and Trush 2000), and at flows greater than 4,800 cfs in the upper reaches of the Merced River (Stillwater Sciences 2001; Kondolf et al. 1996). These flows served as thresholds for evaluating the potential for changes in the frequency and magnitude of bed-mobilizing flows that could affect the quality of spawning and rearing habitat in the Stanislaus, Tuolumne, and Merced Rivers. This analysis is based on modeled peak monthly flows in the wettest years of the 1922–2003 modeling period (Chapter 6, *Flooding, Sediment, and Erosion*, Tables 6-10 through 6-12).

LSJR Alternative 2 (Less than significant)

Under LSJR Alternative 2, modeling of peak flows during the wettest years of the 1922–2003 modeling period indicates that the frequency and magnitude of flows exceeding the thresholds associated with gravel mobilization would not change substantially in the Stanislaus, Tuolumne, and Merced Rivers relative to baseline conditions (Tables 6-10 through 6-12; Chapter 6, *Flooding, Sediment, and Erosion*, Impact FLO-1). Under baseline conditions and LSJR Alternative 2, peak monthly flows would exceed the minimum threshold flows (5,000 cfs in the Stanislaus River, 7,000 cfs in the Tuolumne River, and 4,800 cfs in the Merced River) in 3 years in the Stanislaus River, 9 years in the Tuolumne River, and 7 years in the Merced River (Tables 6-10, 6-11, and 6-12). Therefore, no long-term changes in geomorphic conditions significantly affecting spawning and rearing habitat quality would occur. Adverse impacts would be less than significant.

LSJR Alternative 3 (Less than significant)

Similar to LSJR Alternative 2, changes in peak flows under LSJR Alternative 3 are not expected to affect the frequency and magnitude of gravel mobilization events in the Stanislaus, Tuolumne, and Merced Rivers (Tables 6-9 through 6-12; Chapter 6, *Flooding, Sediment, and Erosion*, Impact FLO-1). Therefore, no long-term changes in geomorphic conditions significantly affecting spawning and rearing habitat quality would occur. Adverse impacts would be less than significant.

LSJR Alternative 4 (Less than significant)

Under LSJR Alternative 4, peak flows associated with gravel mobilization would increase in frequency in the Stanislaus River and decrease in frequency in the Tuolumne and Merced River (Tables 6-10 through 6-12; Chapter 6, *Flooding, Sediment, and Erosion*, Impact FLO-1). However, no substantial long-term effects on geomorphic conditions affecting spawning and rearing habitat quality are expected to occur because of the low frequency of these events over the 82-year modeling period. Furthermore, such events are generally recognized as beneficial for aquatic habitat maintenance (McBain and Trush 2000; Kondolf et al. 2001; Stillwater Sciences 2001, 2004). Therefore, no long-term changes in geomorphic conditions significantly affecting spawning and rearing habitat quality would occur. Adverse impacts would be less than significant.

Impact AQUA-9: Changes in food availability resulting from changes in flow and floodplain inundation

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

Losses and degradation of riparian and floodplain habitat and reductions in natural hydrologic variability that connect these habitats to the aquatic ecosystem have been identified as a major stressor on native fish populations through direct impacts on spawning and rearing habitat availability (Impact AQUA-3) and indirect impacts on aquatic productivity and food web support provided by seasonal floodplain inundation (see Appendix C, *Technical Report on the Scientific Basis for Alternatives San Joaquin River Flow and Southern Delta Salinity Objectives*).

The impacts of the alternatives on food web support for Chinook salmon, steelhead, and other native fishes are qualitatively evaluated based on the frequency and magnitude of floodplain inundation in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR (see Impact AQUA-3). As discussed in Appendix C, establishing a more natural flow regime is anticipated to enhance the processes supporting food production for native fish species and other organisms. Therefore, higher spring flows that mimic the natural seasonal flow pattern are assumed to provide increased food web support by enhancing primary and secondary production on floodplains and potentially increasing inputs or organic carbon and nutrients from floodplains to downstream waters.

LSJR Alternative 2 (Less than significant)

Under LSJR Alternative 2, no substantial long-term negative changes on food web support are expected based on predicted changes in the frequency and magnitude of floodplain inundation over the 82-year modeling period (see Impact AQUA-3, LSJR Alternative 2; Tables 7-16a, 7-16b, 7-17c, and 7-17d). Therefore, adverse impacts would be less than significant.

LSJR Alternative 3 (Less than significant)

Under LSJR Alternative 3, higher spring flows and associated increases in riparian and floodplain inundation in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR (see Impact AQUA-3, LSJR Alternative 3) would potentially increase the abundance of aquatic and terrestrial invertebrates available to juvenile salmon and other native fishes that use floodplain habitats for spawning and/or early rearing (e.g., Sacramento splittail), and increase inputs of organic matter and nutrients to the riverine and estuarine ecosystem. Potential increases in food abundance and growth opportunities for fish on floodplains as well as downstream food web support would contribute to the benefits associated with increases in physical habitat discussed in Impact AQUA-3. This represents a beneficial effect on aquatic resources in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR. Adverse impacts would be less than significant.

LSJR Alternative 4 (Less than significant)

Under LSJR Alternative 4, further increases in the frequency, magnitude, and duration of floodplain inundation relative to LSJR Alternative 3 would further enhance aquatic productivity and food web support for native fish species and other aquatic resources. This represents a beneficial effect on aquatic resources in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR. Adverse impacts would be less than significant.

Impact AQUA-10: Changes in predation risk resulting from changes in flow and water temperature

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

Predation pressures on indicator species are considerable under baseline conditions (SJRGA 2009, 2010). Predation impact mechanisms include changes in ecosystem structure that increase prey vulnerability or increase predator feeding efficiency. Several impact mechanisms may contribute to increased predation, including altered flow regimes, removal of riparian cover, changes in turbidity, and reduced habitat heterogeneity (Moyle 2002; Ferrari et al. 2013). These mechanisms generally alter predator-prey relationships by disrupting or reducing cover, space, and refuge. Increased prey vulnerability is also associated with other environmental conditions, including increased water temperature, water diversions, pollutants, and fishing (Spence et al. 1996; Moyle 2002).

Predation by numerous native and nonnative species is exacerbated by water management, channel modifications, and artificial structures (e.g., dams) within the plan area. Fish, avian, and wildlife species that prey on steelhead and fall-run Chinook salmon in the plan area include striped bass, Sacramento pikeminnow, smallmouth bass, trout, largemouth bass, gulls, mergansers, cormorants, river otters, herons, sea lions, and seals (USDOI 2008). Infrastructure or operational elements of the water conveyance system may lead to behavioral changes, metabolic disruption, or other biological and ecological outcomes that increase prey vulnerability to predators (BPA 2010). Increased water temperatures or other environmental conditions may place increased metabolic demands on susceptible groups of fish and hinder their flight response or capability to take refuge from threats by predation (Spence et al. 1996). Specifically, warm water temperatures may impact the performance of young salmon or enhance habitat conditions favorable to predatory fishes, thereby increasing losses of young Chinook salmon to predators (Boles et al. 1988). Reductions in shaded riverine aquatic cover can expose fish to increased risk of capture by avian or terrestrial predators (Li et al. 1994; BPA 2010).

As discussed in Appendix C, *Technical Report on the Scientific Basis for Alternatives San Joaquin River Flow and Southern Delta Salinity Objectives*, predation has been identified a significant factor limiting Chinook salmon outmigrant survival in the SJR Basin and southern Delta and a major impediment to Central Valley salmon recovery efforts (EA 1992; TID and MID 1992; FishBio 2013; NMFS 2009c; Dauble et al. 2010). The specific mechanisms by which flow, water temperature, and other flow-related variables affect the success of predator populations and their impact on Chinook salmon and other native fishes are not clearly understood. The relative importance of predation in limiting survival of outmigrating salmon also appears to be strongly influenced by reach-specific factors, such as deepening and simplification of natural channels, as well as dams, diversions, and other artificial structures that concentrate predators, enhance prey vulnerability, or direct outmigrants away from preferred migration routes (Brown et al. 1996; Tucker et al. 1998; Kimmer and Brown 2006; SJRGA 2011). Nevertheless, consistent with broadly recommended restoration strategies in the literature (see Appendix C), a number of studies in Central Valley streams have shown that higher, more variable flows that mimic the natural flow regime to which native fish communities are adapted can effectively limit the success of nonnative fish species, including a number of warmwater species that are predators of juvenile salmonids (EA 1992; McBain & Trush 2000; Brown and Ford 2002; Kiernan et al. 2012).

Predation-related impacts are qualitatively evaluated based on the potential for the LSJR alternatives to modify environmental conditions in the three eastside tributaries that influence predator success or the vulnerability of prey species such as Chinook salmon as steelhead.
This assessment is based on potential changes in predator-prey interactions that could result

from altered flow and temperature conditions. Thus, results from Impact AQUA-3 and Impact AQUA-4 are incorporated in the evaluation, where appropriate.

LSJR Alternative 2 (Less than significant)

Under LSJR Alternative 2, changes in habitat availability and water temperatures (described in the Impact AQUA-3 and Impact AQUA-4 discussions) during the Chinook salmon and steelhead rearing and outmigration periods in the Stanislaus, Tuolumne, and Merced Rivers would not result in significant impacts on these species. Therefore, no negative substantial changes are likely to occur in predator populations or the habitat conditions affecting vulnerability of Chinook salmon and steelhead juveniles to predation in the three eastside tributaries. Adverse impacts would be less than significant.

LSJR Alternative 3 (Less than significant)

Under LSJR Alternative 3, increases in spring flows and decreases in water temperature in the Stanislaus, Tuolumne, and Merced Rivers and the LSJR are expected to improve rearing and outmigration conditions for juvenile salmon and steelhead. These conditions are expected to potentially enhance the growth and development of the juveniles and reduce the severity of temperature-related stresses that could increase their vulnerability to predators. Higher flows and cooler water temperatures are also expected to benefit juvenile salmon and steelhead by limiting the distribution and abundance of largemouth bass and other nonnative species, which typically favor lower flows and warmer temperatures, and currently contribute to high mortality rates of juvenile salmon in the lower reaches of these tributaries (see Impact AQUA-3, LSJR Alternative 3). Flows and temperatures in the three eastside tributaries are not expected to decrease substantially in the summer and, therefore, would not affect summer habitat conditions that support predator populations under baseline conditions. Adverse impacts would be less than significant.

LSJR Alternative 4 (Less than significant)

LSJR Alternative 4 is expected to further improve spring habitat conditions supporting juvenile Chinook salmon and steelhead rearing and outmigration (relative to LSJR Alternative 3), and reduce predation impacts by warmwater fishes as described above. Flows and temperatures in the three eastside tributaries are not expected to decrease substantially in the summer and, therefore, would not change summer habitat conditions that support predator populations under baseline conditions. Adverse impacts would be less than significant.

Impact AQUA-11: Changes in disease risk resulting from changes in water temperature

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

Disease impacts fish populations by directly increasing mortality or indirectly increasing mortality by adversely affecting the ability of fish to evade predators or perform other essential behaviors such as feeding, swimming, and defending territories (McCullough 1999). Chinook salmon are susceptible to a variety of diseases, many of which have specific temperature requirements. Certain freshwater diseases are known to be more prevalent in cold water. The mycobacterium *Cytophaga psychrophila* produces disease in salmonids at temperatures of 41°F–50°F, and infectious hematopoietic necrosis (IHN) is a viral disease that is most common at 46.4°F–50°F. BKD has been shown to have optimum temperatures for infection below 59°F (McCullough 1999).

While certain diseases are more prevalent in cold water, most of the more significant diseases afflicting LSJR Chinook salmon increase in virulence as temperature increases. For example, water temperatures greater than 56°F favor the bacterial diseases columnaris and furunculosis, while temperatures greater than 65°F favor the protozoan *Ichthyophthirosis* (Boles et al. 1988). Vibrio is caused by the marine bacterium *Vibrio anguillarum* and produces a hemorrhagic septicemia that has optimum growth conditions in waters above 59°F (McCullough 1999). Most warmwater diseases begin to become serious threats above 59°F, and temperatures in the range of 55°F–59°F appear to be least problematic for salmonids in resisting both cold- and warmwater diseases (McCullough 1999). Steelhead are assumed to be susceptible to the same diseases as Chinook salmon. Although very little information exists to quantify changes in infection levels and mortality rates attributable to these diseases, steelhead are probably more susceptible to diseases in freshwater habitats than Chinook salmon. Because steelhead rear in riverine and estuarine habitats for 1–3 years, compared to the 3- to 7-month rearing period of fall-run Chinook salmon, the exposure to disease or disease carrying organisms in these habitats is increased. This is especially true during summer months when flows are lower and temperatures are higher for steelhead. For this impact assessment, the effects of disease on Chinook salmon are assumed to have similar effects on steelhead and to be generally representative of effects on aquatic resources.

Impacts of disease on Chinook salmon and steelhead are assessed by evaluating potential changes in exposure of juvenile salmonids to water temperatures and that could increase physiological stress and susceptibility to disease. To address temperature-related effects, this assessment focuses on daily water temperatures during the warmest months of the year (March–October) at the mouth of each eastside tributary and in the SJR at Vernalis to determine changes in the percent of time that water temperatures could exceed 59°F under baseline conditions and LSJR Alternatives 2, 3, and 4 (Tables 7-27a, 7-27b, 7-27c, and 7-27d). A 10 percent change in the frequency of modeled average daily water temperatures exceeding this threshold was used to determine the potential for increased disease risk.

Table 7-27a. Percent of Time that the 59°F Threshold in the Stanislaus River at the Confluence is Exceeded

Stanislaus – Confluence	March	April	May	June	July	August	September	October
Baseline	16	28	60	95	97	99	93	55
LSJR Alternative 2	17	30	64	94	97	98	92	51
LSJR Alternative 3	10	26	51	91	97	99	96	44
LSJR Alternative 4	4	15	36	79	99	100	97	47

Table 7-27b. Percent Time that the 59°F Threshold in the Tuolumne River at the Confluence is Exceeded

Tuolumne – Confluence	March	April	May	June	July	August	September	October
Baseline	37	55	84	95	100	100	99	92
LSJR Alternative 2	32	55	81	96	100	100	99	93
LSJR Alternative 3	23	35	56	93	100	100	99	91
LSJR Alternative 4	11	15	44	88	100	100	99	91

Table 7-27c. Percent Time the 59°F Threshold in the Merced River at the Confluence is Exceeded

Merced – Confluence	March	April	May	June	July	August	September	October
Baseline	40	84	91	95	100	100	100	95
LSJR Alternative 2	41	84	91	96	100	100	100	95
LSJR Alternative 3	36	74	85	96	100	100	100	94
LSJR Alternative 4	24	56	72	96	100	100	100	94

Table 7-27d. Percent Time that the 59°F Threshold in the SJR at Vernalis is Exceeded

SJR – Vernalis	March	April	May	June	July	August	September	October
Baseline	31	73	98	100	100	100	100	89
LSJR Alternative 2	32	74	98	100	100	100	100	88
LSJR Alternative 3	27	70	95	100	100	100	100	87
LSJR Alternative 4	17	55	88	100	100	100	100	88

LSJR Alternative 2 (Less than significant)

Under LSJR Alternative 2, no substantial changes are predicted to occur in the frequency of average daily water temperatures exceeding the 59°F threshold at the confluences of the Stanislaus, Tuolumne, and Merced Rivers and in the LSJR relative to baseline conditions (Tables 7-27a, 7-27b, 7-27c, and 7-27d). Therefore, the risk of disease associated with exposure of juveniles to water temperatures exceeding 59°F would be similar to that under baseline conditions. Adverse impacts would be less than significant.

LSJR Alternative 3 (Less than significant)

Under LSJR Alternative 3, the frequency of spring water temperatures exceeding the 59°F threshold would decrease in all three tributaries and in the LSJR, ranging from less than 5 percent decrease in the SJR at Vernalis to nearly a 30 percent decrease in the Tuolumne River (Table 7-27a, 7-27b, 7-27c, and 7-27d). No substantial changes are predicted to occur in the frequency of water temperatures exceeding 59°F during the summer and fall (July–October) although some improvement (-11 percent) is expected in the Stanislaus River in October. Therefore, the risk of disease associated with exposure of juveniles to water temperatures exceeding 59°F during the spring rearing and outmigration would be reduced compared to baseline conditions. Adverse impacts would be less than significant.

LSJR Alternative 4 (Less than significant)

Under LSJR Alternative 4, the frequency of water temperatures exceeding the 59°F threshold would decrease by approximately 10–40 percent in March, April, and May at the mouths of the three tributaries and in the SJR at Vernalis relative to baseline conditions (Tables 7-27a, 7-27b, 7-27c, and 7-27d). Reduced exposure of juvenile salmonids to these water temperatures could extend into June in the Stanislaus and Tuolumne Rivers. Little or no change is predicted to occur in the frequency of water temperatures exceeding 59°F during summer and fall (June–October). Therefore, exposure of juvenile salmonids to water temperatures associated with increased disease risk in the Stanislaus, Tuolumne, and Merced Rivers, and LSJR would be substantially reduced during the spring rearing and outmigration period. Adverse impacts would be less than significant.

Impact AQUA-12: Changes in southern Delta and estuarine habitat resulting from changes in SJR inflows and export effects

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*, for the No Project Alternative technical analysis.

LSJR Alternatives

Alteration of timing and magnitude of freshwater inflows in combination with export pumping has substantially altered flow patterns in the Delta, resulting in both direct losses of fish through entrainment at the CVP and SWP export facilities, and indirect losses through changes in survival associated with altered migration patterns and habitat quality. Estuarine fishes such as delta smelt are particularly sensitive to these alterations, especially in years when spawning takes place in the southern and central Delta where a large proportion of the population (adults, larvae, and juveniles) may be subject to entrainment. Although capable of directed swimming, juvenile salmonids may also be adversely affected by altered hydrodynamics associated with low flows and relatively high rates of export pumping that result in net flows toward the pumps. These changes can also affect the magnitude of Delta outflow and the position of the low salinity zone (measured by X2), which have been shown to be correlated with the distribution and abundance of a number of estuarine fishes and their food resources.

This assessment examines potential changes in fish entrainment risk and estuarine habitat conditions resulting from changes in SJR inflows and export pumping under LSJR Alternatives 2, 3, and 4, as compared to baseline conditions. As described in Appendix F.1, *Hydrologic and Water Quality Modeling,* Section F.1.2, *Water Supply Effects Modeling—Methods*, the WSE model does not include the Delta. Therefore, potential changes in export pumping and outflow were approximated based on changes in modeled monthly flows in the SJR at Vernalis and application of a number of federal and state rules or objectives currently governing Delta operations (Table F.1.7-1 in Appendix F.1). These rules or objectives include monthly restrictions on export pumping rates, export to inflow ratios, and negative flows in Old and Middle River (OMR) to minimize the risk of entrainment and improve net downstream flows during the primary spawning and early rearing period of delta smelt (December–June) and the primary smolt migration period for SJR Chinook salmon and steelhead (April–May). Although this approach does not fully represent the complexities of Delta water management operations, it was considered a reasonable approach for assessing the relative magnitude of potential changes in fish entrainment and estuarine habitat conditions associated with the LSJR alternatives.

LSJR Alternative 2 (Less than significant)

Based on the WSE modeling results and application of several rules and objectives currently governing Delta operations (see Appendix F.1, *Hydrologic and Water Quality Modeling*), LSJR Alternative 2 is not expected to substantially change export pumping rates relative to baseline conditions. Average pumping rates in December–June when juvenile salmonids and other Delta fish species are most likely to be exposed to potential entrainment effects would be similar to baseline levels in December–May and increase by 216 cfs in June (Table F.1.7-3E). These changes represent less than 5 percent of average SJR flows and therefore would have very small effects on Delta outflow and the position of X2. Although increased export pumping in June represents a potential increase in entrainment risk for larval and juvenile fish, concurrent increases in spring SJR flows (averaging +468 cfs in May and +431 cfs in June) and Delta outflow (averaging +433 cfs in May and +216 cfs in June) (Table F.1-.7-3D and Table F.1.7-3F) represent positive effects on larval/juvenile transport and estuarine habitat conditions. In addition, continued compliance with current restrictions on export pumping rates, export to inflow ratios, and OMR flows would be expected to minimize potential impacts on juvenile salmonids and other Delta fish species during these months. Therefore, potential adverse impacts resulting from changes in Delta operations on fish entrainment and estuarine habitat conditions under LSJR Alternative 2 would be less than significant.

LSJR Alternative 3 (Less than significant)

Under LSJR Alternative 3, average pumping rates in December–June when juvenile salmonids and other Delta fish species are most likely to be exposed to potential entrainment effects would be expected to decrease in December–March (-8 to -147 cfs) and increase in April–June (+50 to +801 cfs) relative to baseline conditions (Table F.1.7-4B). Although increased export pumping in April–June represents a potential increase in entrainment risk for larval and juvenile fish, concurrent increases in spring SJR flows (averaging +810 to +2,400 cfs) and Delta outflow (averaging +761 to +2,102 cfs) (Table F.1.7-4A and Table F.1.7-4C) represent positive effects on larval/juvenile transport and estuarine habitat conditions. In addition, continued compliance with current restrictions on export pumping rates, inflow/export ratios, and OMR flows would be expected to minimize potential impacts on juvenile salmonids and other Delta fish species during these months. Therefore, potential adverse impacts resulting from changes in Delta operations on fish entrainment and estuarine habitat conditions under LSJR Alternative 3 would be less than significant.

LSJR Alternative 4 (Less than significant)

Under LSJR Alternative 4, average pumping rates in December–June when juvenile salmonids and other Delta fish species are most likely to be exposed to potential entrainment effects would be expected to decrease in December and January (-135 cfs and -217 cfs) and increase in February–June (+252 to +1,766 cfs) relative to baseline conditions (Table F.1.7-5B). Although increased export pumping in February–June represents a potential increase in entrainment risk for larval and juvenile fish, concurrent increases in spring SJR flows (averaging +586 to 5,149 cfs) and Delta outflow (averaging +293 to 4,260 cfs) (Table F.1.7-5A and Table F.1.7-5C) represent positive effects on larval/juvenile transport and estuarine habitat conditions. In addition, continued compliance with current restrictions on export pumping rates, inflow/export ratios, and OMR flows would be expected to minimize potential impacts on juvenile salmonids and other Delta fish species during these months. Therefore, impacts resulting from changes in Delta operations on fish entrainment and estuarine habitat conditions under LSJR Alternative 4 would not be adverse and would be less than significant.

7.4.4 Impacts and Mitigation Measures: Extended Plan Area

Bypassing flows in the extended plan area, as described in Chapter 5, *Surface Hydrology and Water Quality*, could potentially impact aquatic biological resources in upstream reservoirs on the Stanislaus and Tuolumne Rivers differently in the extended plan area than described in the plan area. The upstream reservoirs on the Stanislaus and Tuolumne Rivers may experience substantial changes in reservoir volume, which are not experienced by the rim reservoirs in the plan area, especially under drought conditions under LSJR Alternative 3 and LSJR Alternative 4 with or without adaptive implementation. This different potential impact occurs because reservoirs in the extended plan area reservoirs are smaller than the downstream rim reservoirs, which could magnify individual changes. Furthermore, required bypass flows may reduce opportunity for these reservoirs to refill once they are drawn down. Reservoir drawdown could reduce the area and volume of water available for in-reservoir aquatic habitat affecting aquatic species including fish. In addition, water temperature in the upstream reservoirs could increase due to lower storage. As a result, the temperature of the water entering the rim dam reservoirs could increase, although an increase in volume of the rim reservoirs resulting from bypassed upstream flows could help maintain cool temperatures in these reservoirs.

Under LSJR Alternative 2 with adaptive implementation or LSJR Alternative 3 with or without adaptive implementation, the type and scale of impacts on aquatic species during individual reservoir drawdown events would be similar to what is experienced during baseline reservoir operations (USGS Reservoir Gage Data). Additionally, these reservoirs might refill during the subsequent wet season, limiting the duration of reduced reservoir elevations if no water supply shortage is forecast for the upcoming year. In the most extreme cases, during drought years and years with substantial increases in bypass flows in the extended plan area particularly under LSJR Alternative 3 and LSJR Alternative 4 with or without adaptive implementation, some reservoirs might be drawn down more quickly, to lower levels, and for longer periods of time than under baseline conditions. If these conditions occurred there would be an adverse impact on aquatic species because the reservoir habitat would be greatly reduced when compared to baseline conditions.

Changes in river flows on the Stanislaus, Tuolumne, and Merced Rivers as described in Chapter 5, *Surface Hydrology and Water Quality*, would result in similar impacts on aquatic resources described for the plan area. An increase in flow would not result in adverse impacts on aquatic species. However, flows in the extended plan area could decrease in the fall relative to baseline under the LSJR alternatives with or without adaptive implementation; such an outcome is not anticipated in the plan area. This could result in reduced habitat for aquatic species. In addition, during drought conditions, particularlyunder LSJR Alternative 3 and LSJR Alternative 4 with or without adaptive implementation, substantial reservoir volume reductions could occur. Under these conditions there is potential for warmer water to be released from reservoirs, which would adversely impact downstream water temperature and aquatic resources. Furthermore, if low reservoir volumes result in low reservoir carryover volumes, these temperature impacts could be increased.

The increased frequency of lower reservoir levels and potential reduction in river flow in the fall resulting from the LSJR alternatives, however, would be limited by the program of implementation under each of the LSJR alternatives. The program of implementation requires minimum reservoir carryover storage targets or other requirements to help ensure that providing flows to meet the flow objectives will not have adverse temperature or other impacts on fish and wildlife or, if feasible, on other beneficial uses. Other requirements, for example, include, but are not limited to, limits on required bypass flows for reservoirs that store water only for nonconsumptive use so that some water can be temporarily stored upstream. The program of implementation also states that the State Water Board will take actions as necessary to ensure that implementation of the flow objectives does not impact supplies of water for minimum health and safety needs, particularly during drought periods. Accordingly, when the State Water Board implements the flow objectives in a water right proceeding, it will consider impacts on fish, wildlife, and other beneficial uses and health and safety needs, along with water right priority. Until the State Water Board assigns responsibility to meet the flow objectives in the Bay-Delta Plan, it is speculative to identify the exact extent, scope, and frequency of reduced diversions, reduced reservoir levels and their effects on fish, in the extended plan area. When implementing the flow objectives, the State Water Board would identify project-specific impacts and avoid or mitigate, to the extent feasible, significant impacts of lower reservoir levels on aquatic species habitat and temperatures in accordance with CEQA.

At the time of preparation of this programmatic analysis, it is unclear to what extent any significant impacts could be fully mitigated to aquatic species due to a reduction in reservoir storage. Thus, the potential exists for significant impacts. Therefore, this analysis conservatively concludes that impacts associated with lower reservoir levels under LSJR Alternative 2 with adaptive implementation and LSJR Alternatives 3 and 4 with or without adaptive implementation are significant. The following mitigation measure is proposed: when considering carryover storage and other requirements to implement the flow water quality objectives in a water right proceeding, the State Water Board shall ensure that reservoir levels upstream of the rim dams do not cause significant fish and wildlife impacts, unless doing so would be inconsistent with applicable laws. The impact is considered significant, even with mitigation, because the mitigation may not fully mitigate the impact in all situations.

Chapter 8
Terrestrial Biological Resources

8.1 Introduction

This chapter describes the environmental setting for terrestrial biological resources and the regulatory background associated with these resources. It also evaluates environmental impacts on terrestrial biological resources that could result from the Lower San Joaquin River (LSJR) alternatives, the significance of any impacts, and, if applicable, offers mitigation measures that would reduce significant impacts. A discussion of aquatic biological species and habitat (e.g., fish and their spawning and rearing areas) is presented in Chapter 7, *Aquatic Biological Resources*.

The Southern Delta Water Quality (SDWQ) alternatives would not affect terrestrial biological resources. As summarized in Section 8.4.2, *Methods and Approach*, the SDWQ alternatives would not result in a change in the water quality at Vernalis and, therefore, would not result in a change from baseline conditions. As discussed in Chapter 5, *Surface Hydrology and Water Quality,* and Appendix F.2, *Evaluation of Historical Flow and Salinity Measurements of the Lower San Joaquin River and Southern Delta,* it is not expected that salinity within the southern Delta would exceed historical monthly salinity levels, which range between 0.2 deciSiemens per meter (dS/m) (0.134 parts per thousand [ppt]) and 1.2 dS/m, (0.768 ppt), which are levels that terrestrial species can tolerate. As such, the SDWQ alternatives are not expected to result in significant adverse modifications to existing terrestrial habitat or result in impacts on plant and animal species and are not analyzed in detail in this chapter. To comply with specific water quality objectives or the program of implementation under SDWQ Alternatives 2 or 3, construction and operation of different facilities in the southern Delta could occur, which could involve impacts on biological resources. These impacts are evaluated in Chapter 16, *Evaluation of Other Indirect and Additional Actions.*

As described in Chapter 1, *Introduction*, the plan area generally includes those portions of the San Joaquin River (SJR) Basin that drain to, divert water from, or otherwise obtain beneficial use (e.g., surface water supplies) from the three eastside tributaries[1] of the LSJR. These include the Stanislaus River from and including New Melones Dam and Reservoir to its confluence with the LSJR; the Tuolumne River from and including New Don Pedro Dam and Reservoir to its confluence with the LSJR; the Merced River from and including New Exchequer Dam and Lake McClure to its confluence with the LSJR; and, the SJR between its confluence with the Merced River and downstream to Vernalis (i.e., LSJR). Within the plan area, there is a designated area of potential effects for terrestrial biological resources (including riparian habitats) for the LSJR alternatives. For the three large reservoirs, this area of potential effects is defined as the *zone of fluctuation*. While the smaller reservoirs that exist downstream of the rim dams[2] also contain habitat for terrestrial biological resources, including wetland and riparian habitat, the LSJR alternatives are not expected to adversely affect those waterbodies as they are used to regulate flows released from the upstream

---

[1] In this document, the term *three eastside tributaries* refers to the Stanislaus, Tuolumne, and Merced Rivers.

[2] In this document, the term *rim dams* is used when referencing the three major dams and reservoirs on each of the eastside tributaries: New Melones Dam and Reservoir on the Stanislaus River; New Don Pedro Dam and Reservoir on the Tuolumne River; and New Exchequer Dam and Lake McClure on the Merced River.

dams and would release any increased flow downstream. For the three eastside tributaries and the LSJR, the area of potential effects includes the areas adjacent to these channels that are affected by the existing flows or the flows that would result from the LSJR alternatives (e.g., riparian vegetation). This area includes the bankfull channel below the floodplain and the inundated areas adjacent to the main channel. Within the plan area, there is also an area of potential indirect effects for terrestrial biological resources. This area of potential indirect effects includes undeveloped and agricultural areas outside of riparian and reservoir areas since this area could experience potential changes in agricultural uses or land cover as a result of potential reduced irrigation water supply.

The extended plan area, also described in Chapter 1, generally includes the area upstream of the rim dams. The area of potential effects for this area is similar to that of the plan area and includes the zone of fluctuation around the numerous reservoirs that store water on the Stanislaus and Tuolumne Rivers. (The Merced River does not have substantial upstream reservoirs that would be affected.) It also includes the upper reaches of the Stanislaus, Tuolumne, and Merced Rivers. Unless otherwise noted, all discussion in this chapter refers to the plan area. Where appropriate, the extended plan area is specifically identified.

In Appendix B, *State Water Board's Environmental Checklist*, the State Water Resources Control Board (State Water Board) determined whether the plan amendments[3] would cause any adverse impact for each environmental category in the checklist in Appendix B and provided a brief explanation for its determination. Impacts that are listed as "Potentially Significant Impacts" are discussed in detail in this chapter. In addition, as discussed in Appendix B, the State Water Board determined that additional types of potential adverse impacts that are not listed in the checklist should be evaluated. Accordingly, this chapter evaluates potential impacts not initially listed in the checklist, but that have been identified in this chapter as potentially significant. Specifically, whether the LSJR alternatives could have a substantial adverse effect on native terrestrial species by increasing the distribution and abundance of invasive plants and nonnative wildlife species in the plan area. Appendix B identified the LSJR alternatives as having a potentially significant impact on aquatic biological resources and terrestrial biological resources because changes in flow requirements may result in changes in river volume or rates, or reservoir water surface elevation fluctuations and may have indirect effects associated with potential changes in agricultural uses or land cover. The potential impacts on terrestrial biological resources are described in this chapter, whereas the potential impacts on aquatic biological resources are discussed in Chapter 7.

LSJR Alternatives 2, 3, and 4 could affect reservoir operations in the Stanislaus, Tuolumne, and Merced Rivers and, therefore, changes in the flows in each of these tributaries, the LSJR, and Delta, resulting in potential impacts on terrestrial biological resources. The comparison of monthly cumulative distributions of flows, in conjunction with the individual monthly average changes in flow, provides an appropriate measure of hydrologic changes resulting from the LSJR alternatives. For the three large reservoirs, the rates of reservoir fluctuations from month to month are compared between baseline and the LSJR alternatives. This information is then used to evaluate the expected type of terrestrial habitat conditions under baseline and LSJR alternative conditions.

The potential impacts of the LSJR alternatives on terrestrial biological resources are summarized in Table 8-1. As described in Chapter 3, *Alternatives Description*, LSJR Alternatives 2, 3 and 4 each include four methods of adaptive implementation. This recirculated substitute environmental

---

[3] These plan amendments are the *project* as defined in State CEQA Guidelines, Section 15378.

document (SED) provides an analysis with and without adaptive implementation because the frequency, duration, and extent to which each adaptive implementation method would be used, if at all, within a year or between years under each LSJR alternative is unknown. The analysis, therefore, discloses the full range of impacts that could occur under an LSJR alternative, from no adaptive implementation to full adaptive implementation. As such, Table 8-1 summarizes impact determinations with and without adaptive implementation.

Impacts related to the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) are presented in Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* and the supporting technical analysis is presented in Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*. Chapter 16, *Evaluation of Other Indirect and Additional Actions,* includes discussion of impacts related to actions and methods of compliance.

Table 8-1. Summary of Terrestrial Biological Resources Impact Determinations

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
Impact BIO-1: Have a substantial adverse effect on any riparian habitat or other sensitive natural terrestrial communities identified in local or regional plans, policies, or regulations or by the California Department of Fish and Wildlife (CDFW) or United States Fish and Wildlife Service (USFWS)			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [b]	Significant	NA
LSJR Alternatives 2, 3, and 4	The change in median monthly flows or overall cumulative distribution of flows on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would not substantially effect riparian habitat or other sensitive terrestrial communities because the plants located within the area of potential effects can survive inundation, are resistant to the effects of scouring and deposition, and are limited by water availability. Fluctuations in reservoir elevations would not be substantially different than those that currently occur. Therefore, the LSJR alternatives would not have significant adverse effects on riparian or wetland habitats or other sensitive terrestrial communities around the reservoirs.	Less than significant	Less than significant
Impact BIO-2: Have a substantial adverse effect on federally protected wetlands as defined by Section 404 of the Clean Water Act (including, but not limited to, marsh, vernal pool, coastal, etc.) through direct removal, filling, hydrologic interruption, or other means			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [b]	Significant	NA
LSJR Alternatives 2, 3, and 4	Monthly median flows or the cumulative distribution of flows on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would generally increase. Increased flow would not adversely affect wetland communities because wetland plants can survive inundation, are resistant to the effects of scouring and deposition, and are growth-limited by water availability. Little change is expected in the frequency and range in water level fluctuation in the reservoirs as a result of the LSJR Alternatives 2, 3, and 4, therefore adverse effects are not expected to occur on wetland communities surrounding the reservoirs. Therefore, substantial adverse effects on wetland communities would not occur.	Less than significant	Less than significant

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
Impact BIO-3: Facilitate a substantial increase in distribution and abundance of invasive plants or nonnative wildlife that would have a substantial adverse effect on native terrestrial species			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [b]	Less than significant	NA
LSJR Alternatives 2, 3, and 4	Changes in flows in the LSJR and the three eastside tributaries and fluctuations in reservoir elevations may result in alteration of vegetation patterns in specific locations, but there is no basis to suggest increased flows would substantially increase the distribution and abundance of invasive plant species. Little change is expected in the frequency and range in water level fluctuation in the reservoirs as a result of the LSJR Alternatives 2, 3, and 4. In addition, the potential for invasive plants and nonnative wildlife species to increase due to a reduction in irrigation water supply availability or potential fallowing would not be expected to exceed existing levels because some agricultural lands would be farmed less intensively, fallowed lands can retain growth, and existing invasive species programs would continue to be implemented. Therefore, an increase in the distribution and abundance of invasive plants or nonnative wildlife is not expected to result from implementation of the LSJR alternatives.	Less than significant	Less than significant
Impact BIO-4: Have a substantial adverse effect, either directly or through habitat modifications, on any terrestrial animal species identified as a candidate, sensitive, or special-status species in local or regional plans, policies, or regulations or by CDFW or USFWS			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [b]	Significant	NA
LSJR Alternatives 2, 3, and 4	Most of the special-status animal species present in the area of potential effects are dependent on riparian habitat. As described above for Impact BIO-1, there would not be a substantial change to available riparian habitat. Similarly, the frequency and range in reservoir elevation fluctuation are not expected to change substantially compared to the baseline conditions, consequently, adverse effects are not expected to occur to special-status species or their habitat at the reservoirs. A potential reduction in irrigation water supply in the area of potential indirect effects would not have a substantial adverse effect on special status species due to indirect habitat	Less than significant	Less than significant

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
	modification because agricultural land cover would not necessarily be fallowed in perpetuity, as lands could be dryland farmed, deficit irrigated, or rotated. This could result in less agricultural intensive practices on some lands. The resulting halt of mechanized agriculture, pesticide and rodenticide application, and anthropogenic disturbance as a result of less agricultural intensive practices is unlikely to result in a substantial adverse effect on sensitive or special-status species. The potential reduction of monocultural irrigated crops is likely to support the species and ecosystem recovery strategy outlined in the USFWS recovery strategy. Therefore, it is not expected that special-status animal species would be adversely affected.		
Impact BIO-5: Conflict with the provisions of an adopted habitat conservation plan, natural community conservation plan, or other approved local, regional, or state habitat conservation plan or conflict with any local policies or ordinances protecting biological resources			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note.[b]	Significant	NA
LSJR Alternatives 2, 3, and 4	The change in median monthly flows or overall cumulative distribution of flows on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR and changes to the range and/or frequency in reservoir fluctuation would not substantially affect riparian habitat or other sensitive terrestrial communities or the special-status animal species dependent on them (Impact BIO-1and Impact BIO-4). In addition, it is expected that wildlife refuges would continue to receive surface water, as needed, and continue to implement existing water management plans. Therefore, impacts on habitat value would not occur and there would not be a potential to conflict with plans protecting biological resources.	Less than significant	Less than significant

NA = not applicable

[a] Four adaptive implementation methods could occur under the LSJR alternatives, as described in Chapter 3, *Alternatives Description*, and summarized in Section 8.4.2, *Methods and Approach*, of this chapter.

[b] The No Project Alternative (LSJR/SDWQ Alternative 1) would result in continued implementation of flow objectives and salinity objectives established in the 2006 Bay–Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion, and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

8.2 Environmental Setting

The Upper SJR flows north through the San Joaquin Valley, a geologic trough between the Coast Ranges to the west and the Sierra Nevada to the east. It is joined by the three eastside tributaries, which convey surface runoff (rain and snow melt) from the Sierra Nevada to the LJSR. The freshwater from the LSJR enters the Delta where it eventually joins the Sacramento River, and the combined rivers flow west through the Carquinez Strait into the San Francisco Bay, along the way mixing with ocean saltwater to create unique and diverse semi-aquatic and terrestrial ecosystems.

Together, the LSJR and the Delta serve as an important habitat to more than 750 animal and plant species (CDFW 2014a). Once a vast system of wetlands and uplands, the LSJR and Delta have been transformed by over 100 years of levee building into a maze of interconnected waterways and low, reclaimed islands (CDFW 2014a). Dams and water diversions have impaired river flow and modified inundation regimes. CDFW (2014a) estimates that less than 10 percent of the historical wetland acreage and less than 2 percent of the historical riparian acreage currently remains in the San Joaquin Valley.

The State Water Board performed a literature review to characterize the terrestrial biological resources in and around the area of potential effects for the LSJR and southern Delta. Information was gathered and reviewed to identify and describe special-status plant and wildlife species that are known to exist, could potentially exist, or historically existed in the area of potential effects. For the purpose of this document, special-status species were defined as follows.

- Species listed, species proposed for listing, or candidates for possible future listing as threatened or endangered under the Endangered Species Act (ESA) (16 U.S.C., § 1531 et seq.) or California Endangered Species Act (CESA). (Fish & G. Code, § 2050 et seq.)
- Plant species designated as rare under the California Native Plant Protection Act. (Fish & G. Code, § 1900 et seq.)
- Plant species considered by the California Native Plant Society (CNPS) to be "rare, threatened, or endangered in California" (Rare Plant Rank 1B and 2).
- Wildlife species considered species of special concern by the California Department of Fish and Wildlife (CDFW) (formerly the California Department of Fish and Game).
- Wildlife species designated as "fully protected species" by CDFW. (Fish & G. Code, §§ 3511, 4700, 5050 and 5515.)

Information on special-status plant and wildlife species was compiled through a review of the following sources.

- CNPS Inventory of Rare and Endangered Plants of California, 2012.
- California Natural Diversity Database (CNDDB), 2011–2012.
- U.S. Fish and Wildlife Service (USFWS) Federal Endangered and Threatened Species Lists for the region, 2011.

8.2.1 LSJR and the Three Eastside Tributaries

This section describes the area of potential effects and the area of potential indirect effects of the LSJR alternatives within the LSJR and the three eastside tributaries on terrestrial resources. Flows would affect vegetation within the immediate area of the rivers and are not expected to affect vegetation or habitat outside the riparian corridor. The area of potential effects includes the channels of the three eastside tributaries to the LSJR and the LJSR, including the areas adjacent to these channels that are affected by the existing flows or the LSJR alternative flows (e.g., riparian vegetation). This includes the bankfull channel below the floodplain (Figures 8-1a and 8-1b). The area of potential indirect effects includes undeveloped and agricultural land cover in the plan area which could experience a reduction in irrigation water supply.

Snowmelt runoff and seasonal rainfall from the Sierra Nevada mountain range are the major sources of water to the SJR and the three eastside tributaries. As a result, peak flows historically occurred in May and June. Natural overbank flooding distributed higher flows outside the main river channel(s) into a complex network of sloughs, which supported large patches of riparian forest and tule marshes. This overland flooding resulted in several thousands of acres of permanent tule marsh and more than 1.5 million acres of seasonally flooded wetlands and native grasslands (CALFED 2000). The natural levees and floodplains formed by these processes supported as many as 2 million acres of large, diverse riparian forests (CDFW 2014a). The LSJR and three eastside tributaries are now largely confined within constructed levees in many locations and bounded by agricultural and urban development. Flows are regulated through dams and water diversions, and floodplain habitats have been fragmented and reduced in size and diversity (USBR 2011a).

Federal, state, and local efforts to preserve existing habitat functions have resulted in the establishment of multiple national wildlife refuges and other wildlife areas, which receive water from the LSJR and the three eastside tributaries. Figure 8-2 shows the location of the national wildlife refuges and the other wildlife areas and Table 8-2 summarizes characteristics of these refuges and areas.

Flow and sediment regulation, through the development of the rim dams and increased water diversions, have been implicated as factors in the decline of riparian communities, both in general and specifically on the LSJR and three eastside tributaries (Capon and Dowe 2006; CDFG 2007; TID and MID 2011). Flow regulation has created artificially stable inter- and intra-annual hydrologic conditions, resulting in decreased peak flows, increased summer base flows, and a reduction of physical processes, such as scour and sediment deposition (Stillwater Sciences 2003a). Modified hydrologic and fluvial processes influence riparian vegetation establishment, survival, and succession. The near elimination of large floods and the corresponding scouring flows that remove vegetation have allowed some riparian habitat to mature into dense, even-aged stands, which impoverishes community structure and reduces sapling recruitment (TID and MID 2011; USBR 2011b). Elimination of floods also has allowed riparian scrub and trees to establish themselves in channels and gravel bars, which anchors substrates that typically are rearranged with every high flow event (TID and MID 2011; USBR 2011b). This evolution has contributed to simplification of channel morphology and loss of channel margins (TID and MID 2011).

Figure 8-2
National Wildlife Refuges and Other Wildlife Areas

Table 8-2. Summary of National Wildlife Refuges and Other Wildlife Areas

Location/ Size (acres[a])	General Characteristics, Including Habitat Types	Identified Wildlife	Surface Water Source(s)	Other Water Source(s) and Information Regarding Water Supply
North Grasslands Wildlife Area				
Merced County (7,400 acres)	Restored and created wetlands, riparian habitat, and uplands. The wildlife area is comprised of three non-contiguous units: (1) China Island Unit (to the east of Newman and Gustine), (2) Salt Slough Unit (Volta), and (3) Gadwall Unit (Los Baños)	Swainson's hawk, Sandhill crane, duck, pheasant, dove.	The China Island Unit receives the majority of its water from USBR and Central California Irrigation District (CCID) cooperative agreements (CDFG 2011a). Specifically, federal L2 and L4[b] contract for 6,967 and 3,483 acre-feet/year (AF/y), respectively (CDFG 2011b). The Salt Slough Unit receives federal L2 and L4 water (6,680 and 3,340 AF/y, respectively) from Grasslands Water District. The Salt Slough Unit also receives water via the following sources: (1) Appropriative (Contract A0145582), 13,500 AF/y, from Salt Slough; (2) Appropriative (Contract A013508) 3 cubic feet per second (cfs) from Salt Slough; and (3) Other, riparian, (Statement S009611), 30 cfs from Salt Slough (CDFG 2011b). Frequently, federal L2 and L4 contracted water cannot be delivered due to maintenance or other issues such as constraints due to mosquito abatement issues (CDFG 2011a). The Gadwell Unit receives water through the Central Valley Project Improvement Act (CVPIA) (Central Valley Joint Venture 2006).	The China Island and Salt Slough Units have groundwater wells, which provide a valuable source of water during drought periods (CDFG 2011a, 2011b). Although, these wells do not meet all water needs of refuge, policies are in place to support pooling of water supplies,[c] water transfers, water reallocations or exchanges of water to meet the needs of these wildlife areas (CDFG 2011a and 2011b). The Gadwall Unit has a groundwater well (USBR 2014 and USBR 2105a).
Stanley Wakefield Wilderness Area				
Stanislaus County (14 acres)	Kerr Community Park	Unknown recorded wildlife	There is no record of water rights or statements that serve this wildlife area (State Water Board 2016). As such, this refuge is likely served by available water in the Stanislaus River.	Assumed no other water supply besides Stanislaus River.

Location/ Size (acres^a)	General Characteristics, Including Habitat Types	Identified Wildlife	Surface Water Source(s)	Other Water Source(s) and Information Regarding Water Supply
West Hilmar Wildlife Area				
Merced County (340 acres)	Oak and cottonwood woodlands and grasslands	Great blue heron, egret, waterfowl, quail, and pheasant	There is no record of water rights or statements that serve this wildlife area (State Water Board 2016). As such, this refuge is likely served by available water in the LSJR.	Assumed no other water supply besides the LSJR.
Calaveras River Wildlife Area				
San Joaquin County (24 acres)	Lower Calaveras-Mormon Slough Watershed unknown	Unknown recorded wildlife	There is no record of water rights or statements that serve this wildlife area (State Water Board 2016). As such, this refuge is likely served by available water in the river. Conservation easement held by CDFW.	Assumed no other water supply besides river.
San Joaquin River National Wildlife Refuge				
Stanislaus and San Joaquin Counties (7,000 acres)	Riparian woodlands, wetlands, grasslands, cropland, irrigated pasture, fallow, and vernal pools	Swainson's hawk, heron, cormorant, and riparian brush rabbit	San Joaquin River National Wildlife Refuge has two appropriative rights and one riparian right. These rights supplied water to the portion of the refuge purchased from El Soyo Dairy. There are also one appropriative and three riparian rights on lands within the refuge boundary that are not owned by USFWS. Modesto Irrigation District (MID) supplies water to the western portions of the refuge. Water used east of the SJR is provided by the privately owned Mapes Ranch. (USFWS 2006.) A total of 19,440 AF/y is needed for the refuge (USFWS 2006). This refuge does not receive CVPIA/Central Valley Project (CVP) water (USFWS 2006).	Groundwater wells are present on the refuge (USFWS 2006).

Location/ Size (acres[a])	General Characteristics, Including Habitat Types	Identified Wildlife	Surface Water Source(s)	Other Water Source(s) and Information Regarding Water Supply
Merced National Wildlife Refuge				
Merced County (10,000 acres)	Over 150 individual wetland units or ponds are managed and contain wetlands, native grasslands, vernal pools, and riparian areas. The refuge is comprised of the following three units: (1) Merced Unit, (2) Arena Plains Unit, and (3) Snobird Unit	Sandhill crane, migratory waterfowl, Swainson's hawk, tricolored blackbird, burrowing owl, marsh wren, coyote, ground squirrel, desert cottontail rabbit, beaver, long tailed weasel, fairy shrimp, tadpole shrimp, and tiger salamander	The refuge receives approximately 16,000 AF/y of federal L2 water from the Merced Irrigation District (Merced ID) (USFWS 2010a). The refuge has an appropriative right for approximately 3,000 AF/y from Deadman Slough during the winter and spring, and approximately 350 AF/y during the spring and summer from Duck Slough (USFWS 2010a). The refuge receives floodwater/tailwater from Deadman Slough and Mariposa Creek/Eastside Bypass when available (USFWS 2010a). Under the "Exceptional Drought" conditions of 2015, the Merced National Wildlife Refuge received 50% or less of normal water allotments (USFWS 2016).	Groundwater wells are present on the refuge (USFWS 2010a). Drainage water is accepted from Merced ID (USFWS 2010a). The refuge follows the policies and procedures on pooling, transfers, reallocations, and exchanges for those established by the CVPIA and in water supply contracts.
San Luis National Wildlife Refuge				
Merced County (29,000 acres)	Wetlands, riparian forests, native grasslands, vernal pools, and uplands (irrigated pasture, croplands, non-irrigated pasture). The refuge is comprised of the following three areas: (1) East of Highway 165, (2) East Bear Creek, and (3) West of Highway 165	California tiger salamander, long-horned fairy shrimp, San Joaquin kit foxes, Tule Elk, green-winged teals northern shoveler, mallard, gadwall, wigeons cinnamon teal, northern pintail, ring-necked duck, canvasback, ruddy duck, snow goose, Ross' goose, white-fronted goose, coot, grebe, blackbird, bittern, dunlin, long-billed dowitcher, least sandpiper, western	The refuge receives federal L2 and L4 water from the San Luis Canal Company, Stevenson Water District, Merced ID, and Grasslands Water District (USFWS 2010b). The L2 water totals approximately 50,000 AF/y, depending on the water suppliers and contracts. The L4 water totals approximately 8,000 AF/y depending on availability from Grasslands Water District (USFWS 2010b). The refuge also has an appropriative right to approximately 20,000 AF/y from Salt Slough (USFWS 2010b). The refuge has floodwater-passive riparian rights from the SJR, and a riparian diversion from Bear Creek, as available (USFWS 2010b). Under the "Exceptional Drought" conditions of 2015, San Luis National Wildlife Refuge received 50 percent or less of normal water allotments (USFWS 2016).	Appropriative sources, groundwater and drainwater provide most of the water supply used to manage the wetlands before CVPIA (L2 and L4 water) became available (USFWS 2010b). Drainage water is accepted from various sources (USFWS 2010a). The refuge follows the policies and procedures on pooling, transfers, reallocations, and exchanges for those established by the CVPIA and in water

[a] Acreages are approximate.

[b] The CVPIA is described in greater detail in Section 8.3.1 *Federal [Regulatory Background]* and refers to two types of refuge water deliveries, Level 2 (L2) and Level 4 (L4). L2 represents the average annual historical water supplies received by land designated for refuges between 1975 and 1984 and L4 identifies the water supplies needed by refuges for the development of full habitat benefits. L2 water is provided primarily from CVP water supplies (USBR. 2014).

[c] Whenever maximum quantities of L2 Water Supplies and/or the Incremental L4 water supplies in a USBR contract (in the case of China Island Unit Contract #01-WC-20-1756 Exhibit B) are reduced, the remaining L2 and/or Incremental L4 Water Supplies may be pooled for use on other refugees following established rules (CDFG 2011a).

Potentially Affected Habitats

Much of the native vegetation in terrestrial habitats along the LSJR and the three eastside tributaries has been replaced by introduced species or is disturbed by cultivation, grazing, and development. The spatial extent of the river floodplains has been reduced by water management (CDFG 2007; USBR 2011b). Despite the loss of habitat associated with these activities, the rivers are generally flanked by a ribbon of riparian and wetland habitats. There is also some riparian habitat and small areas of wetland habitat around the edges of the three large reservoirs on the three eastside tributaries.

A spatial query of the CNDDB reported the following special-status habitats to be within approximately 1,000 feet (ft) of the area of potential effects: coastal and valley freshwater marsh, great valley cottonwood riparian forest, great valley mixed riparian forest, great valley oak riparian forest, and elderberry savanna. Although not reported by the CNDDB within or near the area of potential effects, other sensitive habitats in the vicinity include northern claypan and other vernal pool types, valley needlegrass grassland, serpentine bunchgrass, valley sacaton grassland, alkali flats and playas, and chenopod scrub (State Water Board 1999; CDFG 2012).

ESA defines *critical habitat* for threatened or endangered species as specific geographic areas that contain features essential for the conservation of the species and that may require special management and protection. (16 U.S.C., § 1532(5)(A).) No federally designated critical habitat is within the area of potential effects for the LSJR or SDWQ alternatives (i.e., channels). Outside the area of potential effects (areas adjacent to the main channel) on the Stanislaus and Tuolumne Rivers, are critical habitat areas designated for the California tiger salamander (*Ambystoma californiense*). There is also critical habitat designated outside the area of potential effects on the Merced River for San Joaquin Valley Orcutt grass (*Orcuttia inaequalis*) (USFWS 2012).

The following sections describe the major vegetation communities and types of land cover in the area of potential effects. Figures 8-3, 8-4, 8-5 and 8-6 show major vegetation communities in the area of potential effect for each river. Near the water bodies, habitats are dynamic and constantly shifting in response to environmental factors, such as water chemistry and water availability. Riparian plants possess adaptations that reduce physiological stress and damage when submerged or completely exposed, such as during droughts or reservoir drawdown (Braendle and Crawford 1999; Karrenberg et al. 2002). Capon and Dowe (2006) explain:

> Plants persisting in riparian habitats usually exhibit adaptations that allow them to survive through periodic episodes of fluvial disturbance. These can be either physiological or morphological adaptations, through which plants tolerate flooding as mature individuals, or life history adaptations that enable plants to tolerate the stresses associated with flooding in time or space. . . . Furthermore, this vegetation type exists in locations that already experience wide fluctuations in water availability and wave erosion.

Riparian Forest

The term *riparian*, as used herein, applies to the vegetation zone and other biological resources contiguous to, and affected by, surface and subsurface hydrologic features of perennial or ephemeral rivers and streams or artificial drainage ways. Riparian forests depend on a shallow groundwater table and can survive brief periods of flooding. The nature of San Joaquin Valley riparian zones is dynamic and was historically driven by annual flooding and long summer drought. Annual flooding established a frequent disturbance regime via floodplain inundation, scour, and sediment deposition

Stanislaus River Vegetation Communities

that maintained vegetation recruitment, survival, and mortality while water availability during summer drought limited riparian species distribution. This cycle of flooding and drought is especially significant to pioneer woody plant species, primarily willows (*Salix* spp.) and cottonwoods (*Populus* spp.), which rely on floods for bare seed beds, water, and nutrients, and which grow roots quickly to reach permanent water tables and a secure bank footing to resist subsequent floods (Stillwater Sciences 2003a).

Regeneration statistics are not available for riparian vegetation in California, but increased spring flows are believed to generally support the growth and dispersal of these species (CDFW 2014a). An analysis of historical data conducted in 2006 suggests that Fremont cottonwood (*Populus fremontii*) seed release coincided with peak runoff in almost all years, whereas Goodding's black willow (*Salix gooddingii*) and narrow-leaf willow (*Salix exigua*) seed dispersals typically took place during the spring flood recession after peak runoff (TID and MID 2011).

Riparian habitat has been significantly reduced by stream channelization, riprapping of stream banks, altered hydraulics, livestock grazing, and direct loss of habitat to agriculture and urban development (Riparian Habitat Joint Venture 2004; Moyle and Bennett 2008). As a result, wildlife corridors are narrow, riparian habitats are fragmented, stream temperatures have increased, channel variability has decreased, and little or no regeneration of riparian vegetation is occurring at many sites (Moyle and Bennett 2008; USBR 2011b).

Riparian forest is a broad vegetation category from which at least four major subtypes can be differentiated in the area of potential effects based on the dominant species: cottonwood riparian forest, willow riparian forest, mixed riparian forest, and valley oak riparian forest (Moise and Hendrickson 2002; Sawyer et al. 2009; USBR 2011b).

Cottonwood riparian forest is a multilayered riparian forest found on active, low floodplains. Common dominant trees in the overstory include Fremont cottonwood and Goodding's black willow (Sawyer et al. 2009). The midstory consists of shade-tolerant shrubs and trees, such as Oregon ash (*Fraxinus latifolia*) and California box elder (*Acer negundo*); California wild grape (*Vitis californica*) is also common. The understory typically is dominated by native grasses and forbs, such as stinging nettle (*Urtica dioica*) and sedges (*Carex* spp.)(Sawyer et al. 2009).

Willow riparian forest is dominated by black willow, but red willow (*Salix laevigata*) and arroyo willow (*S. lasiolepis*) are also common. Occasional scattered cottonwoods, ashes, or white alders (*Alnus rhombifolia*) may be present. Cover is generally dense. California buttonbush (*Cephalanthus occidentalis*) is often present (Sawyer et al. 2009).

Mixed riparian forest is a multilayered, winter-deciduous forest generally found on the intermediate terrace of the floodplain of the LSJR and the three eastside tributaries. Species dominance varies by environmental conditions, but typical dominants include Fremont cottonwood, box elder, Goodding's black willow, Oregon ash, and western sycamore (*Platanus racemosa*). Immediately along the water's edge, white alder may be found. The understory of mixed riparian forest is similar to that of cottonwood riparian forest (Sawyer et al. 2009).

Valley oak riparian forest varies from an open- to a closed-canopy habitat. This forest type is found on the higher portions of the floodplain. Besides valley oak (*Quercus lobata*), California sycamore, Oregon ash, and Fremont cottonwood are present. Common understory species are the California wild rose (*Rosa californica*), blackberry (*Rubus armeniacus* and *R. ursinus*), and California wild grape (Sawyer et al. 2009; USBR 2011b).

Riparian forests provide high-quality nesting habitat for raptors, such as red-tailed hawk (*Buteo jamaicenesis*), red-shouldered hawk (*B. lineatus*), Swainson's hawk (*B. swainsoni*), and white-tailed kite (*Elanus leucurus*). Riparian forest trees also provide nesting habitat for cavity-nesting species, such as downy woodpecker (*Picoides pubescens*), wood duck (*Aix sponsa*), northern flicker (*Colaptes auratus*), ash-throated flycatcher (*Myiarchus cinerascens*), oak titmouse (*Baeolophus inornatus*), tree swallow (*Tachycineta bicolor*), and white-breasted nuthatch (*Sitta carolinensis*). Riparian forests support large populations of insects that are prey for migratory and resident birds, including Pacific-slope flycatcher (*Empidonax difficilis*), western wood-pewee (*Contopus sordidulus*), olive-sided flycatcher (*C. cooperi*), warbling vireo (*Vireo gilvus*), orange-crowned warbler (*Vermivora celata*), yellow warbler (*Dendroica petechia*), Bullock's oriole (*Icterus bullockii*), and spotted towhee (*Pipilo maculatus*). Mammal species using riparian forests include coyote (*Canis latrans*), beaver (*Castor canadensis*), river otter (*Lontra canadensis*), raccoon (*Procyon lotor*), desert cottontail (*Sylvilagus audobonii*), and striped skunk (*Mephitis mephitis*) (USBR 2011b).

Scrub

Scrub habitat present in the area of potential effects includes willow scrub, riparian scrub, and elderberry savanna (Moise and Hendrickson 2002).

Willow scrub is a dense assemblage of shrubs found on riverbanks, in active channels subject to scouring flows, and especially on sand and gravel point bars immediately above the active river channels. Willows may survive three consecutive months of inundation (USBR 2011b). Dominant shrubs in willow scrub include sandbar willow (*Salix exigua*), arroyo willow, and red willow, although riparian trees such as Fremont cottonwood may also be present (Sawyer et al. 2009; USBR 2011b).

Riparian scrub consists of woody shrubs and herbaceous species. Depending on site conditions, some areas are dominated by mugwort (*Artemisia douglasiana*) and stinging nettle and various tall weedy herbs; others are dominated by blackberry or wild rose in dense thickets, sometimes with emergent willows. Such scrub associations may be maintained by periodic disturbance from fire or flood.

Elderberry savanna is typically found on floodplains (outside active channels), and is characterized by widely spaced blue elderberry shrubs (*Sambucus mexicana*) interspersed among nonnative grasses and forbs (Sawyer et al. 2009; USBR 2011b).

Bird species common to scrub habitat include various wrens (*Troglodytes* and *Thryomanes*), western wood-pewee, black phoebe (*Sayornis nigricans*), yellow-billed magpie (*Pica nuttalli*), bushtit (*Psaltriparus minimus*), buntings (*Passerina* spp.), tanagers (*Piranga* spp.), and American goldfinch (*Carduelis tristis*) (Sibley 2003; USBR 2011b). Animal species using scrub habitats are similar to those described for riparian forest habitats above, but may contain a wider variety of species, such as reptiles, because there is greater habitat diversity (USBR 2011b).

Emergent Wetlands

Emergent wetlands typically occur in the river bed adjacent to the low-flow river channels (Sawyer et al. 2009; USBR 2011b). Backwaters and sloughs support emergent marsh vegetation such as common tule (*Schoenoplectus acutus*), sedges (*Carex* spp.) and cattails (*Typha* spp.). Marsh species require shallow, periodic flooding of muddy benches and backwater areas. More ephemeral wetlands support an array of native and nonnative herbaceous species, including western goldenrod (*Euthamia occidentalis*), smartweed (*Polygonum* spp.), rushes (*Juncus* spp.), and dock (*Rumex* spp.).

Emergent wetlands support a wide variety of wildlife, including sparrows (*Melospiza* spp.), common yellowthroat (*Geothlypis trichas*), wrens (*Cistothorus*, *Troglodytes*, and *Thryomanes*), and red-winged blackbird (*Agelaius phoeniceus*) (Sibley 2003; USBR 2011b). Mammal species that use this habitat include beaver, voles (*Microtus* spp.), common muskrat (*Ondatra zibethicus*), and Norway rat (*Rattus norvegicus*). Emergent wetlands also sustain a variety of amphibians, especially Pacific chorus frog (*Pseudacris regilla*), American bullfrog (*Rana catesbeiana*) and garter snake (*Thamnophis elegans*) (CDFG 2007; USBR 2011b).

Grassland and Pasture

Grassland and pasture vegetation can exist adjacent to river channels on floodplains or where riparian habitat has been disturbed or converted. These locations are well drained and flood only occasionally. They are typically not connected hydrologically to the LSJR and the three eastside tributaries; therefore, grasslands and pastures are typically outside the area of potential effects affected by flow.

Various assemblages of nonnative annual and perennial grasses are predominating, as well as occasional nonnative and native forbs (Sawyer et al. 2009; USBR 2011b). Native grassland and bunchgrass populations may exist as well but are limited in distribution. Grasslands support a wide variety of bird species, including raptors such as northern harrier (*Circus cyaneus*) and white-tailed kite (*Elanus leucurus*), ring-necked pheasant (*Phasianus colchicus*), mourning dove (*Zenaida macroura*), burrowing owl (*Athene cunicularia*), horned lark (*Eremophila alpestris*), loggerhead shrike (*Lanius ludovicianus*), and sparrows (*Passerculus*, *Spizella*, and *Aimophila*) (Sibley 2003; USBR 2011b). Mammal species that use grasslands include California vole, deer mice (*Peromyscus* spp.), California ground squirrel (*Spermophilus beecheyi*), Botta's pocket gopher (*Thomomys bottae*), desert cottontail (*Sylvilagus audobonii*), striped skunk (*Mephitis mephitis*), American badger (*Taxidea taxus*), fox, and coyote. Common amphibian and reptile species associated with grasslands in the San Joaquin Valley include western toad (*Bufo boreas*), alligator lizard (*Elgaria coerulea*), western fence lizard (*Sceloporus occidentalis*), western racer (*Coluber constrictor*), and gopher snake (*Pituophis catenifer*) (USBR 2011b). There is a very low potential for the LSJR alternatives to affect this type of habitat because it is outside of the river channels and not hydrologically connected.

Agriculture and Other Disturbed Areas

Agricultural lands consist primarily of orchards (citrus, stone fruits), vineyards, and annual crops (cotton, corn, lettuce, strawberries, rice, etc.), and occasionally cattle pasture. Although some land adjacent to the river channels has been developed for agriculture, these locations are typically well drained and flood only occasionally. Cropland can provide food and cover for wildlife species, but the value of the habitat varies greatly with crop type and agricultural practices. Typically, agricultural lands provide low-value habitat for wildlife (CDFG 2007).

Disturbed (ruderal) areas include roads, canals, and levees. As with agricultural habitats, low vegetation cover and low species diversity in disturbed habitats limit their value to wildlife. There is a low potential for the LSJR alternatives to directly affect agriculture and disturbed habitats because they are typically located in upland areas outside of the river channel.

Agricultural lands within the plan area, but outside of areas directly affected by flows or reservoir changes, are considered an area of potential indirect effect. Agricultural practices in this area vary due to numerous considerations including irrigation water availability. Changes could occur to agricultural lands in upland areas throughout the plan area as a result of changes to irrigation water availability. These changes could have potential indirect effects on sensitive species. Currently there are over 600,000 acres of agricultural lands[4] in the plan area (Table 11-2). This land is a mix of various crops and, as such, provides different habitat types and values to wildlife depending on the land cover. Habitat values within this area of potential indirect effects currently fluctuate in response to a number of variables including the type of crop grown on a particular property and different crop mixes on a property and in the area, all of which are influenced by the market and discrete farming decisions and practices. Habitat values are also influenced by common agricultural practices, such as harvesting, spraying, tilling, crop rotation, and fallowing. These activities typically vary within an agricultural season and between years.

Potentially Affected Vegetation

A spatial query of the CNDDB revealed multiple special-status plant species that could occur within potentially affected habitats (CDFG 2012). Most of these species (e.g., *Atriplex* spp.) are associated with habitats such as chenopod scrub, alkali sinks, and vernal pools that by their very nature are isolated from flowing waters. These habitats, although sometimes near active channels, are not hydrologically linked to the channels, and thus the special-status plants that require these habitats would not be affected by the LSJR alternatives. In addition, species associated with grasslands (e.g., big tar plant [*Blepharizonia plumose*]) would generally be located outside of river channels and thus have a very low potential to occur in river channels. Additionally, several species of special-status plants may potentially be found within the area of potential effects (zone of fluctuation) near the edges of the large reservoirs. Table 8-3a shows those vegetation species that could be located within the area of potential effects. Table 8-3b shows those vegetation species that could be located in the area of potential indirect effects.

---

[4] Includes lands identified as Prime, Unique, Farmland of Statewide Importance, Farmland of Local Importance, and grazing lands.

Table 8-3a. Special-Status Plants with Potential to Occur or Known to Occur within the Area of Potential Effects – LSJR and the Three Eastside Tributaries

Scientific Name	Common Name	Status	Habitat Notes
Eryngium racemosum	Delta button-celery	CE, CNPS 1B.1	Associated with riparian scrub
Orcuttia inaequalis	San Joaquin Valley Orcutt grass	FT, CE	Grows on alluvial fans and stream terraces
Packera layneae	Layne's ragwort	FT, CNPS 1B	Associated with chaparral, cismontane woodland, and serpentine or gabbroic habitat
Clarkia biloba ssp. australis	Mariposa clarkia	CNPS 1B.2	Associated with chaparral and cismontane woodland habitat
Clarkia rostrata	Beaked clcarkia	CNPS 1B.3	Associated with cismontane woodland and valley/ foothill grassland
Lupinus spectabilis	Shaggyhair lupine	CNPS 1B.2	Associated with chaparral, cismontane woodland and serpentine habitat
Githopsis pulchella ssp. *serpentinicola*	Serpentine bluecup	CNPS 4.3	Associated with serpentine or Ione soils in oak woodlands
Eriophyllum confertiflorum var. *tanacetiflorum*	Golden yarrow	CNPS 4.3	Associated with oak woodland habitat
Helianthemum scoparium	Bisbee peak rush rose	CNPS 3.2	Associated with oak woodland habitat
Jepsonia heterondra	Foothill jepsonia	CNPS 4.3	Associated with chaparral habitat
Cryptantha mariposae	Mariposa cryptantha	CNPS 1B.3	Associated with chaparral and serpentine habitat
Verbena californica	California vervain	CNPS 1B FT, ST	Cismontane woodland, valley and foothill grassland, usually serpentine seeps and creeks
Allium tuolumnense	Red Hills onion	CNPS 1B	Associated with serpentine soils and found to occur around New Don Pedro Reservoir

Invasive Plants within Potentially Affected Habitats

Invasive plants are species that are not native to the area, generally persist without human assistance, and impact the environment to which they are introduced (Simberloff et al. 1997; USBR 2011b). There are a number of governmental agencies and nongovernmental organizations that have goals to limit or remove invasive species (see Section 8.3.1, *Federal [Regulatory Background]*, and Section 8.3.2, *State [Regulatory Background]*). The term *invasive plant* differs from the classification terms *nonnative*, *exotic*, or *introduced plant* because it describes those nonnative plant species that displace native species on a large enough scale to alter habitat functions and values.

The term *noxious weed* is used by government agencies for invasive nonnative plants that have been defined as pests by law or regulation (CDFG 2007).

Invasive riparian plants, especially giant reed (*Arundo donax*) and salt cedar (*Tamarix* spp.), displace native riparian vegetation and provide lower-quality habitat for native wildlife (CDFG 2007). Invasive plants may not sustain the rich invertebrate communities or provide forage for terrestrial wildlife as effectively as do native riparian plants (CDFG 2007; USBR 2010a). Invasive riparian plants also colonize channel and floodplain surfaces that can alter hydrologic processes and interfere with flood control (Moyle and Bennett 2008; USBR 2010a, 2011b). Removal or control of invasive riparian plants constitutes a substantial investment of capital resources (CDFG 2007; USBR 2010a).

Some of the most prevalent invasive plants in the area of potential effects are: red sesbania (*Sesbania punicea*); salt cedar; giant reed; purple loosestrife (*Lythrum salicaria*); Chinese tallow (*Sapium sebiferum*); tree-of-heaven (*Ailanthus altissima*); Eucalyptus (*Eucalyptus* spp.); pampas grass (*Cortaderia selloana*); fig (*Ficus* spp.); Himalayan blackberry (*Rubus armeniacus*); white mulberry (*Morus alba*); castor bean (*Ricinus communis*); Lombardy poplar (*Populus nigra*); and tree tobacco (*Nicotiana glauca*) (CDFG 2007; USBR 2010a, 2011). Also prevalent in the area of potential effects are emergent and submergent invasive aquatic plants, such as parrot feather, milfoils (*Myriophyllum* spp.), and water primrose (*Ludwigia* spp.); herbaceous weeds, such as thistles (*Centaurea* spp., *Cirsium* spp., *Carduus* spp., etc.); European annual grasses (*Avena* spp., *Cynodon* spp., *Echinochloa* spp., etc.); and numerous forbs that compete with native riparian species for shoreline and low floodplain establishment and growth sites.

Reduction of habitat quality in riparian ecosystems has contributed to the decline of native tree species and opened a niche for invasion by salt cedar in the western United States (Shafroth et al. 1995; Carter and Nippert 2012). In many riparian areas, salt cedar has replaced stands dominated by native Fremont cottonwood, decreasing habitat quality for native species and altering fluvial processes (Shafroth et al. 1995). Smaller peak flows in the river channels as a result of managed flow releases have also reduced leaching of salts from floodplain soils, perhaps favoring the salt-tolerant plants such as salt cedar (Shafroth et al. 1995).

Invasive Plants within Area of Potential Indirect Effects

Invasive plant species occurring within the area of potential indirect effects (all upland agricultural lands outside of river channels and reservoirs) include common herbaceous weeds such as thistles (*Onopordum* spp, *Cirsium spp*, *Carduus* spp, etc.) and knapweed (*Centaurea* spp.). These examples of invasive plant species are typical of those types of species found in and around agricultural lands in the area of potential indirect effects. The California Invasive Plant Council (Cal-IPC) has identified 9 invasive plant species within the South Central Valley region (San Joaquin, Stanislaus, and Merced Counties) for eradication, with an additional 31 species identified for active management (Cal-IPC 2012b). Containment and eradication of invasive plant species on agricultural lands often requires the use of herbicides or mechanical removal

Potentially Affected Wildlife

Historically, the San Joaquin Valley was composed of wetlands, grasslands, broad riparian corridors, scrub, and bunchgrass habitats. The valley supported a diverse assemblage of wildlife species, such as bison, elk, and grizzly bears. However, agricultural, urban, and commercial development have reduced, fragmented, and heavily modified natural habitat on the valley floor. Although few large mammals remain in the San Joaquin Valley, the remnant habitat continues to support a diverse group of vertebrate and invertebrate species (CDFG 2003). Table 8-4a lists the special-status animal species identified by a spatial query of the CNDDB within the area of potential effects (CDFG 2012). Table 8-4b shows those wildlife species that could be located in the area of potential indirect effects, many of which occur adjacent to the river channels.

Table 8-4a. Special-Status Animal Species with Potential to Occur or Known to Occur within the Area of Potential Effects– LSJR and the Three Eastside Tributaries

Scientific Name	Common Name	Status	Habitat Notes
Actinemys marmorata	western pond turtle	CSC	Slack- or slow-water aquatic habitat. Tulloch Reservoir implements a special-species plan. Present around reservoir shoreline at New Don Pedro Reservoir and Lake McClure.
Agelaius tricolor	tricolored blackbird	CSC, MB	Marsh and scrub habitats used for nesting.
Antrozous pallidus	pallid bat	CSC	Grassland, scrub, and forest.
Ardea herodias	great blue heron	CSC, MB	Saltwater and freshwater marshes, sloughs, riverbanks, and reservoirs (lakes). Forages in grasslands and agricultural fields.
Branta hutchinsii leucopareia	Aleutian Canada goose	Delisted, MB	Forages on pastures, harvested fields, and wetlands; roosts on flooded fields and ponds at night.
Buteo swainsoni	Swainson's hawk	CT, MB	Nests in riparian areas.
Calicina breva	Stanislaus harvestman	CSC	Various habitats.
Coccyzus americanus occidentalis	western yellow-billed cuckoo	CE, MB	Uses riparian areas for cover, foraging, and breeding.
Desmocerus californicus dimorphus	valley elderberry longhorn beetle	FT	Dependent on the elderberry shrub, a riparian species.
Egretta thula	snowy egret	CSC, MB	Marshes, swamps, shorelines, mudflats, and ponds.
Haliaeetus leucocephalus	bald eagle	CE, MB	Requires large, old-growth trees or snags in mixed stands near large bodies of water or free-flowing rivers with abundant fish.
Lasiurus blossevillii	western red bat	CSC	Associated with riparian habitat.
Myotis yumanensis	Yuma myotis	CSC	Optimal habitats are open forests and woodlands with sources of water over which to feed.
Neotoma fuscipes riparia	San Joaquin Valley woodrat	FE	Restricted primarily to riparian areas where trees and brush are found.
Pandion haliaetus	Osprey	CSC, MB	Wide range of habitats near water, primarily reservoirs (lakes), rivers, and coastal waters with adequate supplies of fish.
Perognathus inornatus	San Joaquin pocket mouse	CSC	Dependent on riparian forests with dense understory. Present in Caswell Memorial State Park on the Stanislaus River.

Scientific Name	Common Name	Status	Habitat Notes
Rana aurora draytonii	California red-legged frog	FT, CSC	Permanent and semi-permanent aquatic habitats such as creeks and coldwater ponds with emergent and submergent vegetation and riparian species along the edges.
Sylvilagus bachmani riparius	riparian brush rabbit	FE, CE	Dependent on riparian forests with dense understory that include floodplains with upland area for retreat from high waters. Present in Caswell Memorial State Park on the Stanislaus River.

Nonnative Wildlife

The introduction of nonnative wildlife species can be detrimental to native species assemblages. The distribution and abundance of nonnative wildlife species in the area of potential effects are not fully documented, but species include American bullfrog (*Lithobates catesbeiana*), red swamp crayfish (*Procambarus clarkii*), red-eared slider (*Trachemys scripta*), European snails (e.g., *Helix* spp.), and Chinese mitten crab (*Eriocheir sinensis*) (USBR 2010a).

8.2.2 Reservoirs

This section describes the area of potential effects at the three rim dams (New Melones, New Don Pedro, and New Exchequer) and their respective reservoirs (New Melones Reservoir, New Don Pedro Reservoir, and Lake McClure). As a result of the LSJR alternatives, water surface elevations are expected to change, but generally this change would be within the current zone of fluctuation at the three rim dams and reservoirs (Tables 8-7a, 8-7b, and 8-7c and Section 8.4.2, *Methods and Approach*). Therefore, the area of potential effects at the three rim dams and reservoirs is limited to the area along their banks that would experience this change in water level.

Water surface elevations in smaller downstream reservoirs on the three eastside tributaries are maintained through water releases from the rim dams upstream. These downstream reservoirs are used to regulate the flow released by the upstream rim dams. Although more flow might go through these smaller downstream reservoirs as a result of the LSJR alternatives, the reservoirs would simply release the flow downstream, so surface elevations of the smaller downstream reservoirs are not expected to change under the LSJR alternatives.

Potentially Affected Habitats

While there are a multitude of different habitat types within the vicinity of the reservoirs, annual grasses and disturbed/barren habitats make up the majority of the habitat types found within the area of potential effects around the reservoirs. Small segments of riparian and wetland habitat exist around the reservoirs at some locations where tributaries meet the reservoir within the zone of water level fluctuation. Information from the Don Pedro Hydroelectric Project (TID and MID 2014), the Merced River Hydroelectric Project (Merced ID 2010; Merced ID 2011a), and the New Melones Lake Resource Management Plan (USBR 2010b) documents and technical studies (herein after referred to collectively as the reservoir studies) were reviewed to determine whether the presence of special-status habitat types existed in the area of potential effects. There were no special-status habitat types located within the vicinity of New Melones and New Don Pedro reservoirs due to the reservoirs' steep-sided banks and regular water level fluctuations. Investigations done as part of the Merced River relicensing proceeding revealed the presence of limestone salamander, a California fully protected species that inhabits steep-sided talus slopes and rocky habitat around Lake McClure (Merced ID 2011b). Additionally, BLM has established the Bagby Serpentine Area of Critical Environmental Concern in the vicinity of the upstream end of Lake McClure near Bagby. The Bagby Serpentine Area of Critical Environmental Concern also includes land bordering the Lake McClure and the Red Hills Area of Critical Environmental Concern, which is located near New Don Pedro Reservoir and may overlap portions of the area of potential effects at that reservoir.

Annual Grassland

Annual grassland is typically found at the higher elevations of the area of potential effects of the reservoirs where water inundation occurs least frequently. Studies of the vegetation around the reservoirs found annual grasses were present along the reservoir shores just below the high water line creating a "bathtub ring" effect. Many of the vegetative species within this classification are nonnative and invasive. Dominant species include the following: ripgut brome (*Bromus diandrus*), Italian ryegrass (*Lolium multiflorum*), soft chess (*Bromus hordeaceus*), wild oats (*Avena barbata*), silver hairgrass (*Aira carophyllea*), and the highly invasive Bermudagrass (*Cynodon dactylon*) which was found to be very common along the reservoirs.

Terrestrial wildlife species associated with this vegetation type closely follow that of the grassland and pasture vegetation classification as discussed in Section 8.2.1, *LSJR and the Three Eastside Tributaries*.

Disturbed/Barren

The reservoir studies found the areas below the normal maximum surface elevations, which are periodically exposed, were sparsely vegetated and/or bare. As such, the disturbed/barren vegetation classification is similar to the disturbed/barren habitat classification discussed previously in Section 8.2.1, *LSJR and the Three Eastside Tributaries*. Typically, this habitat classification includes areas such as roads, canals, levees, and the area of potential effects below the annual grassland vegetation community. Areas that are not found barren within this classification are sparsely inhabited by the annual grassland species discussed above.

While several terrestrial/semi-aquatic wildlife species (i.e., Western pond turtle) maybe found within the disturbed/barren habitat classification, these areas generally have relatively low habitat value due to steep slopes and reduced vegetation, as they afford few opportunities for native wildlife populations, and support little wildlife biodiversity overall (TID and MID 2014). There is a special-status amphibian species, Limestone salamander, which is present around Lake McClure. It is found mainly on the surface in mixed chaparral habitats during moist periods. During the remainder of the year, they can be found below the surface in habitat that includes limestone caverns, deep talus formations, and massive rock fissures (Merced ID 2011b).

Wetland and Riparian

Studies on riparian and wetland habitat around Lake McClure identified the presence of small, ephemeral wetlands at the mouth of drainages where flows from the drainages and the reservoir water level inundate the finger-like drainage beds (Merced ID 2011a). As snowmelt raises the water level of Lake McClure, these wetlands become fully submerged until reservoir levels drop again during fall months. Dominant species in these wetland areas include broadleaf cattails, various species of rush, leather root (*Hoita macrostachya* [*Psoralea macrostacha*]), and California loosestrife (*Lythrum californicum)*. Where soil conditions are saturated but not inundated, Italian thistle (*Carduus pycnocephalus)* is often the dominant species, providing full ground cover. Where soils are slightly less wet, along shallow drainages, seeps, or directly adjacent to inundated temporary wetlands, Italian ryegrass (*Lolium multiflorum)* is dominant; it often occurs in conjunction with Italian thistle. At most drainages, the riparian vegetation community becomes well-developed and vigorous at the high water line, remaining healthy until the natural landscape no longer supports hydric conditions necessary for riparian vegetation. Button willow also occurs intermittently below the high-water line of Lake McClure.

Areas at the mouth of the drainages that enter Lake McClure are inundated for longer durations than other locations around the reservoir and frequently support wetland vegetative species. Riparian vegetation tends to increase in abundance farther up the drainage, where inundation occurs for a shorter duration during the year, with full expression of riparian vegetation occurring near the high water line of the lake, where inundation occurs less frequently and for shorter durations. Various special-status plant species were found around New Don Pedro Reservoir and Lake McClure as a result of studies that were completed for the FERC relicensing on the Tuolumne and Merced Rivers (Merced ID 2011a; TID and MID 2013b).

BLM Areas of Critical Environmental Concern

The Bureau of Land Management (BLM) is a federal land management agency that is responsible for the management of some of the public lands located around the reservoirs. To better protect certain rare or otherwise valuable habitat, BLM establishes Areas of Critical Environmental Concern (ACECs), which are areas of public land where special management attention is required to protect relevant and important natural or cultural resource values. The current Sierra Resource Management Record of Decision (Sierra ROD), completed in 2008, describes the special resource values present in the two ACECs located near the reservoirs, the Red Hills ACEC in the vicinity of New Don Pedro Reservoir and the Bagby Serpentine ACEC located near the upper portions of Lake McClure. These two ACECs, described in more detail below, were designated due to the presence of rare plant communities that are associated with unique soil characteristics at these two locations.

The Red Hills ACEC includes: Delpiedra soils derived from dunite and serpentine, two federally listed species (*Verbena californica* and *Packera layneae*), four BLM sensitive species (*Allium tuolumnense, Chlorogalum grandiflorum, Lomatium congdonii,* and *Senecio clevelandii heterophyllus*), and the serpentine buckbrush chaparral plant community.

The Bagby Serpentine ACEC, which overlaps a portion of the area of potential effects around Lake McClure, was designated to protect a rare plant community characterized by the presence of serpentine soils. As described in the Sierra ROD, relevant and important values at this location are the Henneke soil series soils developed on a serpentine substrate supporting at least two BLM sensitive serpentine endemic species (*Lupinus spectabilis* and *Cryptantha mariposae*), other serpentine endemics, and the serpentine buckbrush chaparral community.

Both of these ACECs contain portions of the designated area that border the shorelines at New Don Pedro Reservoir and Lake McClure. Special-status plants associated with these ACECs were found to exist in the area of potential effects at these two reservoirs.

Potentially Affected Vegetation

The vegetative species found within the area of potential effects are accustomed and acclimatized to large interannual and annual variations in the reservoirs' water surface elevations that occur as part of reservoir operations. Nonnative plants dominate much of the potential area of effects along the reservoirs' banks and limit the potential for native plant species to grow, however observations have been made during studies around New Don Pedro Reservoir and Lake McClure of several special-status plant species around the edge of the reservoir. Since the range in water level fluctuation is not expected to substantially change compared to baseline conditions, the potentially affected vegetation around reservoirs is confined to the area immediately around the reservoir.

Invasive Plants Within Potentially Affected Habitats

As discussed in Section 8.2.1, *LSJR and the Three Eastside Tributaries*, a number of invasive plants are present within the potentially affected habitat. The reservoir studies documented the dominance of European annual grasses and forbs in the annual grassland habitat found along the reservoirs' banks.

Potentially Affected Wildlife

Those special-status wildlife species with the potential to occur within the area of potential effects around the reservoirs are the same as those listed in Table 8-4. However, the reservoir studies did note the lack of abundance of special-status species within the area of potential effects as a result of the limited amount of appropriate habitat and the overall number of invasive species. An exception was the limestone salamander (*Hydromantus brunus),* which has a designation of California listed as threatened, California fully protected species. This species has a range restricted Lake McClure and its tributaries on steep north and east-facing slopes in chaparral habitats during moist periods and in limestone caverns, deep talus, and rock fissures during the remainder of the year. This species spends much of the time below the surface during the dry season and is generally only found above ground during the rainy season when it emerges. Western pond turtles (*Actinemys marmorata*) were also observed around the shore of New Don Pedro Reservoir. These species are accustomed to the frequent changes in water level elevations.

Nonnative Wildlife

The nonnative wildlife species found within the areas of effects along the reservoirs' banks are the same as those described in Section 8.2.1, *LSJR and the Three Eastside Tributaries*. The reservoir studies identify the abundance of American bullfrogs and red swamp crayfish.

8.2.3 Extended Plan Area

Unlike the plan area, where the elevation primarily decreases from the rim dams and becomes flat in the valley, the extended plan area dramatically increases in elevation to the top of the three eastside tributary watersheds. This elevation change influences the types of habitat and vegetation that are found in the area. The vegetation zonation reflects the increase in elevation with associated declines in temperature, increased precipitation, and winter snow at higher elevations. At the uppermost reaches of the Stanislaus, Tuolumne, and Merced Rivers, alpine vegetation or bare bedrock is dominant. Below the alpine zone are subalpine forest, lodgepole-red fir forest, yellow pine forest, foothill woodlands, and chaparral (Schoenherr 1992:92).

There are several special-status animal species in the extended plan area located within the area of potential effects of the rivers and reservoirs. These include valley elderberry longhorn beetle, willow flycatcher (*Empidonax trailii,* CE), and the harlequin duck (*Histrionicus*, CSC). There are two special-status amphibians in the upper watersheds of the extended plan area. These are the Sierra Nevada yellow-legged frog (*Rana sierrae,* FT, CT) and the Yosemite toad (*Bufos canorus,* FT, CSC) (CDFG 2012).

There are no federal or state endangered or threatened plant species associated with reservoirs in the extended plan area. There are several rare plant species associated with reservoir wetland habitats. These include yellow-lipped pansy monkeyflower *(Mimulus pulchellus),* three-bracted onion *(Allium tribracteatum)* and a moonwort *(Botrychium crenulatum)* (CDFG 2012).

Within the Stanislaus National Forest the following acreages have been identified as wildlife habitat: big game (804,700); small game (112,800); bald eagle (3,000); peregrine falcon (15,000); Sierra red fox (100,000); fisher (220,000); pine marten (245,000); spotted owl (120,000); goshawk (104,000); great grey owl (10,000) (USFS 2016).

8.2.4 Southern Delta

The southern Delta once consisted of tidal marshlands, numerous islands, and hundreds of miles of waterways. Upland islands, meandering natural levees, and terraces supported woody riparian vegetation, grassland, and shrubs. Marshlands were drained and reclaimed for irrigated agriculture (CDFG 2007). Today, agricultural land dominates the southern Delta. Levees typically have waterside slopes that are covered with riprap and actively maintained with regular herbicide application to control vegetation. Interior areas of most islands are actively farmed and contain little or no natural vegetation. Consequently, most remaining undisturbed plant communities and most special-status species occur on in-channel islands with no levees (CDFG 2007).

The vegetation, wildlife, and special-status species of the area of potential effects for the SDWQ alternatives are similar to that of the area of potential effects for the LSJR alternatives. The following is a discussion of vegetation, wildlife, and special-status species that are specific to the area of potential effects for the SDWQ alternatives.

Potentially Affected Habitats

The southern Delta contains numerous and varied vegetation communities and land cover types. The majority of the area of potential effects is nonflooded agriculture, followed by grassland, orchards, and vineyards (particularly in the southwestern portion of the southern Delta) (CDFG 2005). A spatial query of the CNDDB revealed the following special-status habitats reported within the area of potential effects: great valley cottonwood riparian forest, great valley mixed riparian forest, great valley oak riparian forest, and northern claypan vernal pool (CDFG 2012). With the exception of northern claypan vernal pools, these habitats are discussed above. Vernal pool habitats are not discussed further because they are isolated from the waterways that could be modified by the plan amendments. There is no critical habitat designated for terrestrial species in the southern Delta. Near the waterways and within the area of potential effects, the dominant habitat types are aquatic. These habitat types are discussed below.

Tidal Freshwater Emergent Wetland

Tidal freshwater emergent wetland habitat is typically a transitional community between tidal perennial aquatic, riparian, and various terrestrial upland communities. It often occurs at the shallow, slow-moving, or stagnant edges of fresh waterways in the intertidal zone and is subject to frequent, long duration flooding. Tidal freshwater emergent wetland habitat is distributed in narrow, fragmented bands along island levees, in-channel islands, shorelines, sloughs, and shoals. In the southern Delta, bulrushes (*Scirpus* spp.), tules, and common reed (*Phragmites australis*) are often the dominant plant species within this community type.

Tidal Mudflat

Tidal mudflat habitat typically occurs as sparsely vegetated sediment deposits in the intertidal zone between the mean higher high tide and the mean lower low water level. It is typically associated with the tidal freshwater wetland community at its upper edge and the tidal perennial aquatic community at its lower edge. The tidal mudflat natural community is ephemeral and owes its physical existence to sediment erosion and deposition processes that vary throughout the Delta. At least two special-status plant species, Mason's lilaeopsis (*Lilaeopsis masonii*) and Delta mudwort (*Limosella subulata*), are found in this community type (Fiedler et al. 2007).

Nontidal Perennial Aquatic

Nontidal perennial aquatic habitat can be found in association with any terrestrial habitat and often transitions into nontidal freshwater perennial emergent wetland and riparian habitats. Specific plant species vary with water depth and distance from shore and include submerged aquatic species (e.g., pondweed [*Potamogeton* spp.] and Brazilian waterweed [*Egeria densa*]) and floating aquatic vegetation (e.g., duckweed [*Lemna* spp.]) and water hyacinth [*Eichhornia crassipes*]). This community is often dominated by nonnative species and may alter the environment by increasing rates of sediment and organic matter accumulation (BDCP 2010).

Nontidal Freshwater Perennial Emergent Wetland

These perennially-saturated wetlands are composed of emergent vegetation that cannot tolerate perpetual exposure to saline or brackish conditions. Nontidal freshwater perennial emergent wetland habitat occurs adjacent to nontidal perennial aquatic and riparian natural communities, typically occurring as associated pockets of habitat (BDCP 2010).

Potentially Affected Vegetation

A spatial query of the CNDDB revealed special-status plant species with potential to occur within the area of potential effects (Table 8-5) (CDFG 2012). The species associated with riparian forests are discussed above for the LSJR alternatives. Vegetation unique to the southern Delta area of potential effects is discussed below.

Table 8-5. Special-Status Plants with Potential to Occur or Known to Occur within the Area of Potential Effects – Southern Delta

Scientific Name	Common Name	Status	Habitat Notes
Cirsium crassicaule	slough thistle	CNPS 1B.1	Chenopod scrub, marshes and swamps, sloughs, and riparian scrub.
Eryngium racemosum	Delta button-celery	CE	Riparian scrub.
Hibiscus lasiocarpos	woolly rose-mallow	CNPS 2.2	Freshwater marsh.
Lathyrus jepsonii var. jepsonii	Delta tule pea	CNPS 1B.2	Freshwater and brackish marshes.
Lilaeopsis masonii	Mason's lilaeopsis	CNPS 1B.1	Intertidal brackish and freshwater marshes along streambanks.
Limosella subulata	Delta mudwort	CNPS 2.1	Marshes and swamps, muddy or sandy intertidal flats.
Symphyotrichum lentum	Suisun Marsh aster	CNPS 1B.2	Freshwater and brackish marshes.
Trichocoronis wrightii var. *wrightii*	Wright's trichocoronis	CNPS 2.1	Meadows, marshes and swamps, riparian forest, and alkaline vernal pools.

CE = California listed as endangered
CNPS = California Native Plant Society rarity rank

Invasive Plants within Potentially Affected Habitats

Some of the most prevalent invasive plants in the area of potential effects are thistles, European annual grasses, salt cedar, giant reed, Chinese tallow, tree-of-heaven, Eucalyptus, pampas grass, edible fig, Himalayan blackberry, white mulberry, castor bean, Lombardy poplar, tree tobacco, and emergent and submergent invasive aquatic plants (CDFG 2007; USBR 2010a, 2011). Invasive plants displace native vegetation and provide lower-quality habitat for native wildlife (CDFG 2007). Invasive plant stands may not sustain rich invertebrate communities or provide forage for terrestrial wildlife as effectively as do native communities (CDFG 2007; USBR 2010a). Invasive riparian plants also colonize channel and floodplain surfaces that can alter hydrologic processes and interfere with flood control (Moyle and Bennett 2008; USBR 2010a, 2011).

Potentially Affected Wildlife

More than 200 species of wildlife utilize the terrestrial habitats of the Delta (CDFG 2003). Wildlife habitats in the area of potential effects include agricultural land, riparian forest, riparian scrub, emergent freshwater marsh, mudflats, grassland, and rangeland. The Delta is particularly important to waterfowl migrating via the Pacific Flyway. The principal attraction for waterfowl is winter-flooded fields, mainly cereal crops, which provide food and extensive seasonal wetlands. The Delta and other Central Valley wetlands provide winter habitat for 60 percent of the 5 million waterfowl on the Pacific Flyway and 90 percent of all waterfowl that winter in California (CDFG 2003). Approximately 27 species of waterfowl are found in the Delta and LSJR (CDFG 2003). Raptor species, including bald eagle, prairie falcon (*Falco mexicanus*), and great-horned owl (*Bubo virginianus)*, hunt in the wetlands, grasslands, and riparian habitats. Many passerines, including species of flycatchers, swallows, warblers, blackbirds, and sparrows, nest, forage, or overwinter in the variety of habitats associated with the Delta. Upland game birds include dove, pheasant, chukar, and quail. Shorebirds include gulls, terns, plovers, sandpipers, herons, and egrets (CDFG 2003).

Small mammals find suitable habitat in the Delta and upland areas. Vegetated levees, remnants of riparian forest, and undeveloped islands still sustain approximately 40 species of mammals (CDFG 2003). Species include muskrat, mink, river otter, beaver, raccoon, gray fox, California ground squirrel, antelope ground squirrel, and skunk.

Herpetofauna of the area include garter, gopher, night, and king snakes; western pond turtle; leopard, fence, alligator, and side-blotched lizards; skinks and whiptails; red-legged frogs, yellow-legged frogs, tree frogs, and bullfrogs; and tiger and slender salamanders. The southern Delta is also home to thousands of insect and other invertebrate species, such as over a hundred beetle species and many rare native bees (e.g., Adrenidae) (Powell and Hogue 1979).

The loss or alteration of most of the natural habitat in the Delta has resulted in the decline of the Delta's sensitive and rare terrestrial species. A spatial query of the CNDDB revealed multiple special-status animal species within the area of potential effects (Table 8-6) (CDFG 2012). Many of the species are avian and dependent on the availability of riparian habitat.

Nonnative Wildlife

The introduction of nonnative wildlife species can be detrimental to native species assemblages. The distribution and abundance of nonnative wildlife species in the area of potential effects are not fully documented in the southern Delta, but among the species that occur are red fox (*Vulpes vulpes*), common starling (*Sturnus vulgaris*), American bullfrog, brown-headed cowbird (*Molothrus ater*), and feral pig and cat (CDFG 2003).

Table 8-6. Special-Status Animals with Potential to Occur or Known to Occur within the Area of Potential Effects – Southern Delta

Scientific Name	Common Name	Status	Habitat Notes
Actinemys marmorata	western pond turtle	CSC	Uses slack- or slow-water aquatic habitat.
Agelaius tricolor	tricolored blackbird	CSC, MB	Uses marsh and scrub habitats for nesting.
Ambystoma californiense	California tiger salamander	FT, CE	Inhabits grassland and oak woodland habitats below 1,500 feet which have scattered ponds, intermittent streams, or vernal pools.
Anthicus sacramento	Sacramento anthicid beetle	CSC	Inhabits sandy substrate among willows in riparian habitats.
Athene cunicularia	burrowing owl	CSC, MB	Uses open, dry grasslands, deserts, prairies, farmland, and scrublands with abundant active and abandoned mammal burrows inside levees.
Buteo swainsoni	Swainson's hawk	CT, MB	Nests in a variety of tree species often in or near riparian habitat. Forages in grasslands and agricultural fields.
Circus cyaneus	northern harrier	CSC, MB	Nests and forages in grasslands and agricultural fields, often at the edge of marshes.
Coccyzus americanus occidentalis	western yellow-billed cuckoo	CE, MB	Uses riparian areas for cover, foraging, and breeding.
Desmocerus californicus dimorphus	valley elderberry longhorn beetle	FT	Dependent on the elderberry shrub, a riparian species.
Falco columbarius	Merlin	MB	Prefers open habitats such as grasslands, marshlands, deserts, coasts, sand dunes and steppes.
Neotoma fuscipes riparia	San Joaquin Valley woodrat	FE	Restricted primarily to riparian areas where trees and brush are found.
Perognathus inornatus	San Joaquin pocket mouse	CSC	Dependent on riparian forests with dense understory.
Sylvilagus bachmani riparius	riparian brush rabbit	FE, CE	Dependent on riparian forests with dense understory that include floodplains with upland area for retreat from high waters.
Taxidea taxus	American badger	CSC	Uses grasslands and levees.
Xanthocephalus	yellow-headed blackbird	CSC, MB	Uses wetlands.

8.3 Regulatory Background

8.3.1 Federal

Relevant federal programs, policies, plans, or regulations related to terrestrial biological resources are described below.

Clean Water Act

The CWA generally applies to all navigable waters of the United States and is discussed in Chapter 5, *Surface Hydrology and Water Quality*.

Central Valley Project Improvement Act

The Central Valley Project Improvement Act (CVPIA) was enacted in 1992 to balance the needs of fish and wildlife resources with other uses of CVP water. The purposes of the CVPIA are as follows.

- Protect, restore, and enhance fish, wildlife, and associated habitats in the Central Valley and Trinity River Basins of California.
- Address impacts of the CVP on fish, wildlife, and associated habitats.
- Improve the operational flexibility of the CVP.
- Increase water-related benefits provided by CVP to the State of California through expanded use of voluntary water transfers and improved water conservation.
- Contribute to California's interim and long-term efforts to protect the Bay-Delta Estuary.
- Achieve a reasonable balance among competing demands for use of CVP water, including the requirements of fish and wildlife, agricultural, municipal and industrial, and power contractors.

The CVPIA added mitigation, protection, and restoration of fish and wildlife to the purposes of the CVP, dedicated 800,000 AF of CVP yield for the primary purpose of implementing fish, wildlife, and habitat restoration, and created a Central Valley Project Restoration Fund to carry out CVPIA programs, projects, plans, and habitat restoration, improvement, and acquisition provisions.

Section 3406(d) of the act requires the Secretary of the Interior to

> provide, either directly or through contractual agreements with other appropriate parties, firm water supplies of suitable quality to maintain and improve wetland habitat areas on units of the National Wildlife Refuge System in the Central Valley; on Gray Lodge, Los Baños, Volta, North Grasslands, and Mendota state wildlife management areas; and on the Grasslands Resources Conservation District in the Central Valley of California.

The volumes of water necessary are divided into Level 2 water supply needs that are to be made immediately available and Level 4 water supply needs, which are to be made available no later than 10 years after CVPIA's enactment.

CVPIA and Section 210(b) of the Reclamation Reform Act of 1982 also require the preparation and submittal of Water Management Plans from certain entities that enter into repayment contracts or water service contracts with the U.S. Bureau of Reclamation (USBR) (USBR 2015b). These plans document the use and amount of water under different federal levels. The following national wildlife refuges and other wildlife areas have submitted water management plans because of their use of contracted water: North Grasslands Wildlife Area; SJR National Wildlife Refuge; Merced National Wildlife Refuge; and San Luis National Wildlife Refuge.

Federal Endangered Species Act of 1973

The purpose of the ESA is to protect and recover imperiled species and the ecosystems upon which they depend. (16 U.S.C., § 1531 et seq.) ESA is administered by USFWS and NMFS. In general, NMFS is responsible for protecting ESA-listed threatened or endangered marine species and anadromous fishes, while other listed species (e.g., freshwater and terrestrial species) are under USFWS jurisdiction. An *endangered species* is defined as "… any species which is in danger of extinction throughout all or a significant portion of its range." (16 U.S.C., § 1532, subd. (6).) A *threatened species* is defined as "… any species that is likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range." (16 U.S.C., § 1532, subd. (20).) ESA Section 9 makes it illegal to *take* (i.e., harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, or collect, or attempt to engage in such conduct) any endangered fish or wildlife species. (16 U.S.C., §§ 1538; 1532, subd. (19).) For threatened fish and wildlife species, ESA Section 4(d) allows for the adoption of protective regulations, including provisions extending the Section 9 take prohibition to that species. (16 U.S.C., § 1538, subd. (d).)

ESA also requires the designation of critical habitat for listed species. *Critical habitat* is defined as: (1) specific areas within the geographical area occupied by the species at the time of listing, if they contain physical or biological features essential to a species' conservation, and those features may require special management considerations or protection; and (2) specific areas outside the geographical area occupied by the species if the agency determines that the area itself is essential for conservation (NMFS 2011; NMFS 2009a; ICF International 2012).

If a federal agency believes that its action will jeopardize a listed species or destroy or adversely modify critical habitat, the agency must request formal consultation with USFWS or NMFS, as appropriate, under Section 7 of ESA. (16 U.S.C., § 1536.) USFWS or NMFS then issues a biological opinion (BO) as to whether the action is likely to jeopardize a listed species or to destroy or adversely modify its critical habitat. If an action will result in jeopardy, the USFWS or NMFS will provide the consulting federal agency with reasonable and prudent alternative actions to avoid jeopardy. For any non-federal action otherwise prohibited by Section 9, the applicant must apply to the Secretaries for an incidental take permit under ESA Section 10. (16 U.S.C., § 1539.) Species that are candidates for listing are not protected under ESA; however, USFWS advises that a candidate species could be elevated to listed status at any time, and, therefore applicants should regard these species with special consideration.

Recovery Plan for Upland Species of California

The *Recovery Plan for Upland Species of California* (Recovery Plan) was released by USFWS in 1998. This plan addresses 34 species of plants and animals that occur in the San Joaquin Valley that are either federally listed as threatened or endangered, or are candidates for listing or species of concern. The ultimate goal is to delist the 11 endangered and threatened species addressed in the plan and ensure the long-term conservation of the other 23 species (USFWS 1998). The plan provides for both an ecosystem approach and a community-level strategy to conservation planning. USFWS also uses the plan to determine recommendations and requirements during endangered species consultation for these species. The Recovery Plan should be taken into consideration when analyzing potential impacts on upland natural community habitats in the San Joaquin Valley to ensure that projects do not prevent or impair the future long-term implementation success of the Recovery Plan.

National Wildlife Refuge System Improvement Act of 1997

Comprehensive Conservation Plans (CCP) are required under the National Wildlife Refuge System Improvement Act of 1997 and are prepared by USFWS. In 2006 the USFWS prepared a final CCP for the SJR National Wildlife Refuge to guide the management of the refuge for the next fifteen years. The primary goals of the CCP are: conserve and protect the natural diversity of migratory birds, resident wildlife, fish, and plants through restoration and management of riparian, upland, and wetland habitats on refuge lands; contribute to the recovery of threatened/endangered species, as well as the protection of populations of special-status wildlife and plant species and their habitats; provide optimum wintering habitat for Aleutian Canada geese to ensure their continued recovery; coordinate the natural resource management of the SJR National Wildlife Refuge in the context of the larger Central Valley/San Francisco ecoregion; provide the public with opportunities for compatible, wildlife-dependent visitor services to enhance understanding, appreciation, and enjoyment of natural resources at the SJR National Wildlife Refuge. As identified by Table 8-2 there are several national wildlife refuges, with CCPs, that receive surface water from either the three eastside tributaries or the LSJR. They include: SJR National Wildlife Refuge, Merced National Wildlife Refuge, and the San Luis National Wildlife Refuge.

Federal Power Act

Under the Federal Power Act (FPA), the Federal Energy Regulatory Commission (FERC) is responsible for determining under what conditions to issue licenses, or relicense, non-federal hydroelectric projects. Under the provisions of Section 10(j) of the FPA, each hydroelectric license issued by FERC is required to include conditions for the protection, mitigation, or enhancement of fish and wildlife resources affected by the project. These required conditions are to be based on recommendations of federal and state fish and wildlife agencies. FERC may reject or alter the recommendations on several grounds, including if FERC determines they are inconsistent with the purposes and requirements of the FPA or other applicable law. The State Water Board exercises authority over hydropower projects through Section 401 of the Clean Water Act, which requires an applicant for a federal license or permit that conducts an activity that results in a discharge into the navigable waters of the United States to apply for a certification from the state that the discharge will comply with state and federal water quality standards. The certification will include conditions requiring compliance with the Bay-Delta Plan's water quality objectives, including the LSJR flow requirements. FERC does not have authority to review or set aside the water quality certification.

Additionally, under FPA Section 4(e), federal land management agencies can also require measures for the protection, mitigation and enhancement of fish and wildlife resources, including for the protection of terrestrial habitat. BLM is the primary federal land management agency with mandatory conditioning authority under the FPA for federal land around Lake McClure and New Don Pedro Reservoir. In many instances, this has resulted in hydropower operators regulated by FERC developing invasive species management plans and other wildlife management plans.

8.3.2 State

Relevant state programs, policies, plans, or regulations related to terrestrial biological resources are described below.

California Endangered Species Act of 1970

CESA (Fish & G. Code, § 2050 et seq.; Cal. Code Regs, tit. 14, § 783 et seq.) expresses state policy to conserve, protect, restore, and enhance any endangered or threatened species or its habitat. Under CESA, the California Fish and Game Commission has the responsibility for maintaining a list of threatened and endangered species. (Fish & G. Code § 2070.) CESA generally prohibits *take* (defined, in part, as hunt, pursue, catch, capture, or kill) of listed species, although it may allow for take incidental to otherwise lawful activities. (Fish & G. Code, § 2080 et seq.) CDFW also maintains lists of species of special concern that are intended to designate species at conservation risk, stimulate research on poorly known species, and achieve conservation and recovery of species before they are listed under CESA.

Protections under Other Provisions of the California Fish and Game Code

California Fish and Game Code Section 1385 et seq. (known as the California Riparian Habitat Conservation Act) requires that the preservation and enhancement of riparian habitat shall be a primary concern of state agencies whose activities impact riparian habitat. (Fish & G. Code, § 1389.) The California Fish and Game Code also designates certain mammal, amphibian, reptile, fish, and bird species as “fully protected,” making it unlawful to take or possess these species except under certain circumstances. Limestone salamander, which is present around Lake McClure, is a fully protected species. (Fish & G. Code, §§ 3511 [birds], 4700 [mammals], 5050 [reptiles and amphibians], 5515 [fish].) According to CDFW, most fully protected species have also been listed as threatened or endangered. California Fish and Game Code Sections 3503, 3503.5, and 3800 prohibit the possession, take, or needless destruction of the nests or eggs of any bird, and the take of any nongame bird.

California Native Plant Protection Act of 1977

The California Native Plant Protection Act of 1977 (Fish & G. Code, § 1900 et seq.) gives the Fish and Game Commission the authority to designate native plants as endangered or rare, and prohibits the take of designated plants with some exceptions.

California Invasive Species Plans

There are several state invasive species plans used to control the infiltration of invasive species and reduce their prevalence. Various state agencies, including CDFW, the California Department of Food and Agriculture (CDFA), California Department of Parks and Recreation, and California State Lands Commission, have oversight over invasive species. Existing state invasive species control programs include the following.

- The California State Parks Division of Boating and Waterways (CDBW) is the lead agency for the survey and control of Brazilian waterweed, water hyacinth, and South American spongeplant in the Delta, its tributaries, and the Suisun Marsh.
- The Noxious Weed Information Project (NWIP), a product of CDFA, provides maps and other information for CDFA, biologists, and the general public (CDFA 2016).
- Cal-IPC’s mission is to protect California's lands and waters from ecologically-damaging invasive plants through science, education, and policy. Cal-IPC works closely with agencies, industry, and nonprofit organizations to support research, restoration work, and public education (Cal-IPC

2012). It also operates the CalWeedMapper online database that describes, maps, and identifies management opportunities for controlling invasive plants in California.

California Weed Management Areas

California's Weed Management Area (WMA) program was created in 1999 (Food & Agr. Code, § 7270 et seq.) to address the destructive impact of invasive and noxious weeds. CDFA reviews proposals from established weed management areas, which are local stakeholder groups working on weed projects, and awards funding. Weed management areas must have their goals and objectives defined in a strategic plan to receive funding.

The Sierra-San Joaquin Noxious Weed Alliance (Fresno, Madera, and Mariposa Counties) was formed in 1998 and leads programs targeting the early detection and eradication of noxious weeds, as well as specific programs targeting star thistle. The Central Sierra Partnership Against Weeds covers Calaveras and Tuolumne Counties. In Calaveras County, projects have focused specifically on the location and eradication of certain invasive species (Cal-IPC 2012).

8.3.3 Regional or Local

Relevant regional or local programs, policies, plans, or regulations related to terrestrial biological resources are described below. Although local policies, plans, or regulations are not binding on the State of California, below is a description of relevant ones.

San Joaquin County Multi-Species Habitat Conservation Plan

The *San Joaquin County Multi-Species Habitat Conservation and Open Space Plan* was approved in 2001. The geographic scope covers all of San Joaquin County and includes lands within the legal Delta boundary (County of San Joaquin 2000). The habitat conservation plan (HCP) is a 50-year plan and covers a wide variety of federal, state, and other special-status species in San Joaquin County. One of the primary goals of the HCP is to preserve open space, which includes wetland and riparian habitats. Participation in the HCP is voluntary for both local jurisdictions and project applicants. Only agencies adopting the HCP would be covered by the HCP. In addition, the HCP provides for agricultural conservation easements to support species. Approximately 13,000 acres have been entered into a conservation easement (SJCOG n.d). Approximately 64,000 acres is expected to be placed under conservation easements over the life of the permit for the HCP.

General Plans

General plans guide land development within their jurisdictions. Policies and objectives related to natural resources identified in local general plans typically complement state and federal regulations regarding biological resources and protect open space and native biotic communities. General plan policies related to terrestrial biological resources are summarized below.

Calaveras County

The Open Space Element of the *Calaveras County General Plan* addresses the relationship between open space and the protection of rare and endangered species and ecologically sensitive areas (Calaveras County 1996). Policy V-1A and Policy V-2A require review of proposed developments for potential impacts on significant habitats or potential to cause sedimentation of water bodies. Policy V-3A requires review of proposed development for potential impacts on riparian areas.

Tuolumne County

The *Tuolumne County General Plan* (1996) includes policies to maintain biological resource conservation programs (Policy 4.J.2), and support no net loss of wetlands (Policy 4.J.5) and other sensitive habitats (Policy 4.J.6).

Stanislaus County

The Conservation/Open Space Element (Chapter 3) of the *Stanislaus County General Plan* (Stanislaus County 1994) establishes goals and policies for the management of natural resources and the preservation of open space lands. Policy 3 protects sensitive wildlife habitat and plant life identified by the county or by state or federal agencies, Policy 4 protects woodlands and other native hardwood habitat, and Policy 30 protects the habitats of rare and endangered fish and wildlife species.

Merced County

Policies in the Open Space/Conservation chapter of the *Merced County General Plan* (1990) are primarily focused on development and land use. Specific policies ensure adequate protection and monitoring of development projects near rare and endangered species habitats and protect significant aquatic and waterfowl habitats from excessive water withdraws.

Mariposa County

The *Mariposa County General Plan* (2006) outlines programs for the management and conservation of natural resources, including water conservation to sustain riparian communities (Policy 11-2d). The diversity of native ecosystems and plant and animal species in the county is preserved through the Mariposa County Environmental Conservation Program, standards that reduce or eradicate invasive species, and compliance with state and federal regulations (Policy 11-4a).

San Joaquin County

The *San Joaquin County General Plan* includes open space policies that protect resource areas from adverse impacts of development, including protection of habitat for threatened, rare, and endangered species. The County requires that water projects incorporate safeguards for fish and wildlife, and stipulates that no public action shall significantly diminish the county’s wildlife and vegetative resources. The plan protects strips of habitat along waterways and encourages the restoration and enhancement of degraded ecosystems (County of San Joaquin 1992).

8.4 Impact Analysis

This section identifies the thresholds of significance criteria used to evaluate the potential impacts on terrestrial biological resources. It further describes the methods of analysis used to evaluate the potential impacts and to determine the significance of those impacts. Measures to mitigate (i.e., avoid, minimize, rectify, reduce, eliminate, or compensate for) significant impacts accompany the impact discussion, if any significant impacts are identified.

8.4.1 Thresholds of Significance

The thresholds for determining the significance of impacts for this analysis are based on the State Water Board's Environmental Checklist in Appendix A of the Board's CEQA regulations. (Cal. Code Regs., tit. 23, §§ 3720–3781.) Terrestrial biological impacts were determined to be potentially significant in the State Water Board's Environmental Checklist (see Appendix B, *State Water Board's Environmental Checklist*) and therefore are discussed in this analysis. The thresholds derived from the checklist have been modified, as appropriate, to meet the circumstances of the alternatives. (Cal. Code Regs., tit. 23, § 3777, subd. (a)(2).) In this chapter, Impact BIO-3, involving invasive plants and nonnative wildlife, is an additional potential impact meriting analysis as to whether the alternatives could result in the following.

- Have a substantial adverse effect on any riparian habitat or other sensitive natural terrestrial communities identified in local or regional plans, policies, or regulations or by CDFW or USFWS.
- Have a substantial effect on federally protected wetlands as defined by Section 404 of the Clean Water Act (including, but not limited to, marsh, vernal pool, coastal, etc.) through direct removal, filling, hydrological interruption, or other means.
- Facilitate a substantial increase in distribution and abundance of invasive plants or nonnative wildlife that would have a substantial adverse effect on native terrestrial species.
- Have a substantial adverse effect, either directly or through habitat modifications, on any terrestrial animal species identified as a candidate, sensitive, or special-status in local or regional plans, policies, or regulations or by CDFW or USFWS.
- Conflict with the provisions of an adopted habitat conservation plan, natural community conservation plan, or other approved local, regional, or state habitat conservation plan or conflict with any local policies or ordinances protecting biological resources.

Where appropriate specific quantitative or qualitative criteria are described in Section 8.4.2, *Methods and Approach,* for evaluating these thresholds.

As discussed in Appendix B, the LSJR and SDWQ alternatives would result in either no impact or less-than-significant impacts on the following related to terrestrial biological resources and, therefore, are not discussed within this chapter.

- Interfere substantially with the movement of any native resident or migratory fish or wildlife species or with established native resident or migratory wildlife corridors, or impede the use of native wildlife nursery sites.

8.4.2 Methods and Approach

This section describes the methods and approach for analyzing the LSJR and SDWQ alternatives.

LSJR Alternatives

This chapter evaluates the potential biological terrestrial impacts associated with the LSJR alternatives. Each LSJR alternative includes a February–June unimpaired flow[5] requirement (i.e., 20, 40, or 60 percent) and methods for adaptive implementation to reasonably protect fish and wildlife beneficial uses, as described in Chapter 3, *Alternatives Description*. In addition, a minimum base flow is required at Vernalis at all times during this period. The base flow may be adaptively implemented as described below and in Chapter 3. State Water Board approval is required before any method can be implemented, as described in Appendix K, *Revised Water Quality Control Plan*. All methods may be implemented individually or in combination with other methods, may be applied differently to each tributary, and could be in effect for varying lengths of time, so long as the flows are coordinated to achieve beneficial results in the LSJR related to the protection of fish and wildlife beneficial uses.

The Stanislaus, Tuolumne, and Merced Working Group (STM Working Group) will assist with implementation, monitoring, and assessment activities for the flow objectives and with developing biological goals to help evaluate the effectiveness of the flow requirements and adaptive implementation actions. Further details describing the methods, the STM Working Group, and the approval process are included in Chapter 3 and Appendix K. Without adaptive implementation, flow must be managed such that it tracks the daily unimpaired flow percentage based on a running average of no more than 7 days. The four methods of adaptive implementation are described briefly below.

1. Based on best available scientific information indicating that more flow is needed or less flow is adequate to reasonably protect fish and wildlife beneficial uses, the specified annual February–June minimum unimpaired flow requirement may be increased or decreased to a percentage within the ranges listed below. For LSJR Alternative 2 (20 percent unimpaired flow), the percent of unimpaired flow may be increased to a maximum of 30 percent. For LSJR Alternative 3 (40 percent unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 30 percent or increased to a maximum of 50 percent. For LSJR Alternative 4 (60 percent unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 50 percent.
2. Based on best available scientific information indicating a flow pattern different from that which would occur by tracking the unimpaired flow percentage would better protect fish and wildlife beneficial uses, water may be released at varying rates during February–June. The total volume of water released under this adaptive method must be at least equal to the volume of water that would be released by tracking the unimpaired flow percentage from February–June.
3. Based on best available scientific information, release of a portion of the February–June unimpaired flow may be delayed until after June to prevent adverse effects to fisheries, including temperature, that would otherwise result from implementation of the February–June flow requirements. The ability to delay release of flow until after June is only allowed when the unimpaired flow requirement is greater than 30 percent. If the requirement is greater than 30 percent but less than 40 percent, the amount of flow that may be released after June is

---

[5] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.

limited to the portion of the unimpaired flow requirement over 30 percent. For example, if the flow requirement is 35 percent, 5 percent may be released after June. If the requirement is 40 percent or greater, then 25 percent of the total volume of the flow requirement may be released after June. As an example, if the requirement is 50 percent, at least 37.5 percent unimpaired flow must be released in February–June and up to 12.5 percent unimpaired flow may be released after June. If after June the STM Working Group determines that conditions have changed such that water held for release after June should not be released by the fall of that year, the water may be held until the following year. See Chapter 3 and Appendix K for further details.

4. Based on best available scientific information indicating that more flow is needed or less flow is adequate to reasonably protect fish and wildlife beneficial uses, the February–June Vernalis base flow requirement of 1,000 cubic feet per second (cfs) may be modified to a rate between 800 and 1,200 cfs.

The operational changes made using the adaptive implementation methods above may be approved if the best available scientific information indicates that the changes will be sufficient to support and maintain the natural production of viable native SJR Watershed fish populations migrating through the Delta and meet any biological goals. The changes may take place on either a short-term (e.g., monthly or annually) or longer-term basis. Adaptive implementation is intended to foster coordinated and adaptive management of flows based on best available scientific information in order to protect fish and wildlife beneficial uses. Adaptive implementation could also optimize flows to achieve the objective, while allowing for consideration of other beneficial uses, provided that these other considerations do not reduce intended benefits to fish and wildlife. While the measures and processes used to decide upon adaptive implementation actions must achieve the narrative objective for the reasonable protection of fish and wildlife beneficial uses, adaptive implementation could result in flows that would benefit or reduce impacts on other beneficial uses that rely on water. For example, terrestrial riparian species could benefit by receiving additional flows during key germination times in the late spring.

Information from Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*, and results from the State Water Board's Water Supply Effects (WSE) model presented in Chapter 5, *Surface Hydrology and Water Quality,* and Appendix F.1, *Hydrologic and Water Quality Modeling,* was reviewed. The quantitative results included in the figures, tables, and text of this chapter present WSE modeling of the specified unimpaired flow requirement for each LSJR alternative (i.e., 20, 40, or 60 percent). This chapter also incorporates a qualitative discussion of adaptive implementation under each of the LSJR alternatives that includes the potential environmental effects associated with adaptive implementation.
To inform the qualitative discussion and account for the variability allowed by adaptive implementation, modeling was performed to predict conditions at 30 percent and 50 percent of unimpaired flow (as reported in Appendix F.1). The modeling also allows some inflows to be retained in the reservoirs until after June, as could occur under method 3, to prevent adverse temperature effects. This variety of modeling scenarios provides information to support the analysis and evaluation of the effects of the alternatives and adaptive implementation. This chapter incorporates a qualitative discussion of the potential terrestrial biological resource impacts of adaptive implementation under each of the LSJR alternatives. For more information regarding the modeling methodology and quantitative flow and temperature modeling results, see Appendix F.1.

Rivers

Plans, policies, and regulations reviewed in the preparation of this analysis have indicated that the area of potential effects includes a variety of riparian communities, freshwater marsh, and elderberry savanna (See Section 8.2.1, *LSJR and the Three Eastside Tributaries*; State Water Board 1999; USFWS 2012; Riparian Habitat Joint Venture 2004; Moyle and Bennett 2008; Moise and Hendrickson 2002; Sawyer et al. 2009; CDFG 2012, 2003). Impact BIO-1 focuses on potential impacts on riparian habitats in the context of the California Riparian Habitat Conservation Act. Impacts on freshwater marsh are discussed in Impact BIO-2. Impacts on the elderberry savanna are not further considered because this community occurs on floodplains (USBR 2010a), and some increased inundation as a result of the LSJR alternatives (Chapter 6, *Flooding, Sediment, and Erosion,* Impact FLO-2) would be beneficial overall (as discussed under Impact BIO-4). However, individual elderberry shrubs are found in riparian vegetation and habitat within or near river channels that may be frequently inundated; as such, the effects on species relying on elderberry shrubs are included in Impact BIO-4.

General trends identified in the WSE for the LSJR alternatives are used in the analysis to qualitatively evaluate impacts on terrestrial biological resources. Annual averages or monthly averages for flow in each river are used where appropriate. In addition, as described in Chapter 5, *Surface Hydrology and Water Quality,* Section 5.4.3, the cumulative distribution[6] of flows for February–June are also used to compare baseline conditions to LSJR alternative conditions. The cumulative distribution of flows is used because they provide an accurate summary of the range of flows expected over a number of years. The comparison of monthly cumulative distributions of flows, in conjunction with the individual monthly average changes in flow, provides an appropriate measure of hydrologic changes resulting from the LSJR alternatives. Therefore, this information is used to evaluate the expected type of terrestrial habitat conditions under baseline and LSJR alternative conditions (see Appendix F.1, *Hydrologic and Water Quality Modeling*, Sections F.1.3 and F.1.4, for additional information and summary data regarding cumulative distributions). These trends are summarized below.

- For LSJR Alternative 2, modeled monthly flows on the Stanislaus River were generally similar to baseline flows, although with some small shifting of flows from March to June. Flows for the Merced and Tuolumne Rivers and the LSJR were generally similar to or greater than baseline flows, depending on the month (Tables 5-16 and 5-17a, 5-17b, 5-17c, and 5-17d).
- For LSJR Alternatives 3 and 4, modeled monthly flows would generally increase relative to baseline flows on the Merced, Tuolumne, and Stanislaus Rivers and the LSJR (Tables 5-16 and 5-17a, 5-17b, 5-17c, and 5-17d). In most cases, these rivers would experience substantial increases in median flows from February–June relative to baseline.
- For LSJR alternatives 3 and 4, modeled results indicated occasional reductions in the highest flows caused by a reduced need for flood control releases when compared to baseline conditions. Flood control releases were most likely to occur when the reservoirs were filling

---

[6] The cumulative distribution of a particular variable (i.e., reservoir elevations) provides a basic summary of the distribution of values. This term is not referring to, and should not be confused with, the term cumulative impacts, which is a specific CEQA term. A discussion of cumulative impacts for CEQA purposes is provided Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*; Chapter 16, *Evaluation of Other Indirect and Additional Actions;* and Chapter 17, *Cumulative Impacts, Growth-Inducing Effects, and Irreversible Commitment of Resources.*

with storm flows or when the reservoirs had to be emptied in the fall in preparation for storms in winter and spring. Flood control releases occurred more often in wet years and were more common at Don Pedro Reservoir and Lake McClure (i.e., the two smaller reservoirs). During wet years, reservoir releases were greater under LSJR Alternatives 3 and 4, so reservoir storage would reach the maximum allowed limit less often and flood control releases would not be needed as much.

- The largest changes in flow associated with the LSJR alternatives occurred from February–June, but there were some smaller effects outside of this period. Changes from July–January were primarily related to changes in flood control releases, retention of unimpaired flow for later release in the fall as part of adaptive implementation described under the LSJR alternatives in Section 8.4.3, *Impacts and Mitigation Measures*, during wet conditions, and retention of water in the reservoirs to maintain carryover storage (by reducing diversions in dry years).
- Actions required by the NMFS BO (Stanislaus River reasonable and prudent alternative, including Action 3.1.3), are included in the baseline for modeling purposes. Under the modeled conditions of the LSJR alternatives, these flows would be met or exceeded. The WSE modeling of the LSJR alternatives assumes that a certain percent of unimpaired flow would be met. However, if the NMFS BO flows are higher than the percent unimpaired flow, then the NMFS BO flow becomes the target flow.

Modeling results predict that LSJR Alternatives 3 and 4 would increase flows on the LSJR February–June. These flows would be distributed between Old River, Middle River, and the SJR downstream of Vernalis and would contribute to an environment that is also affected by water diversions, tidal action, and Sacramento River inflow. Flows caused by the LSJR alternatives would largely be confined within existing channels. Therefore, as described in Chapter 6, there would not be a significantly increased risk of flooding. Also, the effects of Alternatives 3 and 4 on water surface elevation in the southern Delta would be relatively small because water surface elevation in much of the region is dominated by tidal effects. Any increase in elevation of the groundwater table or seepage that may result from higher water levels would be small and would tend to benefit native terrestrial Delta species. Therefore, this analysis does not consider potential impacts of the LSJR alternatives below Vernalis.

Reservoirs

Baseline conditions and LSJR alternative water surface elevations for the three reservoirs (New Melones, Don Pedro, and Lake McClure), are presented in Appendix F.1, *Hydrologic and Water Quality Modeling* (Tables F.1.3-5c, F.1.3-5i, F.1.3-5m, F.1.3-6b, F.1.3-6f, F.1.3-6j, F.1.3-7b, F.1.3-7f, F.1.3-7j, F.1.3-8b, F.1.3-8f, F.1.3-8j). Vegetation along the shores of New Melones Reservoir, New Don Pedro Reservoir, and Lake McClure, as well as birds and other wildlife that may use the reservoirs, are accustomed to fluctuations in reservoir elevation that occur under baseline conditions. WSE results for baseline conditions indicate that for most years there are large fluctuations in water surface elevations in the three reservoirs. The median range between the yearly minimum and maximum elevations over the 82-year baseline simulation was 63 ft for New Melones Reservoir, 54 ft for New Don Pedro Reservoir, and 88 ft for Lake McClure. New Melones Reservoir minimum fluctuation range is 24 ft and its maximum fluctuation range is 232 ft ; New Don Pedro Reservoir minimum fluctuation range is 25 ft and maximum fluctuation range is 151 ft ; and Lake McClure's minimum fluctuation range is 29 ft and maximum fluctuation range is 320 ft . Because terrestrial biological resources that use the reservoirs are accustomed to large interannual and annual variations in the reservoirs' water surface elevation that occur as part of normal reservoir operations, small changes in reservoir elevations are unlikely to affect terrestrial biological resources. Tables 8-7a, 8-7b, and 8-7c characterize the potential water surface fluctuations under the LSJR alternatives. For the purpose of comparison, the tables summarize the percent of time the reservoirs would fluctuate more than 10 ft from one month to the next. The results show that the fluctuation of water surface elevations under the LSJR alternatives is expected to be similar to baseline conditions.

This information was presented to qualitatively evaluate direct and indirect impacts on terrestrial biological resources as a result of the implementation of the LSJR alternatives in Impacts BIO-1 through BIO-5. Direct impacts were defined as actions that were likely to result in immediate plant or animal mortality or complete habitat loss. Indirect impacts were defined as delayed effects, nonfatal stresses upon plants and animals, and/or habitat degradation.

LSJR Alternatives and the Southern Delta

Habitats and the dominant terrestrial wildlife and plant species in the southern Delta tolerate fluctuations in salinity and regularly experience tidal influences and salinity inputs from other sources (e.g., upstream sources). Salinity in the southern Delta generally ranges between 0.2 dS/m and 1.2 dS/m during all months of the year, and salinity at Vernalis is almost always below the current objective (maximum 30-day running average of 0.7 from April through August or 1.0 dS/m from September through March). In addition, a strong relationship is observed between salinity at Vernalis and salinity in the southern Delta; the measured EC[7] at Brandt Bridge is increased by a maximum of 0.2 dS/m above the Vernalis salinity (Figure F.1.5-2a) and is increased by a maximum of 0.4 dS/m at Tracy Boulevard (Figure F.1.5-2b). The volume of water needed to meet the Vernalis EC objective is included in the WSE modeling results and, therefore, is in the impact determinations for the LSJR alternatives. This information is used to qualitatively assess the effects of the LSJR alternatives on water quality, specifically salinity, in the southern Delta with respect to terrestrial habitat and species (Impacts BIO-1 and BIO-4).

Area of Potential Indirect Effects

Agricultural practices and land cover depend on a wide variety of factors, including the unique circumstances and decisions made by farmers in the plan area, market conditions, and the location of different agricultural properties and crops; therefore, this chapter provides a qualitative evaluation of potential indirect effects on sensitive wildlife species and habitat resulting from a reduction of irrigation water supply to agricultural fields using information regarding agricultural land cover and practices. Habitat requirements for San Joaquin Valley representative, or keystone species, such as blunt nosed leopard lizard, San Joaquin kit fox, and Swainson's hawk are discussed in the context of potential changes in agricultural land cover that could occur in the area of potential indirect effects. A qualitative discussion of the potential for invasive species to occur as a result of reduced irrigation water supply is also discussed.

---

[7] In this document, EC is *electrical conductivity*, which is generally expressed in deciSiemens per meter (dS/m). Measurement of EC is a widely accepted indirect method to determine the salinity of water, which is the concentration of dissolved salts (often expressed in parts per thousand or parts per million). EC and salinity are therefore used interchangeably in this document.

Extended Plan Area

The analysis of the extended plan area generally identifies how the impacts may be similar to or different from the impacts in the plan area (i.e., downstream of the rim dams) depending on the similarity of the impact mechanism (e.g., changes in reservoir levels, reduced water diversions, and additional flow in the rivers) or location of potential impacts in the extended plan area. Where appropriate, the program of implementation is discussed to help contextualize the potential impacts in the extended plan area.

SDWQ Alternatives

The habitats and the dominant terrestrial wildlife and plant species in the southern Delta tolerate fluctuations in salinity and regularly experience tidal influences and salinity inputs from other sources (e.g., upstream sources). Therefore, terrestrial biological resources in the Southern Delta can only be significantly affected if salinity levels change so substantially that existing habitat or plants could not survive. As discussed in Chapter 5, *Surface Hydrology and Water Quality*, the existing water quality in the southern Delta generally ranges between 0.2 dS/m and 1.2 dS/m during all months of the year. In addition, there is a strong relationship between salinity at Vernalis and salinity in the southern Delta, which increases by a maximum of 0.4 dS/m above the Vernalis salinity at locations downstream.

The program of implementation for the SDWQ alternatives would still include the requirement for USBR to maintain salinity at Vernalis in accordance with its water rights. Therefore, the SDWQ alternatives are not expected to affect the overall quantity or quality of the habitats in the southern Delta. Exact data on the salt tolerance of individual plant species present in the Delta is not readily available and depends on a host of interrelated factors. However, native Delta plant species are adapted to brackish waters and salinity levels that have historically existed in the southern Delta. Additionally, periodic salinity intrusion into the Delta may help to reduce the abundance and/or distribution of certain harmful invasive species and give native species a competitive advantage (Carter and Nippert 2012). There is no mechanism for the SDWQ alternatives, which would only modify the salinity objectives, to result in fill or physical modification of wetlands that occur within the southern Delta.

The modeling results indicated that under SDWQ Alternatives 2 or 3, exceedances (described in Section 8.3.2, *State [Regulatory Background]*) would not increase relative to baseline and the salinity in the LSJR and southern Delta would remain similar to baseline or be reduced (Appendix F.1, Section F.1.5.2, *Salinity Modeling Results*). As a result, there is limited potential for the SDWQ alternatives to impact terrestrial species in the southern Delta as salinity in the southern Delta would remain within the historical range, and the terrestrial plant and animal species can adapt to the variable salinity levels that the southern Delta currently experiences. Consequently, there would be little to no change from baseline; therefore, the SDWQ alternatives are not discussed further in this chapter. However, to comply with specific water quality objectives or the program of implementation under SDWQ Alternatives 2 or 3, construction and operation of different facilities in the southern Delta could occur, which could involve impacts on biological resources. These impacts are evaluated in Chapter 16, *Evaluation of Other Indirect and Additional Actions*.

Table 8-7a. Percent of Time Water Surface Elevation Fluctuation Greater than 10 Feet from Month to Month for New Melones Reservoir

	OCT	NOV	DEC	JAN	FEB	MAR	APR	MAY	JUN	JUL	AUG	SEP
Baseline % Fluctuation	5	1	16	24	34	26	28	52	46	62	68	10
LSJR Alternative 2 Fluctuation	2	1	10	21	29	20	15	38	30	52	60	6
LSJR Alternative 3 Fluctuation	5	1	12	27	24	21	11	27	17	34	34	4
LSJR Alternative 4 Fluctuation	6	2	13	28	15	11	9	21	4	21	23	5

Note: lower percentages indicate less fluctuation greater than 10 feet occurring at a reservoir.

Table 8-7b. Percent of Time Water Surface Elevation Fluctuation Greater than 10 Feet from Month to Month for New Don Pedro Reservoir

	OCT	NOV	DEC	JAN	FEB	MAR	APR	MAY	JUN	JUL	AUG	SEP
Baseline % Fluctuation	0	2	15	17	28	20	10	32	55	79	96	6
LSJR Alternative 2 Fluctuation	0	2	17	18	29	21	9	27	45	78	91	4
LSJR Alternative 3 Fluctuation	1	4	22	27	34	28	5	22	33	73	78	18
LSJR Alternative 4 Fluctuation	2	4	23	28	28	24	5	28	17	22	48	13

Note: lower percentages indicate less fluctuation greater than 10 feet occurring at a reservoir.

Table 8-7c. Percent of Time Water Surface Elevation Fluctuation Greater than 10 Feet from Month to Month for Lake McClure

	OCT	NOV	DEC	JAN	FEB	MAR	APR	MAY	JUN	JUL	AUG	SEP
Baseline % Fluctuation	44	10	15	24	33	52	57	80	38	96	98	93
LSJR Alternative 2 Fluctuation	32	1	9	17	27	46	56	74	32	93	95	79
LSJR Alternative 3 Fluctuation	43	4	16	23	29	48	48	71	20	88	91	67
LSJR Alternative 4 Fluctuation	35	10	18	27	28	39	26	48	22	60	90	49

Note: lower percentages indicate less fluctuation greater than 10 feet occurring at a reservoir.

8.4.3 Impacts and Mitigation Measures

Impact BIO-1: Have a substantial adverse effect on any riparian habitat or other sensitive natural terrestrial communities identified in local or regional plans, policies, or regulations or by CDFW or USFWS

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 *Water Quality Control Plan for the San Francisco/Sacramento–San Joaquin Delta Estuary* (2006 Bay–Delta Plan). See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

Riparian habitats are tolerant of seasonal fluctuations in river flows. Adaptations, such as extremely rapid life cycles that maximize opportunities for replenishment of the soil seed bank prior to subsequent inundation flooding or the onset of drought, allow for species to thrive in variable environments (Capon and Dowe 2006). Despite this tolerance of variability, exceptionally low summer stages (drought) or high water stages year-round can lead to desiccation or inundation mortality, respectively, and are two of the major drivers affecting the composition and success of sensitive habitats and plant species along rivers. In general, unimpaired flow regimes are more seasonally variable. The result of flow regulation has, in many cases, been a reduction in vegetation heterogeneity that has led to eventual loss of biodiversity (Capon and Dowe 2006).

Most riparian vegetation within the area of potential effects is riparian forest or willow scrub. The typical dominant species of these habitats (e.g., sandbar willow) are particularly resistant to damage by scour or burial (USBR 2010a). In addition, scour and deposition of sediment can sustain floodplain habitats and create opportunities for plant establishment, thus sustaining the diversity of riparian vegetation.

In many locations and times of year throughout the area of potential effects, the LSJR alternatives could increase surface water or groundwater elevations, potentially resulting in submergence of the root zones and aboveground aspects of vegetation. This condition may cause dieback of nonnative and upland species that are not adapted to periodic inundation, while an increase in water availability during the growth period for riparian vegetation (generally late spring to early fall) could encourage the growth of native species. Additionally, it is expected that the LSJR alternatives could periodically inundate some areas that do not currently support riparian vegetation. This periodic inundation could create conditions suitable for dispersal and establishment of riparian plants through sediment deposition, water transport of plant seeds and fragments to new locations, increased water availability, and reduced competition from upland plant species (e.g., nonnative grasses) that are intolerant of prolonged submergence. Certain plants, such as deep-rooted trees, are more likely to persist in variable environments because they are able to access groundwater (Capon and Dowe 2006). Therefore, manipulation of flow regimes during critical seasons can potentially augment recruitment and survival of riparian tree species, particularly willows and cottonwoods (Moise and Hendrickson 2002). Activities that support the establishment and success of native species are generally consistent with the goals and policies contained in the SJR National Wildlife Refuge CCP, the San Joaquin County Multi-Species HCP, and applicable general plans.

The ability of a reservoir to support riparian vegetation is a function of reservoir size (larger reservoirs generally have a greater circumference and, therefore, more potential for hydrologic connectivity), adjacent land use, and the speed and frequency at which drawdown occurs. Riparian plants are typically resilient to changes in reservoir levels (Waring 1992). Other habitat features like the presence of small tributaries entering the main reservoir can create small areas of wetland and riparian habitats around the reservoir edge. Riparian habitats at the reservoirs in the area of potential effects are currently subject to fluctuating water levels (see Tables 8-7a, 8-7b, and 8-7c for the expected changes in water level fluctuation for each reservoir). Furthermore, in many cases there is a lack of vegetation in the zone of fluctuation created by variations in water surface elevation. Within this zone, it is difficult for plant species (e.g., riparian or other sensitive plant species) to fully establish because of the propensity for flooding and loss of topsoil from wave erosion however some areas of wetland and riparian habitat have been established (Merced ID 2011a). Shore erosion may occur at all water surface elevations but is generally most severe when water surface elevations change rapidly (Baird and Associates 2004). Water surface elevation fluctuations at the major rim reservoirs tend to follow seasonal patterns, with high water levels occurring during the late spring and early summer and progressively lower water levels occurring during the late summer and fall.

Habitats and the dominant terrestrial wildlife and plant species in the southern Delta tolerate fluctuation in salinity and regularly experience tidal influences and salinity inputs from other sources (e.g., upstream sources). Exact data on the salt tolerance of individual plant species present in the Delta are not readily available and depend on a host of interrelated factors. However, native Delta plant species are adapted to brackish waters and salinity levels that have historically existed in the southern Delta as described above in Section 8.4.2, *Methods and Approach*, and in Chapter 5, *Surface Hydrology and Water Quality*. Additionally, periodic salinity intrusion into the Delta may help to reduce the abundance and/or distribution of certain harmful invasive species and give native species a competitive advantage (Carter and Nippert 2012).

LSJR Alternative 2 (Less than significant/Less than significant with adaptive implementation)

Rivers

The modeling results indicate that under LSJR Alternative 2, the Stanislaus River would experience median flows similar to baseline flows (Table 5-16 and 5-17c). The largest changes in median flow associated with LSJR Alternative 2 relative to baseline in the Stanislaus River were a decrease of 15 percent in March and an increase of 24 percent in June. The overall cumulative distribution of the flows (i.e., the range of flows distributed between the minimum flow [thousand acre-feet] and the maximum flow over the entire 82-year historic modeling period) would be similar under LSJR Alternative 2 when compared to baseline conditions (Table 5-16 and 5-17c). This means that the total volume of water available February–June on the Stanislaus River would be similar when compared to baseline conditions. The baseline flows on the Stanislaus are high from February–June as a result of the Vernalis Adaptive Management Program flow requirements and the mandated pulse flows required by the NMFS BO; however, the flow requirements under LSJR 2 (the maximum of the NMFS BO flows or 20 percent of the unimpaired flow) produce river flows that are similar to baseline. Impacts on riparian habitat or other sensitive natural terrestrial communities would be less than significant.

Modeling results indicate that the median monthly flows would generally be very similar to or greater than baseline flows on the Tuolumne and Merced Rivers, and LSJR under LSJR Alternative 2. Furthermore, the overall volume of water described by the cumulative distribution of flows February–June would be slightly greater than baseline (Table 5-16 and 5-17a, 5-17b, and 5-17d). Therefore, significant impacts on riparian vegetation or other sensitive plant communities on the Tuolumne and Merced Rivers and LSJR are not expected. Impacts would be less than significant.

Scour and deposition of sediment would not be expected to adversely affect riparian vegetation because riparian scrub is tolerant of these types of physical processes. Furthermore, flows under LSJR Alternative 2 on all three eastside tributaries and the LSJR are not expected to result in substantial bed mobilization or channel modification, as discussed in Chapter 6, *Flooding, Sediment, and Erosion*, Section 6.4.3, *Impacts and Mitigation Measures*, and Chapter 7, *Aquatic Biological Resources*, Section 7.4.3, *Impacts and Mitigation Measures*, when compared to baseline conditions. For these reasons, significant impacts on riparian communities and other sensitive plant communities are not expected. Impacts would be less than significant.

Reservoirs

Under LSJR Alternative 2, all three reservoirs would generally experience little change or a decrease in substantial water surface elevation fluctuations (i.e., fluctuations greater than 10 ft) relative to baseline (Tables 8-7a, 8-7b, and 8-7c). This would result in a more stable nearshore environment. A decrease in the fluctuation of reservoir water surface elevation may permit some vegetation establishment in the zone of fluctuation. However, such colonization would be limited by substrate suitability because these nearshore areas often lack topsoil in the zone of historical fluctuation due to erosion caused by existing surface water elevation changes and wave action. The changes in surface water elevation fluctuation expected under the LSJR alternatives at Lake McClure are not expected to adversely impact habitat for limestone salamander. Riparian habitat or other sensitive plant communities at the reservoirs are not expected to be substantially altered because established riparian habitat, terrestrial communities, and special-status plant species are also sustained by groundwater and are adapted to brief changes in water surface elevations at the reservoirs. Impacts on riparian habitat, other sensitive terrestrial plant communities, or special-status plant species at the reservoirs would be less than significant.

Southern Delta

Modeled results indicate that EC values in the southern Delta could increase or decrease depending on which SDWQ Alternative is implemented (Tables 5-25 and 5-26a, 5-26b, and 5-26c), but overall salinity in the southern Delta would be slightly reduced (Tables 5-29a, 5-29b, and 5-29c) under LSJR Alternative 2. These changes with respect to terrestrial habitat would be very small, if imperceptible. April–September is the irrigation season when, historically, salinity increases as a result of agricultural irrigation runoff. Tables 5-29a, 5-29b, and 5-29c indicate that the change in the April–September (irrigation season) EC values are generally small. Of the three sites evaluated, the largest changes are expected to occur in Old River at Tracy Boulevard. Table 5-29c indicates that the largest changes in the April–September (irrigation season) EC distribution at Tracy Boulevard from baseline to LSJR Alternative 2 was a reduction in the maximum values of 0.62 dS/m (1.038–0.977

dS/m). These changes with respect to terrestrial habitat would be very small, if measurable at all, because riparian habitat plant species in the southern Delta tolerate variable salinity conditions. Therefore, LSJR Alternative 2 is not expected to impact the overall quantity or quality of the habitats in the southern Delta, and impacts would be less than significant.

Adaptive Implementation

Based on best available scientific information indicating that a change in the percent of unimpaired flow is needed to reasonably protect fish and wildlife, adaptive implementation method 1 would allow an increase of up to 10 percent over the 20 percent February–June unimpaired flow requirement (to a maximum of 30 percent of unimpaired flow). A change to the percent of unimpaired flow would take place based on required evaluation of current scientific information and would need to be approved as described in Appendix K, *Revised Water Quality Control Plan*. Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time. However, an increase of up to 30 percent of unimpaired flow would potentially result in different effects as compared to 20 percent unimpaired flow, depending upon flow conditions and frequency of the adjustment. The increased flows would potentially benefit riparian habitat because increased water levels during the late spring early summer months would entail a longer growing season with water levels at higher elevations, and as such would promote additional riparian vegetation recruitment at higher elevations along the steam banks and channels.

Based on best available scientific information indicating that a change in the timing or rate of unimpaired flow is needed to reasonably protect fish and wildlife, adaptive implementation method 2 would allow changing the timing of the release of the volume of water within the February–June timeframe. While the total volume of water released February–June would be the same as LSJR Alternative 2 without adaptive implementation, the rate could vary from the actual (7-day running average) unimpaired flow rate. Method 2 would not authorize a reduction in flows required by other agencies or through other processes, which are incorporated in the modeling of baseline conditions. As such, flows would not substantially decrease with respect to baseline conditions and would not substantially affect any riparian habitat or other sensitive natural terrestrial communities.

Adaptive implementation method 3 would not be authorized under LSJR Alternative 2 since the unimpaired flow percentage would not exceed 30 percent.

Adaptive implementation method 4 would allow an adjustment of the Vernalis February–June flow requirement. WSE results show that under LSJR Alternative 2 the 1,200 cfs February–June base flow requirement at Vernalis would require a flow augmentation in the three eastside tributaries and LSJR only 2.7 percent of the time in the 82-year record analyzed. Similarly, flow augmentation would be required 0.7 percent of the time to meet a 1,000 cfs requirement and 0.5 percent of the time for an 800 cfs Vernalis base flow requirement. These results indicate that changes due to method 4 under this alternative would rarely alter the flows in the three eastside tributaries or the LSJR. As such, flows under adaptive implementation method 4 would not substantially decrease with respect to baseline conditions and would not substantially affect any riparian habitat or other sensitive natural terrestrial communities.

Impacts associated with adaptive implementation method 1 may be slightly different from those associated with methods 2 and 3. With method 1, if the specified percent of unimpaired flow were changed from 20 percent to 30 percent on a long-term basis, the conditions and impacts could become more similar to those described under LSJR Alternative 3. It is anticipated that over time the unimpaired flow requirement could increase or not change at all within a year or between years, depending on fish and wildlife conditions and hydrology. If method 2 is implemented, the total annual volume of water associated with LJSR Alternative 2 (i.e., 20 percent of the February–June unimpaired flow) would not change. As a result, the total volume of water that would remain in the river would not change with adaptive implementation method 2 and impacts associated with total volume of water would not change. Terrestrial biological resources, such as riparian species that are dependent on the timing or magnitude of flow, could potentially be affected by method 2. This method would not allow flows to go below what is required by existing requirements on the three eastside tributaries and the SJR. As such, impacts would be similar to those described above for LSJR Alternative 2 without adaptive implementation. Implementing method 4 is expected to have little effect on conditions in the three eastside tributary rivers and LSJR because it rarely would cause a change in flow and the volume of water involved would be relatively small. Consequently, the impact determination of LSJR Alternative 2 with adaptive implementation would be the same as described for LSJR Alternative 2 without adaptive implementation. Impacts would be less than significant.

LSJR Alternative 3 (Less than significant/Less than significant with adaptive implementation)

Rivers

Modeled results indicate LSJR Alternative 3 would generally result in higher monthly flows on the Stanislaus, Merced, and Tuolumne Rivers and the LSJR (Tables 5-16 and 5-17a, 5-17b, 5-17c, and 5-17d). In most cases, these rivers would experience substantial increases in median flows from February–June under LSJR Alternative 3 relative to baseline. Changes during other months would be smaller. In some limited instances, LSJR Alternative 3 would result in reducing/peak flows when compared to baseline, primarily as a result of a reduced need for flood control releases.

Riparian habitat generally would not experience lower flows than they currently do under baseline conditions as a result of this alternative. Plants persisting in riparian habitats are adapted to survive periodic episodes of fluvial (high flow) disturbance (Capon and Dowe 2006). Therefore, any expected higher flows under this alternative would have limited potential to submerge existing vegetation frequently enough and long enough to result in impacts on native riparian plant communities or special-status plant species. The flows modeled for LSJR Alternative 3 are such that riparian vegetation is expected to adjust to the new flow regime (State Water Board 1999).
Any increase in flows would be expected to ultimately result in a net increase in acreage and diversity of riparian and emergent wetland vegetation, depending on the degree of channelization of the river and the encroachment of conflicting land uses. Increasing flows would result in occasional wetting of channels that are typically dry under current conditions and would have potentially beneficial effects. This may promote the natural process of succession, during which willow riparian forest may transition to valley oak riparian forest. Vegetation that has been established in the channel during low baseline flows may be eliminated. Although the alternative may result in a measurable shift in riparian habitats, compositional changes in this dynamic habitat would not be adverse. These changes would support the establishment and persistence of riparian and wetland vegetation. Furthermore, as described in Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*, periodic high flows promote regeneration of riparian habitats. In periods of inundation during spring nonflood releases, floodplains and side channels may be inundated, and surface or groundwater would be accessible to plants over a greater area than at present. Riparian tree species along these rivers have evolved life

history strategies that depend on the river's historical hydrology, including the annual cycles of winter floods and spring snowmelt, as well as infrequent large spring floods (Stillwater Sciences 2003b). The limited instances of lower flows when compared to higher baseline flow conditions on the three eastside tributaries and the LSJR under this alternative are not expected to adversely affect riparian habitat because these reductions generally occur when flow is high and are associated with flood control conditions. Thus, they are not expected to cause a lack of water needed to support riparian vegetation. Therefore, when considering the expected increase in flows and the limited instances in which there would be a reduction in flows, it is not expected that there would be significant impacts on riparian communities and other sensitive plant communities. Impacts would be less than significant.

Reservoirs

The frequency and range in fluctuations of water surface elevations at the reservoirs would generally decrease or remain similar to baseline conditions and generally would not experience a significant increase in fluctuations greater than 10 ft throughout the year (Tables 8-7a, 8-7b, and 8-7c). From December–March, there would be small increases in reservoir elevation fluctuations—greater than 10 ft (increases of 5 percent or less)—at New Don Pedro Reservoir and Lake McClure, but in other months, these fluctuations would decrease relative to baseline. As described above for LSJR Alternative 2, conditions in the zone of fluctuation would generally remain similar to those under baseline conditions at the reservoir, in part because the disturbed substrate would provide limited opportunities for additional vegetation establishment. Impacts on riparian habitat or other sensitive terrestrial communities, such as habitat for limestone salamander around Lake McClure and the Red Hills and Bagby Serpentine ACECs, or special-status plant species would be less than significant.

Southern Delta

Modeled results indicate that EC values in the southern Delta would decrease (Table 5-25 and Tables 5-27a, 5-27b, and 5-27c), and overall salinity in the southern Delta would be reduced (Tables 5-29a, 5-29b, and 5-29c) under LSJR Alternative 3. These changes with respect to terrestrial habitat would be very small, if imperceptible. Therefore, LSJR Alternative 3 is not expected to impact the overall quantity or quality of the habitats in the southern Delta. Impacts would be less than significant.

Adaptive Implementation

Under LSJR Alternative 3, impacts associated with adaptive implementation method 1 may be slightly different from those associated with adaptive implementation methods 2 and 3.

Implementing method 1 would allow an increase or decrease of up to 10 percent in the February–June, 40 percent unimpaired flow requirement (with a minimum of 30 percent and maximum of 50 percent) to optimize implementation measures to meet the narrative objective, while considering other beneficial uses, provided that these other considerations do not reduce intended benefits to fish and wildlife. Adaptive implementation must be approved using the process described in Appendix K, *Revised Water Quality Control Plan*. Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time. Adaptive implementation method 1 could affect the amount of water available for water supply and the volume of water and level of flow in the LSJR and the three eastside tributaries. However, the frequency and duration of such a change is unknown. If the specified percent of unimpaired flow were changed from 40 percent to 30 percent or 40 percent to 50 percent on a long-term basis, the conditions and impacts could become more similar to LSJR Alternatives 2 or 4, respectively. It is anticipated that over time the unimpaired flow requirement could increase, decrease, or not change at all within a year or between years, depending on fish and wildlife conditions and hydrology. At those times of increased flows, 50 percent unimpaired flow would increase the volume of water in the LSJR and the three eastside tributaries compared to 40 percent unimpaired flow. This would potentially benefit riparian habitat because the increased water levels during the late spring early summer months would entail a longer growing season with water levels at higher elevations, and as such would promote additional riparian vegetation recruitment at higher elevations along the steam banks and channels.

Under adaptive implementation methods 2 or 3, the overall volume of water from the February–June time period or after June would be the same as LSJR Alternative 3 without adaptive implementation, but the volume within each month could vary. Impacts associated with the total volume of water would not be affected by method 2 or 3, but terrestrial biological resources, such as riparian species, that are dependent on the timing or magnitude of flow could potentially be affected. Wetland resources are somewhat dependent on the timing or magnitude of flow; however these resources are adapted to natural flood and drought cycles. Higher flows under adaptive implementation method 1 would not exceed the higher range of flows that could be experienced under baseline for some water years. However, given that these two methods would not allow flows to go below what is required by existing requirements on the three eastside tributaries and the LSJR, impacts would be similar to those described above for LSJR Alternative 3 without adaptive implementation. Finally, adaptive implementation method 3 is incorporated into the modeling; thus, the range of terrestrial biological effects is reflected in the results presented above for LSJR Alternative 3 without adaptive implementation.

Implementing method 4 is expected to have little effect on conditions in the three eastside tributary rivers. WSE results show that under Alternative 3 the 1,200 cfs February–June base flow requirement at Vernalis would require a flow augmentation in the three eastside tributaries and LSJR only 1.2 percent of the time in the 82-year record analyzed. Similarly, flow augmentation would be required only 0.2 percent of the time to meet either a 1,000 cfs or 800 cfs Vernalis base flow requirement. These results indicate that method 4 would rarely alter the flows in the three eastside tributaries or the LSJR under this alternative.

Consequently the impact determination of LSJR Alternative 3 with adaptive implementation would be the same as described for LSJR Alternative 3 without adaptive implementation. Impacts would be less than significant.

LSJR Alternative 4 (Less than significant/Less than significant with adaptive implementation)

Rivers

Monthly flows on all three eastside tributaries and the LSJR would generally increase under LSJR Alternative 4 (Table 5-16 and 5-17a, 5-17b, 5-17c, and 5-17d). In most cases, these rivers would experience substantial increases in median flows from February–June under LSJR Alternative 4 relative to baseline. Changes during other months would be smaller. In some limited instances, LSJR Alternative 4 would result in a reduction in flow, and these reductions would affect the highest flows when compared to baseline.

The impacts under LSJR Alternative 4 for the increase in average flows on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would be the same as described above under LSJR Alternative 3. Therefore, when considering the expected increase in flows and the limited instances in which there would be a reduction in flows, significant impacts on riparian communities and other sensitive plant communities are not expected. Impacts would be less than significant.

Reservoirs

The frequency and range of water surface elevation fluctuations at the reservoirs would generally decrease or remain similar to baseline conditions such that there would not be a significant increase in month to month fluctuations greater than 10 ft (Tables 8-7a, 8-7b, and 8-7c). As described for LSJR Alternative 3, the disturbed substrate would provide limited opportunities for additional vegetation establishment. These modifications to riparian habitat or other sensitive terrestrial communities, such as habitat for limestone salamander around Lake McClure and the Red Hills and Bagby Serpentine ACECs, or special-status plant species would be less than significant.

Southern Delta

Modeled results indicate exceedances of the EC objectives in the southern would decrease (Table 5-25 and Tables 5-28a, 5-28b, and 5-28c), and overall salinity in the southern Delta would be reduced (Tables 5-29a, 5-29b, and 5-29c) under LSJR Alternative 4. These changes with respect to terrestrial habitat would be very small, if imperceptible. Therefore, LSJR Alternative 4 is not expected to impact the overall quantity or quality of the habitats in the southern Delta. Impacts would be less than significant.

Adaptive Implementation

Under LSJR Alternative 4, impacts associated with adaptive implementation method 1 may be slightly different from those associated with methods 2 and 3.

Adaptive implementation method 1 would allow a decrease of up to 10 percent in the annual February–June 60 percent unimpaired flow (to 50 percent) to optimize implementation measures to meet the narrative objective, while considering other beneficial uses, provided that these other considerations do not reduce intended benefits to fish and wildlife. Adaptive implementation must be approved using the process described in Appendix K, *Revised Water Quality Control Plan*. Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time. Adjusting the percent of unimpaired flow through adaptive implementation is not anticipated to result in impacts different than those identified under LSJR Alternative 3 because LSJR Alternative 3 includes 50 percent within its range of adaptive implementation.

Adaptive implementation methods 2 and 3 would manage flows from February–June or outside of that time period. Given that these two methods would not allow flows to go below what is required by existing requirements on the three eastside tributaries and the SJR, impacts would be similar to those described above for LSJR Alternative 4 without adaptive implementation. Finally, method 3 is incorporated into the modeling; thus, the range of terrestrial biological effects is reflected in the results presented above for LSJR Alternative 3 without adaptive implementation.

Implementing method 4 is expected to have little effect on conditions in the three eastside tributary rivers and LSJR. WSE results show that under Alternative 4 the 1,200 cfs February–June base flow requirement at Vernalis would require a flow augmentation in the three eastside tributaries and LSJR only 0.7 percent of the time in the 82-year record analyzed. Similarly, flow augmentation would be required only 0.2 percent of the time to meet a 1,000 cfs requirement and is not affected at all for an 800 cfs requirement. These results indicate that method 4 would rarely alter the flows in the three eastside tributaries or the LSJR under this alternative.

Consequently, the impact determination of LSJR Alternative 4 with adaptive implementation would be the same as described for LSJR Alternative 4 without adaptive implementation. Impacts would be less than significant.

Impact BIO-2: Have a substantial adverse effect on federally protected wetlands as defined by Section 404 of the Clean Water Act (including, but not limited to, marsh, vernal pool, coastal, etc.) through direct removal, filling, hydrological interruption, or other means

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay–Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

The LSJR alternatives do not have the potential to significantly physically fill, divert, or isolate wetland communities and would not discharge dredged or fill material into waters of the United States (e.g., wetlands). Most potential effects on wetland communities as a result of a change in flows would be comparable to the effects of periodic flood flows that have occurred historically (Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*). The effects of these alterations on wetland vegetation would be similar to those previously described for riparian vegetation because wetland plants can also survive inundation, are resistant to the effects of scouring deposition, and are growth-limited by water availability (USBR 2010a). Many effects are beneficial, such as greater availability of water to support growth of riparian or wetland vegetation and the deposition of new sediment rich in organic material. The primary and most ecologically important difference from baseline flows would be the duration and seasonality of inundation; increased flows could inundate some areas for longer periods than baseline seasonal flows would. At the local level, these alterations could adversely or beneficially affect wetlands and riparian habitat, depending on site-specific hydrologic changes. In the long term, plant communities may shift in elevation or species composition to accommodate changes in river flows (USBR 2010a).

LSJR Alternative 2 (Less than significant/Less than significant with adaptive implementation)

Rivers

As described under Impact BIO-1, modeled monthly flows on the Stanislaus River are expected to be similar to baseline flows. Flows for the Tuolumne and Merced Rivers and the LSJR are expected to be generally similar to or generally greater than baseline flows, depending on the month. As a result, there would be no substantial adverse change to conditions supporting wetlands in the area of potential effects. Impacts would be less than significant.

Reservoirs

Under LSJR Alternative 2, reservoir levels would generally fluctuate at a similar or reduced frequency compared to baseline. There are no known significant assemblages of wetlands along the shores of the reservoirs that would be inundated as a result of changes in reservoir elevations. Any impacts from higher water levels would be temporary and would last only until the marsh habitat could respond by shifting in elevation and species composition to accommodate the changes. There are some wetlands and riparian habitat around the reservoirs within the zone of fluctuation; however, these areas are not expected to experience negative impacts due to LSJR Alternative 2 since water elevation fluctuations are not expected to change significantly compared to baseline conditions (Tables 8-7a, 8-7b, and 8-7c). There are also barren areas at the reservoirs because of the lack of suitable soil and the continued fluctuation of water surface elevations. More stable reservoir elevations may result in perennial water availability, which may benefit the establishment and maintenance of wetland vegetation along the shores of the reservoirs. Consequently, impacts would be less than significant.

Adaptive Implementation

As discussed in Impact BIO-1, adaptive implementation method 1 could result in higher flows during some times of the year than under the specified unimpaired flow requirement of 20 percent. However, it is anticipated that over time the unimpaired flow requirement could increase, decrease, or not change at all within a year or between years, depending on fish and wildlife conditions and hydrology. Adaptive implementation method 2 could result in a reallocation of flows between months. Wetland resources are somewhat dependent on the timing or magnitude of flow; however these resources are adapted to natural flood and drought cycles. Higher flows under adaptive implementation method 1 would not exceed the higher range of flows that could be experienced under baseline for some water years. But adaptive implementation method 2 is unlikely to cause flows to be less than baseline flows or to cause overall annual volumes that are released to be different from baseline because method 2 would not authorize a reduction in flows required by other agencies or through other processes, which are incorporated in the modeling of baseline conditions. Method 3 would not be authorized under LSJR Alternative 2 since the unimpaired flow percentage would not exceed 30 percent. Adaptive implementation method 4 would allow an adjustment of the Vernalis February–June minimum flow requirement; however, changes due to method 4 under this alternative would rarely alter the flows in the three eastside tributaries or the LSJR. At the local level, these alterations could adversely or beneficially affect wetlands and riparian habitat, depending on site-specific hydrologic changes. In the long term, plant communities may shift in elevation or species composition to accommodate changes in river flows. Consequently the impact determination of LSJR Alternative 2 with adaptive implementation would be the same as described above for LSJR Alternative 2 without adaptive implementation. Impacts would be less than significant.

LSJR Alternative 3 (Less than significant/Less than significant with adaptive implementation)

Rivers

LSJR Alternative 3 would represent a change in the timing of river flows that would better correspond with the growth and dispersal periods for native wetland vegetation. These native wetland plant communities have evolved life history characteristics that coincide with the unimpaired flow patterns (Moyle and Bennett 2008; CDFW 2014a). LSJR Alternative 3 may encourage the establishment of wetlands and plant assemblages that mimic the original wetland ecosystems that existed before hydromodification. Furthermore, LSJR Alternative 3 is not expected to result in flows of higher velocity than are known to occur in the system or that would result in substantial scour (see Chapter 6, *Flooding, Sediment, and Erosion,* and Chapter 7, *Aquatic Biological Resources*). Impacts on wetland communities would be less than significant.

Reservoirs

Under LSJR Alternative 3, fluctuations in water surface elevation at the reservoirs would generally decrease or remain similar to baseline conditions and generally would not experience a significant increase in fluctuations greater than 10 ft throughout the year (Tables 8-7a, 8-7b, and 8-7c). Although there are no large wetland areas, there are small segments of wetland and riparian habitat along the shores of these reservoirs within the zone of water elevation fluctuation. These habitats are not expected to be negatively impacted by LSJR Alternative 3 since water surface elevation fluctuations would be similar to baseline conditions, and would not lead to further isolation of these small wetland areas. Therefore, LSJR Alternative 3 would not substantially alter or reduce wetland communities at the reservoirs. Impacts would be less than significant.

Adaptive Implementation

Similar to LSJR Alternative 2 with adaptive implementation methods 1, 2, and 4, LSJR Alternative 3 may result in some modifications, at the local level, to wetland assemblages. Adaptive implementation method 3 would keep the overall volume of water from the February–June time period or after June the same as LSJR Alternative 3 without adaptive implementation, but the volume within each month could vary. Wetland resources are somewhat dependent on the timing or magnitude of flow but are also adapted to natural flood and drought cycles. Nevertheless, higher flows under adaptive implementation method 1 would not exceed the flows that could be experienced under normal operations for some water years. Given that method 3 would not allow flows to go below what is required by existing requirements on the three eastside tributaries and the SJR, impacts would be similar to those described above for LSJR Alternative 3 without adaptive implementation. In the long term, plant communities may shift in elevation or species composition to accommodate changes in river flows. Consequently the impact determination of LSJR Alternative 3 with adaptive implementation would be the same as described above for LSJR Alternative 3 without adaptive implementation. Impacts would be less than significant.

LSJR Alternative 4 (Less than significant/Less than significant with adaptive implementation)

Rivers

As described above for LSJR Alternative 3, LSJR Alternative 4 flows are expected to better coincide with the growth and dispersal periods for native wetland vegetation (spring time) and not result in substantial scour. LSJR Alternative 4 would have a less-than-significant impact on existing wetland communities within the area of potential effects along the rivers.

Reservoirs

The reservoir water surface elevation levels are generally not expected to experience large fluctuations with any greater frequency than under baseline conditions (Tables 8-7a, 8-7b, and 8-7c). As described above, there are small segments of wetland and riparian habitat along the shores of the reservoirs within the zone of water elevation fluctuation. These habitats are not expected to be negatively affected by LSJR Alternative 4 because water surface elevation fluctuations are expected to be similar to baseline conditions and, therefore, would not lead to isolation of these small wetland areas. Impacts would be less than significant.

Adaptive Implementation

Similar to LSJR Alternative 3 with adaptive implementation methods 1, 2, 3, and 4, LSJR Alternative 4 with adaptive implementation may result in some modifications at the local level to wetland assemblages. However, in the long term, plant communities may shift in elevation or species composition to accommodate changes in river flows. Consequently, the impact determination of LSJR Alternative 4 with adaptive implementation would be the same as described above for LSJR Alternative 4 without adaptive implementation. Impacts would be less than significant.

Impact BIO-3: Facilitate a substantial increase in distribution and abundance of invasive plants or nonnative wildlife that would have a substantial adverse effect on native terrestrial species

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay–Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

There are currently nonnative plant species present in the area of potential effects along the rivers and at the reservoirs, as well as in the area of potential indirect effects (see Section 8.2.1, *LSJR and the Three Eastside Tributaries*, under the subsections *Potentially Affected Habitats*, and *Potentially Affected Vegetation*, for a description of the invasive plant species). Invasive species programs have been established to reduce and control the spread of these species, including invasive species management plans developed in compliance with FERC regulations, various regional invasive species plans, and goals established by local weed management areas (see Section 8.3, *Regulatory Background*, for a description of the relevant invasive species plans and regulations).

LSJR Alternatives 2, 3, and 4 (Less than significant/Less than significant with adaptive implementation)

Invasive plants and animals already exist throughout the area of potential effects. It is acknowledged that baseline flow regimes both harm native plants and encourage nonnative species because flows and habitats are often mismatched (e.g., riparian habitats that need more variable flows do not receive them) (Moyle et al. 2010; CDFW 2014a). However, there is insufficient evidence to conclude that the baseline flow regime is the definitive factor in the establishment and spread of invasive species. It is likely that other habitat modifications, such as wetland reclamation and agricultural cultivation, are very important factors in the spread of invasive species. The LSJR alternatives would create a more variable flow regime in which flows vary by season to more closely mimic the natural hydrograph. This is expected to favor native species that have evolved life history characteristics that respond to seasonal flow patterns (Moyle and Bennett 2008; CDFW 2014a). However, more variable flow regimes constitute an ecosystem perturbation, and habitat disturbance can encourage the establishment and spread of invasive species (Davis and Thompson 2000). In light of these factors, the modifications in flow regimes under the LSJR alternatives are not anticipated to change the relative abundance of native and nonnative terrestrial species. Although modifying flows in the system may foster the development of expanded riparian zones, the diversity and richness of these habitats would generally follow baseline conditions. Compositional shifts may occur locally, but the relative abundance of these species at the ecosystem level would be consistent with baseline conditions. Likewise, the use of these habitats by nonnative wildlife species would continue and the relative abundance of these species is expected to be unchanged. While the LSJR alternatives (including the various adaptive implementation methods) may result in some alteration of vegetation patterns at specific locations, there is no information available to suggest that modified flows would substantially alter or facilitate the establishment of invasive plant or animal species. Furthermore, native species are more ecologically adapted to more natural flows (Moyle and Bennett 2008; CDFW 2014a; Moyle et al. 2010). There are also not expected to be increases in abundance or distribution of nonnative plants or wildlife species in the area of potential effects around the reservoirs since there are not likely to be large changes in water surface fluctuation compared to baseline conditions (Tables 8-7a, 8-7b, and 8-7c). Therefore, it is anticipated that impacts would be less than significant.

Area of Potential Indirect Effects

Decreased surface water diversions associated with LSJR Alternative 2 has the potential to result in decreased surface water available for agricultural irrigation in the plan area. Existing agricultural lands that do not receive irrigation water may not necessarily be fallowed in perpetuity or potentially converted to non-agricultural uses. Some agricultural activities on existing agricultural land would continue to occur in the form of dryland farming, rotational farming, or deficit irrigation depending on the type of crop affected, market conditions, and the individual decisions of farmers. These activities would help limit the distribution and abundance of invasive plant and wildlife species. Additionally, the potential for invasive plants and nonnative wildlife species to increase due to reduction in irrigation water availability would not be expected to exceed existing levels because if land is fallowed agricultural activities could occur to maintain the land even during periods when no crops are being grown on a particular field. In the event that the LSJR alternatives result in permanent reversion of some currently irrigated agricultural lands within the area of potential indirect effects to upland habitats or unirrigated grazing lands, a mix of native and nonnative vegetation could be expected to become re-established in the area. Such plant growth, even if heavily weighted towards non-native species, may foster a return to, or at least tend towards, increases in habitat diversity. This can favor increased species abundance or species richness (Crooks 2002). In some instances, non-native plant species may be useful catalysts for ecosystem restoration (Ewel & Putz 2004). Swainson's hawk (*Buteo swainsoni*) nesting densities in Central California have been noted to be the highest in areas with either a mixture of native habitat and agriculture or a high diversity of irrigated crops (England et al 1995). Finally, the invasive species programs as described in Section 8.3, *Regulatory Background*, would continue to be implemented throughout the plan area to reduce and control invasive species. Therefore, impacts would be less than significant.

Impact BIO-4: Have a substantial adverse effect, either directly or through habitat modifications, on any terrestrial animal species identified as a candidate, sensitive, or special-status species in local or regional plans, policies, or regulations or by CDFW or USFWS

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay–Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

Numerous candidate, sensitive or special-status animal species (special-status species) are found within the area of potential effects (see Tables 8-4a and 8-6), including around Lake McClure, where a fully protected species, Limestone salamander, was found to be present. Western pond turtle were also observed around the shore of Lake McClure and New Don Pedro Reservoir. Many of these special-status animal species are dependent on riparian habitat. The baseline flows have constrained riparian vegetation by reducing the amount of wetted habitat; however, land use changes and levee development along rivers have also led to a reduction in riparian habitat (see Appendix C, *Technical Report on the Scientific Basis for Alternative San Joaquin River Flow and Southern Delta Salinity Objectives*). The loss of riparian vegetation has been an important factor in the decline of the California yellow warbler, western yellow-billed cuckoo, Least Bell's Vireo, and little willow flycatcher (Riparian Habitat Joint Venture 2004). Within California's Central Valley, all of these species depend on riparian vegetation for cover, foraging, and breeding. Valley elderberry longhorn beetle depends on elderberry shrub, a riparian species. Two mammal species, San Joaquin woodrat and riparian brush rabbit, also require riparian vegetation. Therefore, declines in riparian vegetation have likely caused declines in populations of these special-status species (CDFW 2014a). The analysis considered whether the LSJR alternatives may cause some temporary habitat disturbances, especially within, and nearby, stream channels, which might adversely affect some special-status animals. The analysis also examined whether the LSJR alternatives would have beneficial effects on some special-status species, particularly to the extent that increased flows encourage additional riparian habitat establishment. Habitat modifications that benefit special-status terrestrial animal species would be consistent with the goals of ESA, CESA, and the USFWS Recovery Plan.

Candidate, sensitive, or special-status animal species (special-status species) are found within the area of potential indirect effects (see Tables 8-4b). The analysis considers whether a reduction in irrigation water supply to existing agricultural lands would indirectly result in land cover that could substantially adversely affect a special-status species.

LSJR Alternative 2 (Less than significant/Less than significant with adaptive implementation)

Rivers

As discussed in Impact BIO-1, modeled monthly flows on the Stanislaus River are expected to be similar to baseline flows. Flows for the Tuolumne and Merced Rivers and the LSJR are expected to be similar to or greater than baseline flows, depending on the month. In addition, as described under Impact BIO-1, adaptive implementation could increase the volume of water in the rivers compared to what would occur under 20 percent unimpaired flow at those times of increased releases/flows. Increases in flow are expected to be largest during the riparian recruitment period (i.e., end of April–June). While established riparian species are adapted to periodic fluctuations in flow, there is potential for increased spring flows to help establish new vegetation. The viability of this habitat is key for the continued existence of many special-status species, and the loss of riparian vegetation has been an important factor in their decline. A discussion of potential impacts on special-status species that could reside in the area of potential effects is included below. Special-status species include: elderberry longhorn beetle, California red-legged frog, California tiger salamander, western spadefoot toad, giant garter snake, western pond turtle, special-status bird species, several bat species, riparian brush rabbit, and San Joaquin Valley woodrat. Overall, impacts on these special-status species on the Stanislaus, Tuolumne, and Merced Rivers and LSJR would be less than significant.

In the area of potential effects, elderberry shrubs typically are located on the higher portions of levees and streambanks within the levees and are generally not subject to regular inundation or scouring, although they can withstand periodic inundation (USBR 2010a). LSJR Alternative 2 is not likely to result in direct loss of elderberry shrubs or any resident beetles. LSJR Alternative 2 would generally increase the amount of water available to elderberry roots, which may stimulate growth of elderberry shrubs and ultimately have a beneficial effect on habitat for this species on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR. Impacts would be less than significant.

The area of potential effects contains suitable habitat for California red-legged frogs, California tiger salamanders, and western spadefoot toads. However, there are no known populations in close proximity to the channels affected by LSJR Alternative 2 (CDFG 2012). The best aquatic habitats for amphibian and reptile use are the backwaters and ponds that are not influenced greatly by rising and falling flows. In addition, any amphibian and reptile use of the channels in the LSJR area of potential effects would already be subject to rising and falling flows, and such populations would be adapted to this variable habitat. Thus, LSJR alternatives would not have a significant adverse effect on the primary habitat elements for special-status amphibians. Impacts would be less than significant.

Special-status aquatic reptiles, including giant garter snake and western pond turtle, may occur in the portions of the river channel that would be inundated by the LSJR Alternative 2. These species require aquatic habitat for breeding and foraging during spring and summer. Additional flows during these seasons, as well as in winter, would have a beneficial effect on these species. Although water velocities would increase in certain areas, it is expected that velocity would not be substantially altered from historical flow regimes. Impacts on upland habitats that these species use for refuge are not expected under the LSJR alternatives because flows generally would be restricted to the river channel. Impacts would be less than significant.

Many special-status birds build nests in large trees or shrubs that would be elevated above the areas affected by LSJR Alternative 2. Some special-status species nest closer to the ground in emergent in-stream or on-terrace marsh vegetation that could be present in portions of the river channel. Non-flood flows during the breeding season (typically February–September) are expected to increase on the Tuolumne and Merced Rivers and the LSJR under LSJR Alternative 2, and there would be a potential for increased flows to inundate nest sites of ground nesters. However, these areas already are subject to regular or periodic inundation from seasonal flood flows, the breeding populations are adapted to this variable environment, and the aggregate of the individual breeding periods for the different species results in a relatively large window of breeding time. As the flow alters the channels of the rivers, ground nesters would move with the establishment of emergent vegetation that they use as nesting habitat. Impacts would be less than significant.

Various special-status mammal species occur in the area of potential effects, including several bat species, riparian brush rabbit, and San Joaquin Valley woodrat. Changes in flows associated with LSJR Alternative 2 would be largely confined to existing channels and are not expected to affect upland breeding and foraging sites required by these mammals. Impacts would be less than significant.

Reservoirs

Special-status species found to occur in the area of potential effects around the reservoirs include Limestone salamander, which has been documented to occur at Lake McClure, and western pond turtle, which were observed within the zone of fluctuation around New Don Pedro Reservoir (TID and MID 2013a). Implementation of LSJR Alternative 2 is not expected to negatively impact special-status species around the reservoirs since the resulting water surface elevation fluctuations are not expected to be very different from the baseline conditions (Tables 8-7a, 8-7b, and 8-7c). Western pond turtles typically select nesting sites with at least some vegetation (low grasses and forbs), therefore these sites would not be impacted by frequent inundation and would therefore not be negatively impacted by implementation of LSJR Alternative 2.

Southern Delta

Modeled results indicate that EC values in the southern Delta could increase or decrease depending on which LSJR alternative is implemented (Tables 5-25 and Tables 5-26a, 5-26b, and 5-26c), but overall salinity in the southern Delta would be slightly reduced (Tables 5-29a, 5-29b, and 5-29c) under LSJR Alternative 2. These changes would be very small, if imperceptible. According to Impact BIO-1, LSJR Alternative 2 is not expected to impact the overall quantity or quality of the habitats in the southern Delta. Since habitats are not expected to be affected, the special-status species are not expected to be affected. Impacts would be less than significant.

Adaptive Implementation

Adaptive implementation of method 1 would allow an increase of up to 10 percent over the 20-percent minimum February–June unimpaired flow requirement (to a maximum of 30 percent of unimpaired flow). A change to the percent of unimpaired flow would take place based on required evaluation of current scientific information and would need to be approved as described in Appendix K, *Revised Water Quality Control Plan*. Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time. Adaptive implementation method 2 would allow changing the timing of the release of the volume of water within the February–June timeframe. While the total volume of water released February–June would be the same as LSJR Alternative 2 without adaptive implementation, the rate could vary from the actual (7-day running average) unimpaired flow rate. Method 2 would not authorize a reduction in flows required by other agencies or through other processes, which are incorporated in the modeling of baseline conditions. Method 3 would not be authorized under LSJR Alternative 2 since the unimpaired flow percentage would not exceed 30 percent. Adaptive implementation method 4 would allow an adjustment of the Vernalis February–June minimum flow requirement. WSE results show that changes due to method 4 under this alternative would rarely alter the flows in the three eastside tributaries or the LSJR.

If method 1 is implemented, an increase of up to 30 percent of unimpaired flow would potentially result in different effects as compared to 20 percent unimpaired flow, depending upon flow conditions and frequency of the adjustment, and more similar to those described under LSJR Alternative 3. Generally increased flows are expected to be largest during the riparian recruitment period (i.e., end of April–June). While established riparian species are adapted to periodic fluctuations in flow, there is potential for increased spring flows to help establish new vegetation. The viability of this habitat is key for the continued existence of many special-status species, and the loss of riparian vegetation has been an important factor in their decline. It is anticipated that an increase in flow would not result in a loss of riparian habitat. If method 2 is implemented, the total annual volume of water associated with LJSR Alternative 2 (i.e., 20 percent of the February–June unimpaired flow) would not change. As a result, the total volume of water that would remain in the river would not change with adaptive implementation method 2, and impacts associated with total volume of water would not change. Resources that are dependent on the timing or magnitude of flow could potentially be affected by method 2. Riparian resource recruitment in stream channels is somewhat dependent on the timing or magnitude of flow; however these resources are adapted to natural flood and drought cycles. Higher flows under adaptive implementation method 1 would not exceed the higher range of flows that could be experienced under baseline for some water years. However, given that this method would not allow flows to go below what is required by existing requirements on the three eastside tributaries and the SJR, impacts would be similar to those described above for LSJR Alternative 2 without adaptive implementation. Impacts would be less than significant.

Area of Potential Indirect Effects

Decreased surface water diversions associated with LSJR Alternative 2 with adaptive implementation has the potential to result in decreased surface water available for agricultural irrigation in the plan area. Existing agricultural lands that do not receive irrigation water may not necessarily be fallowed in perpetuity or potentially converted to non-agricultural uses. Other less intensive uses, such as dryland farming, deficit irrigation (i.e., reduction in irrigation), and grazing could take place on lands that experience a reduction in irrigation water. For example, some crops (e.g., alfalfa and pasture) are able to survive under deficit irrigation where only a portion of the crop water demands are met (Putnam et al. 2015a, 2015b). If the full water requirements were continually restricted, they could still potentially remain in agricultural use (Putnam et al. 2015a, 2015b). Furthermore, a reduction of irrigation water supply would not reduce the amount of other habitat within the plan area suitable for sensitive species, including riparian corridors, rangeland, and native and introduced trees.

While agricultural lands can be an important tool for species conservation, their value is usually derived from comparing habitat function to urban or industrial land use types. Therefore, it is expected that potential removal or reduction of active agriculture on lands which remain in a fallowed or other undeveloped or open space use would not result in a significant adverse effect on special-status and sensitive species. Moreover, a reduction of active agricultural management, soil tilling, crop harvesting, and herbicide and pesticide application, primarily in the plan area, would potentially benefit special-status species by reducing disturbance to potentially suitable habitat and by reducing overall population and habitat fragmentation. Special-status species within the plan area, such as California tiger salamander (*Ambystoma californiense*), San Joaquin kit fox (*Vulpes macrotis mutica*), Swainson's hawk (*Buteo swainsoni*), and various other California native wildlife populations declined as a result of the conversion California's annual grasslands to agricultural lands (CDFG 2000; Estep 1989; Loredo et al. 1996; Wheeler 2003; CDFW n.d.). Several Central Valley species identified in the USFW Recovery Plan (USFWS 1998) that occur in the San Joaquin Valley and in intermittent areas of the plan area, including the kit fox (noted as a keystone species for the Valley) and the blunt nosed leopard lizard (*Gambelia sila*), are particularly susceptible to active agricultural activities. Active agricultural activities have been identified as being detrimental to their habitat and survival (USFWS 1998). In particular, the principal factors in the decline of the San Joaquin kit fox were loss, degradation, and fragmentation of habitats associated with agricultural, industrial, and urban developments in the San Joaquin Valley. The conservation strategy for San Joaquin kit fox has been identified as strategically retiring agricultural lands that have serious drainage problems to reduce the effects of widespread habitat fragmentation of populations (USFWS 1998). Similarly, effects on the blunt nosed leopard lizards have been attributed to active agriculture as more than 95 percent of the original natural communities have been destroyed and collectively have caused the reduction and fragmentation of populations and decline of this species (USFWS 1998).

Lands that receive less irrigation water could prove valuable in providing habitat connectivity and reducing fragmentation for special-status and sensitive species, depending on the location of the land and the acreage. The special-status terrestrial wildlife habitat value for idle fields or pasture lands is typically higher than that of active agricultural fields due to the lack of seasonal anthropogenic disturbances and a reduction of the overall vegetative uniformity (USFWS 2009; USFWS 2010c; CDFW 2014b; Woodbridge 1991). For example, there is limited habitat functionality of orchard trees for nesting or roosting under active agricultural management. The existing limited habitat value would be exceeded by eventual establishment of native or suitably adapted introduced vegetation. This vegetation would not be subjected to the regular pruning, harvesting, and other disturbance activities typically associated with orchard trees, thereby providing more secure nesting opportunities. Similarly, native grass and shrub communities would provide greater foraging habitat value than intensively managed crops experiencing regular and periodic disturbance (e.g., plowing, mowing) and rodent control. All of these active agriculture activities reduce the available prey base for raptors. Populations of California tiger salamander, found in the San Joaquin Valley and in the plan area, would also benefit from the development of rodent communities in undisturbed land. Rodent holes are suitable habitat for the California tiger salamander and a reduction of heavily controlled rodent activities on active agricultural lands would result in a potential increase in habitat for this species. As such, the potential reduction of irrigation water to agricultural lands under LSJR Alternative 2 with adaptive implementation, with the resultant halting of mechanized agriculture, pesticide and rodenticide application, and anthropogenic disturbance is unlikely to result in a substantial adverse effect on sensitive or special-status species. Further, the potential reduction of monocultural irrigated crops is likely to support the species and ecosystem recovery strategy outlined in the USFWS recovery strategy. As such, it is not expected that a reduction in irrigation water supply would result in a substantial adverse indirect effects through habitat modification on special-status species. Impacts would be less than significant.

LSJR Alternatives 3 and 4 (Less than significant/Less than significant with adaptive implementation)

Rivers

Overall, median monthly flows would be higher on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR under LSJR Alternatives 3 and 4. In some limited instances, LSJR Alternatives 3 and 4 would result in a reduction in flow, primarily during the wettest years, as a result of a reduced need for flood control releases. The overall volume of water February–June would be greater when compared to baseline conditions (Table 5-16) under the specified unimpaired flow requirements (i.e., 40 percent and 60 percent) and under the adaptive implementation methods 1, 2, and 3. Impacts on riparian habitat would be less than significant. Thus, the changes in riparian habitat are not anticipated to affect special-status animal species dependent upon riparian habitat, as described under the discussion for LSJR Alternative 2. Therefore, it is anticipated that impacts on special-status species as a result of LSJR Alternatives 3 and 4 would be less than significant.

Reservoirs

Special-status species found to occur in the area of potential effects around the reservoirs include Limestone salamander and western pond turtle. Results from the limestone salamander survey conducted around Lake McClure (Merced ID 2011b) indicate that while high water elevations occasionally inundate suitable habitat for limestone salamanders, these inundations rarely occur during periods when the salamanders are above ground. During rare periods when high water levels coincide with above-ground activity, it is likely that salamanders would be able to relocate upslope to avoid submersion. Western pond turtles typically select nesting sites with at least some vegetation (low grasses and forbs), therefore these sites would not likely be impacted by inundation due to water level fluctuation at the reservoirs. Implementation of LSJR Alternatives 3 and 4 is not expected to negatively impact special-status species around the reservoirs since the resulting water surface elevation fluctuations would not be very different from the baseline conditions (Tables 8-7a, 8-7b, and 8-7c).

Southern Delta

Modeled results indicate violations of the EC objectives in the southern Delta would decrease (Table 5-25 and Tables 5-27a, 5-27b, and 5-27c), and overall salinity in the southern Delta would be reduced (Tables 5-29a, 5-29b, and 5-29c) under LSJR Alternatives 3 and 4. These changes would be very small, if imperceptible. According to Impact BIO-1, LSJR Alternatives 3 and 4 are not expected to impact the overall quantity or quality of the habitats in the southern Delta. Since habitats are not expected to be affected, the special-status species are not expected to be affected. Impacts would be less than significant.

Area of Potential Indirect Effects

Decreased surface water diversions associated with LSJR Alternatives 3 or 4 with or without adaptive implementation have the potential to result in decreased surface water available for agricultural irrigation in the plan area. As discussed above under LSJR Alternative 2, with adaptive implementation, existing agricultural lands that do not receive irrigation water may not necessarily be fallowed in perpetuity or potentially converted to non-agricultural uses. Other less intensive uses such as dryland farming, deficit irrigation (i.e., reduction in irrigation), and grazing, could take place on lands that experience a reduction in irrigation water. For example, some crops (e.g., alfalfa and pasture) are able to survive under deficit irrigation where only a portion of the crop water demands are met (Putnam et al. 2015a, 2015b). If the full water requirements were continually restricted, they could still potentially remain in agricultural use (Putnam et al. 2015a, 2015b). Furthermore, a reduction in irrigation water supply would not reduce the amount of other habitat within the plan area suitable for sensitive species, including riparian corridors, rangeland, and native and introduced trees.

Similar to the discussion above for LSJR Alternative 2 with adaptive implementation, agricultural lands can be an important tool for species conservation, their value is usually derived from comparing habitat function to urban or industrial land use types. Therefore, it is expected that potential removal of active agriculture on lands which remain in a fallowed or other undeveloped use or open space uses would not result in a significant adverse effect on special-status and sensitive species. Moreover, a reduction of active agricultural management, soil tilling, crop harvesting, and herbicide and pesticide application, would potentially benefit special-status species by reducing disturbance to potentially suitable habitat and by reducing overall population and habitat fragmentation(CDFG 2000; Estep 1989; Loredo et al. 1996; Wheeler 2003; CDFW n.d.). Active agricultural activities have been identified as being detrimental to the habitat and survival of several special-status species, including the San Joaquin kit fox (*Vulpes macrotis mutica*) and blunt nosed leopard lizard (*Gambelia sila*) (USFWS 1998).

Lands that receive less irrigation water could prove valuable in providing habitat connectivity and reducing fragmentation for special-status and sensitive species, depending on the location of the land and the acreage. The special-status terrestrial wildlife habitat value for idle fields or pasture lands is typically higher than that of active agricultural fields due to the lack of seasonal anthropogenic disturbances and a reduction of the overall vegetative uniformity (USFWS 2009; USFWS 2010c; CDFW 2014b; Woodbridge 1991).

As such, the potential reduction of irrigation water to agricultural lands under the flow requirements, with the resultant halting of mechanized agriculture, pesticide and rodenticide application, and anthropogenic disturbance is unlikely to result in a substantial adverse effect on sensitive or special-status species. Further, the potential reduction of monocultural irrigated crops is likely to support the species and ecosystem recovery strategy outlined in the USFWS recovery strategy. As such, potential impacts on sensitive or special-status species as a result of a reduction in irrigation water under LSJR Alternatives 3 or 4 with or without adaptive implementation would be less than significant.

Impact BIO-5: Conflict with the provisions of an adopted habitat conservation plan, natural community conservation plan, or other approved local, regional, or state habitat conservation plan or conflict with any local policies or ordinances protecting biological resources

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay–Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

An activity could conflict with a conservation plan, such as the SJR Wildlife Refuge CCP and the San Joaquin County Multi-Species HCP, management plans of existing national wildlife refuges or other wildlife areas, natural community conservation plants, or local policies or ordinances, if it would substantially reduce the effectiveness of the plan's conservation strategies or otherwise prevent attainment of the plan's goals and objectives. Conflicts can result from reducing the viability of populations that are targets of the plan's goals, objectives, and conservation strategies. Also, other actions can conflict with implementing conservation plans and reduce the habitat value of conserved lands (e.g., by creating adjacent, incompatible land uses), interfere with the management of conserved lands (e.g., by eliminating access or water supplies), or eliminate opportunities for conservation activities (e.g., by developing land identified for preservation in the plan).

LSJR Alternative 2 (Less than significant/Less than significant with adaptive implementation)

LSJR Alternative 2 would not create adjacent incompatible land uses, develop land, or otherwise result in actions incompatible with conservation plans or activities as this alternative does not require or result in those types of activities. As described in Impact BIO-1 through Impact BIO-4, it is expected flows under LSJR Alternative 2 with adaptive implementation would have an overall cumulative distribution (i.e., the range of flows distributed between the minimum flow [thousand acre-feet] and the maximum flow over the entire 82-year historic modeling period) similar to baseline conditions on the Stanislaus River. The median monthly flows would generally be very similar to or greater than baseline flows on the Tuolumne and Merced Rivers and the LSJR under LSJR Alternative 2 with adaptive implementation. Furthermore, the overall volume of water described by the cumulative distribution of flows February–June would be slightly greater than baseline, with adaptive implementation. Similarly, implementation of LSJR Alternative 2 with adaptive implementation is not expected to lead to significant changes in water level fluctuation around the reservoirs and would not be incompatible with habitat conservation plans or activities at those locations. As such, the river flows and reservoir elevations are not expected to reduce the viability of populations that are targets of the various plan goals.

LSJR Alternative 2 could adjust existing water supply diversions; however, the average annual adjustment could be a reduction of approximately 3 percent in the entire plan area and vary between 2 and 6 percent in each of the tributaries (Table 5-19). This is within the general variability of surface water supply diversions provided from the three eastside tributaries and the LSJR (Table 5-20). As such, adjustments to water supply diversions are not expected to reduce the viability of populations that are targets of various plan goals.

LSJR Alternative 2 with adaptive implementation, is not expected to reduce the viability of populations that are targets of the various plan goals. Therefore, conflicts with an adopted habitat conservation plan, natural community conservation plan, or other approved local, regional, or state habitat conservation plan would not occur. Impacts would be less than significant.

LSJR Alternatives 3 and 4 (Less than significant/Less than significant with adaptive implementation)

LSJR Alternatives 3 and 4 would not create adjacent incompatible land uses, develop land, or otherwise result in actions incompatible with conservation plans or activities as these two alternatives do not require or result in those types of activities.

As described in Impact BIO-1 through Impact BIO-4, it is expected that flows under LSJR Alternatives 3 and 4 with or without adaptive implementation, would generally result in higher monthly flows on the three eastside tributaries and the LSJR. The expected increases in flows and the limited instances in which there would be a reduction in flows, would generally benefit biological species. Similarly, implementation of LSJR Alternatives 3 and 4 with adaptive implementation is not expected to lead to significant changes in water level fluctuation around the reservoirs and would not be incompatible with habitat conservation plans or activities. As such, the river flows and reservoir elevations are not expected to reduce the viability of populations that are targets of the various plan goals.

As discussed in Table 8-2, there are national wildlife refuges and other wildlife areas that receive water from the three eastside tributaries and the LSJR. Some of these have management plans and some do not. The wildlife areas that do not have management plans (Stanley Wakefield Wilderness Area, West Hilmar Wildlife Area, and Calaveras River Wildlife Area) rely on surface water supplies from flows of the rivers they are adjacent. Under LSJR Alternatives 3 and 4 with adaptive implementation these areas would typically experience higher flows when compared to baseline conditions. As such, it's expected that these areas would not experience elimination or reduced water supplies. Although these areas do not have management plans, given the flows in the rivers, and the discussion under Impacts BIO-1 through BIO-4, biological species would not be affected. The following wildlife refuges and areas have management plans or CCPs: North Grasslands Wildlife Area; SJR National Wildlife Refuge; Merced National Wildlife Refuge; and San Luis National Wildlife Refuge (Table 8-1 and Section 8.3, *Regulatory Background*). These refuges and areas rely on surface water supplies from the rivers through different mechanisms, including: appropriative rights; riparian rights; and contracts, as described in their water management plans (Table 8-1). Groundwater supplies augment surface water supplies, or provide water supply, for those areas that have groundwater wells (Table 8-1).

As described in Tables 5-19 and 5-20, water supply diversions may be reduced under LSJR Alternatives 3 and 4. This outcome has the potential to affect the sources of water for the wildlife areas. However, groundwater wells would continue to be used on all wildlife areas under the LSJR alternatives to provide water and augment water supply when needed, as they are currently under baseline conditions. In addition, existing policies and procedures in place on pooling, transfers, reallocations, and exchanges would be followed to ensure adequate water supply. These existing policies and procedures are established either within the management plans or in the CVPIA, or in water supply contracts. Furthermore, the wildlife areas have prioritized the habitat cover types that receive water during different year water types, depending on the availability of water, and this would continue under LSJR Alternatives 3 and 4. For example, under baseline conditions L4 (see Table 8-2) water is frequently not delivered to some wildlife areas, and the areas follow their plans and policies with respect to prioritization of the habitat cover types that receive water. Given the management of the different areas' water supplies, it is anticipated that adjustments to water supply under LSJR Alternatives 3 and 4 would not be expected to reduce the viability of populations that are targets of various plan goals.

LSJR Alternatives 3 and 4 with adaptive implementation are not expected to reduce the viability of populations that are targets of the various plan goals. Therefore, conflicts with an adopted habitat conservation plan, natural community conservation plan, or other approved local, regional, or state habitat conservation plan would not occur. Impacts would be less than significant.

8.4.4 Impacts and Mitigation Measures: Extended Plan Area

Bypassing flows, as described in Chapter 5, *Surface Hydrology and Water Quality,* in the extended plan area could potentially impact terrestrial biological resources in upstream reservoirs on the Stanislaus and Tuolumne Rivers differently in the extended plan area than described for the plan area. The reservoirs on the Stanislaus and Tuolumne Rivers may experience substantial changes in reservoir volume, especially under drought conditions under LSJR Alternatives 3 and 4, which are not experienced by the rim reservoirs in the plan area. This different potential impact occurs because these reservoirs are smaller than the downstream rim reservoirs, which could magnify individual changes. Reservoir drawdown would reduce the area and volume of water available for foraging, hunting, and fishing by avian and mammal species (e.g., shore birds, ducks, hawks, and bears). Reservoir drawdown could also remove the hydrologic connection of shoreline wetlands from the reservoir water. If this occurred, it would cause them to dry out during the drawdown period and could affect species reliant on these habitats. Amphibians dependent on wetlands or reservoir-associated aquatic habitat could also be affected. The extent and severity of the effect to mobile species would be reduced by their ability to move and use another reservoir or nearby aquatic resources. Sensitive plant species and wetland habitat that occur within the high water mark of the reservoirs may be affected the most. However, sensitive plant species in these reservoir fringe communities already experience desiccation during baseline reservoir drawdown and the impacts on them would not be substantially increased. Amphibian species in these fringe communities could be affected the most but some could also move to adjacent aquatic habitats such as inflowing streams and rivers.

Under LSJR Alternative 2 and under LSJR Alternative 3 in most years, the type and scale of impacts on these species and wetlands during individual reservoir drawdown events would be similar to what is experienced during baseline reservoir operations (USGS Reservoir Gage Data). Additionally, these reservoirs would refill during the subsequent wet season, limiting the duration of reduced reservoir elevation levels. In the most extreme cases, during drought years and years with substantial increases in bypasses in the extended plan area under LSJR Alternative 2 with adaptive implementation and LSJR Alternatives 3 and 4 with or without adaptive implementation, some reservoirs might be drawn more quickly, to lower levels, and for longer periods than under baseline conditions. If these conditions occurred, there would be adverse impacts on terrestrial species, primarily plant species and wetland habitats, because the reservoir habitat would be greatly reduced when compared to baseline conditions. Under these conditions, impacts on wetlands and wetland-associated species would be substantially longer than under baseline conditions.

The riparian habitat is limited along the steep bedrock banks of the rivers in the extended plan area. An increase in flow is not expected to impact terrestrial biological species (similar to the plan area). However, flows in the extended plan area could decrease in the fall relative to baseline under the LSJR alternatives, which is not anticipated to occur in the plan area. This could result in the potential for reduced habitat conditions for terrestrial species.

The increased frequency of lower reservoir levels and potential reduction in river flow in the fall resulting from the LSJR alternatives, however, would be limited by the program of implementation under each of the LSJR alternatives. The program of implementation requires minimum reservoir carryover storage targets or other requirements to help ensure that providing flows to meet the flow objectives will not have adverse temperature or other impacts on fish and wildlife. Other requirements, for example, include, but are not limited to, limits on required bypass flows for reservoirs that store water only for non-consumptive use so that some water can be temporarily stored upstream. The program of implementation also states that the State Water Board will take actions as necessary to ensure that implementation of the flow objectives does not impact supplies of water for minimum health and safety needs, particularly during drought periods. Accordingly, when the State Water Board implements the flow objectives in a water right proceeding, it will consider impacts on fish, wildlife, and other beneficial uses and health and safety needs, along with water right priority. Until the State Water Board assigns responsibility to meet the flow objectives in the Bay-Delta Plan, it is speculative to identify the exact extent, scope, and frequency of reduced diversions, reduced reservoir levels and their effects on wildlife and plant species, in the extended plan area. When implementing the flow objectives, the State Water Board would identify project-specific impacts and avoid or mitigate significant impacts of lower reservoir levels on wildlife species and habitat in accordance with CEQA.

At the time of preparation of this programmatic analysis, it is unclear to what extent any significant impacts could be fully mitigated to wildlife, wetland and other sensitive plant species. Thus, the potential exists for significant impacts. Therefore, this analysis conservatively concludes that impacts associated with lower reservoir levels under LSJR Alternatives 2 with adaptive implementation and LSJR Alternatives 3 and 4 with or without adaptive implementation are significant. The following mitigation measure is proposed: when considering carryover storage and other requirements to implement the flow water quality objectives in a water right proceeding, the State Water Board shall ensure that reservoir levels upstream of the rim dams do not cause significant wildlife impacts, unless doing so would be inconsistent with applicable laws. The impact is considered significant, even with mitigation, because the mitigation may not fully mitigate the impact in all situations.

Chapter 9
Groundwater Resources

9.1 Introduction

This chapter describes the environmental setting for groundwater resources, including the physical characteristics of the four groundwater subbasins (Eastern San Joaquin, Modesto, Turlock, and Extended Merced[1]) that underlie the surface water delivery areas from the three eastside tributaries.[2] It discusses the regulatory background associated with protecting groundwater resources and groundwater management and evaluates the potential environmental impacts on the groundwater basins, as a resource, which could result from the Lower San Joaquin River (LSJR) alternatives, if applicable, it also offers mitigation measures that would reduce significant impacts.

This chapter analyzes increased groundwater pumping, reduced groundwater recharge from surface water percolation, and related effects (e.g., subsidence) that may occur as a result of the effect of the LSJR alternatives on surface water supplies to the irrigation district service areas. This chapter discusses those potential groundwater supply and groundwater recharge effects under current regulatory conditions. Those current regulatory conditions include the Sustainable Groundwater Management Act (SGMA) (Wat. Code, § 10720 et seq.), which took effect January 1, 2015, and requires the formation of local agencies to protect and manage groundwater resources. SGMA is discussed in more detail below. Southern Delta water quality (SDWQ) alternatives are not discussed in this chapter because the SDWQ alternatives would not result in a change in groundwater pumping or groundwater recharge from surface water that currently takes place in the plan area. To comply with specific water quality objectives or the program of implementation under SDWQ Alternatives 2 or 3, construction and operation of different facilities in the southern Delta could occur, which could involve impacts on groundwater resources. These impacts are evaluated in Chapter 16, *Evaluation of Other Indirect and Additional Actions.*

As stated above, this chapter analyzes the groundwater basins in the study area as a resource. For a discussion of potential effects to agricultural lands from the LSJR and SDWQ alternatives, see Chapter 11, *Agricultural Resources*. Irrigation districts in the study area provide some municipal water supplies; this topic is discussed briefly in Section 9.2, *Environmental Setting*. However, multiple communities and water purveyors in the study area either do not have water supply contracts with the irrigation districts or are located outside the irrigation district service areas. Therefore, the potential impacts on municipal water suppliers and domestic wells from LSJR and SDWQ alternatives are addressed in Chapter 13, *Service Providers*.

As described in Chapter 2, *Water Resources,* the plan area overlay seven of the subbasins in the San Joaquin Groundwater Basin (Figure 2-3). The study area for groundwater, as defined in this chapter, includes the four main groundwater subbasins (the Eastern San Joaquin, Modesto, Turlock, and Merced) plus a small area of the Chowchilla Subbasin that is between the Merced Subbasin and the

---

[1] The *Extended Merced Basin* is used to reference the Merced Basin and a portion of the Chowchilla Basin, as defined in the body of the text above.

[2] In this document, the term *three eastside tributaries* refers to the Stanislaus, Tuolumne, and Merced Rivers.

Chowchilla River; this area is part of the surface water delivery area for the Merced River (Figure 9-1). The Merced Subbasin, with this added area, is referenced as the *Extended Merced Subbasin*. The study area represents the primary area that could potentially experience groundwater effects associated with the LSJR alternatives. The remaining portion of the Chowchilla Subbasin south of the Chowchilla River, the Tracy Subbasin, and the Delta-Mendota Subbasin, are not part of the study area because they are not part of the surface water delivery area for the three eastside tributaries.

The extended plan area, also described in Chapter 1, *Introduction*, generally includes the area upstream of the rim dams.[3] Unless otherwise noted, all discussion in this chapter refers to the plan area. Where appropriate, the extended plan area is specifically identified. In addition to the seven subbasins in the plan area, the extended plan area also includes the Yosemite Valley Basin.

In Appendix B, *State Water Board's Environmental Checklist*, the State Water Resources Control Board (State Water Board) determined whether the plan amendments[4] would cause any adverse impact for each environmental category in the checklist and provided a brief explanation for its determination. The Appendix B checklist identified LSJR alternatives as having a "Potentially Significant Impact" on groundwater resources as identified in Section IX(b) and VI(c). Accordingly, this chapter evaluates the potential impacts of the LSJR alternatives on groundwater resources and whether the alternatives would substantially deplete groundwater supplies or interfere substantially with groundwater recharge such that there would be a significant net deficit in aquifer volume or a significant lowering of the local groundwater table level. It also evaluates whether the potential impacts of the LSJR alternatives would result in subsidence. The potential impacts associated with groundwater resources and the LSJR alternatives are summarized in Table 9-1.

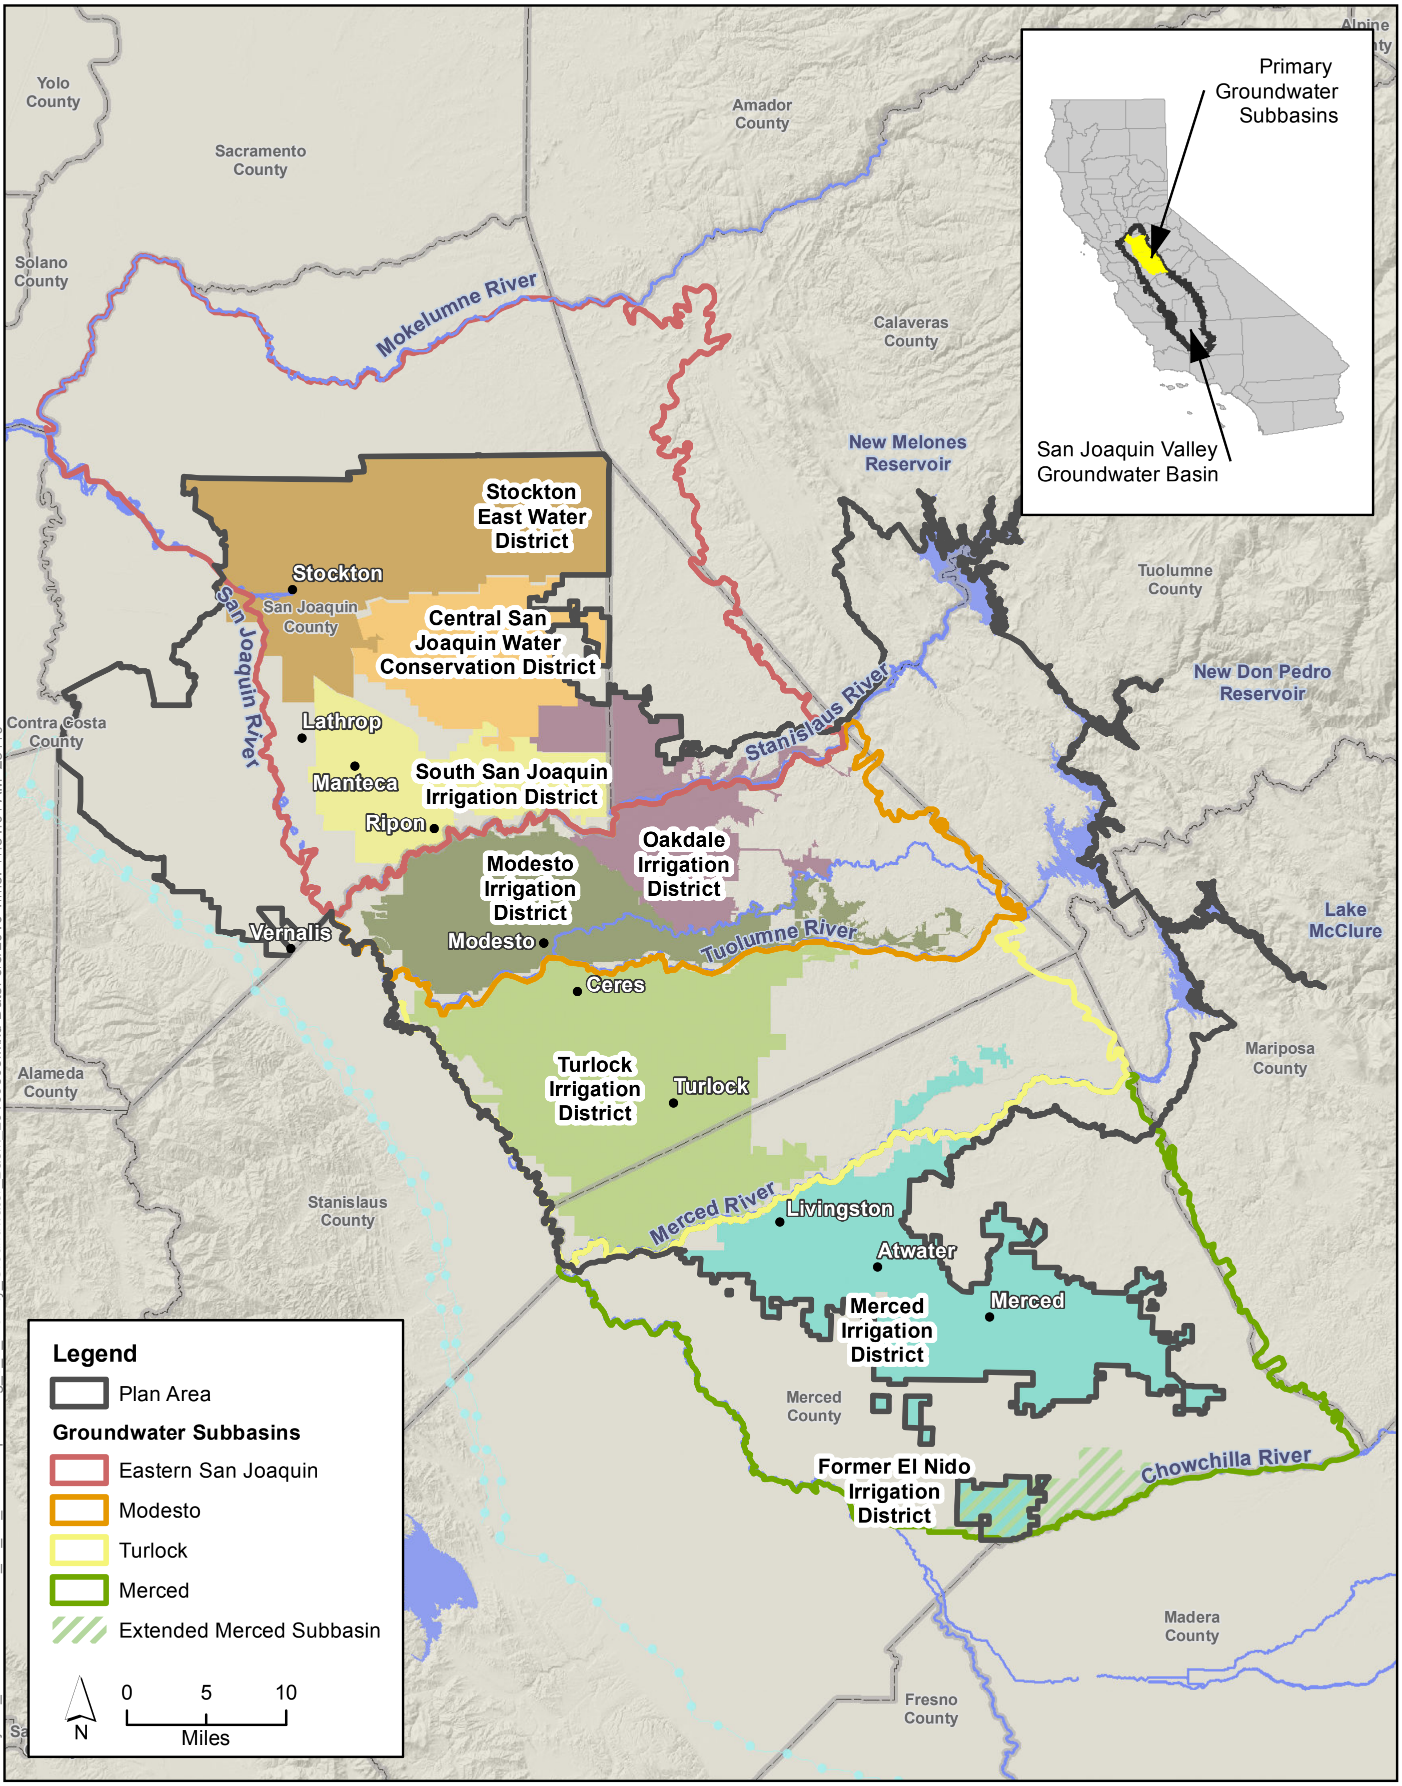
The impacts of the LSJR alternatives on groundwater elevations, aquifer storage, and risk of subsidence cannot be determined with certainty because groundwater conditions vary within each aquifer subbasin and water users would have varied responses to reduced surface water deliveries. In addition, SGMA, mentioned above, will impact groundwater management as it places a mandatory duty upon local agencies in high- and medium-priority groundwater basins to form groundwater sustainability agencies (GSAs) by June 30, 2017, in order to adopt and implement groundwater sustainability plans (GSPs) to sustainably manage groundwater resources.[5] Upon GSP adoption, SGMA grants a local GSA specific authorities to manage and protect its groundwater basin including, but not limited to, the ability to require reporting of groundwater withdrawals and to control groundwater extractions by regulating, limiting, or suspending extractions from wells. (Wat. Code, § 10726.4.) If a local agency is unwilling or unable to manage its groundwater resources to prevent undesirable results including, but not limited to, chronic lowering of groundwater levels, significant and unreasonable reductions in groundwater storage, and significant and unreasonable degraded water quality, then SGMA empowers the State to provide interim management until local agencies are able to assume management. SGMA is discussed in more detail in Section 9.3, *Regulatory Background.*

---

[3] In this document, the term *rim dams* is used when referencing the three major dams and reservoirs on each of the eastside tributaries: New Melones Dam and Reservoir on the Stanislaus River; New Don Pedro Dam and Reservoir on the Tuolumne River; and New Exchequer Dam and Lake McClure on the Merced River.

[4] These plan amendments are the *project* as defined in State CEQA Guidelines, Section 15378.

[5] The Modesto and Turlock Subbasins are listed as high-priority basins and the Eastern San Joaquin, Merced, and Chowchilla Subbasins are listed as high-priority and critically overdrafted basins. For critically overdrafted basins subject to SGMA, plans must be adopted by January 31, 2020. For all other basins subject to SGMA, the deadline is January 31, 2022. See the Sustainable Groundwater Management Act discussion in Section 9.3.2, *State [Regulatory Background].*



K:\Projects_2\SWRCB\00427_11_SJ_River\mapdoc\Fig_9_1_Vicinity_Groundwater_Basin_20160608.mxd Date: 6/8/2016 Time: 11:51:01 AM 25110

Figure 9-1
Vicinity Map of Groundwater Subbasins

However, since the groundwater protections that will be afforded by SGMA cannot be determined at this time with precision, this chapter evaluates the potential impacts on groundwater levels from LSJR alternatives without including SGMA as an ameliorating factor, which means that estimates of impacts are likely more conservative (i.e., worse) than would occur in the groundwater basins over time. Potential impacts from LSJR alternatives were evaluated by estimating increased levels of pumping to replace reduced surface water supplies and estimating reduced deep percolation of surface water in response to decreased conveyance and application of surface water. This analysis assumes that an average annual reduction in the groundwater balance for a subbasin caused by increased groundwater pumping and reduced recharge from surface water equivalent to 1 inch or more of water across the subbasin could be potentially significant: it could result in long-term groundwater resource impacts, including groundwater overdraft (i.e., pumping more than recharge over the long term), and reduced water levels at existing wells.

The impact analysis for this chapter uses results from the State Water Board's Water Supply Effects (WSE) model to determine if the LSJR alternatives would result in impacts on groundwater resources by increasing groundwater pumping and reducing groundwater recharge relative to the baseline water balance for each of the four subbasins in the study area. The WSE model estimates the various levels of demand and surface water diversions for each LSJR alternative. If crop needs are not fully satisfied by minimum groundwater pumping and surface water diversions, additional groundwater pumping is added based on the capacity of the groundwater pumping and distribution infrastructure. Because baseline is representative of 2009 infrastructure, the primary groundwater analysis utilizes estimates of maximum groundwater pumping that were possible in 2009. However, recent drought conditions have resulted in more wells being drilled. Therefore, estimates of maximum groundwater pumping for 2014 were also assessed. A detailed description of the groundwater analysis methods and results is provided in Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*. A summary of the Appendix G analysis relevant to this chapter is provided in Section 9.4, *Impact Analysis.*

Impacts related to the No Project Alternative (LSJR/SDWQ Alternative 1) are presented in Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* and the supporting technical analysis is presented in Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1).* Chapter 16, *Evaluation of Other Indirect and Additional Actions,* includes discussion of impacts related to actions and methods of compliance.

Table 9-1. Summary of Groundwater Resources Impact Determinations

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
Impact GW-1: Substantially deplete groundwater supplies or interfere substantially with groundwater recharge			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [b]	Less than significant	NA
LSJR Alternative 2	The average annual groundwater balance is expected to be reduced by less than the equivalent of 1 inch across each of the subbasins. This is not expected to produce a measurable decrease in groundwater elevations. Therefore, there would not be a substantial depletion of groundwater supplies or substantial interference with groundwater recharge. However, if adaptive implementation method 1 were implemented on a long-term basis (an increase in the February–June percent of unimpaired flow from 20% up to 30%), the average annual groundwater balance could potentially be reduced by the equivalent of more than 1 inch across the Extended Merced Subbasin. If this occurred, it would eventually produce a measurable decrease in groundwater elevations. Therefore, there could be a potentially significant and unavoidable depletion of groundwater supplies or interference with groundwater recharge, and resulting potential migration of groundwater contamination in this subbasin under LSJR Alternative 2 with adaptive implementation.	Less than significant	Significant and unavoidable[c]
LSJR Alternative 3	The average annual groundwater balance could potentially be reduced by more than the equivalent of 1 inch in three subbasins (Modesto, Turlock, and Extended Merced). If this occurred, it would eventually produce a measurable decrease in groundwater elevations. The effect would be more severe during dry years and in areas farther from the SJR, the valley low point towards which groundwater slowly moves. Therefore, there could be a potentially significant and unavoidable depletion of groundwater supplies or substantial interference with groundwater recharge, and resulting potential migration of groundwater contamination under this alternative.	Significant and unavoidable	Significant and unavoidable

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
LSJR Alternative 4	The average annual groundwater balance could potentially be reduced by more than the equivalent of 1 inch in all four subbasins. If this occurred, it would eventually produce a measurable decrease in groundwater elevations. The effect would be more severe during dry years and in areas farther from the SJR, the valley low point toward which groundwater slowly moves. Therefore, there could be a potentially significant and unavoidable depletion of groundwater supplies or interference with groundwater recharge, and resulting potential migration of groundwater contamination under this alternative.	Significant and unavoidable	Significant and unavoidable
Impact GW-2: Cause subsidence as a result of groundwater depletion			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [b]	Less than significant	NA
LSJR Alternative 2	The average annual groundwater balance is expected to be reduced by less than the equivalent of 1 inch across each of the subbasins. This is not expected to produce a measurable decrease in groundwater elevations or associated subsidence. However, if adaptive implementation method 1 were implemented on a long-term basis (an increase in the February–June percent of unimpaired flow from 20% up to 30%), the average annual groundwater balance could potentially be reduced by the equivalent of more than 1 inch across the Extended Merced Subbasin. If this occurred, it could worsen subsidence that is already occurring in this subbasin. Therefore, subsidence could potentially significantly increase under LSJR Alternative 2 with adaptive implementation.	Less than significant	Significant and unavoidable[c]

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
LSJR Alternatives 3 and 4	The average annual groundwater balance could potentially be reduced by more than the equivalent of 1 inch across three subbasins (Modesto, Turlock, and Extended Merced) under LSJR Alternative 3 and across all four subbasins under LSJR Alternative 4. If this occurred, it could worsen subsidence that is already occurring in the Extended Merced Subbasin. Therefore, there could be a potentially significant and unavoidable increase in subsidence under LSJR Alternatives 3 and 4.	Significant and unavoidable	Significant and unavoidable

[a] Four adaptive implementation methods could occur under the LSJR alternatives, as described in Chapter 3, *Alternatives Description*, and summarized in Section 9.4.2, *Methods and Approach*.

[b] The No Project Alternative (LSJR/SDWQ Alternative 1) would result in the continued implementation of flow objectives and salinity objectives identified in the 2006 *Water Quality Control Plan for the San Francisco Bay/Sacramento-San Joaquin Delta Estuary* (2006 Bay-Delta Plan). See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

[c] Implementing adaptive implementation method 1 on a more frequent basis could result in a change in the impact determination for LSJR Alternative 2, as summarized in this table, and described in detail in Section 9.4.3*, Impacts and Mitigation Measures*.

9.2 Environmental Setting

This section describes the location, geology, aquifers, recharge and precipitation, groundwater quality, and groundwater use of the seven subbasins in the plan area, with a primary focus on the four subbasins in the study area. The boundaries of the seven subbasins underlying the plan area are described in Table 9-2.

9.2.1 San Joaquin Valley Groundwater Basin and Subbasins

The northern portion of the San Joaquin Valley Groundwater Basin, as defined in the California Department of Water Resources (DWR) Bulletin 118,[6] approximately coincides with the San Joaquin River (SJR) Hydrologic Region.

Although groundwater aquifers are connected between all the subbasins, rivers are generally used as the subbasin boundaries, with the SJR forming the western boundary, and the Mokelumne, Stanislaus, Tuolumne, and Merced Rivers forming the northern and southern boundaries of the four main subbasins underlying the plan area. The Merced-Madera County line and Chowchilla River are used for part of the southern boundary for the Merced Subbasin, but towards the west, the southern boundary is north of the county line and Chowchilla River and follows irrigation district boundaries. The eastern boundary for the four subbasins underlying the study area abuts the Sierra Nevada foothills. There are fewer wells along the eastern edge of the subbasins; the extent of the aquifers is largely unknown in areas without large municipal production wells as domestic wells are generally

---

[6] DWR's Bulletin 118 series of reports summarize and evaluate California groundwater resources.

unreliable indicators. Aquifer characteristics of these subbasins (Table 9-3) are described in *California's Groundwater*, the 2003 update of the DWR Bulletin 118 (DWR 2003a).

Table 9-2. Groundwater Subbasins Underlying the Plan Area

Subbasin	Subbasin Boundaries	Total Subbasin Surface Area (thousands of acres)	Critically Overdrafted
Eastern San Joaquin	Mokelumne River (north/northwest); San Joaquin River (SJR) (west); Stanislaus River (south); consolidated bedrock (east)	707	X
Tracy[a]	Mokelumne River and SJR (north); Diablo Range (west); San Joaquin-Stanislaus County line (south); SJR (east)	345	
Modesto	Stanislaus River (north); SJR (west); Tuolumne River (south); Sierra Nevada foothills (east)	247	
Turlock	Tuolumne River (north); SJR (west); Merced River (south); crystalline basement rock of the Sierra Nevada foothills (east)	349	
Merced	Merced River (north); SJR (west); Madera-Merced County line (south); Sierra Nevada foothills (east)	491	X
Delta-Mendota[a]	Stanislaus-San Joaquin County line (north); Coast Ranges (west); Fresno Slough (south); SJR and Chowchilla Bypass (east)	747	X
Chowchilla[a]	Triangular region bounded by the southern boundary of the Merced Subbasin (north); SJR and the eastern boundary of the Columbia Canal Company Service Area (west); a border extending south of Dry Creek to the juncture of Merced, Mariposa, and Madera Counties (south and east)	159	X

Sources: DWR 2003a, 2003b, 2003c, 2003d, 2003e, 2003f, 2003g, 2003h, 2016.

[a] The Tracy, Delta-Mendota, and Chowchilla Subbasins comprise very little of the plan area.

Table 9-3. Characteristics of Freshwater Aquifers of the Northern San Joaquin Valley Groundwater Subbasins

	Subbasin Occurrence											
Aquifer Characteristic	Eastern San Joaquin	Tracy	Modesto	Turlock	Merced	Chowchilla	Delta-Mendota	Aquifer Age	Thickness (feet)	Estimated Yield (gpm)	General Description	Comments
Younger Alluvium		X	X	X	X	X		Recent	0–100	Can yield significant water	Dredge tailing and stream channel deposits	Unconsolidated sedimentary deposits.
Older Alluvium (undifferentiated)		X		X	X	X		Pliocene to Pleistocene	150	–[a]	Alluvial fan deposits	One of main water-yielding units of the unconsolidated sedimentary deposits.
Older Alluvium (differentiated)[b]			X					Pliocene to Pleistocene	100–650	–	Alluvial fan deposits	One of main water-yielding units of the unconsolidated sedimentary deposits.
Alluvium and Modesto/ Riverbank Formations	X						X	Recent to Late Pleistocene	0–150	650+	Alluvial and interfan deposits	

Aquifer Characteristic	Subbasin Occurrence							Aquifer Age	Thickness (feet)	Estimated Yield (gpm)	General Description	Comments
	Eastern San Joaquin	Tracy	Modesto	Turlock	Merced	Chowchilla	Delta-Mendota					
Flood basin deposits (undifferentiated)	X	X	X	X	X	X	X	Recent to Pliocene	0–1,400	Low	Flood basin deposits	Unconsolidated sedimentary deposits. Generally poor water quality with occasional areas of fresh water. Basinward (finer-grained) lateral equivalents of the Tulare, Laguna, Riverbank, Modesto, and Recent formations occur within the Delta.
Laguna Formation	X							Pliocene to Pleistocene	400–1,000	Average of 900, but up to 1,500	Fluvial	
Mehrten Formation	X		X	X	X			Miocene to Pliocene	200–1,200	Approximately 1,000	Reworked volcaniclastics (permeable) and dense tuff breccia (confining units)	

Aquifer Characteristic	Subbasin Occurrence							Aquifer Age	Thickness (feet)	Estimated Yield (gpm)	General Description	Comments
	Eastern San Joaquin	Tracy	Modesto	Turlock	Merced	Chowchilla	Delta-Mendota					
Tulare Formation		X					X		1,400	Up to 3,000	Clay, silt, and gravel	Poor water quality above the Corcoran Clay, which occurs near the top of the formation.

gpm = gallons per minute

[a] California Department of Water Resources (DWR) has not estimated subbasin yield.

[b] Differentiated units are the Modesto, Riverbank, Victor, and Laguna formations.

Geology and Hydrogeology

Each groundwater subbasin may have multiple aquifers. Aquifers are underground layers of water-bearing permeable rock or unconsolidated materials (gravel, sand, or silt) from which groundwater wells can pump water. Each subbasin can be described by its surface area, boundaries (at bedrock or along streams), and geological layers (physical characteristics). This section provides a description of groundwater basin geology and the distribution and movement of groundwater within subbasin aquifers in the plan area.

Two distinct geologic areas are located in the eastern and western portions of the San Joaquin Valley Groundwater Basin. The eastern portion of the basin contains the Ione, Mehrten, Riverbank, and Modesto formations, which are composed primarily of sediments originating from the Sierra Nevada. The western portion of the basin is composed of the Tulare Formation, which is the primary freshwater unit. The Tulare Formation originated as eroded sediments from the Coast Ranges deposited in the San Joaquin Valley as alluvial fan, flood basin, delta or lacustrine, and marsh deposits. The presence of thick, fine-grained lacustrine (originating in lakes) and marsh deposits distinguishes the Tulare Formation from other hydrologic units. These fine-grained units can be up to 3,600 feet (ft) thick in the Tulare Lake Groundwater Basin, but more commonly occur as regional, laterally extensive deposits tens to hundreds of feet thick that create vertically differentiated aquifer systems. The most widespread of these fine-grained units, the Corcoran Clay, divides the groundwater in the Tulare Formation into an upper semi-confined zone and a lower confined zone.

Freshwater-bearing aquifers within the subbasins include younger alluvium, older alluvium, flood basin deposits, lacustrine and marsh deposits, continental deposits, Turlock Lake, terrace deposits, Laguna Formation, Mehrten Formation, Tulare Formation, Alluvium and Modesto/Riverbank Formations, Ione Formation, and Valley Springs. The older alluvium consists of loosely and moderately compacted sand, silt, and gravel, is moderately to locally highly permeable, and is one of the main water-yielding units of the unconsolidated sedimentary deposits (City of Tracy 2011; DWR 2003a, 2003b, 2003c, 2003d, 2003e). The younger alluvium contains actively accumulating deposits, including sediments deposited in the channels of streams, and consists of unconsolidated silt, fine-to-medium grained sand, and gravel that are highly permeable and, where saturated, can yield significant amounts of water (City of Tracy 2011). Because of their fine-grained nature, flood basin deposits generally have low permeability and yield low quantities of water that is typically also of poor quality (City of Tracy 2011; DWR 2003a, 2003b, 2003c, 2003d, 2003e). The Tulare Formation generally yields poor-quality water above the Corcoran Clay layer, but contains freshwater deposits below the Corcoran Clay. The Alluvium and Modesto/Riverbank formations consist primarily of sand and gravel in the fan areas, while clay, silt, and sand are dominant in the interfan areas. Because these units are not very thick, most wells penetrate them to tap deeper aquifers. The Laguna Formation consists of discontinuous layers of stream-laid sand and silt, with lesser amounts of clay and gravel. Table 9-3 summarizes aquifer characteristics in each subbasin from which irrigation districts and water districts draw.

Groundwater Use and Budget

The subbasin water budget is the fundamental description of the groundwater conditions and is the basis for evaluating groundwater impacts. The storage volume for the subbasin may be quite large if the freshwater aquifers extend relatively deep (e.g., 500 ft); however, water surface elevation (or depths to groundwater) is more often used to describe the subbasin storage and to identify whether the subbasin storage is steady (sustainable) or in decline (in overdraft). The inflows to the basin (recharge) may be from adjacent subbasins; from overlying rivers and streams; or from infiltration from rainfall, irrigation canals, reservoirs, and water applied to crops (i.e., applied water). The outflows from the subbasin are predominantly pumping from wells by irrigation districts, municipalities, or individual users for irrigating crops or as potable water sources. However, outflows can also include seepage to springs and rivers when the groundwater elevation is higher than that of the surface water. Figure 9-2 shows a conceptual water budget with various inflows and outflows.

Irrigated agriculture accounts for approximately 95 percent of the total water use in the Modesto, Turlock, and Merced Subbasins, with municipal water use accounting for approximately the remaining 5 percent (USGS 2010). Of that total water use, groundwater accounts for approximately 38 percent of the total supply in the SJR Hydrologic Region (DWR 2013). As discussed in Chapter 13, *Service Providers*, many San Joaquin Valley cities rely on groundwater either wholly or partially to meet municipal needs.

Groundwater pumping in this region has caused a decrease in groundwater levels in recent years (DWR 2015a), which indicates that groundwater pumping is exceeding the amount of water that recharges the basin. When groundwater pumping is greater than recharge over a period of years, the basin or subbasin is considered overdraft. Overdraft is characterized by groundwater levels that decline over a period of years and never fully recover, even in wet years. Overdraft can lead to significant impacts such as increased extraction costs, costs of well deepening or replacement, land subsidence, and degradation of groundwater quality (DWR 2003a).

Groundwater levels in the San Joaquin Valley Groundwater Basin have generally declined as a result of extensive agricultural pumping. Groundwater levels have declined by as much as 100 ft in some areas, primarily in the southern and western-most portions of the basin outside of the plan area (USGS 1999). In 2014, DWR evaluated groundwater elevation levels in California’s 515 alluvial groundwater basins and subbasins, prioritizing groundwater basins on multiple factors including reliance on groundwater as a primary source of water for municipal and agricultural use. DWR identified the four subbasins underlying the plan area as high priority (DWR 2014a). Subsequently, DWR was statutorily required to identify groundwater basins and subbasins in a condition of critical overdraft, which was defined as “when a continuation of present water management practices would probably result in significant adverse overdraft-related environmental, social, or economic impacts.” The resulting list of 21 critically overdrafted basins included the Eastern San Joaquin, Merced and Chowchilla Subbasins (DWR 2016; Table 9-2).

Water Balance Processes within Subbasins

This section describes the movement of water into and out of the groundwater subbasins in the plan area and the resulting known effects on groundwater elevations. This section also describes known subsidence issues in and surrounding the plan area.

Horizontal Groundwater Flow

Patterns of groundwater movement and rates of recharge in the San Joaquin Valley Groundwater Basin have been significantly altered from pre-agricultural and urban development conditions. Prior to development, groundwater generally moved from recharge areas in the higher grounds surrounding the San Joaquin Valley towards the valley trough. Most groundwater discharges (i.e., losses) resulted from evapotranspiration and groundwater discharge to surface waters. In contrast, the majority of groundwater recharge in subbasins today comes from surface water for irrigation. Losses today typically result from groundwater pumped from both the shallow, semi-confined upper aquifer (400–800 ft) and lower confined aquifer(s) (500–4,000 ft) of the San Joaquin Valley Groundwater Basin (Trump 2008). This is generally true unless one aquifer is substantially more permeable or if local groundwater quality issues that affect groundwater pumping exist. Groundwater in the plan area generally moves from high ground down towards the SJR and Delta. However, groundwater may also move into areas of substantial drawdown, such as toward the cone of depression in the eastern half of the Turlock Subbasin or the high groundwater pumping areas west of the SJR (USGS 2015).

Inflows and Outflows

Each subbasin has a different surface area and different geological features (i.e., aquifer characteristics), and is subject to different pumping volumes. The inflows (i.e., recharge) are more difficult to estimate than outflows (e.g., pumping and other discharges), but the inflows must be similar to the pumping and other discharges in order to maintain groundwater levels in the subbasins. Mean annual rainfall in the plan area is low, ranging from 9 to 15 inches. Natural groundwater recharge from rainfall, streamflow, and lakes in the subbasins provide an important inflow component of the groundwater balance of each subbasin. This inflow is augmented by percolation of applied irrigation water and seepage from the distribution systems that convey this water (MAGPI 2008; TGBA 2008). Seepage originates from reservoirs, unlined water conveyances, and distribution canals. Major outflows occur through well pumping. However, other outflows include groundwater flowing to neighboring basins, seepage to springs, rivers, wetlands, and uptake by plants.

Interaction between Rivers and Groundwater

Stream seepage from the Stanislaus, Tuolumne, and Merced Rivers provides some portion of recharge to the underlying groundwater aquifers. Groundwater can flow to springs or rivers when the river elevation is less than the nearby groundwater elevation. Some sections of rivers are “losing” (i.e., the river recharges the groundwater) and other sections of rivers are “gaining” (i.e., groundwater discharges to the river). The upper reaches of the Stanislaus, Tuolumne, and Merced Rivers (downstream of Goodwin, La Grange, and Crocker-Huffman Dams) are losing rivers, with groundwater recharged by streamflow. The lower reaches of the rivers are gaining rivers, with groundwater discharging to the rivers (TGBA 2008; MAGPI 2008). Between 1997 and 2006, the net groundwater discharge to the lower reaches of the Tuolumne and Merced Rivers and along the entire reach of the SJR was estimated as a combined average of nearly 30 thousand acre-feet per year (TAF/y) (TGBA 2008). Other studies indicate that the SJR downstream of the Merced River is gaining (USGS 2015). Modeling results of groundwater-surface water interactions are not entirely consistent with this upstream versus downstream pattern. For example, based on modeling results performed for San Joaquin County to simulate a 5-year period (1989–1993), the Tuolumne River and upper SJR were gaining rivers, while the Stanislaus River and LSJR (from the Merced River to Vernalis) were losing rivers (NSJCGBA 2004).

In either the losing or gaining scenario, groundwater-surface water interactions are unlikely to have a large impact on total river flow. A recent modeling study of a region east of the SJR extending from north of the Stanislaus River to south of the Merced River indicated that groundwater-surface water interactions have a relatively small effect on river flow, generally changing flow by plus or minus 2 cubic feet per second (cfs) per mile (USGS 2015).

Graphics...00427.11 (10-5-2015)

Figure 9-2
Conceptual Water Budget

The depth to groundwater table (i.e., elevation of standing water in wells) of the near-surface unconfined aquifer is controlled by the surface water elevations of rivers and the amount of water moving in and out of the aquifer. SJR elevation generally increases from approximately 20 ft above mean sea level (MSL) in the north (mouth of Stanislaus River), to approximately 80 ft above MSL in the south (near the Merced–Madera County line), and to approximately 150–200 ft above MSL in the eastern portions of the subbasins along the Sierra Nevada foothills

Groundwater Balance and Elevations

A groundwater balance occurs naturally in an undeveloped aquifer system where inflows and outflows of groundwater are equal. Pumping for urban or agricultural uses changes the balance of the system and may lead to declining groundwater levels and land subsidence (USGS 1999). The general water balance condition (i.e., sustainable pumping or overdraft) of a subbasin can be identified by observing groundwater elevations over a number of years. Declining groundwater levels indicate overdraft, which occurs when average outflow from a subbasin exceeds average inflow to a subbasin. Steady or rising groundwater levels indicate that average pumping is less than or equal to the average net inflow. Increasing pumping in a subbasin is likely to reduce the average groundwater level (i.e., drawdown), with a noticeable effect on groundwater levels over a number of years.

Sustainable (or safe) yield represents a level of groundwater pumping that will not harm other resources. However, it is difficult to determine the sustainable yield of a subbasin because of the large degree of uncertainty associated with all components of the water budget. This includes the difficulty of determining whether a certain level of groundwater pumping will reduce accretions to surface water bodies by an amount that will be detrimental to surface water resources. Furthermore, sustainable yield estimates are highly dependent on recharge from surface water applications for irrigation and seepage from distribution systems. As such, if surface water applications are modified, then the subbasin's sustainable yield changes.

DWR and other agencies monitor groundwater elevations through a network of wells. Each groundwater management plan (GWMP, discussed in Section 9.3.3, *Regional or Local [Regulatory Background]*) prepared for the subbasins includes groundwater elevation contours for each year or every 3–5 years. The depth to groundwater in each well can also be plotted to determine the increases and decreases in the groundwater elevations through time. Groundwater elevations generally decrease during drought periods because the balance between recharge from surface irrigation and pumping for irrigation shifts to more pumping. This shift results in less recharge to the subbasins from surface water diversions and deliveries. Seasonal changes can also affect water table elevations. For example, groundwater elevations may increase slightly during the winter, from higher recharge, and decrease during the summer, from increased groundwater pumping. Seasonal changes in groundwater elevations are less apparent in subbasins with substantial surface water deliveries because the increased pumping coincides with the increased surface water recharge (from canals and applied water).

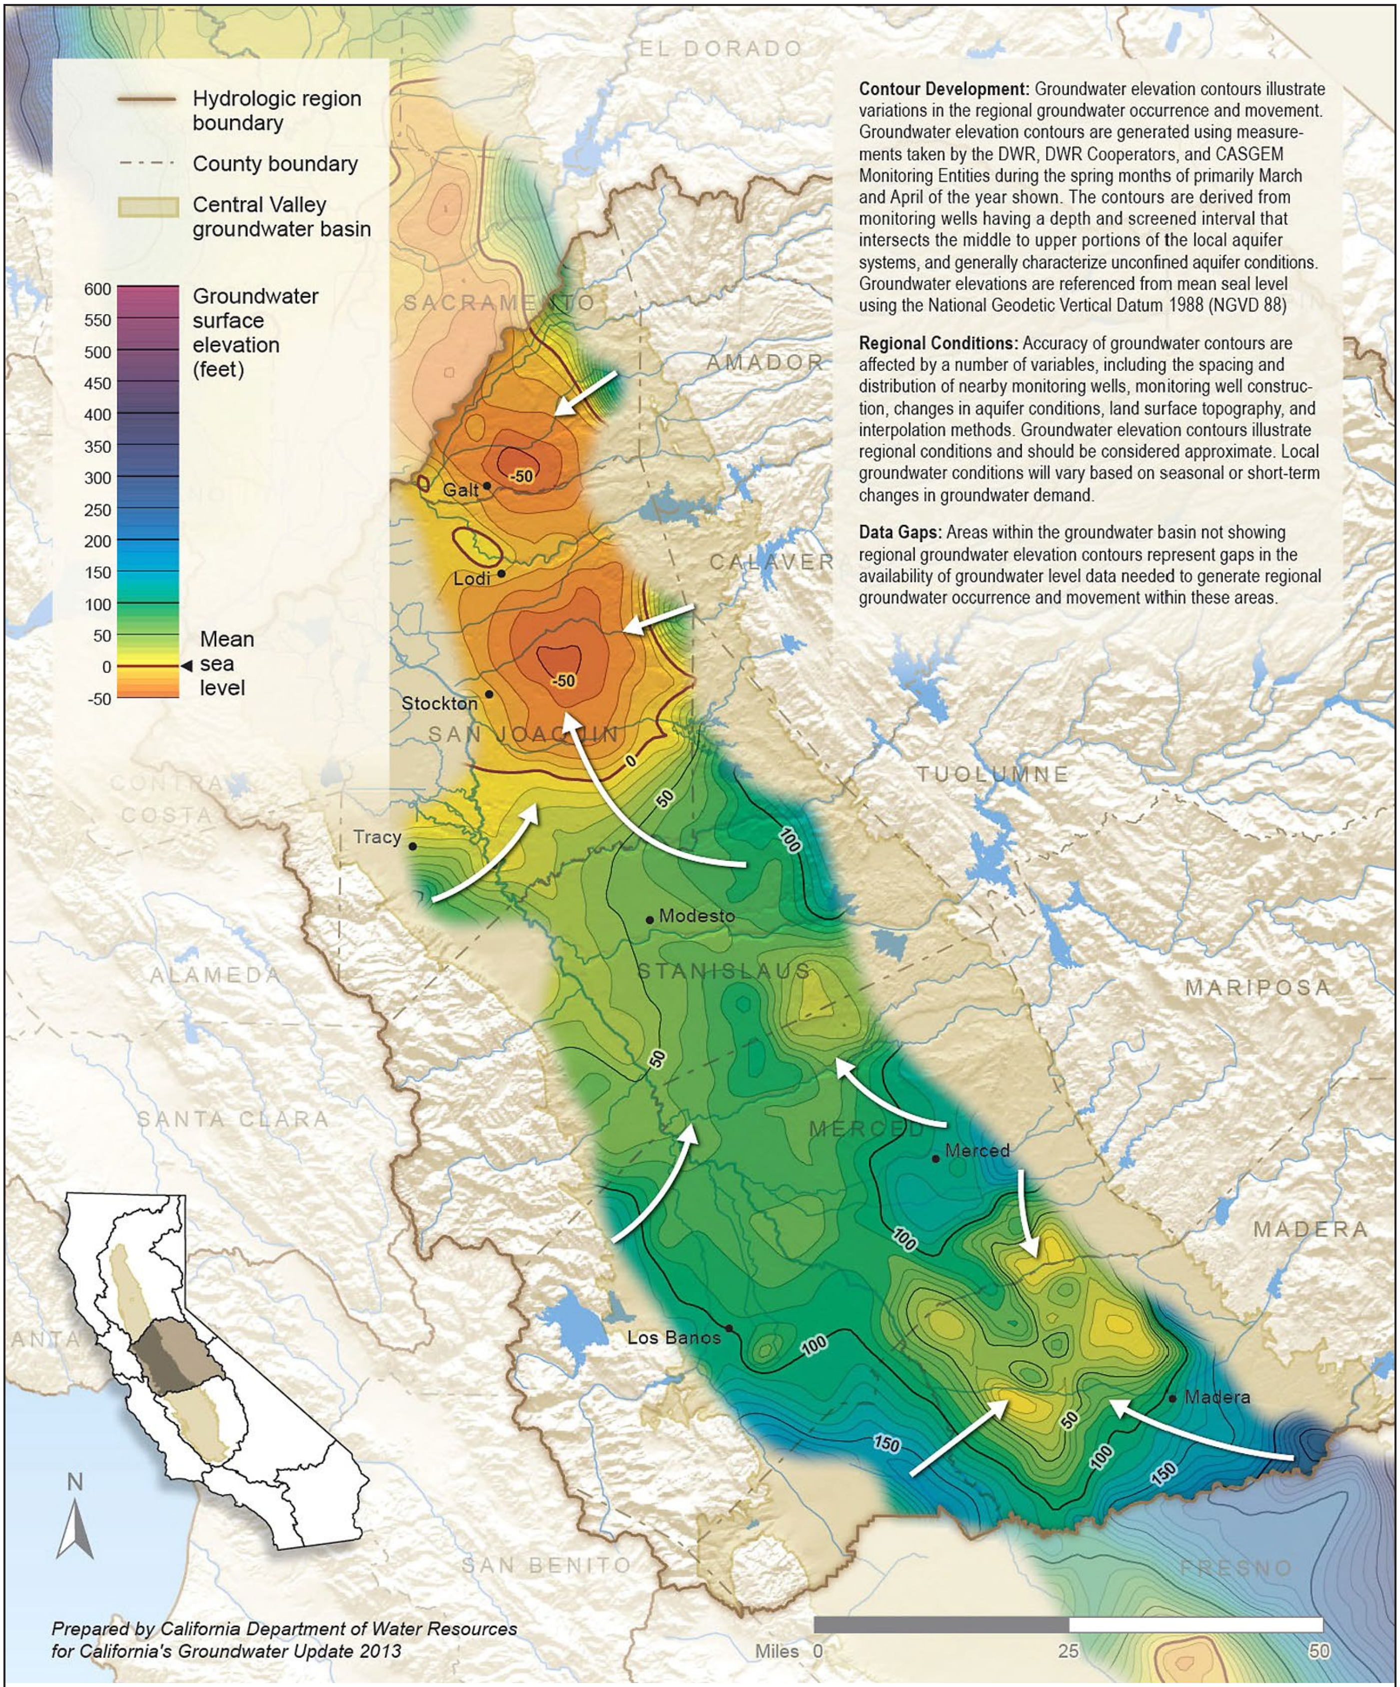
Figure 9-3 shows recent (2010) groundwater elevations in the San Joaquin Valley portion of the SJR region. The elevation contours show that groundwater elevations are shallowest along the Central Valley floor adjacent to the SJR and its tributaries, and are deepest along the eastern side of the Central Valley, where it abuts the lower foothills of the Sierra Nevada. The elevation contours also show areas of lower elevation (e.g., cones of depression) in some portions of the Turlock and Eastern San Joaquin subbasins (DWR 2015a). Between 2005 and 2010 the subbasins underlying the plan area saw generally small changes in groundwater elevations (Figure 9-4). However, larger decreases occurred along the eastern edges of the irrigation districts and some areas near and east of Stockton experienced increases in groundwater levels (DWR 2015a). More information regarding groundwater elevations related to each subbasin is provided in Section 9.2.2, *Subbasin Groundwater Use*.

Figure 9-5 shows the depth below ground surface to the groundwater level as contours for the San Joaquin Valley portion of the SJR region. The depth to groundwater is generally less than 20 ft along the SJR and western portions of each subbasin underlying the plan area, and increases to more than 100 ft in the eastern portions of the subbasins underlying the plan area. Despite intensive agricultural practices predominant in the valley, depth to groundwater is shallowest along the SJR because the volume of water transferred by SJR tributaries has resulted in a high, near-surface water table as an outcome of recharging shallow aquifers. The deeper depths to groundwater in the eastern portions of the subbasins are due to widespread agricultural development and a lack of surface water. In some locations near the SJR, groundwater is too close to the surface for agriculture, and districts have resorted to pumping groundwater to enhance drainage (DWR 2015a). However, Turlock Irrigation District (TID) and Modesto Irrigation District (MID) have decreased their drainage pumping between 1960 and 2004 (USGS 2015).

Although much of the plan area saw only small changes in groundwater elevations in recent years (Figure 9-4), the San Joaquin Valley has a long history of declining groundwater levels due to overpumping. The most significant decline has occurred south of the study area; however, the four subbasins underlying the study area have all experienced groundwater level declines and overdraft (Table 9-4). The average groundwater level decline is difficult to estimate from scattered wells with incomplete data through time. Overdraft estimates vary because of the use of different data, time periods, and underlying assumptions. Much of the data is incomplete or only represents a certain geography (e.g., county) of a total subbasin. Further, numbers can vary widely depend on what time period reviewed and specific yield[7] values used. Withdrawals and recharge from unconsolidated heterogeneous aquifer systems, like those underlying many locations in the San Joaquin Valley causes measurable elastic (recoverable) land subsidence. Removing water from storage in fine-grained silts and clays that are interbedded in the aquifer system can cause these highly compressible sediments to compact inelastically and permanently. Land subsidence from inelastic (non-recoverable) compaction is a common consequence of the significant groundwater level changes that can result from dependence on groundwater (Borchers et al. 2014).

---

[7] *Specific yield* is the ratio of the volume of water a saturate soil will yield by gravity drainage to the total volume of the soil.



Contour Development: Groundwater elevation contours illustrate variations in the regional groundwater occurrence and movement. Groundwater elevation contours are generated using measurements taken by the DWR, DWR Cooperators, and CASGEM Monitoring Entities during the spring months of primarily March and April of the year shown. The contours are derived from monitoring wells having a depth and screened interval that intersects the middle to upper portions of the local aquifer systems, and generally characterize unconfined aquifer conditions. Groundwater elevations are referenced from mean seal level using the National Geodetic Vertical Datum 1988 (NGVD 88)

Regional Conditions: Accuracy of groundwater contours are affected by a number of variables, including the spacing and distribution of nearby monitoring wells, monitoring well construction, changes in aquifer conditions, land surface topography, and interpolation methods. Groundwater elevation contours illustrate regional conditions and should be considered approximate. Local groundwater conditions will vary based on seasonal or short-term changes in groundwater demand.

Data Gaps: Areas within the groundwater basin not showing regional groundwater elevation contours represent gaps in the availability of groundwater level data needed to generate regional groundwater occurrence and movement within these areas.

[a] Values based on average water level decline, subbasin acres, and specific yield from DWR Bulletin 118.

[b] The overdraft is primarily located in the eastern part of the Turlock Subbasin.

[c] Exact years vary: Modesto Subbasin 1970–1990; Turlock 1971–1991; Merced Subbasin 1960–1992.

The extensive withdrawal of groundwater from the unconsolidated deposits has causes widespread land subsidence in the San Joaquin Valley (USGS 1986). Long-term groundwater level declines can result in a vast one-time release of "water of compaction" from compacting silt and clay layers in the aquifer system, which causes land subsidence (USGS 1999). Land subsidence in the region due to groundwater pumping began in the mid-1920s (USGS 1975; USGS 1991; USGS 1999). As surface water imports increased during the early 1950s through early 1970s and groundwater pumping decreased, groundwater levels began to recover and reduced the rate of land subsidence in some areas (USGS 1986). During the droughts of 1976–1977 and 1987–1992, reduced surface water availability once again led to increased groundwater pumping and re-initiating subsidence in the San Joaquin Valley. However, following each of these droughts, recovery to pre-drought water levels was rapid and subsidence virtually ceased (Swanson 1998; USGS 1999). During the more recent droughts of 2007–2009 and 2012–present, groundwater pumping and subsidence has increased in some parts of the San Joaquin Valley (Faunt 2015), including in the southern portion of the study area.

In the southern portion of the study area, increased dependence on groundwater during the recent drought resulted in groundwater levels approaching or surpassing historic lows, which caused aquifer-system compaction and land subsidence that most likely is permanent (Sneed and Brandt 2015). Between 2008 and 2010, the southern portion of the study area (Extended Merced Subbasin) experienced some level of subsidence, with the highest subsidence rate occurring around El Nido, which saw a decline of 540 millimeters (mm) (subsidence rate of 270 mm/y). This is among the highest subsidence rates ever measured in the San Joaquin Valley. Assuming the same rate of subsidence occurred during 2007–2014 as occurred during 2008–2010 at the local subsidence maximum near El Nido, approximately 2 meters of subsidence may have occurred during 2007–2014 (Sneed and Brandt 2015; Farr et al. 2015). The periphery of the El Nido subsidence area, both inside and outside the study area, showed seasonally variable subsidence and compaction rates. Groundwater-dependent areas that have not historically depended on surface water supplies experienced fairly consistent rates of groundwater level decline during and between drought periods. Those areas that increased groundwater-dependence while surface water was curtailed experienced subsidence during the drought periods, but very little subsidence between drought periods (Sneed and Brandt 2015).

9.2.2 Subbasin Groundwater Use

This section provides an overview of groundwater use in the four main subbasins underlying the plan area (Eastern San Joaquin, Modesto, Turlock, and Merced) and allows for comparisons between subbasins. The overview is followed by more specific information for each subbasin, including information about irrigation districts, and the groundwater and surface water users of each irrigation district.

In some cases, the numeric values provided in the overview differ from the values in specific subbasin sections; this is due to differences in agencies' analysis. For example, most numbers shown in the tables are from DWR Bulletin 118, while other data and information come from county databases, DWR's 2013 Water Plan Groundwater Update (DWR 2015a), irrigation district agricultural water management plans (AWMPs), GWMPs, integrated regional water management plans (IRWMPs), and urban water management plans (UWMPs). While numbers may be inconsistent throughout this section, in general, the inconsistencies are minor and support scientifically sound conclusions about groundwater trends within the subbasins and the irrigation districts. Irrigation districts manage groundwater resources within their service areas; the groundwater subbasins underlying the plan and study areas are not adjudicated (DWR 2011).

More than half of all land within the study area is irrigated agriculture and the largest use of groundwater is for agricultural purposes. Although agricultural groundwater pumping is not generally measured, total groundwater pumping in each subbasin can be estimated indirectly from the DWR agricultural land surveys. The estimate uses the acres of each crop category within each subbasin or irrigation district boundary. Surface water is assumed to provide the majority of the irrigation districts' water; groundwater pumping is estimated for the irrigated areas that are not supplied with surface water.

Irrigation districts that divert water from the Stanislaus, Tuolumne, or Merced Rivers or the LSJR may also pump groundwater from the subbasins for agricultural or domestic water supplies. These irrigation districts include: South San Joaquin Irrigation District (SSJID), Oakdale Irrigation District (OID), Stockton East Water District (SEWD), Central San Joaquin Water Conservation District (CSJWCD), MID, TID, and Merced Irrigation District (Merced ID). Throughout the rest of this chapter, these districts that regularly receive surface water from the Stanislaus, Tuolumne, and Merced Rivers are collectively referred to as the "irrigation districts."

Other water suppliers in the study area include the Northern San Joaquin Water Conservation District (NSJWCD), Woodbridge Irrigation District (WID), Eastside Water District (EWD), and Ballico-Cortez Water District (BCWD). NSJWCD and WID pump groundwater from the northern portion of the Eastern San Joaquin Subbasin and receive surface water from the Mokelumne River (NSJCGBA 2004). EWD and BCWD are large groundwater users in the Turlock Subbasin; they also receive some surplus surface water from TID and Merced ID during wet weather seasons (TGBA 2008).

Table 9-5 shows the number of irrigated acres that lie within each groundwater subbasin separated by whether the acres are within or outside of the irrigation districts. These acres were estimated using information from the AWMPs prepared by irrigation districts in recent years (2012–2014) and DWR's 2010 agricultural land survey.[8] For more information, see Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*.

The total irrigated land within each subbasin generally indicates the potential for agricultural pumping effects on the subbasin water balance. The Modesto Subbasin has the fewest acres of irrigated land overall, both by acreage and by percentage (116,000 acres and 47 percent total land, respectively) and the Turlock Subbasin has the greatest percentage of irrigated land (77 percent). However, the best indication of the potential for groundwater impacts that may occur if surface water diversions are reduced in drought years is the percentage of the irrigated area that falls within the irrigation district service areas and usually relies on surface water. Within irrigation district service areas, the Merced Subbasin has the fewest number of irrigated acres, both by acreage and by percentage (86,000 acres and 32 percent, respectively); the Modesto Subbasin has the greatest number of irrigated acres that falls within irrigation district service areas, when determined by percentage (77 percent).

Groundwater Quality

Groundwater quality varies substantially throughout the San Joaquin Valley Groundwater Basin. Poor water quality conditions caused by agricultural and industrial contaminants are more common in the surface aquifer at shallower depths. In addition to agricultural and industrial sources, trace elements (such as arsenic, manganese, vanadium, and uranium) that are naturally occurring in rocks and soils can come in contact with the water and present water quality problems.

Groundwater quality of the subbasins varies depending on the location, substrate material, and land use (e.g., agricultural or urban). The State Water Board's Groundwater Ambient Monitoring and Assessment Program (GAMA), referenced under Section 9.3.2, *State [Regulatory Background]*, provides a comprehensive assessment of the State's groundwater quality. GAMA's Priority Basin Project included the four groundwater basins in the study area. While GAMA demonstrated that groundwater quality in the four subbasins is relatively good (i.e., low salinity and low contaminant levels), organic constituents (i.e. volatile organic compounds [VOCs] and pesticides) and inorganic constituents (i.e., trace elements and nutrients such as nitrite and nitrate) have been detected in some of the primary aquifers in the study area. The GAMA Priority Basin Project is discussed in greater detail in Chapter 13, *Service Providers*.

---

[8] DWR 2010 agricultural land survey data are available as geographic information systems (GIS) coverages for each of DWR's Detailed Analysis Units (DAU).

Elevated salinity levels, measured as total dissolved solids (TDS) or electrical conductivity (EC),[9] are common in San Joaquin Valley groundwater. Salinity is generally lower along the eastern side of the San Joaquin Valley Groundwater Basin than on the western side, and is generally higher in the shallow aquifer than the deep aquifer. The relatively low groundwater salinity on the eastern side can be attributed to the low salinity of Sierra Nevada runoff and application of surface water as a major irrigation source in the subbasins. However, there are some localized issues. For example, increased levels in groundwater salinity have been detected in the Stockton area due to a lateral saline front to the west (NSJCGBA 2004). In the Merced Groundwater Basin, high TDS concentrations are principally the result of the migration of a deep saline water body which originates in regionally deposited marine sedimentary rocks that underlie the San Joaquin Valley. Under natural pressure, the saline groundwater body is migrating upward. But pumping by deep wells in the western and southern parts of the Merced Subbasin may be causing these saline brines to upwell and mix with fresh water aquifers more rapidly than under natural conditions (MAGPI 2008).

As discussed above, over pumping of groundwater has been depleting the groundwater resources in the Central Valley. A change in groundwater gradient associated with groundwater pumping can indirectly influence groundwater quality in the subbasins. If there is a source of groundwater contamination in an area, groundwater pumping can influence the movement of contaminants toward wells. See Section 13.2.1, *Lower San Joaquin River and Tributaries,* for details of how over-pumping can affect groundwater quality.

For example, while the San Joaquin Valley is not characterized by high concentrations of nitrates at the depth zone used for public supply, application of fertilizers and animal manure to agricultural land has caused downward movement of nitrates into the soil. As groundwater pumping continues and as irrigation water containing elevated concentrations of nitrate moves toward and through deeper parts of the aquifer, high concentrations of nitrates in the public water supply could be a concern in the future (Belitz et al. 2015).The slow movement of water from the surface through the unsaturated zone to deep aquifers means that it may be many years after a persistent chemical has entered the ground before it affects the quality of groundwater supplies (Morris et al. 2003). Although the occurrence of trace elements (e.g., arsenic and uranium) is not anthropogenic, these elements can leach into groundwater and be mobilized by human activities (Smedley and Kinniburgh 2002; Barringer and Reilly 2013). For example, the downward infiltration of irrigation water with elevated bicarbonates caused movement of uranium in an area of the eastern San Joaquin Valley (Belitz et al. 2015).

Over 98 percent of Californians using a public water supply receive safe drinking water that meets all health standards (State Water Board 2013). In general, municipal drinking water wells do not exceed federal and state maximum contaminant levels (MCLs) for water quality. This is because municipal wells are generally deep, and water quality tends to be better in deeper aquifers. Furthermore, water quality is managed such that if the concentration of contaminants in well water exceeds criteria, the well can be brought offline or its water can be blended with higher quality water from other wells. In addition, water quality in community water systems are frequently

---

[9] In this document, EC is *electrical conductivity*, which is generally expressed in deciSiemens per meter (dS/m). Measurement of EC is a widely accepted indirect method to determine the salinity of water, which is the concentration of dissolved salts (often expressed in parts per thousand or parts per million). EC and salinity are therefore used interchangeably in this document.

monitored by the Division of Drinking Water and the service providers pursuant to various regulatory requirements stated in Section 13.3, *Regulatory Background*.

However, drinking water quality is still a concern in some areas of the four subbasins. Between 2002 and 2010, approximately one-fifth of the state's active community water system wells used by groundwater-reliant communities (i.e., groundwater is the primary source of drinking water) had contaminated groundwater with detections above an MCL two or more times (State Water Board 2013). Of the 510 active wells (serving 148 community water systems) within the four subbasins, 134 wells (serving 54 community water systems) had two or more MCL exceedances between 2002 and 2010. These exceedances reflect raw, untreated groundwater quality; as stated above, water systems that rely on contaminated groundwater typically treat their well water before it is served to the public. For example, the City of Livingston recently improved filtration in order to reduce arsenic concentrations that were above the state's MCL (Giwargis 2014).

Private drinking water wells may have more significant water quality issues than municipal wells because they are often shallower than municipal wells and, therefore, are more susceptible to surface contaminants. However, the state does not regulate the water quality of private drinking water wells, and does not require private drinking water well owners to test for water quality. As such, there is no comprehensive dataset on private drinking water quality, and there is a lack of water quality data for private drinking water wells within the study area.

Although, as stated above, groundwater pumping can influence the movement of contaminants toward wells, specifically determining the changes to groundwater quality is speculative as it is dependent of many factors including, but not limited to, location and depth of the well, the amount and frequency of groundwater pumping, number and proximity of nearby wells, hydrogeological characteristics of the aquifer (e.g., consolidated clays with low permeability or unconsolidated sands with high permeability), distance between the well(s) and the contaminant(s), contaminant characteristics (e.g., highly mobile in water or adhering primarily to soil), and land use near the well. Groundwater quality may also be affected by other factors such as improperly constructed wells that interconnect groundwater strata or introduce surface waters into underground waters (Wat. Code, § 231) or by unused or abandoned wells that, due to the pumping of nearby wells, can draw poor quality water down and into the drinking water aquifer (State Water Board 2015).

Table 9-5. Summary of Irrigated Land in the Plan Area Subbasins

Subbasin	Total Land (1,000 acres)	Total Irrigated Area (1,000 acres and percent of total land)	Total Irrigated Area: Outside Irrigation Districts (1,000 acres and percent of total irrigated area)	Total Irrigated Area: Within Irrigation Districts (1,000 acres and percent of total irrigated area)
Eastern San Joaquin	707	386 (55%)	192 (50%)	194 (50%)
Modesto	247	116 (47%)	27 (23%)	89 (77%)
Turlock	349	269 (77%)	118 (44%)	151 (56%)
Merced	491	269 (55%)	182 (68%)	86 (32%)
Total	1,794	1,039 (58%)	518 (50%)	521 (50%)

Note: Irrigated acres are based on GIS analysis of DWR 2010 agricultural land survey data, at the detailed analysis unit (DAU) level, and 2012 AWMPs. For more information, see Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*.

Table 9-6 shows the estimated groundwater pumping in each subbasin. The estimated groundwater pumping for normal years within the subbasins is estimated based on the acres of irrigated lands outside of the irrigation districts, the volume of municipal pumping for cities, and the minimum pumping volume reported within each irrigation district in normal years with full surface water diversions. Groundwater pumping for irrigated lands outside of the irrigation districts is estimated by multiplying estimates of applied water rates for different crop types by the number of acres of each crop type, as described in Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*.

Groundwater pumping for irrigated lands outside the irrigation districts remains relatively constant during droughts. This is because crop needs are generally met with groundwater regardless of surface water availability (although crops may require more applied water in drought years than in normal years). However, groundwater pumping for irrigated lands within the irrigation districts typically increases in years when the available surface water supply is reduced. When surface water diversions are reduced during dry years, irrigation districts (or individual growers) may increase groundwater pumping to compensate for a portion of, or all of, the reduced surface water diversions. If historical conditions have provided nearly full surface water diversions in most years, an irrigation district may have a limited a capacity in regards to the quantity of groundwater that can be pumped. Minimum and maximum groundwater pumping in the irrigation districts are estimated, as described in Appendix G. Minimum groundwater pumping is expected every year; whereas maximum groundwater pumping is expected only when surface water is in such short supply that irrigation district wells would be fully utilized.

Table 9-6 Estimated Groundwater Pumping in the Plan Area Subbasins

Subbasin	Districts	District Irrigated Lands (1,000 acres)	Minimum Pumping (TAF/y)[a]	Maximum Pumping (TAF/y)[a]	Municipal Pumping (TAF/y)[b]	Irrigated Land Outside Districts (1,000 acres)	Pumping for Irrigated Lands Outside of Districts (TAF/y)[a, c]	Minimum Total Pumping (TAF/y)
Eastern San Joaquin	Total	194	167	353	47	192	446	658

SSJID = South San Joaquin Irrigation District
OID = Oakdale Irrigation District
SEWD = Stockton East Water District
CSJWCD = Central San Joaquin Water Conservation District
TID = Turlock Irrigation District
MID = Modesto Irrigation District
Merced ID = Merced Irrigation District
WID = Woodbridge Irrigation District
TAF/y = thousand acre-feet per year.
NA = Not Applicable (because groundwater pumping for WID land that is not supplied by surface water is included with the pumping for lands outside of the irrigation districts).

[a] Values derived as described in Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*. These values are for the 2009 base year. Minimum and maximum pumping estimates for 2014 were also assessed as described in Section 9.4.3, *Impacts and Mitigation Measures*, and Appendix G.

[b] Source: Domestic/municipal pumping from DWR Bulletin 118 (DWR 2003a, 2003b, 2003c, 2003d, 2003e).

[c] Values may be slightly high because some surface water may be available to these areas (e.g., some Mokelumne River water for NSJWCD, some Merced ID deliveries to land outside the District, and surface water diversions by riparian users along the rivers).

[d] Minimum pumping estimate assumes that SEWD provides 50 TAF/y for urban use (based on SEWD AWMP) and that SEWD receives 67 TAF/y from Calaveras River (NSJCGBA 2004). Of the 99,000 acres of irrigated land, approximately 48,000 belongs to CSJWCD and 51,000 belongs to SEWD.

[e] Portion of Woodbridge ID with surface water supply from the Mokelumne River. This information is relevant because it means that this land within the subbasin does not depend entirely on groundwater.

[f] Merced ID irrigated land and groundwater pumping estimated for the Turlock and Chowchilla Subbasins not included.

Eastern San Joaquin Subbasin

The Eastern San Joaquin Subbasin has approximately 386,000 acres of irrigated land; 50 percent of these acres are potentially supplied with surface water from SSJID, OID, SEWD, CSJWCD, and WID (Table 9-5). The subbasin underlies the Cities of Manteca, Lathrop, and Stockton, which use groundwater for a large portion of their drinking water supply.

The Eastern San Joaquin Subbasin has been well studied. Unlike the other three subbasins discussed in this chapter (Modesto, Turlock, and Merced), there have been multiple efforts to estimate the water budget components and the subbasin's sustainable yield. Bulletin 118 (DWR 2003b) presents results from two studies. One study estimated a sustainable yield of approximately 740 TAF/y, based on the estimated agricultural pumping (762 TAF/y) plus municipal and industrial pumping (47 TAF/y) minus the overdraft (70 TAF/y) (SJCFCWCD 1985). The other study estimated the sustainable yield of San Joaquin County, which includes more than the Eastern San Joaquin Subbasin, to be 618 TAF/y (USBR 1996). Historically, pumping from agricultural, urban, and rural, wells has been greater than the subbasin's safe yield (SSJID 2012). The subbasin's estimated minimum total agricultural and municipal groundwater pumping is 658 TAF/y (Table 9-6). This pumping estimate represents a minimum amount of pumping; actual average pumping is greater in some years, especially during dry years when surface water supply is reduced.

Declining groundwater levels over a period of time indicate that groundwater use within a subbasin is unsustainable. Groundwater levels have declined over the past 40 years at an average rate of 1.7 feet per year (ft/y) and have dropped as much as 100 ft in some areas (USACE 2001). As of 2010, there was a fairly large cone of depression centered east of Stockton below SEWD and CSJWCD service areas (Figure 9-3). However this cone of depression is not as severe as it once was; between 2005 and 2010, groundwater elevations within some portions of this area showed some signs of improvement (Figure 9-4). During the recent drought, groundwater levels in the San Joaquin County continued to decline; between Spring 2014 and Spring 2015 average groundwater levels declined an average of 3 ft throughout the county, and between Spring 2015 and Spring 2016, average groundwater levels declined an additional 2 ft throughout the county (Breitler 2016). Additionally, reduced groundwater levels below Stockton have caused the migration of saline water from the west to move eastward into the basin. In some areas below Stockton, salinity concentrations in groundwater exceed drinking water standards (SEWD 2014).

In 2014, DWR's California Statewide Groundwater Elevation Monitoring (CASGEM) Program ranked the Eastern San Joaquin Subbasin as a high-priority groundwater basin, partially due to the basin's history of groundwater reliance for agricultural and municipal uses, seawater intrusion along a 16-mile front on the east side of the Delta, large areas of nitrate contamination, and long-term overdraft conditions (DWR 2014b). Additionally, DWR identified the Eastern San Joaquin Subbasin as a critically overdrafted basin (DWR 2016).

South San Joaquin Irrigation District

The SSJID derives its water supply from three sources: (1) surface water diverted from the Stanislaus River at Goodwin Dam, (2) groundwater, and (3) irrigation return flows from OID (SSJID 2011). Although the district receives the majority of its water from the Stanislaus River, groundwater provides important reserves that can supplement surface water during droughts (SSJID 2011). The Cities of Manteca, Ripon, and Escalon comprise approximately 10,000 acres of the SSJID service area (SSJID 2012). In 2005, SSJID began delivering treated surface water to Lathrop, Manteca, and Tracy through the South County Water Supply Program. SSJID also delivers untreated SSJID water to the City of Ripon (SSJID 2015); as of 2011, Ripon used these deliveries exclusively for groundwater recharge (SSJID 2011). The cities use groundwater to meet much of their demands, and some district growers use groundwater as a regular source for irrigation water. SSJID has leased private wells during droughts to augment water supplies to farmers, which can help to minimize cuts to city water supplies (SSJID 2011).

Groundwater recharge within the SSJID service area consists of seepage from SSJID canals and reservoirs and deep percolation of precipitation and applied irrigation water. On average, total recharge for 1994-2008 is estimated to be approximately 97 TAF/y with 52 percent of recharge originating from canal seepage and 48 percent originating from deep percolation of applied water (SSJID 2012). However, even with recharge efforts, groundwater levels continue to decline east of Stockton and north of SSJID's service area where surface water supplies are limited. Groundwater levels in that area have declined to such an extent that groundwater flow under SSJID flows northerly rather than to the west (SSJID 2015). Declining groundwater levels continued during the recent drought; between Spring 2014 and Spring 2015, groundwater levels declined in 23 wells (of 29 wells with adequate groundwater level monitoring data to allow determination of groundwater level trends) in SSJID's service area. Of the remaining 6 wells, 4 wells showed localized increases in groundwater levels and 2 wells had no change in groundwater levels (SJCFCWD 2015).

Groundwater pumped for irrigation use in SSJID is generally of good quality. SSJID monitors 28 production wells for EC using permanently installed sensors. The San Joaquin County Flood Control and Water Conservation District (SJCFCWD) conducts annual groundwater quality monitoring in 26 wells in San Joaquin County, including within the district's service area. Monitored parameters include TDS, turbidity, chloride, and EC (SSJID 2012).

Oakdale Irrigation District

OID overlies two groundwater subbasins; 43 percent (23,000 irrigated acres) overlies the Eastern San Joaquin Subbasin (OID 2012; Table 9-6) and 57 percent of OID's service area (31,000 irrigated acres) overlies the Modesto Subbasin. OID is described in the Modesto Subbasin section below.

Stockton East Water District

SEWD provides surface water for agricultural and urban uses and for groundwater recharge (SEWD 2014). SEWD has a number of surface water supply contracts with various entities; it can receive up to 40 TAF/y from New Hogan Reservoir, with an additional 27 TAF/y of New Hogan Reservoir water that is not used by Calaveras County Water District (NSJCGBA 2004). SEWD also has a contract with the U.S. Bureau of Reclamation (USBR) to receive 75 TAF/y from New Melones Reservoir through the Central Valley Project (CVP) (SEWD 2011a). However, during dry years, water delivery amounts may vary depending upon USBR water allocations. In the past, SEWD contracted with SSJID and OID to receive up to 30 TAF/y from the Stanislaus River. The agreement ended in 2009 but was extended beyond 2010 and may be renewed pending further studies (SEWD 2014). As of 2011, SEWD had two wells that are only used for emergency and dry year supply (SEWD 2011b). In critically dry years, SEWD contracts with farmers along their pipeline to pump groundwater to supply the treatment plant (SEWD 2011b).

SEWD delivers a minimum of 20 TAF/y of treated surface water to the City of Stockton, California Water Service Company, and San Joaquin County. The volume delivered to each retailer is based on the percentage of total groundwater and surface water used in each retailer's area during the previous year, which is updated every year. As of 2010, SEWD has 178 agricultural customers. Based on the 2010 SEWD water inventory, 127,575 AF of water was needed for crop irrigation. Based on actual agricultural water sales, 23,116 AF of surface water was provided by SEWD to agricultural customers, and 117,424 AF of private groundwater[10] was used for agricultural irrigation (SEWD 2014).

Measurements over the past 40 years show a fairly continuous decline in groundwater levels in the eastern San Joaquin County. As a result of groundwater pumping over many decades, a cone of depression exists east of the Stockton urban area (Figure 9-3). Groundwater levels and the extent of the overdraft issues in SEWD's service area have historically fluctuated depending on surface water availability and the district's reliance on groundwater. Water table levels in the southern and eastern areas of Stockton generally rose more than 50 ft during an 8-year period (1977–1985). Groundwater levels in the Stockton urban area and SEWD service area also rose after the 1987–1994 drought as surface water once again became more available and groundwater dependence declined. By 1999, the water table in the Stockton area was higher than the level recorded 20 years prior, reversing a downward trend that had taken place for many years as a result of pumping by various users (SEWD 2011b). SEWD has continued a conjunctive use management approach; between 2011 and 2014, SEWD pumped no groundwater. However, in 2015, as a result of extreme drought conditions and the 100-percent curtailment of water supply from New Melones Reservoir, SEWD resumed pumping groundwater (SEWD 2016). Due to resumed pumping, between Spring 2014 and Spring 2015, groundwater levels declined in 56 wells (of 69 wells with adequate groundwater level monitoring data to allow determination of groundwater level trends) in SEWD's service area. Of the remaining 13 wells, 9 wells showed localized increases in groundwater levels and 4 wells had no change in groundwater levels (SJCFCWD 2015).

Central San Joaquin Water Conservation District

The CSJWCD includes approximately 65,200 acres, of which approximately 48,000 acres are irrigated (Table 9-6); 670 acres of the districts total acreage are within the sphere of influence for the City of Stockton (NSJCGBA 2004). Historically, CSJWCD relied substantially on groundwater pumping for irrigation. CSJWCD is now contracted with USBR to receive up to 80 TAF/y of surface water from the Stanislaus River. However, during dry years, water delivery amounts may vary depending upon USBR water allocations, and the total contracted amount has never been fully delivered. Irrigation facilities have been installed and are operated by individual landowners through a surface water incentive program sponsored by the CSJWCD to mitigate declining groundwater levels in the area. SSJID and OID have occasionally made water available to CSJWCD for irrigation. Surface water deliveries from the New Melones Conveyance System allowed groundwater levels to increase by as much as 15 ft in some localized areas within the CSJWCD service area (NSJCGBA 2004). However, more recently groundwater levels have declined; between Spring 2014 and Spring 2015, groundwater levels declined in 36 wells (of 37 wells with adequate groundwater level monitoring data to allow determination of groundwater level trends) in CSJWCD's service area. The remaining well had no change in groundwater levels (SJCFCWD 2015).

Communities

The Eastern San Joaquin Subbasin has multiple communities and water purveyors that do not have water supply contracts with the irrigation districts discussed above or are located outside the

---

[10] SEWD does not sell groundwater but does quantify its use.

irrigation district service areas. The Cities of Lodi, Stockton, Lathrop, Manteca, and Ripon and Escalon rely solely or partially on groundwater to meet their needs (City of Ripon 2004; NSJCGBA 2004; San Joaquin County 2009). See Chapter 13, *Service Providers*, for additional information about municipal water use in the Eastern San Joaquin Subbasin.

Modesto Subbasin

There are approximately 116,000 acres of irrigated land in the Modesto Subbasin; 77 percent of these acres potentially being supplied with surface water from OID or MID (Table 9-5). The subbasin's estimated minimum total agricultural and municipal groundwater pumping is 187 TAF/y (Table 9-6).

Net groundwater overdraft for a portion of the subbasin has been estimated to be between 11 and 15 TAF/y (Table 9-4). DWR Bulletin 118 indicates groundwater levels in this subbasin decreased approximately 0.5 foot/year between 1970 and 2000 (DWR 2003c). Between 2005 and 2010, the largest decreases in groundwater elevation occurred in the eastern portion of this subbasin in the region not irrigated with surface water (Figure 9-4). Groundwater recharge is primarily from deep percolation of applied irrigation water and canal seepage from MID and OID facilities (STRGSA 1995, MID 2015). Seepage from Modesto Reservoir is also a significant contributor, contributing an estimated 24 TAF/y (MID 2015). Recharge on a lesser basis occurs from the subsurface flows originating from the eastern foothills and mountains, infiltration from minor streams, and percolation of direct precipitation.

In 2014, DWR's CASGEM Program ranked the Modesto Subbasin as a high priority groundwater basin, partially due to the basin's history of groundwater reliance for agricultural and municipal use, and water quality degradation due to industrial and agricultural practices (DWR 2014c).

Oakdale Irrigation District

OID overlies two groundwater subbasins; 57 percent of OID's service area (31,000 irrigated acres) overlies the Modesto Subbasin, with the other 43 percent (23,000 irrigated acres) overlies the Eastern San Joaquin Subbasin (OID 2012; Table 9-6). More than 95 percent of the water served by OID is surface water diverted from the Stanislaus River at Goodwin Dam into the Joint Supply Canal and the South Main Canal (USBR and SJRGA 1999). During dry periods when surface water supplies are limited, surface water is supplemented by groundwater pumping from 25 OID wells, with a combined maximum annual production capacity of approximately 38 TAF/y (OID 2012). Annual well production ranges between 1.5 and 16 TAF/y because wells are not operated continuously (OID 2012). Most private wells in the district are for small farm and domestic use (STRGBA 2005).

Groundwater recharge within OID consists of seepage from OID canals and deep percolation of precipitation and applied irrigation water. Estimates of recharge were derived from the groundwater balance analysis; average estimated recharge for all of OID was 12 TAF/y from drainage canals, 36 TAF/y from irrigation canals, 24 TAF/y from infiltration of applied water (to irrigated land), and 15 TAF/y from infiltration of precipitation. Because OID contributes to surface water recharge of the aquifer, groundwater levels in the portions of the Eastern San Joaquin Subbasin underlying the OID service area have decreased much less than groundwater levels than the rest of the subbasin (OID 2012).

Modesto Irrigation District

MID delivers water to approximately 59,000 acres of land (Table 9-6). MID has approximately 90 groundwater wells that maintain water levels below the root zone (i.e., drainage) in the western portion of the district. MID also supplements irrigation supplies from New Don Pedro Reservoir with groundwater when surface water is limited (MID 2012). Groundwater use in the MID service area varies year-to-year, typically increasing during drought years (STRGBA 2005). As of 2016, MID only pumps and delivers groundwater to supplement water supplies to agricultural customers and does not pump nor deliver groundwater supply to urban suppliers (City of Modesto and MID 2011, City of Modesto and MID 2016). The City of Modesto satisfies approximately half of its demand with MID surface water and half with groundwater from its own wells and recharges approximately 20 TAF/y through its 11,000 dry wells (City of Modesto and MID 2011; MID 2012).

Most of the groundwater recharge within the subbasin is the result of deep percolation of applied surface water to agricultural lands, seepage from canals and reservoirs, and deep percolation of precipitation and urban storm runoff. In recent years, MID has increased recharge activities; in 2009, total groundwater recharge was estimated at approximately 81 TAF, which increased to 152 TAF in 2012 (MID 2012; MID 2015). The majority of recharge comes from MID irrigation water; in 2009, total groundwater recharged by MID irrigation water is estimated to be 58 TAF/y (MID 2012), which increased to 108.5 TAF in 2012 (MID 2015). Additionally, approximately 91 percent of MID canals are concrete-lined, resulting in a relatively small amount of canal seepage (MID 2015).

Communities

The Modesto Subbasin has multiple communities and water purveyors that do not have water supply contracts with the irrigation districts discussed above or are located outside of the irrigation district service areas. The Cities of Oakdale and Riverbank and smaller communities in Stanislaus County generally rely solely on groundwater to meet their needs (City of Oakdale 2009; STRGBA 2005). See Chapter 13, *Service Providers*, for additional information about municipal water use in the Modesto Subbasin.

Turlock Subbasin

There are approximately 269,000 acres of irrigated land in the Turlock Subbasin; 56 percent of these acres potentially being supplied with surface water from TID or a small portion from Merced ID (Tables 9-5 and 9-6). Between 1997 and 2006, total agricultural and municipal groundwater pumping in this subbasin was approximately 457 TAF/y (TGBA 2008). The subbasin’s estimated minimum total agricultural and municipal groundwater pumping is 498 TAF/y (Table 9-6).

Groundwater recharge sources include irrigation of crops and landscape vegetation, precipitation, percolation from the Tuolumne and Merced Rivers, seepage from irrigation canals and Turlock Lake, groundwater recharge programs, percolation from Sierra Nevada foothill streams, and upward seepage from deeper aquifers (below the Corcoran Clay) (TID 2008). The upper reaches of the Tuolumne and Merced Rivers provide infiltration recharge (i.e., losing rivers), but the aquifer contributes water (through springs and seeps) to the lower reaches of the Tuolumne and Merced Rivers (i.e., gaining rivers) (TID 2008). Recharge from croplands is estimated to be 375 TAF/y, while recharge from landscaping within urban areas is estimated to be 18 TAF/y (TGBA 2008).

Net groundwater overdraft for the subbasin is estimated to be between 9 and 85 TAF/y (Table 9-4). Between 1970 and 2000, groundwater levels in the Turlock Subbasin declined approximately 7 ft (or 0.25 ft/y), with greater declines in the eastern portion of the subbasin after 1982 (DWR 2003d). There is a fairly large cone of depression in the eastern portion of the Turlock Subbasin below land primarily irrigated with groundwater. In 2010, groundwater elevations were at a high of 100 ft above MSL in the middle portion of the subbasin, but dropped down to 25 ft above MSL in the eastern portion of the subbasin (Figure 9-3). Between 2005 and 2010, groundwater elevations in this eastern portion of the subbasin decreased by up to 30 ft (Figure 9-4).

In 2014, DWR's CASGEM Program ranked the Turlock Subbasin as a high priority groundwater basin, partially due to the basin's history of groundwater reliance for agricultural and municipal use, and overdraft issues (DWR 2014d).

Turlock Irrigation District

TID utilizes a combination of surface water and groundwater to supply water to its agricultural users (TGBA 2008). Agricultural land within the TID service area is primarily irrigated with surface water, which is also a main source of recharge within the Turlock Subbasin (City of Modesto 2008). TID pumps approximately 65 TAF/y for drainage in the western portion of the district, and "rents" wells from growers during drought years (e.g., 1977, 1997–1992) (TGBA 2008). In addition, some growers pump groundwater to supplement their surface water allotments, while others use groundwater to meet their entire irrigation requirement. The minimum pumping within the district for drainage and irrigation is estimated to be 100 TAF/y, while the maximum groundwater pumping within the district is estimated to be 275 TAF/y (TGBA 2008).

Total recharge within the service area is estimated to average 238 TAF/y, with deep percolation of applied water and of precipitation averaging 156 TAF/y and 44 TAF/y (3.5 inches), respectively. Within the district, average groundwater pumping is estimated to be approximately 103 TAF/y (TID 2012).

Merced Irrigation District

Merced ID overlies three groundwater subbasins: 5 percent overlies the Turlock Subbasin, 86 percent overlies the Merced Subbasin, and the remaining 9 percent overlies the portion of the Chowchilla Subbasin that is analyzed with the Merced Subbasin as the "Extended Merced Subbasin" (Table 9-6). Merced ID is described in more detail under the Merced Subbasin section below.

Eastside Water District and Ballico-Cortez Water District

EWD and BCWD depend on groundwater from the Turlock Subbasin for water supply to irrigate approximately 54,000 acres and 67,000 acres, respectively (TID 2008). All irrigation facilities within the EWD and BCWD service areas are privately owned and operated. Growers have installed irrigation supply wells, as needed, to irrigated their crops (TGBA 2008). Growers pumped an estimated 180 TAF/y between 1997 and 2006 (City of Modesto 2008). With the exception of those properties adjacent to the rivers that have riparian water rights and can utilize surface water for irrigation, these districts rely upon groundwater for their entire water supply (City of Modesto 2008). The only other source of water supply is a very limited amount of surface water purchased in wet years from the TID and Merced ID canals adjacent to EWD. EWD does not own or operate water supply infrastructure (TGBA 2008). Groundwater levels in the vicinity have dropped dramatically since the mid-1950s. Groundwater levels within the EWD service area are declining approximately 2 ft/year, creating an average annual deficit of approximately 80 TAF (ESRWMP 2013).

Other Growers

Between 1997 and 2006, growers outside TID, EWD, and BCWD (i.e., located along the river margins and east of the EWD and BCWD service areas) pumped an average of 115 TAF/y (ESRWMP 2013). As agricultural development continues in these areas, dependence upon groundwater will likely increase (City of Modesto 2008).

Communities

The Turlock Subbasin has multiple communities and water purveyors that do not have water supply contracts with the irrigation districts discussed above or are located outside the irrigation district service areas. The Cities of Ceres, Delhi, Denair, Hickman, Hilmar, Hughson, Keyes, and Turlock generally rely solely on groundwater to meet their needs (TGBA 2008). Between 1997 and 2016, average municipal pumping was 44 TAF/y (TID 2008), somewhat less than DWR's estimated 65 TAF/y (DWR 2003d, Table 9-6). See Chapter 13, *Service Providers*, for additional information about municipal water use in the Turlock Subbasin.

Merced Subbasin

There are approximately 269,000 acres of irrigated land in the Merced Subbasin; 32 percent of these acres are potentially supplied with surface water from Merced ID (Table 9-5). The subbasin's natural recharge is 47 TAF/y, and approximately 243 TAF/y of applied water recharge occurs in the subbasin (Merced ID 2013a). Recharge and conservation projects provided an annual in-lieu recharge (i.e., replacing pumping with surface water) of approximately 60 TAF/y (MAGPI 2008). The subbasin's estimated minimum total agricultural and municipal groundwater pumping is 642 TAF/y (Table 9-6).

Long-term well level records show that groundwater elevations have declined with time throughout most of the subbasin; between 1980 and 2008, average levels declined 14 ft (MAGPI 2008). This is approximately half of the decline of 1 ft/y described above for 1970–2000 (DWR 2003e). Overdraft estimates for the subbasin range between 20 and 44 TAF/y (Table 9-4), with more severe water level declines in the eastern portion of the subbasin (DWR 2003e). Well data for 2010 indicate gradually increasing groundwater elevations from the SJR to the mountains and from north to south, which is what would be expected based on the effect of river elevation and topography on groundwater elevations (Figure 9-3). However, the southeast corner of the Merced Subbasin, an area with little surface water supply, has a cone of depression with groundwater elevations close to sea level (Figure 9-3).

In 2014, DWR's CASGEM Program ranked the Merced Subbasin as a high priority groundwater basin, partially due to the basin's history of groundwater reliance for agricultural and municipal use, and known overdraft and water quality degradation issues (DWR 2014e). Additionally, the CASGEM Program ranked the Chowchilla Subbasin (which, combined with the Merced Subbasin, comprises the Extended Merced Subbasin) as a high priority basin, partially due to the basin's history of groundwater reliance for agricultural use, and known overdraft, subsidence, and water quality degradation issues (DWR 2014f). In 2016, DWR identified both the Merced and Chowchilla Subbasins as critically overdrafted basins (DWR 2016).

Merced Irrigation District

As noted above, Merced ID overlies three groundwater subbasins; 5 percent of Merced ID's service area overlies the Turlock Subbasin, 9 percent overlies the Chowchilla Subbasin (or Extended Merced Subbasin), and the remaining 86 percent of Merced ID lands are located in the Merced Subbasin (Table 9-6). The portion of Merced ID that overlies the Chowchilla Subbasin is land that originally comprised the El Nido Irrigation District, which was incorporated into Merced ID in 2005 (Merced ID 2013a). Merced ID primarily uses surface water diversions from the Merced River to supply irrigation water to its service area. Merced ID supplements its surface water supply with groundwater for irrigation. The extent of Merced ID's groundwater supplementation varies year-to-year, depending on the availability of surface water (TGBA 2008). Merced ID owns, operates, and maintains 235 groundwater wells, of which 198 were operational in 2013. Some wells are operated to drain high water levels in the western part of the district's service area. However, the majority of these wells are left on standby to be operated for irrigation during years of surface water shortages. Merced ID's service area contains 1,764 acres of high ground (i.e., land higher than nearby canals) that are served by 8 TAF/y of groundwater pumping, although pumping has been reduced to 4 TAF/y with booster pumps that supply surface water from the canals (Merced ID 2013a). Between 2000 and 2008, Merced ID average groundwater pumping was 31 TAF/y, and active Merced ID customers pumped 32 TAF/y (Merced ID 2013a). During this period, it is estimated that private customers pumped between zero and 153 TAF/y (Merced ID 2013a).

Between 2000 and 2008, groundwater recharge within the Merced ID service area was estimated as deep percolation of applied water (60 TAF/y), canal seepage (98 TAF/y) and in-lieu recharge (32 TAF/y). Therefore, the total annual average estimated recharge from the Merced ID was 190 TAF/y (Merced ID 2013a). Merced ID delivers some water to Madera County, in the Chowchilla Subbasin, and other surrounding areas, such as Stevinson Irrigation District, the Merced Wildlife Refuge, and the City of Merced.

Communities

The Merced Subbasin has multiple communities and water purveyors that do not have water supply contracts with the irrigation district discussed above or are located outside the irrigation districts' service areas. The Cities of Atwater, Livingston, and Merced; the Black Rascal Mutual Water Company; Le Grand and Planada Community Service District; the Meadowbrook Water Company; and the Winton Water and Sanitary District generally rely solely on groundwater to meet their needs (MAGPI 2008). In 2007, total municipal pumping was estimated to be 50 TAF/y (Merced ID 2013a). The City of Merced receives the majority of its water supply from groundwater. However, the city is evaluating long-term and short-term water transfers and other options to obtain surface water and augment its groundwater supply (Merced ID 2013a). See Chapter 13, *Service Providers*, for additional information about municipal water use in the Eastern San Joaquin Subbasin.

9.2.3 Extended Plan Area

The extended plan area has no designated groundwater basins with the exception of the Yosemite Basin in Yosemite National Park in Mariposa County. This lack of designated groundwater basins is primarily due to the generally shallow-to-bedrock geology. Groundwater occurs in fractures in the bedrock and the local and regional rock fracture system characteristics influence water levels and well yields. Consequently, groundwater areas are often small, localized, and isolated from each other (DWR 2003h).

9.2.4 Southern Delta

Agricultural users in the southern Delta apply surface water to irrigate their crops. Some of the agricultural users apply additional surface water to reduce the salts in the root zone of the crops. However, the water sources in the southern Delta are primarily surface water coming from the southern Delta channels and not from groundwater pumping. Therefore, groundwater resources in the southern Delta are not discussed in this chapter.

9.3 Regulatory Background

9.3.1 Federal

Relevant federal programs, policies, plans, or regulations related to groundwater resources are described briefly below but relate principally to preventing the discharge of pollutants into waters of the United States and protecting public health by regulating drinking water. Additional information on both of the federal statutes listed below is found in Chapter 13, *Service Providers*.

Clean Water Act

The federal Clean Water Act (33 U.S.C., §§ 1251–1376) places primary responsibility for developing water quality standards on the states. The CWA establishes the basic structure for regulating discharges of pollutants into the waters of the United States and gives USEPA the authority to implement pollution control programs, such as setting wastewater standards for industry. The statute employs a variety of regulatory and non-regulatory tools to reduce pollutant discharges into waters of the United States, finance municipal wastewater treatment facilities, and manage polluted runoff.

Safe Drinking Water Act

The federal Safe Drinking Water Act (42 U.S.C., § 300 et seq.) protects public health by regulating the nation's public drinking water supply. In addition to drinking water itself, the act requires the protection of its sources, such as rivers, lakes, reservoirs, springs, and groundwater wells. The act authorizes the USEPA to set national health-based standards for drinking water, such as MCLs, to protect against contaminants that may adversely affect public health. In California, as of July 1, 2014, the State Water Board's Division of Drinking Water implements the Safe Drinking Water Act.

9.3.2 State

Relevant state programs, policies, plans, or regulations related to groundwater resources are described below. Until SGMA became effective in January 2015, the State regulated groundwater in a relatively minor capacity and considered groundwater management to be a local responsibility.

Sustainable Groundwater Management Act

On January 1, 2015, it became California state policy (Wat. Code, § 113) that "groundwater resources be managed sustainably for long-term reliability and multiple economic, social, and environmental benefits for current and future beneficial uses" and that sustainable groundwater management "is best achieved locally through the development, implementation, and updating of plans and programs based on the best available science." SGMA (Wat. Code, § 10720 et seq.) provides the framework to implement this policy by requiring that local agencies in high- and medium-priority basins[11] (DWR 2014a) form GSAs by June 30, 2017 that will develop and implement GSPs that achieve sustainable groundwater management within 20 years.

SGMA defines sustainable groundwater management as "the management and use of groundwater in a manner that can be maintained during the [50 year] planning and implementation horizon without causing undesirable results." Undesirable results are defined as any of the following effects.

- Chronic lowering of groundwater levels (not including overdraft during a drought if a basin is otherwise managed).
- Significant and unreasonable reduction of groundwater storage.
- Significant and unreasonable seawater intrusion.
- Significant and unreasonable degraded water quality, including the migration of contaminant plumes that impair water supplies.
- Significant and unreasonable land subsidence that substantially interferes with surface land uses.
- Depletions of interconnected surface water that have significant and unreasonable adverse effects on beneficial uses of the surface water.

(Wat. Code, § 10721, subd. (x).) SGMA requires that critically overdrafted high- and medium-priority basins adopt GSPs by January 31, 2020 (DWR 2016). In the study area, that deadline applies to the Eastern San Joaquin, Merced, and Chowchilla Subbasins, which are listed as high-priority and critically overdrafted. All other high- or medium-priority basins must adopt GSPs by January 31, 2022. In the study area, this includes the Modesto and Turlock Subbasins, which are listed as high-priority basins.

If local agencies are unwilling or unable to manage their groundwater resources, SGMA authorizes the State Water Board to step in to protect a groundwater basin in limited circumstances: (1) if no agency has opted by the June 30, 2017 to serve as a GSA for a basin,[12] (2) when a GSA does not complete a GSP by the relevant deadline (2020 or 2022), or (3) when the GSP is inadequate or the GSP is not being implemented in a manner that is likely to achieve the plan's sustainability goal(s), and the basin is either in a condition of long-term overdraft or, after January 31, 2025, the State Water Board determines that the basin is in a condition where groundwater extractions result in significant depletions of interconnected surface waters.

SGMA is intended to promote coordinated management of a groundwater basins through GSA formation. While it is too early to know how GSAs will approach sustainable groundwater management, and GSPs will vary in terms of groundwater management components and implementation methods, sustainably management is a legal obligation. SGMA requires

---

[11] 127 of California's 515 alluvial groundwater basins, which account for 96 percent of California's annual groundwater pumping, were identified as high- or medium-priority. Prioritization factors include, but are not limited to, the level of population overlying the basin or subbasin, the projected rate of population growth for the basin or subbasin, the number of public supply wells dependent on the basin or subbasin, the irrigated acreage overlying the basin or subbasin, and the degree of reliance on groundwater. (Wat. Code, § 10933, subd. (b).)

[12] In addition, if an agency fails to form a GSA by the deadline, local groundwater users must begin reporting groundwater use to the State Water Board.

consideration of all stakeholder interests within their regions, including beneficial users of water, environmental interests, disadvantaged communities, tribes, and others. SGMA also includes provisions to protect water rights, including stating that nothing in SGMA "determines or alters surface water rights or groundwater rights under common law or any provisions of law that determines or grants surface water rights." However, between SGMA's enactment on January 1, 2015, and until the time that a GSP or its functional equivalent is adopted, SGMA prohibits groundwater extractions from being used as evidence of, or to establish or defend against, any claim of prescription. (Wat. Code, § 10720.5.) As a practical matter this means that pumping more groundwater after enactment of the Act and prior to adoption of the GSP will not later provide the basis for a claim that a groundwater right is larger than the right that existed on December 31, 2014.

Porter-Cologne Water Quality Control Act

As discussed in Chapter 1, *Introduction*, and Chapter 5, *Surface Hydrology and Water Quality*, the Porter-Cologne Water Quality Control Act is California's primary authority for regulating surface and groundwater quality. (Wat. Code, § 13000 et seq.) Under the Porter-Cologne Act, the state is divided into nine regions, and a Regional Water Board has the primary responsibility for protecting water quality within each region. The State Water Board oversees the Regional Water Boards' implementation of the Porter-Cologne Act and, together with the Regional Water Boards, implements the federal Clean Water Act. The Regional Water Boards have primary responsibility for the formulation and adoption of water quality control plans for their respective regions, subject to State Water Board and USEPA approval. The State Water Board may also adopt water quality control plans, which will supersede regional water quality control plans for the same waters to the extent of any conflict.

The SJR Basin falls within the jurisdiction of the Central Valley Regional Water Quality Control Board (Central Valley Water Board). The *Central Valley Board's Water Basin Plan for the Sacramento River and San Joaquin River Basins* (Basin Plan) specifies that all groundwater in the Region are considered as suitable or potentially suitable, at a minimum, for the following beneficial uses (Central Valley Water Board 2016).

- Municipal and domestic water supply (MUN)
- Agricultural supply (AGR)
- Industrial service supply (IND)
- Industrial process supply (PRO)

The Basin Plan provides certain exceptions for when these beneficial uses can be de-designated (e.g., when there is contamination or pollution in the groundwater that cannot reasonably be treated using either best management practices or best economically achievably treatment practices).

Groundwater Quality Protection Strategy for the Central Valley Region

In 2008, the Central Valley Water Board adopted Resolution No. R5-2008-0181 in Support of Developing a Groundwater Strategy for the Central Valley Region. In 2010, the Central Valley Water Board adopted Resolution No. R5-2010-0095 the Groundwater Quality Protection Strategy for the Central Valley Region, "a Roadmap", a long-term strategy that identifies high-priority activities. The roadmap recognizes the Central Valley Water Board's core responsibilities and existing commitments, and builds on existing processes. The roadmap is intended to be an overarching framework for long-range planning and is not a new regulatory program (Central Valley Water Board 2012).

California Statewide Groundwater Elevation Monitoring Program

The CASGEM program (Wat. Code, § 10920 et seq.) established a permanent, locally-managed program of regular and systematic monitoring and reporting in all of California's alluvial groundwater basins. The program relies on the many established local long-term groundwater monitoring and management programs and designates specific monitoring entities to report groundwater elevation data to DWR, which makes it available to the public. There is at least one CASGEM monitoring entity in each of the four subbasins underlying the study area (DWR 2015c). Monitoring entities began submitting CASGEM groundwater elevation data to DWR in January, 2012.

Groundwater Ambient Monitoring and Assessment Program

The GAMA is a comprehensive groundwater quality monitoring program based on interagency collaboration between the State Water Board, Regional Water Boards, DWR, Department of Pesticide Regulations, U.S. Geological Survey, and Lawrence Livermore National Laboratory (LLNL), and cooperation with local water agencies and well owners. GAMA is described in greater detail in Chapter 13, *Service Providers.*

Other State Authorities

State water law includes other more general authorities for the protection of groundwater resources including, but not limited to, the following.

Waste and Unreasonable Use

California Constitution Article X, Section 2 and California Water Code Section 100 prohibit the waste, unreasonable use, unreasonable method of use, and unreasonable method of diversion of water. The constitutional doctrine of reasonable use applies to all water users, regardless of basis of water right, serving as a limitation on every water right and every method of diversion (Peabody v. Vallejo [1935] 2 Cal.2d 351, 367, 372). California Water Code Section 275 directs the State Water Board (and DWR) to take all appropriate proceedings or actions to prevent waste or violations of the reasonable use standard. Thus, the State Water Board may initiate proceedings, either administratively or in court, to prevent the waste and unreasonable use of water.

The State Water Board also has authority to address the waste, unreasonable use, unreasonable method of use, and unreasonable method of diversion of water through quasi-legislative action. Questions of waste, unreasonable use, and unreasonable methods of use or diversion are factual and are determined according to the circumstances of a particular situation, limiting the utility of the regulatory process to only those cases where waste or unreasonableness can be clearly identified and prevented by an appropriately tailored regulatory response. Due to the highly complex nature of findings and proceedings, the State Water Board has only made the findings required to proscribe waste, unreasonable use, and unreasonable method of use or diversion through regulation twice. (Cal Code Regs., tit. 23, §§ 735, 862.)

Groundwater Adjudications

An adjudication is an action filed in Superior Court by one or more groundwater pumpers to comprehensively determine groundwater rights in a specified area. Through adjudication, the courts can assign specific rights to water users and can compel the cooperation of those who might otherwise refuse to limit their pumping of groundwater. The court retains continuing jurisdiction over the adjudicated area and typically appoints a watermaster to ensure pumping conforms to the adjudication's limits. In 2015, the Legislature passed Assembly Bill (AB) 1390 (Alejo), a statute to streamline the methods and procedures for groundwater adjudications (Code of Civil Proc., § 830 et seq.), and Senate Bill (SB) 226 (Pavley), a statute adding a new chapter to SGMA that requires adjudications in groundwater basins subject to SGMA be consistent with SGMA. (Wat. Code, § 10720.1 et seq.)

In addition, the State Water Board has the authority to file an adjudicative action to restrict groundwater pumping, or to impose a physical solution, or both, where necessary to protect groundwater quality. (Wat. Code, §§ 2100-2102.)

Area of Origin Limitations

The State Water Board has permitting authority over subterranean streams flowing in known and definite channels. (Wat. Code, § 1200.) Groundwater not flowing in a subterranean stream, such as water percolating through a groundwater basin, is not subject to the State Water Board's permitting jurisdiction. However, the State Water Board may exercise its authority under the doctrines of reasonable use and the public trust to address diversions of surface water or groundwater that reduce instream flows and adversely affect fish, wildlife, or other instream beneficial uses.

Pumping groundwater for export is prohibited "within the combined Sacramento and Delta-Central Sierra Basins…unless the pumping is in compliance with a groundwater management plan that is adopted by [county] ordinance." (Wat. Code, § 1220.) The statute enables, but does not require, the board of supervisors of any county within any part of the combined Sacramento and Delta-Central Sierra Basin to adopt GWMPs. GWMPs have been adopted in some counties, as described below.

9.3.3 Regional or Local

Relevant regional or local programs, policies, or regulations related to groundwater resources are described below. Although local policies, plans, and regulations are not binding on the State of California, below is a description of relevant ones.

Agricultural Water Management Plans

California Water Code Section 10800 et seq. requires an agricultural water supplier with greater than 25,000 irrigated acres to adopt and implement an AWMP to efficiently manage water resources within its service area. Several irrigation districts have prepared AWMPs that identify methods for dealing with water supply shortages; including reliance on groundwater. 2012 AWMPs that are relevant to the irrigation districts and four subbasins are summarized in Table 9-7. The AWMPs were reviewed for how they allocate water and their policies for water shortages; Table 9-8 compares the methods used in the AWMPs for dealing with surface water shortages.

In April 2015, Executive Order (EO) B-29-15 lowered the irrigated acreage requirement to 10,000 irrigated acres. Those agricultural water suppliers that supply water to 10,000 to

25,000 acres of irrigated lands are required to develop AWMPs and submit the plans to DWR by July 1, 2016 (these plans are called the 2015 AWMPs). EO B-29-15 also requires that 2015 AWMPs include a detailed drought management plan that describes the actions and measures the supplier will take to manage water demand during drought

Table 9-7. Relevant Agricultural Water Management Plans

Groundwater Management Plans

Prior to SGMA's passage, groundwater management planning was a voluntary activity by local agencies in accordance with either AB 3030 (Costa), which was passed in 1992, or SB 1938 (Machado), which was passed in 2008 (consequently, those types of plans are commonly referred to as "AB 3030 plans" or "SB 1938 plans"). Both types of plans are discussed in more detail below. Under SGMA, an AB 3030 or SB 1938 plan that existed as of January 1, 2015 (the day SGMA took effect) can be submitted by January 1, 2017, for review by DWR as to whether that existing plan meets SGMA's requirements and therefore is approved as an alternative to a GSP. (Wat. Code, § 10733.6.) However, most AB 3030 and SB 1938 plans to not require sustainable groundwater management such as calculating the annual safe yield of a basin, limiting groundwater pumping to the safe yield, and enforcing the limitation. Unless approved as an alternative, AB 3030 and SB 1938 plans that are in areas subject to SGMA remain in effect until a GSP is adopted and may not be amended. In addition, in areas subject to SGMA, no new AB 3030 or SB 1938 plans may be adopted, only GSPs. (Wat. Code, § 10750.1.)

AB 3030 (Wat. Code, § 10750 et seq.) created a systematic procedure for an existing local agency to voluntarily develop a GWMP. AB 3030 also encouraged local agencies to cooperatively manage groundwater resources within their jurisdictions and to provide a methodology for developing GWMPs for groundwater basins defined in DWR Bulletin 118. The AB 3030 GWMPs introduced 12 technical components that could be, but were not required to be, included in the plans: (1) the control of saline water intrusion; (2) identification and management of wellhead protection areas and recharge areas; (3) regulation of the migration of contaminated groundwater; (4) administration of a well abandonment and well destruction program; (5) mitigation of conditions of overdraft; (6) replenishment of groundwater extracted by water producers; (7) monitoring of groundwater levels and storage; (8) facilitating conjunctive use operations; (9) identification of well construction policies; (10) construction and operation by the local agency of groundwater contamination cleanup, recharge, storage, conservation, water recycling, and extraction projects; (11) development of relationships with state and federal regulatory agencies; and (12) review of land use plans and coordination with land use planning agencies to assess activities (DWR 2014d). SB 1938 modified AB 3030's approach by making the development of GWMPs mandatory for any public agency seeking State funds administered through DWR for the construction of groundwater projects. SB 1938 also established mandatory components that the plans had to include to be deemed adequate: (1) basin management objectives relating to the monitoring and management of groundwater levels within the groundwater basin; (2) groundwater quality degradation, inelastic surface subsidence, and changes in surface flow and surface water quality that directly affect groundwater levels or quality or are caused by groundwater pumping in the basin; (3) agency cooperation such that the development of the plan involved other agencies and that the plan enables the local agency to work cooperatively with other public entities whose service area or boundary overlies the groundwater basin; (4) a map of the local agencies' service area that is subject to the GWMP as well as the boundary of the DWR Bulletin 118 boundary and the boundaries of other local agencies that overlie the basin in with the agency is located; and (5) monitoring protocols designed to detect changes in groundwater levels, groundwater quality, inelastic surface subsidence (in basins for which subsidence has been identified as a potential problem), and flow and quality of surface water that directly affect groundwater levels or quality, or are caused by groundwater pumping in the basin (DWR 2014e). GWMP requirements were again modified by AB 359

(Huffman), which became effective in 2013. AB 359 added additional required technical components and modified several GWMP adoption procedures (DWR 2014f).

GWMPs that are relevant to the irrigation districts and four subbasins are summarized in Table 9-9. The GWMPs do not always include the entire subbasin but describe the general subbasin characteristics. GWMPs vary in terms of groundwater management components and implementation methods included. The plans generally require the protection of existing groundwater resources and identify ways to reduce groundwater pumping or increase the recharge of groundwater basins through surface water diversions.

Integrated Regional Water Management Plans

Integrated Regional Water Management (IRWM) Planning is a collaborative stakeholder process that promotes sustainable water use. IRWM Planning identifies and implements water management efforts on a regional scale to ensure sustainable water uses, reliable water supplies, better water quality, efficient urban development, protection of agriculture, environmental stewardship, and a strong economy. IRWM plans acknowledge that regions have distinct identities and hydrologic and ecologic conditions, and that water supply reliability should be a primary water management objective to be considered in these integrated plans. IRWMPs that are relevant to the irrigation districts and four subbasins are summarized in Table 9-10.

Urban Water Management Plans

The California Urban Water Management Planning Act (UWMPA) requires California's urban water suppliers to initiate planning strategies to ensure the appropriate level of reliability in their water service to meet the needs of the various categories of customers during normal, dry, and multiple dry years. To do this, urban water suppliers must prepare a UWMP every 5 years. UWMPs served as a resource for planners and policy makers over a 25-year planning time fame, and include information about groundwater and surface water supplies, historic and projected water use, recycled water, water use efficiency programs in a contracting water district's service area, and contingency planning for the possibility of water shortages.

2015 UWMPs (due to DWR by July 1, 2016) do not reflect new requirements for groundwater management under SGMA. However, DWR recommended that 2015 UWMPs include a discussion of current or planned activities to meet anticipated SGMA requirements (DWR 2016). 2010 UWMPs that are relevant to the irrigation districts and four subbasins are summarized in Table 9-11; 2010 UWMPs that are relevant to the urban water suppliers are summarized in Chapter 13, *Service Providers*. UWMPs vary in terms of water shortage management responses and implementation methods included.

Groundwater Management Ordinances

Several ordinances applicable to groundwater resources that underlie the Stanislaus, Tuolumne, and Merced Rivers and SJR have been passed. These include ordinances in Merced, San Joaquin, Stanislaus, and Tuolumne Counties. No ordinances exist or have been proposed for groundwater resources in Mariposa County. Ordinances for Merced, San Joaquin, Stanislaus, and Tuolumne Counties are discussed in the following sections.

Merced County

Merced County's groundwater management ordinance was promulgated in 2015. It requires a permit for drilling a new well, mining groundwater, and exporting groundwater outside of the county. The ordinance also requires new well owners to install a metering device to report water usage to the county (Miller 2015).

San Joaquin County

San Joaquin County's groundwater management ordinance was promulgated in 1996. It requires a permit for any groundwater exports from the Eastern San Joaquin Subbasin. Before a permit will be issued, an applicant is required to demonstrate that the proposed export will not exacerbate the existing groundwater overdraft conditions. The ordinance was developed to protect investments supporting groundwater bank development (NSJCGBA 2004).

Stanislaus County

Stanislaus County's first groundwater management ordinance was promulgated in 2013. It restricts out-of-county transfers of groundwater or pumping to replace surface water sold to buyers outside of the county (Carlson 2013). In 2014, San Joaquin County expanded their groundwater management ordinance to align the county's requirements, prohibitions, and exemptions with SGMA. It also required applicants for permits to demonstrate that new wells will not have a detrimental effect on the county's groundwater resources (SCDER 2015).

Tuolumne County

Tuolumne County's groundwater management ordinance requires a permit for exporting groundwater outside of the county (Tuolumne Utilities District 2010).

9.4 Impact Analysis

This section identifies the thresholds or significance criteria used to evaluate the potential impacts on groundwater resources. It further describes the methods of analysis used to determine significance of impacts on groundwater resources. Measures to mitigate (i.e., avoid, minimize, rectify, reduce, eliminate, or compensate for) significant impacts accompany the impact discussion, if any significant impacts are identified.

9.4.1 Thresholds of Significance

The thresholds for determining the significance of impacts for this analysis are based on the State Water Board's Environmental Checklist in Appendix A of the Board's CEQA regulations. (Cal. Code Regs., tit. 23, §§ 3720–3781.) The thresholds derived from the checklist have been modified, as appropriate, to meet the circumstances of the alternatives. (Cal. Code Regs., tit. 23, § 3777, subd. (a)(2).) Impacts on groundwater resources were identified as potentially significant in the State Water Board's Environmental Checklist (see Appendix B, *State Water Board's Environmental Checklist*) and, therefore, are discussed in this analysis as to whether the alternatives could result in the following.

- Substantially deplete groundwater supplies or interfere substantially with groundwater recharge.
- Potentially cause subsidence as a result of groundwater depletion.

9.4.2 Methods and Approach

LSJR Alternatives

This chapter evaluates the potential groundwater impacts associated with the LSJR alternatives. Each LSJR alternative includes a February-June unimpaired flow[13] requirement (i.e., 20, 40, or 60 percent) and different methods for adaptive implementation to reasonably protect fish and wildlife beneficial uses, as described in Chapter 3, *Alternatives Description*. The sections below describe steps for processing the State Water Board's WSE model results for the groundwater analysis, methods of analysis for adaptive implementation in this chapter, and baseline results to which the LSJR alternatives are compared to determine the significance of impacts on groundwater.

Processing of WSE Model Results

Geographical Treatment of Aquifer

The impact analysis uses results from the WSE model to determine if the LSJR alternatives would result in impacts on groundwater resources by increasing groundwater pumping and reducing groundwater recharge relative to the baseline water balance for each of the four subbasins that would potentially be affected (Eastern San Joaquin, Turlock, Modesto, and Extended Merced). Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives:*

---

[13] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.

Methodology and Modeling Results, contains a detailed description of the groundwater analysis methods and results; a summary of the analysis is provided here. For analysis purposes, the Merced Subbasin was extended south to the Chowchilla River because the Merced ID land that was formerly the El Nido ID is in the northern part of the Chowchilla Subbasin between the Merced Subbasin and the Chowchilla River (Figure 9-1). This extension added an additional 26,000 acres to the Merced Subbasin, bringing the total area to 517,000 acres. In the analysis, the combination of the Merced Subbasin and the land between the Merced Subbasin and the Chowchilla River is called the Extended Merced Subbasin.

In order to assess the effects of the LSJR alternatives on groundwater, groundwater in the four subbasins was considered to be four separate pools of water, each with no separation between shallow and deep aquifers. In reality, water can move slowly between subbasins, and there may be differences in effects between shallow (semi-confined) and deep (confined) sections of the aquifer. To the extent that water moves between subbasins, some of the groundwater impacts could have slight effects on adjoining subbasins, which would reduce the effects within the subbasins of concern. In some areas, deeper sections of the aquifer may be separated from shallower sections by substrate with low permeability. The evaluation of groundwater effects was not separated by depth because: (1) there is some connectivity between the different depths, and (2) increased groundwater pumping would occur in both shallow and deep wells. Substrate with low permeability (e.g., the Corcoran Clay at the western side of the four subbasins of interest) might slow the interaction between deeper, confined and shallower, unconfined sections of the aquifer, but water pumped from a deeper confined section of the aquifer would eventually be replaced by water from above or from surrounding subbasins. Furthermore, within the four subbasins, there are numerous deep and shallow drinking water and agricultural wells, making it infeasible to assign increases in pumping to separate sections of the aquifer as a whole. These simplifying assumptions of separating the aquifer by subbasin and not by depth are acceptable because the purpose of the analysis is to estimate the general magnitude of the average effect of the LSJR alternatives on the subbasins, not effects at specific well locations.

Apportionment of Diversions Simulated by WSE Model

For each LSJR alternative, the WSE model produced estimates of the amount of diversions that were available from each river. These results were post-processed within the WSE model and in a groundwater analysis spreadsheet to estimate groundwater effects. As part of this post-processing, the diversions for each river were partitioned between different types of deliveries and losses.

In the first step of post-processing, the following volumes, assumed not to be subject to a water shortage, were subtracted from the total diversions for each river to calculate how much water remained.

- Municipal and industrial water supplies – volumes include Stanislaus River water for DeGroot Water Treatment Plant (for the Cities of Lathrop, Manteca, and Tracy through the South County Water Supply Program) and Tuolumne River water for the City of Modesto. These municipal and industrial water suppliers use a relatively small portion of the total surface water diversion from the Stanislaus and Tuolumne Rivers. (The model assumes that municipal water providers would not experience a reduction in surface water supply; this assumption is only used for calculating groundwater impacts and agricultural impacts. Potential impacts on municipal and industrial water users are evaluated in Chapter 13, *Service Providers*.)

- Water for riparian water rights – includes Cowell Agreement[14] diversions on the Merced River.
- Spills – includes water that is present at the downstream ends of the distribution systems. These volumes are assumed to be the same for each LSJR alternative.
- Seepage from off-stream reservoirs – Woodward Reservoir, Turlock Lake, and Modesto Reservoir.

After subtracting the volumes listed above from the total diversions for each river, the remaining water was apportioned to the irrigation districts as applied surface water and conveyance losses (where conveyance losses are a fraction of applied surface water and spills). Applied water for agricultural purposes is a key component of the water balance; it comes from both surface water and groundwater, and includes water that is used consumptively by the crops (evapotranspiration) and water that percolates deep into the ground below the fields. The surface water portion of applied water was estimated as described above based on the WSE model results. The groundwater portion of applied water was estimated as described further below.

As a result of this post-processing method, when diversions were less than what was needed to meet full demands (of all categories of deliveries and losses), generally the only two categories of water that were assumed to be reduced were applied surface water and conveyance losses (which depend on the applied water). The model assumes reductions in applied water available to the irrigation districts. This assumption allows for a simplified approach to calculating groundwater impacts and produces a conservative estimate of agricultural impacts as described in Chapter 11, *Agricultural Resources* (i.e., agricultural impacts may be overestimated rather than underestimated).

In the WSE model, SEWD and CSJWCD diversions from the Stanislaus River were calculated separately from the SSJID and OID diversions. This is because SEWD and CSJWCD are CVP contractors and only receive water after SSJID and OID water rights have been met. As a result, in some years SEWD would not be able to provide Stanislaus River water to its municipal users, but these municipal needs would be met by either Calaveras River water or groundwater. The division of water between CSJWCD and SEWD was based on their contracts for Stanislaus River water. The division of Stanislaus River water between SSJID and OID and Tuolumne River water between MID and TID was calculated as part of post-processing. The division assumes that each district would receive the same percentage of surface water demand for consumptive use, as described in Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*.

Assessment of Irrigation District Groundwater Pumping

Within the irrigation districts, there is a minimum amount of groundwater pumping that occurs every year. If the amount of minimum groundwater pumping plus the amount of applied surface water is insufficient to meet the irrigation district's total demand for applied water (consumptive use and deep percolation), then additional groundwater pumping would occur up until a maximum amount. Minimum and maximum groundwater pumping estimates were based on an evaluation of irrigation district pumping estimates in CALSIM, 2012 AWMPs, 2010 GWMPs, and information provided by the irrigation districts. The final values primarily came from the AWMPs and the irrigation districts; they are listed in Appendix G. While maximum groundwater pumping can reduce agricultural impacts, it increases the potential for groundwater impacts.

---

[14] The Cowell Agreement is a 1930's adjudicated agreement between MID and landowners flanking portions of the Merced River riparian areas. Per the Cowell Agreement, MID provides up to 50 cfs in February and up to 100 cfs in March downstream of the Crocker Huffman Diversion Dam.

Because baseline is representative of 2009 infrastructure, the primary groundwater analysis utilizes estimates of maximum groundwater pumping that were possible in 2009. However, recent drought conditions have resulted in more wells being drilled. Therefore, estimates of maximum groundwater pumping for 2014 were also assessed, as discussed below in Section 9.4.3, *Impacts and Mitigation Measures*. All 2014 maximum groundwater pumping estimates are greater than the 2009 maximum groundwater estimates, with the exception of Merced ID, where 2009 and 2014 estimates are the same. This is reasonable because Merced ID's 2009 capacity for increased groundwater pumping was almost sufficient to meet full demand in drought years.

As mentioned above and described in Appendix G, the primary data sources used for estimating the parameters needed for the groundwater assessment were the AWMPs, GWMPs, CALSIM, and information provided by the irrigation districts. Because there are many sources of information available regarding groundwater and because there is a large degree of uncertainty in the values, the values chosen for this analysis and the results of this analysis are not always the same as the water balance terms discussed in Section 9.2, *Environmental Setting*.

Evaluation of Irrigation District Groundwater Balance and Impacts

For the analysis of potential groundwater impacts associated with the LSJR alternatives, the net annual change in the irrigation district groundwater balance was estimated for each groundwater subbasin. The annual net contribution of irrigation district water to the groundwater subbasins was calculated by summing the off-stream reservoir seepage, conveyance losses, and deep percolation and subtracting total groundwater pumping for each irrigation district overlying the subbasin. As discussed in Section 9.2.2, *Subbasin Groundwater Use*, two irrigation districts (OID and Merced ID) affect the results for two subbasins because their service area boundaries are not confined to a single subbasin. The OID service area overlies the Eastern San Joaquin and Modesto Subbasins and the Merced ID service area overlay the Turlock and Extended Merced Subbasins. Hereafter, this chapter refers to the subbasin groundwater balance as the "irrigation district groundwater balance." For SEWD and CSJWCD, only the portion of their water use that could be affected by water supply from the Stanislaus River was included in the analysis.

The effect of the LSJR alternatives on the irrigation district groundwater balance is evaluated by comparing the irrigation district groundwater balance under each of the LSJR alternatives with the irrigation district groundwater balance under baseline conditions. The difference in the irrigation district groundwater balance was then divided by the total surface area of the groundwater subbasin; the result would have units of volume per area, expressed in inches (Table 9-12), which represents the height of the volume of water if it were spread evenly over the subbasin. Normalizing the change in groundwater balance by the subbasin area translates the effect into height and directly shows how average groundwater level could be impacted under the LSJR alternatives. An average decrease in irrigation district groundwater balance equivalent to 1 inch per year or more was considered to be a significant impact.

The estimated average specific yield for the Eastern San Joaquin, Modesto, Turlock, and Extended Merced Subbasins ranges from 7 to 10 percent, based on aquifer information presented in DWR Bulletin 118 (DWR 2003b, 2003c, 2003d, 2003e). The specific yield is the ratio of the volume of water a sample of saturated soil will yield by gravity drainage to the total volume of the soil (i.e., the portion of groundwater that could be available for extraction from the saturated soil). For example, a specific yield of 10 percent means that a reduction in groundwater volume equivalent to 1 inch across the subbasin is comparable to an average decrease in groundwater level of approximately

10 inches in an unconfined aquifer. This 10-inch decline in the groundwater level is similar to the estimated historical groundwater level declines shown the first two columns of Table 9-4. This 10-inch decline in groundwater levels would occur in addition to any decline in groundwater levels that occurred under baseline conditions. As such, a 1-inch decrease in the irrigation district groundwater balance across a subbasin caused by the LSJR alternatives could eventually produce a measurable decline in groundwater levels and a substantial depletion of groundwater resources. Therefore, a threshold of a 1-inch reduction in the irrigation district groundwater balance is used in the impact analysis in Section 9.4.3, *Impacts and Mitigation Measures*.

If a groundwater basin has a large volume of average inflow, outflow from the basin is also high because groundwater would drain to the rivers when groundwater elevations are high. Under these conditions, it is possible to pump groundwater without affecting groundwater elevations, although river flows would likely be affected. As discussed in Section 9.2, *Environmental Setting*, DWR's evaluation of groundwater in the San Joaquin Valley Groundwater Basin shows evidence of decreasing groundwater elevations, existing wide-scale groundwater pumping, and limited accretions to the rivers from groundwater. As such, it appears that the four subbasins are not in a state of excess supply. Therefore, a reduced groundwater supply, resulting from reduced recharge and increased pumping, would have a measurable effect on groundwater elevations in many locations.

Evaluation of Subsidence

Substantial groundwater depletion in an area with soils that are susceptible to inelastic compaction could result in subsidence. For this analysis, subsidence is considered to be significant if substantial groundwater depletion is expected to occur (i.e., if the GW-1 impact is significant and unavoidable) in an area where subsidence has previously occurred. Within the study area the main area of subsidence is in the southern portion of the Extended Merced Subbasin, especially in the area near El Nido. Despite reports of periods of declining groundwater levels, subsidence has not been reported for the other three subbasins of interest.

Adaptive Implementation

This chapter evaluates the potential groundwater impacts associated with the LSJR alternatives. Each LSJR alternative includes a February–June unimpaired flow requirement (i.e., 20, 40, or 60 percent) and methods for adaptive implementation to reasonably protect fish and wildlife beneficial uses, as described in Chapter 3, *Alternatives Description*. In addition, a minimum base flow is required at Vernalis at all times during this period. The base flow may be adaptively implemented as described below and in Chapter 3. State Water Board approval is required before any method can be implemented, as described in Appendix K, *Revised Water Quality Control Plan*. All methods may be implemented individually or in combination with other methods, may be applied differently to each tributary, and could be in effect for varying lengths of time, so long as the flows are coordinated to achieve beneficial results in the LSJR related to the protection of fish and wildlife beneficial uses.

The Stanislaus, Tuolumne, and Merced Working Group (STM Working Group) will assist with implementation, monitoring, and assessment activities for the flow objectives and with developing biological goals to help evaluate the effectiveness of the flow requirements and adaptive implementation actions. The STM Working Group may recommend adjusting the flow requirements through adaptive implementation if scientific information supports such changes to reasonably protect fish and wildlife beneficial uses. Scientific research may also be conducted within the adaptive range to improve scientific understanding of measures needed to protect fish and wildlife and reduce scientific uncertainty through monitoring and evaluation. Further details describing the methods, the STM Working Group, and the approval process are included in Chapter 3 and Appendix K.

Without adaptive implementation, flow must be managed such that it tracks the daily unimpaired flow percentage based on a running average of no more than 7 days. The four methods of adaptive implementation are described briefly below.

1. Based on best available scientific information indicating that more flow is needed or less flow is adequate to reasonably protect fish and wildlife beneficial uses, the specified annual February–June minimum unimpaired flow requirement may be increased or decreased to a percentage within the ranges listed below. For LSJR Alternative 2 (20 percent unimpaired flow), the percent of unimpaired flow may be increased to a maximum of 30 percent. For LSJR Alternative 3 (40 percent unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 30 percent or increased to a maximum of 50 percent. For LSJR Alternative 4 (60 percent unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 50 percent.
2. Based on best available scientific information indicating a flow pattern different from that which would occur by tracking the unimpaired flow percentage would better protect fish and wildlife beneficial uses, water may be released at varying rates during February–June. The total volume of water released under this adaptive method must be at least equal to the volume of water that would be released by tracking the unimpaired flow percentage from February–June.
3. Based on best available scientific information, release of a portion of the February-June unimpaired flow may be delayed until after June to prevent adverse effects to fisheries, including temperature, that would otherwise result from implementation of the February-June flow requirements. The ability to delay release of flow until after June is only allowed when the unimpaired flow requirement is greater than 30 percent. If the requirement is greater than 30 percent but less than 40 percent, the amount of flow that may be released after June is limited to the portion of the unimpaired flow requirement over 30 percent. For example, if the flow requirement is 35 percent, 5 percent may be released after June. If the requirement is 40 percent or greater, then 25 percent of the total volume of the flow requirement may be released after June. As an example, if the requirement is 50 percent, at least 37.5 percent unimpaired flow must be released in February–June and up to 12.5 percent unimpaired flow may be released after June. If after June the STM Working Group determines that conditions have changed such that water held for release after June should not be released by the fall of that year, the water may be held until the following year. See Chapter 3 and Appendix K for further details.
4. Based on best available scientific information indicating that more flow is needed or less flow is adequate to reasonably protect fish and wildlife beneficial uses, the February-June Vernalis base flow requirement of 1,000 cfs may be modified to a rate between 800 and 1,200 cfs.

The operational changes made using the adaptive implementation methods above may be approved if the best available scientific information indicates that the changes will be sufficient to support and maintain the natural production of viable native SJR Watershed fish populations migrating through the Delta and meet any biological goals. The changes may take place on either a short-term (for example monthly or annually) or longer-term basis. Adaptive implementation is intended to foster coordinated and adaptive management of flows based on best available scientific information in order to protect fish and wildlife beneficial uses. Adaptive implementation could also optimize flows to achieve the objective, while allowing for consideration of other beneficial uses, provided that these other considerations do not reduce intended benefits to fish and wildlife. While the measures and processes used to decide upon adaptive implementation actions must achieve the narrative objective for the reasonable protection of fish and wildlife beneficial uses, adaptive implementation could result in flows that would benefit or reduce impacts on other beneficial uses that rely on water.

The quantitative results included in the figures, tables, and text of this chapter present WSE modeling of the specified unimpaired flow requirement for each LSJR alternative (i.e., 20, 40, or 60 percent). However, the modeling does allow some inflows to be retained in the reservoirs after June, as could occur under adaptive implementation method 3, to prevent adverse temperature effects and this is included in the results presented in this chapter. If the percent of unimpaired flow is not specified in this chapter, these are the percentages of unimpaired flow evaluated in the impact analysis. However, as part of adaptive implementation method 1, the required percent of unimpaired flow could change by up to 10 percent if the STM Working Group agrees to adjust it. The highest possible percent of unimpaired flow associated with an LSJR alternative is also evaluated in the impact analysis if long-term implementation of method 1 has the potential to affect a determination of significance. For example, if the determination for LSJR Alternative 2 at 20 percent unimpaired flow is less than significant, but the determination for LSJR Alternative 3 at 40 percent unimpaired flow is significant, then LSJR Alternative 2 is also evaluated at the 30 percent unimpaired flow. This use of modeling provides information to support the analysis and evaluation of the effects of the alternatives and adaptive implementation. For more information regarding the modeling methodology and quantitative flow and temperature modeling results, see Appendix F.1, *Hydrologic and Water Quality Modeling*.

Baseline

Results of the baseline groundwater analysis are presented here to illustrate the modeling methods and to show what was used as the basis of comparison for the LSJR alternatives. See Appendix G, *Agricultural Economic Effects of the Lower San Joaquin River Flow Alternatives: Methodology and Modeling Results*, for a more extensive discussion of the model results.

In the first step of the analysis the WSE model diversions were partitioned between different types of deliveries and losses. For example, Figure 9-6 shows this partitioning for baseline conditions for the Stanislaus River. On the Stanislaus River, the largest portion of baseline diversions usually goes to the consumptive use of applied water by agriculture (CUAW). This is also true for the Tuolumne and Merced Rivers (Appendix G). However, during drought conditions the amount of water available for agriculture is greatly reduced. This is particularly apparent in the results for 1934, 1977, and 1992 (Figure 9-6).

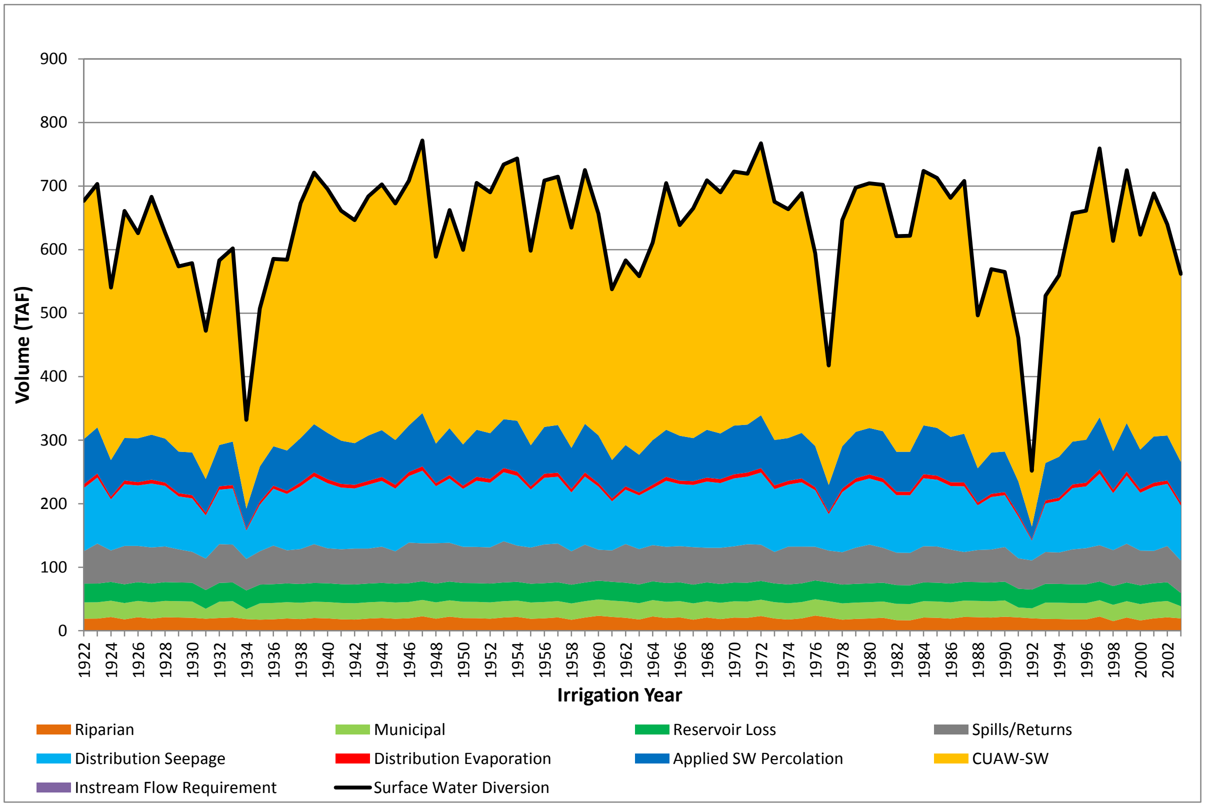

Figure 9-6. Partitioning of Baseline Diversions from the Stanislaus River into End Uses

In years with low water supply, surface water diversions are not sufficient to meet full agricultural demand for applied water (for CUAW and deep percolation). As a result, groundwater pumping increases. Even under baseline conditions, there are years when increases in groundwater pumping are expected to be unable to meet the full agricultural demand of the irrigation districts that obtain surface water from the Stanislaus, Tuolumne, and Merced Rivers (Figures 9-7a, 9-7b, and 9-7c, respectively).

The capacity of each irrigation district to pump groundwater varies and depends on existing infrastructure (Table 9-6 and Appendix G). The capacity for increased groundwater pumping by Merced ID is almost sufficient to meet full demand in drought years. There is moderate capacity to compensate for a reduction in surface water supply on the Stanislaus River, but this comes largely from SEWD and CSJWCD, which can fully compensate for a reduction in their Stanislaus River supply. In contrast, SSJID and OID have only a limited ability to increase groundwater pumping because their surface water supply has historically been reliable, and they have not needed to increase their groundwater pumping capacity. The Tuolumne River irrigation districts, TID and MID, have similarly limited ability to increase groundwater pumping (Table 9-6 and Appendix G).

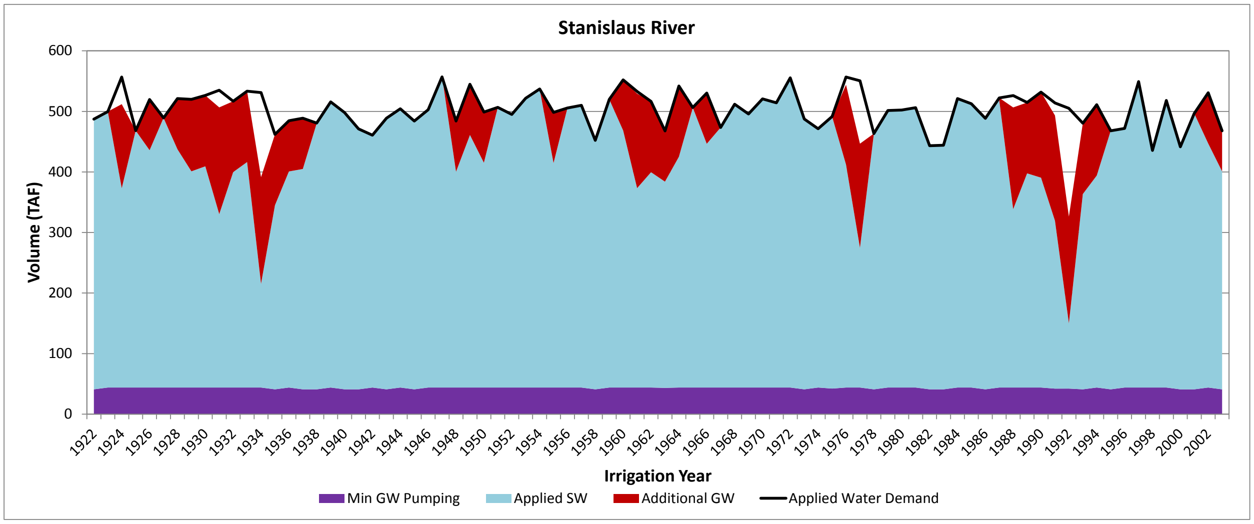

Figure 9-7a. Baseline Groundwater and Surface Water Application to Meet Applied Water Demand for the Stanislaus River

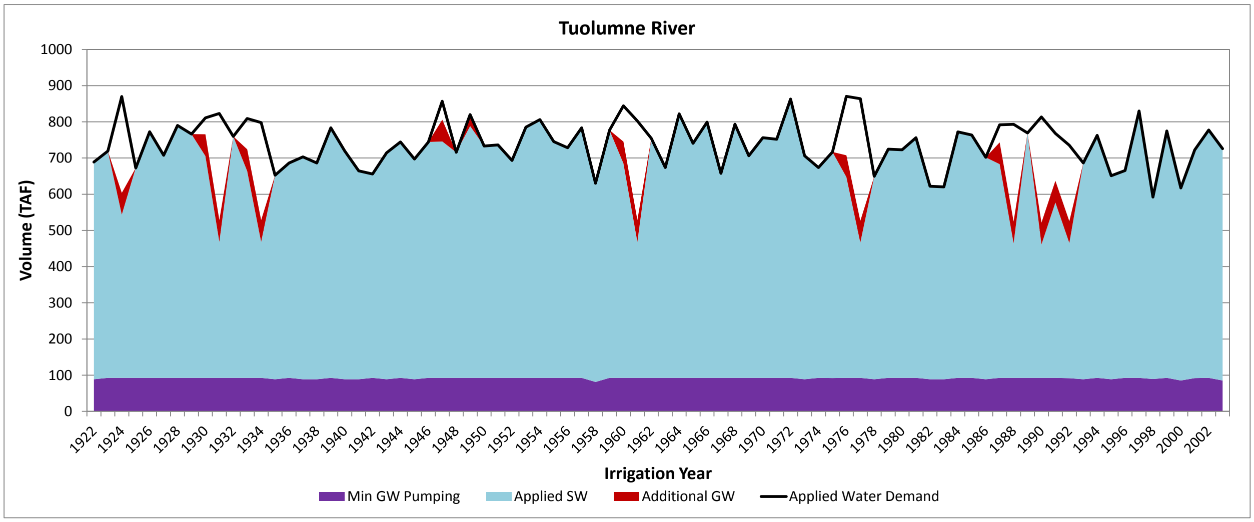

Figure 9-7b. Baseline Groundwater and Surface Water Application to Meet Applied Water Demand for the Tuolumne River

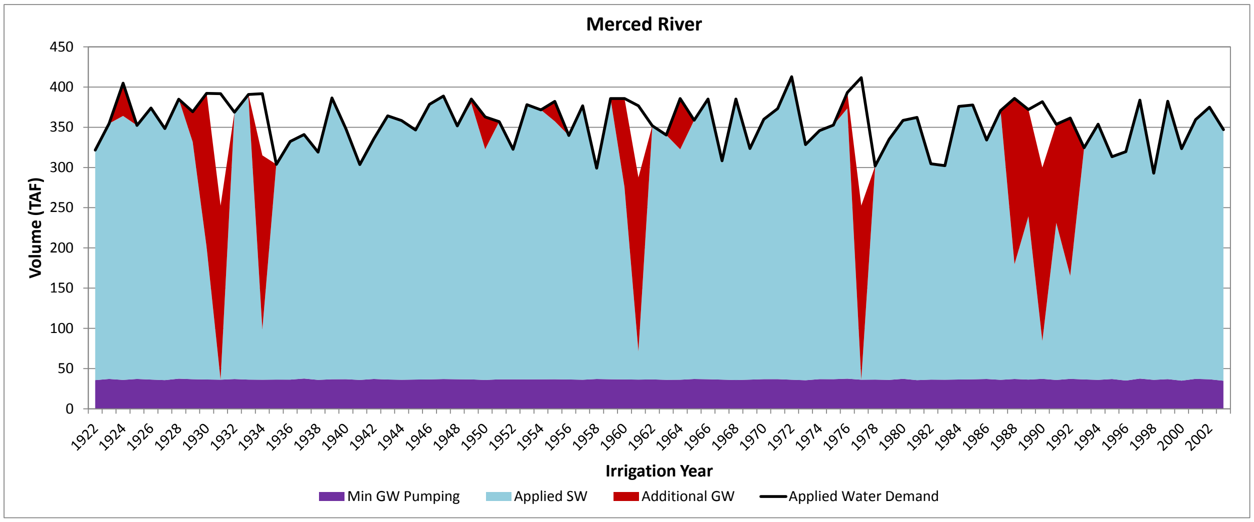

Figure 9-7c. Baseline Groundwater and Surface Water Application to Meet Applied Water Demand for the Merced River

Under baseline conditions, during most years, irrigation districts contribute more surface water to groundwater stores (i.e., recharge) than the irrigation districts remove by groundwater pumping. However, under drought conditions, seepage from the conveyance system and deep percolation from applied surface water is reduced while groundwater pumping increases. For example, in the Stanislaus River drought conditions can cause the irrigation districts to temporarily become net users of groundwater (Figure 9-8). However, in general the irrigation district contributions to groundwater help to offset the groundwater pumping for irrigated land outside of the irrigation districts, which is primarily irrigated with groundwater (Table 9-6).

The baseline contribution of the irrigation districts to the subbasins is typically 100–200 TAF/y if surface water supply meets the irrigation district needs (Figure 9-9). However, during drought, contributions to groundwater are reduced, and in some years, the irrigation districts overlying the Eastern San Joaquin and Extended Merced Subbasins become net users of groundwater under baseline conditions. Drought affects the net irrigation district contribution to groundwater more often in the Eastern San Joaquin Subbasin than for the other subbasins. However, during the worst droughts, drought affects the Extended Merced Subbasin more severely. The severity and frequency of water shortages and the ability of the irrigation districts to increase groundwater pumping directly affects the irrigation district contributions to the subbasins.

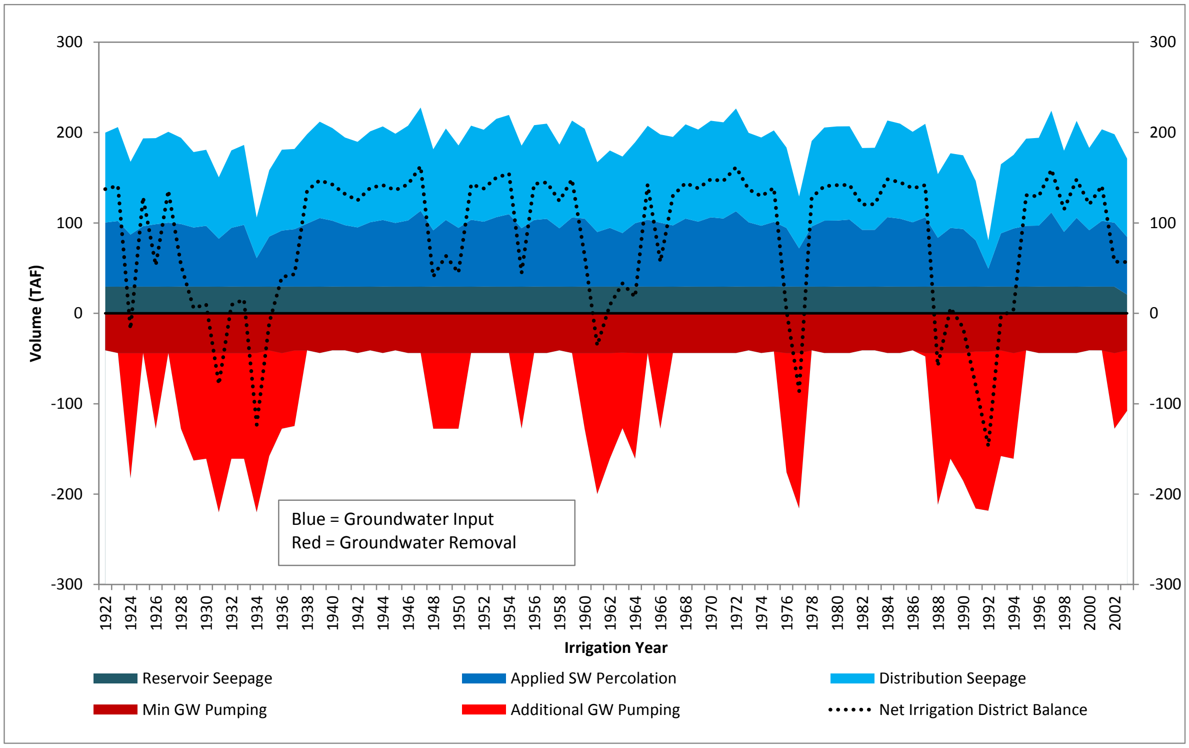

Figure 9-8. Effect of Stanislaus River Irrigation Districts on Baseline Groundwater Balance

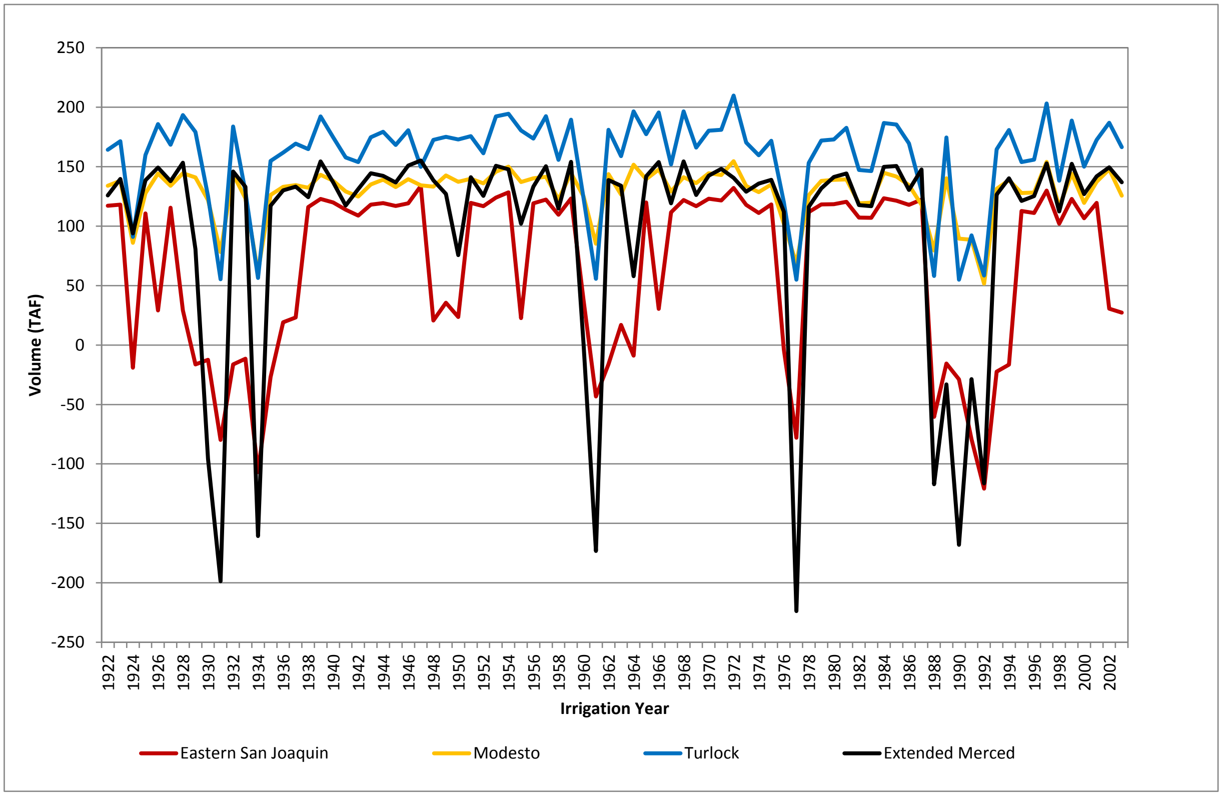

Figure 9-9. Net Annual Contribution to Groundwater Subbasins by the Irrigation Districts under Baseline Conditions

Extended Plan Area

In this chapter, the analysis of the extended plan area generally identifies how the impacts may be similar to or different from the impacts in the plan area (i.e., downstream of the rim dams) depending on the similarity of the impact mechanism (e.g., changes in reservoir levels, reduced water diversions, and additional flow in the rivers) or location of potential impacts in the extended plan area. Where appropriate, the program of implementation is discussed to help contextualize the potential impacts in the extended plan area.

SDWQ Alternatives

The SDWQ alternatives are not considered in this analysis, as described in Section 9.2.4, *Southern Delta*, and Appendix B, *State Water Board's Environmental Checklist*, because increased groundwater pumping or reduced groundwater recharge would not occur as a result of a change to the salinity objective.

9.4.3 Impacts and Mitigation Measures

Impact GW-1: Substantially deplete groundwater supplies or interfere substantially with groundwater recharge

No Project Alternative (LSJR/SDWQ Alternative 1)

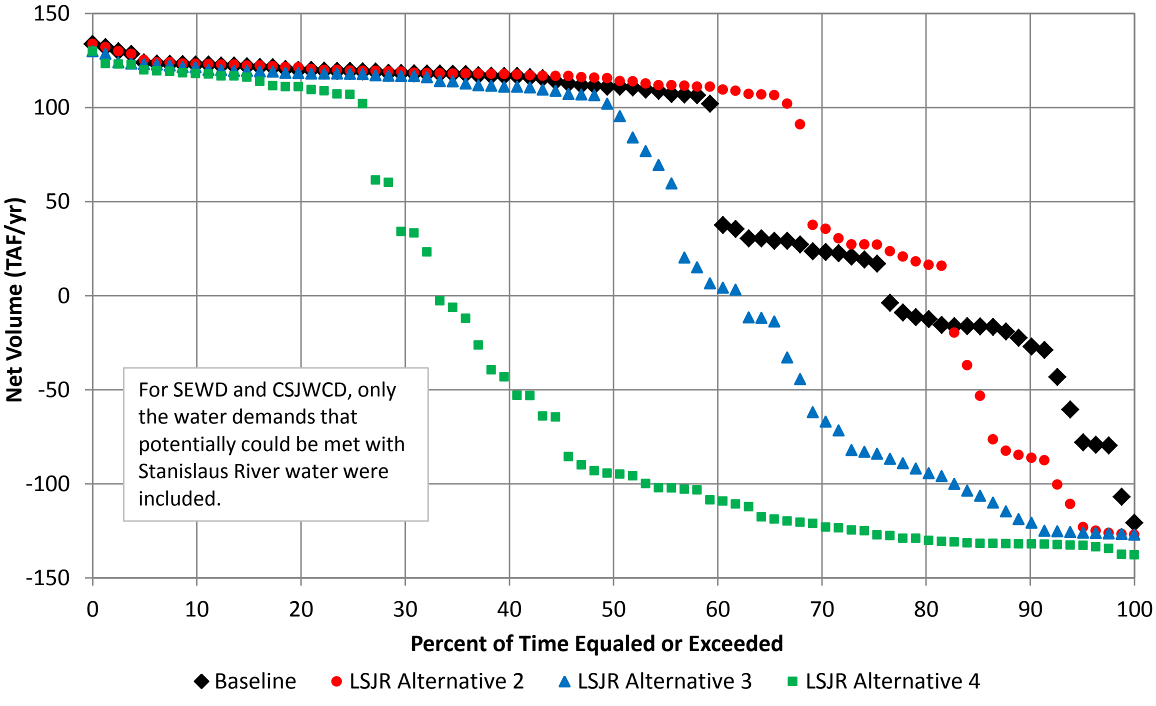
The No Project Alternative would result in implementation of flow objectives identified in the 2006 *Water Quality Control Plan for the San Francisco Bay/Sacramento-San Joaquin Delta Estuary* (2006 Bay-Delta Plan). See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the technical analysis of the No Project Alternative.

LSJR Alternatives

Baseline groundwater pumping is extensive in the four subbasins. Groundwater pumping is conducted by the irrigation districts and water districts, other water purveyors (e.g., cities and counties), and individual landowners. In dry years, irrigation districts use groundwater to compensate for reduced surface water supplies. However, on average, the irrigation districts (SSJID, OID, MID, TID, Merced ID, and the portions of SEWD and CSJWCD that use Stanislaus River water) provide net recharge to the groundwater aquifer and help compensate for groundwater pumping outside of the irrigation district lands, which is greater than groundwater pumping within the irrigation districts (Table 9-6).

A reduction in surface water supply may affect the groundwater aquifer by simultaneously causing a reduction in recharge volume (by reducing deep percolation from the distribution system and agricultural fields) and an increase in groundwater pumping (to replace lost surface water supplies). If the irrigation districts were able to use groundwater to fully replace any decreases in surface water needed for irrigation of crops, then the effect of the LSJR alternatives on groundwater would be approximately equal to the decrease in river diversions (with a minor difference due to evaporation from the distribution system). If the irrigation districts were not able to use groundwater to compensate for a reduction in surface water supply, then the effect of the LSJR alternatives on groundwater would be equal to the reduction in percolation from the distribution system plus the reduction in percolation from applied water. Because the irrigation districts have some ability to replace reductions in surface water supply with groundwater, the effect of the LSJR alternatives on the change in the groundwater balance is a volume that is between the reduction in diversion volume (maximum groundwater effect) and the reduction in percolation volume from the distribution system and applied water (minimum groundwater effect).

A comparison of the irrigation districts' estimated baseline net groundwater balances to the estimated values for the LSJR alternatives indicates that, as the specified percent of unimpaired flow increases, pumping increases, and groundwater recharge is reduced. Figures 9-10 through 9-13 illustrate this effect and show the percent of the time that net irrigation district contributions to each groundwater basin were equaled or exceeded for each LSJR alternative. Lower values (i.e., less recharge) typically occurs under dry conditions, with more reductions in recharge occurring when higher percentages of unimpaired flow are required. The irrigation districts almost always have a positive effect on the groundwater balance in the Modesto and Turlock Subbasins (Figures 9-11 and 9-12, respectively); however, the Turlock Subbasin balance is occasionally negative under LSJR Alternative 4 (Figure 9-12). The net effect of the irrigation districts on the groundwater balance may be negative, even under baseline conditions, in the Eastern San Joaquin and Extended Merced Subbasins (Figures 9-10 and 9-13, respectively).



For SEWD and CSJWCD, only the water demands that potentially could be met with Stanislaus River water were included.

Figure 9-10. Annual Net Contribution to the Eastern San Joaquin Subbasin by SSJID, OID, SEWD, and CSJWCD

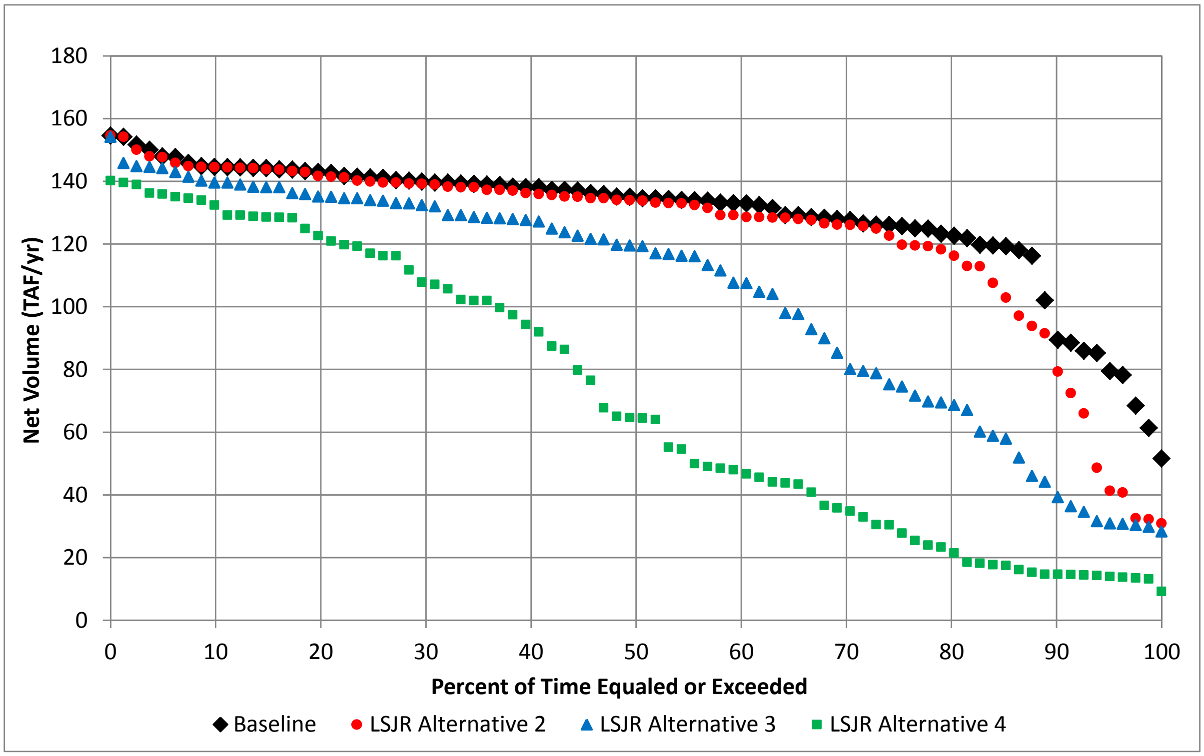


Figure 9-11. Annual Net Contribution to the Modesto Subbasin by MID and OID

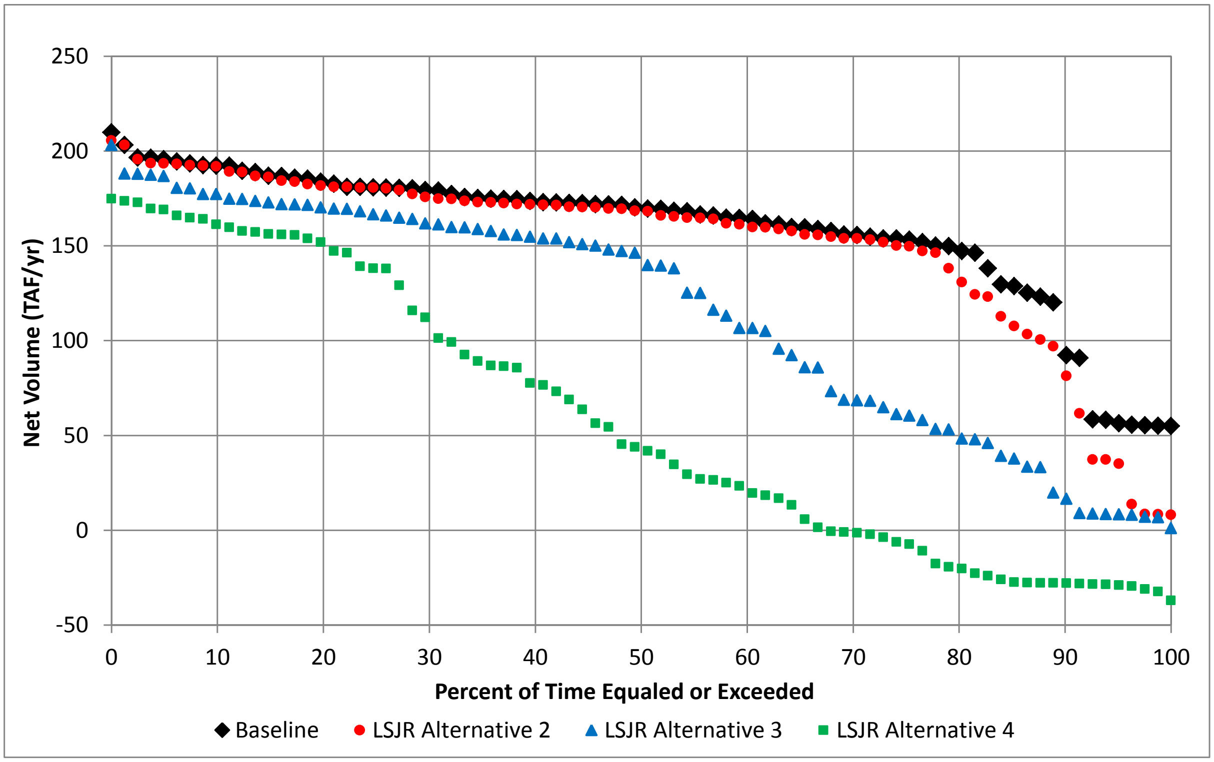

Figure 9-12. Annual Net Contribution to the Turlock Subbasin by TID and MID

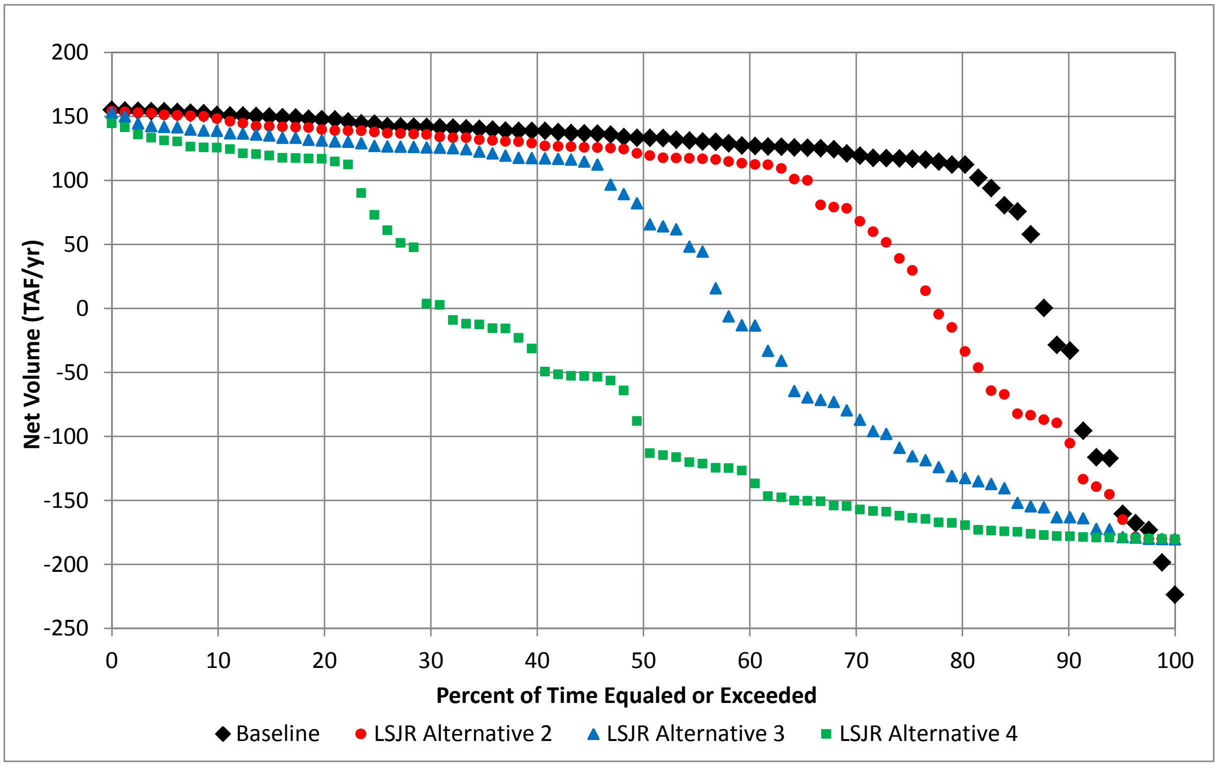

Figure 9-13. Annual Net Contribution to the Extended Merced Subbasin by MID

As described in Section 9.4.2, *Methods and Approach*, this analysis was performed using estimates of maximum groundwater pumping capacity based on 2009 infrastructure. Table 9-12 provides a summary of the average annual net change in the groundwater balance caused by each LSJR alternative, expressed in terms of inches of water spread over the entire subbasin. Table 9-12 also includes results assuming maximum groundwater pumping capacity based on 2014 infrastructure. These results are addressed in more detail in the following sections, which discuss the potential impacts associated with each alternative.

Table 9-12. Average Annual Net Change in Irrigation District Groundwater Balance Associated with the LSJR Alternatives per Subbasin Area

				Decrease in Groundwater Balance Per Subbasin Area (inches)			
				LSJR Alternative 2		LSJR Alternative 3	LSJR Alternative 4
Groundwater Subbasin	Total Area (1,000 acres)	Baseline Irrigation District Groundwater Balance (TAF) (positive indicates recharge)	Baseline Irrigation District Recharge Per Subbasin Area (inches)	20 Percent Unimpaired Flow	Adaptive Implementation Method 1: 30 Percent Unimpaired Flow		
Results assuming maximum groundwater pumping based on 2009 infrastructure							
Eastern San Joaquin	707	65	1.1	0.0	0.1	0.6	1.7
Modesto	247	129	6.3	0.3	0.6	1.2	2.8
Turlock	349	158	5.4	0.3	0.7	1.5	3.4
Extended Merced	517	99	2.3	0.7	1.2	1.9	3.5
Results assuming maximum groundwater pumping based on 2014 infrastructure							
Eastern San Joaquin	707	64	1.1	0.0	0.2	0.7	1.9
Modesto	247	120	5.8	0.4	1.1	2.2	5.0
Turlock	349	146	5.0	0.3	1.1	2.2	5.0
Extended Merced	517	99	2.3	0.7	1.2	1.9	3.5

LSJR Alternative 2(Less than significant/Significant and unavoidable with adaptive implementation)

Estimated average net irrigation district groundwater balance under LSJR Alternative 2 is predicted to be either similar to or slightly less than under baseline conditions, with the decrease being most noticeable in the Extended Merced Subbasin (Figures 9-10 through 9-13). The predicted small changes are driven by the small changes to average surface water diversions under LSJR Alternative 2. Under baseline and LSJR Alternative 2, the irrigation districts contribute to groundwater recharge in most years, with the exception that the irrigation district groundwater balance becomes negative in the Eastern San Joaquin and Extended Merced Subbasins during approximately the driest 20 percent and 10 percent of years, respectively (Figures 9-10 through 9-13). The average reduction in annual net groundwater recharge under LSJR Alternative 2 relative to baseline is equivalent to 0.0-0.7 inches of water across each of the four subbasins (with 0.0 inches being for the Eastern San Joaquin Subbasin and 0.7 inches being for the Extended Merced Subbasin [Table 9-12]). These changes are less than the 1 inch threshold for significance.

When the maximum groundwater pumping capacity for 2014 is used in the analysis instead of the estimates for 2009, the results show small increases in baseline pumping in the Eastern San Joaquin, Modesto, and Turlock Subbasins under baseline conditions. However, the only noticeable change in the effect of LSJR Alternative 2 on groundwater recharge would be slightly less recharge for the Modesto Subbasin (reduction in recharge would increase from 0.3 to 0.4 inches across the subbasin [Table 9-12]). The largest effect of switching from the 2009 to 2014 maximum groundwater pumping capacity is in the Modesto Subbasin because MID had a relatively large increase in groundwater pumping capacity between 2009 and 2014 (Table G.2-4) and the smallest acreage (Table 9-12).

As described in Section 9.2.1, *San Joaquin Valley Groundwater Basin and Subbasins*, a change in groundwater flow can indirectly influence groundwater quality. Under LSJR Alternative 2, the direction of groundwater flow would not change such that any existing localized groundwater contamination in the subbasins would be affected. Therefore, there would likely be no degradation of groundwater quality under LSJR Alternative 2. Furthermore, LSJR Alternative 2 would not cause a significant amount of applied surface water, which has relatively low EC, to be replaced with applied groundwater, which has relatively high EC (surface water from the Stanislaus, Tuolumne, and Merced Rivers generally has much lower salinity than groundwater). Consequently, LSJR Alternative 2 would not cause an increase in salinity concentrations in the groundwater subbasins.

Therefore, at the 20 percent unimpaired flow level, the slight reduction in recharge under LSJR Alternative 2, as compared to baseline, would not likely result in groundwater quality impacts or a significant reduction in groundwater levels.

Adaptive Implementation

As discussed above, based on best available scientific information indicating that a change in the percent of unimpaired flow is needed to reasonably protect fish and wildlife, adaptive implementation method 1 would allow an increase of up to 10 percent over the 20 percent February-June unimpaired flow requirement (to a maximum of 30 percent of unimpaired flow). A change to the percent of unimpaired flow would take place based on required evaluation of current scientific information and would need to be approved as described in Appendix K, *Revised Water Quality Control Plan.* Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time. However, an increase of up to 30 percent of unimpaired flow would potentially result in different effects, as compared to 20 percent unimpaired flow, depending upon flow conditions and frequency of the adjustment. If this adjustment occurs frequently or for extended durations, impacts under LSJR Alternative 2 could become more like the impacts under LSJR Alternative 3. At the 30 percent unimpaired flow level, impacts on groundwater would increase relative to the 20 percent unimpaired flow level (Table 9-12) and could reach the equivalent of 1.2 inches across the Extended Merced Subbasin (i.e., greater than the threshold of significance). If the 2014 maximum groundwater pumping capacity values are used for the assessment, estimated groundwater impacts become significant for the Modesto and Turlock Subbasins and the Extended Merced Subbasin (Table 9-12).

As described in Section 9.2.1, *San Joaquin Valley Groundwater Basin and Subbasins*, a change in groundwater pumping can indirectly influence groundwater quality. Under LSJR Alternative 2 with adaptive implementation, a reduction in groundwater levels in the Extended Merced Subbasin could cause a degradation of groundwater quality as a result of changes in the direction of groundwater flow. However, specifically determining the changes to groundwater quality is speculative as it is dependent of many factors including, but not limited to, the location of groundwater pumping, the amount of groundwater pumped, the frequency at which pumping would occur, location of contaminants, the type of contaminants (e.g., water soluble or not), proximity of contamination to aquifers, hydrogeological characteristics of the aquifer, individual well construction, well depth, groundwater levels, and localized conditions, such as proximity to unused or abandoned wells. However, while specifically determining the changes to groundwater quality is speculative, it is reasonable to assume that localized groundwater contamination that exists in the subbasins could move in undesirable directions (i.e., toward water supply wells) and reduction in deep percolation of the relatively low EC surface water could also affect groundwater quality by causing a gradual increase in salinity. Consequently, LSJR Alternative 2, with the incorporation of adaptive implementation method 1, could potentially substantially deplete groundwater supplies and interfere with groundwater recharge and affect groundwater quality in these subbasins. Therefore, impacts on groundwater resources would be potentially significant and unavoidable.

Based on best available scientific information indicating that a change in the timing or rate of unimpaired flow is needed to reasonably protect fish and wildlife, adaptive implementation method 2 would allow changing the timing of the release of the volume of water within the February-June time frame. While the total volume of water released February–June would be the same as LSJR Alternative 2 without adaptive implementation, the rate could vary from the actual (7 day running average) unimpaired flow rate. Adaptive implementation method 2 would not authorize a reduction in flows required by other agencies or through other processes, which are incorporated in the modeling of baseline conditions. A change in the timing of the flow releases would not have an effect on groundwater recharge or groundwater quality. Adaptive implementation method 3 would not be authorized under LSJR Alternative 2 since the unimpaired flow percentage would not exceed 30 percent. Adaptive implementation method 4 would allow an adjustment of the Vernalis February–June flow requirement. WSE model results indicate changes due to adaptive implementation method 4 under this alternative would rarely alter the flows in the three eastside tributaries or the LSJR, and thus would not affect groundwater. Accordingly, LSJR Alternative 2, with the incorporation of adaptive implementation methods 2 and 4, would not substantially deplete groundwater supplies and affect groundwater quality.

An SED must identify feasible mitigation measures for each significant environmental impact identified in the SED. (Cal. Code Regs., tit. 23, § 3777, subd. (b)(3).) Mitigation to reduce significant impacts on groundwater resources could include the State Water Board or local agencies exercising their various authorities over groundwater users, including authorities under SGMA.

SGMA is now the state's primary sustainable groundwater management law. Under the SGMA framework, local agencies are tasked with protecting and managing high and medium priority groundwater basins with state intervention to begin by specified dates if local agencies are unwilling or unable to manage. The SGMA deadlines for state intervention are still prospective; therefore, State Water Board mitigation to protect the groundwater basin from the indirect impacts of the LSJR alternatives is infeasible at this time, but mitigation under local authorities is both feasible and required.

Possible mitigation measures to reduce or avoid any potential effects include those listed below.

- Identify the basin's sustainable yield and implement enforceable groundwater management measures (for maximum pumping or minimum water levels) so that reductions in groundwater pumping would result if certain thresholds are met.
- Establish water conservation measures, such as increased efficiency for municipal and industrial uses or conversion of irrigated land to crops that require less water, such that reductions in groundwater pumping would result.
- Establish a conjunctive water management program that would divert surface water during non-irrigation months (e.g., October–April) during wet years into unlined canals and designated fields to recharge the groundwater basin.

Local governments have police powers and groundwater management authority, but that authority was not exercised in most of the state to protect groundwater resources, including in areas that have long been recognized as being critically overdrafted. Although local governments could and should have regulated groundwater pumping to avoid, arrest, or reverse conditions of long-term overdraft, this regulatory authority was not typically used under baseline conditions. However, SGMA now requires that local agencies form GSAs by June 30, 2017. In the critically overdrafted Eastern San Joaquin, Merced, and Chowchilla Subbasins, those GSAs must develop and implement GSPs by January 31, 2020, while GSAs in the Modesto and Turlock Subbasins must adopt GSPs by January 31, 2022. Each GSP must also include measureable objectives as well as milestones in increments of 5 years, to achieve the sustainability goal in the basin within 20 years of the implementation of the GSP. (Wat. Code, § 10727.2.)

Thus, at this time, local agencies are vested with the mandatory duty to achieve sustainable groundwater management, which includes not causing undesirable results such as significant and unreasonable reduction of groundwater storage and degradation of water quality. Therefore, these local agencies with authority over the Extended Merced Subbasin can and should exercise their full authorities to address substantial depletion of groundwater supplies and water quality degradation, both under SGMA and their police powers. Under that authority, they can and should also implement those mitigation measures identified above. Doing so would prevent groundwater depletion and water quality impacts, mitigate those impacts, or both.

The State Water Board has several authorities that are independent of SGMA, including authority to take action to prevent waste, unreasonable use, unreasonable method of use, and unreasonable method of diversion of water. The State Water Board may exercise this authority through quasi-adjudicative or quasi-legislative proceedings. However, it is infeasible for the State Water Board to impose mitigation measures to prevent waste and unreasonable use at this time because it is undertaking a programmatic analysis of the potential groundwater resource impacts and does not have specific facts associated with an individual project to legally and technically apply requirements to prevent waste and unreasonable use in an adjudicative proceeding. In addition, while the State Water Board may impose water conservation or efficiency requirements through the adoption of regulations, the amount of time, high cost, and commitment of staff resources associated with such rule-making proceedings also renders adopting the mitigation measures now infeasible. Adopting regulations right now would require considerable staff time to research, formulate and develop, require extensive stakeholder outreach, and require numerous public meetings before the regulations would take effect. The State Water Board currently has limited resources to pursue adoption of such regulations as most of its budget for the water right program is supported by fees imposed on water right permit and license holders, and is used for program activities related to the diversion and use of water subject to the permit and license system. Only a small amount of funding is available for other regulatory activities and it is speculative to anticipate that additional funding will be made available.

The State Water Board's water quality control planning process relies on periodic reviews of the Bay-Delta Plan. As a result, the planning process continually accounts for changing conditions related to water quality and water planning. As additional information and data are gathered regarding groundwater pumping in the subbasins, SGMA milestones, and SGMA compliance, the State Water Board can and will revisit and analyze the groundwater condition during the periodic review of the water quality control plan. Where and when appropriate, it will also exercise its independent but complementary authorities under SGMA to ensure sustainable management of the groundwater basins in the plan area. Due to the infeasibility of mitigation by the State Water Board at this time and the inherent uncertainty in the degree to which this mitigation may be implemented by local agencies, particularly in the near-term, impacts on groundwater resources under LSJR Alternative 2 with adaptive implementation would remain significant and unavoidable.

LSJR Alternative 3 (Significant and unavoidable/Significant and unavoidable with adaptive implementation)

Estimated net irrigation district groundwater balance under LSJR Alternative 3 is predicted to be lower than under baseline conditions. The effect of LSJR Alternative 3 on groundwater could be largest in years with less than median water availability, but even wet years could experience some small effects in the Modesto, Turlock, and Extended Merced Subbasins (Figures 9-10 through 9-13). Under LSJR Alternative 3, the irrigation districts would still contribute to groundwater recharge in most years, although the irrigation district groundwater balance could become negative in the Eastern San Joaquin and Extended Merced Subbasins during approximately the driest 40 percent of years (i.e., more often than under baseline and LSJR Alternative 2) (Figures 9-10 through 9-13). Even when the net irrigation district groundwater balance is positive, a decrease in the recharge could be detrimental because it could reduce the amount of compensation for groundwater pumping that happens outside of the irrigation district lands.

Under LSJR Alternative 3 there would be more water in the rivers that could recharge the groundwater basins. However, it is unlikely that recharge from the rivers would increase significantly because the amount of recharge from the rivers is not large under existing conditions (USGS 2015) and the average wetted width of the channel would not increase greatly as a result of LSJR Alternative 3. If groundwater level decreases over time, the aquifer may eventually no longer intersect with portions of the rivers. This could also cause an increase in groundwater recharge from the rivers, but is not likely to be substantial enough to compensate for changes in the irrigation district groundwater balances.

Physical changes to the subbasins would occur over time. In wet years, LSJR Alternative 3 could have little effect on groundwater levels, but in dry years, groundwater levels could potentially substantially decrease. The potential calculated reduction in recharge in terms of inches across the subbasins is just an indicator of substantial effect. As described in Section 9.4.2, *Methods and Approach*, 1 inch of water translates to an approximately 10-inch decrease in groundwater level. A decrease in groundwater levels would not be uniform across the subbasins. It would vary depending on the location and amount of recharge, groundwater extraction, and potential movement of groundwater from other locations.

The average reduction in net irrigation district groundwater balance under LSJR Alternative 3 could exceed 1 inch across the Modesto, Turlock, and Extended Merced Subbasins (Table 9-12). When the maximum groundwater pumping capacity for 2014 is used in the analysis instead of the estimates for 2009, the results show small increases in pumping in the Eastern San Joaquin, Modesto, and Turlock Subbasins under baseline conditions. The results also show somewhat greater increases in groundwater pumping under LSJR Alternative 3, which could potentially result in a larger decrease in groundwater elevations (Table 9-12). The largest modeled difference in results between the 2009 and 2014 maximum groundwater pumping capacities are in the Modesto Subbasin because MID had a relatively large increase in groundwater pumping capacity between 2009 and 2014 (Table G.2-4) and had the smallest acreage (Table 9-12). There is no change in the Extended Merced Subbasin because the subbasin saw no change in the estimated maximum groundwater pumping capacity between 2009 and 2014.

As described in Section 9.2.1, *San Joaquin Valley Groundwater Basin and Subbasins*, a change in groundwater pumping can indirectly influence groundwater quality. Under LSJR Alternative 3, reduction in groundwater levels in the Modesto, Turlock, and Extended Merced Subbasins could cause a degradation of groundwater quality as a result of changes in the direction of groundwater flow. Specifically determining the changes to groundwater quality is speculative as it is dependent upon many factors including, but not limited to, the location of groundwater pumping, the amount of groundwater pumped, the frequency at which pumping would occur, location of contaminants, the type of contaminants (e.g., water soluble or not), proximity of contamination to aquifers, hydrogeological characteristics of the aquifer, individual well construction, well depth, groundwater levels, and localized conditions, such as proximity to unused or abandoned wells. However, while specifically determining the changes to groundwater quality is speculative, it is reasonable to assume that localized groundwater contamination that exists in the subbasins could move in undesirable directions (i.e., toward water supply wells) and that reduction in deep percolation of the relatively low EC surface water could also affect groundwater quality by causing a gradual increase in salinity.

Because the average annual reduction in irrigation district groundwater balance under LSJR Alternative 3 would exceed 1 inch across the Modesto, Turlock, and the Extended Merced Subbasins, LSJR Alternative 3 could potentially substantially deplete groundwater supplies and interfere with groundwater recharge and affect groundwater quality in these subbasins. Therefore, impacts on groundwater resources would be potentially significant and unavoidable.

Adaptive Implementation

As discussed under LSJR Alternative 2, adaptive implementation methods 2 and 4 are not expected to result in impacts on groundwater resources. Adaptive implementation method 3 would result in a shift in the volume of February–June water available to other parts of the year and is included in the modeling results presented above for LSJR Alternative 3. Because this method would not affect diversions or the total annual volume of river flow, this method would not affect groundwater, and it would result in impacts similar to those already described. Adaptive implementation method 1 would allow an increase or decrease of up to 10 percent in the February-June 40 percent unimpaired flow requirement (with a minimum of 30 percent and maximum of 50 percent) to optimize implementation measures to meet the narrative objective, while considering other beneficial uses, provided that these other considerations do not reduce intended benefits to fish and wildlife. Adaptive implementation must be approved using the process described in Appendix K, *Revised Water Quality Control Plan*. Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time. If the specified percent of unimpaired flow were changed from 40 percent to 30 percent or 40 percent to 50 percent on a long-term basis, the conditions and impacts could become more similar to LSJR Alternatives 2 or 4, respectively. If the adjustment occurs frequently or for extended durations, based on the modeling results for LSJR Alternative 2, with adaptive implementation method 1 incorporated (i.e., 30 percent unimpaired flow), and LSJR Alternative 4, with adaptive implementation method 1 incorporated (i.e., 50 percent unimpaired flow), impacts would remain potentially significant and unavoidable.

An SED must identify feasible mitigation measures for each significant environmental impact identified in the SED. (Cal. Code Regs., tit. 23, § 3777, subd. (b)(3).) Mitigation to reduce significant impacts on groundwater resources could include the State Water Board or local agencies exercising their various authorities over groundwater users, including authorities under SGMA.

As discussed in detail under LSJR Alternative 2 with adaptive implementation, the State Water Board has several authorities that are independent of SGMA but it is local agencies that are vested with the mandatory duty to achieve sustainable groundwater management, which includes not causing undesirable results such as significant and unreasonable reduction of groundwater storage and degradation of water quality. Therefore, these local agencies, with authority over Eastern San Joaquin Basin, Modesto, Turlock, and Extended Merced Subbasins can and should exercise their full authorities to address substantial depletion of groundwater supplies and water quality degradation, both under SGMA and their police powers. Under that authority, they can and should also implement those mitigation measures identified in LSJR Alternative 2 with adaptive implementation above. Doing so would prevent groundwater depletion and water quality impacts, mitigate those impacts, or both. Due to the inherent uncertainty in the degree to which this mitigation may be implemented by local agencies, however, impacts on groundwater resources under LSJR Alternative 3, with or without adaptive implementation, would remain potentially significant and unavoidable.

As further stated under LSJR Alternative 2 with adaptive implementation, the State Water Board can and will revisit and analyze the groundwater condition during the periodic review of the water quality control plan. Where and when appropriate, it will also exercise its independent but complementary authorities under SGMA to ensure sustainable management of the groundwater basins in the plan area.

LSJR Alternative 4 (Significant and unavoidable/Significant and unavoidable with adaptive implementation)

LSJR Alternative 4 could result in the greatest potential increase in groundwater pumping and reduction in recharge from the four subbasins, as compared to baseline levels (Table 9-12). LSJR Alternative 4 could result in physical environmental effects, such as decreases in water quality or a significant reduction in groundwater levels, similar to the impacts described under LSJR Alternative 3. However, LSJR Alternative 4 could result in less groundwater recharge from surface water and require more groundwater to be pumped than would be required under LSJR Alternative 3. As such, the impacts on groundwater levels and quality associated with LSJR Alternative 4 would potentially be greater than the impacts associated with LSJR Alternative 3.

Estimated annual net groundwater contributions from the irrigation districts under LSJR Alternative 4 are predicted to be much lower than under baseline conditions. The effect of LSJR Alternative 4 on groundwater pumping and recharge could be largest in years with less than median water availability, but even wet years could experience some small effects in the Modesto, Turlock, and Extended Merced Subbasins (Figures 9-11 through 9-13). Under LSJR Alternative 4, the irrigation districts would still contribute to groundwater recharge in many years, although the irrigation district groundwater balance could become negative in the Eastern San Joaquin, Turlock, and Extended Merced Subbasins during approximately 65 percent, 30 percent, and 70 percent of years, respectively (i.e., much more often than under baseline conditions) (Figures 9-10, 9-12, and 9-13). Even when the annual irrigation district groundwater balance is positive, a decrease in the recharge could be detrimental because it would reduce the amount of compensation for groundwater pumping that happens outside of the irrigation district lands.

As discussed under LSJR Alternative 3, increased flow in the rivers is expected to have only a small effect on the groundwater balance. The larger effects caused by a reduction in groundwater recharge, and an increase in groundwater pumping could vary year-to-year and location to location.

The average reduction in net irrigation district groundwater balance associated with LSJR Alternative 4 could exceed 1 inch across all four subbasins (Table 9-12). When the maximum groundwater pumping capacity for 2014 is used in the analysis instead of the estimates for 2009, average net contribution from the irrigations districts decreases further, as compared to baseline, by the equivalent of an additional 0.2, 2.2, 1.6, and 0.0 inches for the Eastern San Joaquin, Modesto, Turlock, and Extended Merced Subbasins, respectively (Table 9-12). This is larger than for LSJR Alternatives 2 and 3 because the irrigation districts would need use their expanded pumping capacity more often because of the greater reduction in surface water supply under LSJR Alternative 4.

Under LSJR Alternative 4, reduction in groundwater levels could cause a potential degradation of groundwater quality as described for LSJR Alternative 3. However, under LSJR Alternative 4, degradation of water quality could be worse because all four subbasins would be affected. For example, LSJR Alternative 4 includes groundwater impacts on the Eastern San Joaquin Subbasin, where reduced groundwater levels below Stockton have caused the migration of saline water from the west to move eastward into the basin. In some areas below Stockton, salinity concentrations in groundwater exceed drinking water standards (SEWD 2014). The rate of this intrusion of saline water could increase under LSJR Alternative 4.

The average reduction in net irrigation district groundwater balance under LSJR Alternative 4 could exceed 1 inch across the Eastern San Joaquin, Modesto, Turlock, and the Extended Merced

Subbasins. Thus, LSJR Alternative 4 could potentially substantially deplete groundwater supplies and interfere substantially with groundwater recharge and affect groundwater quality. Therefore, impacts on groundwater resources are potentially significant and unavoidable.

Adaptive Implementation

As discussed under LSJR Alternative 2, adaptive implementation methods 2 and 4 are not expected to result in changes to the impacts on groundwater resources. For reasons discussed under LSJR Alternative 3, adaptive implementation method 3 would not affect impacts associated with LSJR Alternative 4. Adaptive implementation method 1 would allow a decrease of up to 10 percent in the February–June, 60 percent unimpaired flow requirement (to 50 percent) to optimize implementation measures to meet the narrative objective, while considering other beneficial uses, provided that these other considerations do not reduce intended benefits to fish and wildlife. Adaptive implementation must be approved using the process described in Appendix K, *Revised Water Quality Control Plan*. Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time. If the specified percent of unimpaired flow were changed from 60 percent to 50 percent on a long-term basis, the conditions and impacts could become more similar to LSJR Alternative 3 (i.e., less severe for groundwater resources, but still significant).

An SED must identify feasible mitigation measures for each significant environmental impact identified in the SED. (Cal. Code Regs., tit. 23, § 3777, subd. (b)(3).) Mitigation to reduce significant impacts on groundwater resources could include the State Water Board or local agencies exercising their various authorities over groundwater users, including authorities under SGMA.

As discussed in detail under LSJR Alternative 2 with adaptive implementation, the State Water Board has several authorities that are independent of SGMA but it is local agencies that are vested with the mandatory duty to achieve sustainable groundwater management, which includes not causing undesirable results such as significant and unreasonable reduction of groundwater storage and degradation of water quality. These local agencies, with authorities over Eastern San Joaquin, Modesto, Turlock, and the Extended Merced Subbasins**,** therefore, can and should exercise their full authorities to address substantial depletion of groundwater supplies and water quality degradation, both under SGMA and their police powers. Under that authority, they can and should also implement those mitigation measures identified in LSJR Alternative 2 with adaptive implementation above. Doing so would prevent groundwater depletion and water quality impacts, mitigate those impacts, or both. Due to the inherent uncertainty in the degree to which this mitigation may be implemented by local agencies, however, impacts on groundwater resources under LSJR Alternative 4, with or without adaptive implementation, would remain potentially significant and unavoidable.

As further stated under LSJR Alternative 2 with adaptive implementation, the State Water Board can and will revisit and analyze the groundwater condition during the periodic review of the water quality control plan. Where and when appropriate, it will also exercise its independent but complementary authorities under SGMA to ensure sustainable management of the groundwater basins in the plan area.

Impact GW-2: Cause subsidence as a result of groundwater depletion

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the technical analysis of the No Project Alternative.

LSJR Alternative 2 (Less than significant/Significant and unavoidable with adaptive implementation)

As described under Impact GW-1 for LSJR Alternative 2, the estimated average net irrigation district groundwater balance under LSJR Alternative 2 is predicted to be either similar to or slightly less than under baseline conditions, with the decrease being most noticeable in the Extended Merced Subbasin (Figures 9-10 through 9-13). The average reduction in annual net groundwater recharge under LSJR Alternative 2 relative to baseline is equivalent to 0.0-0.7 inches of water across each of the four subbasins (Table 9-12).

These changes are less than the 1 inch threshold for significant reduction in groundwater levels, meaning that the reduction in groundwater levels at the 20 percent unimpaired flow level is less than significant. Therefore, under LSJR Alternative 2, as compared to baseline, the slight reduction in groundwater recharge would not likely result in subsidence.

Adaptive Implementation

As described under Impact GW-1, LSJR Alternative 2 with adaptive implementation methods 2 and 4 would not affect groundwater supplies and therefore would not cause subsidence. Adaptive implementation method 3 would not be authorized under LSJR Alternative 2. However, adaptive implementation method 1 would allow an increase of up to 10 percent over the 20 percent February-June unimpaired flow requirement (to a maximum of 30 percent of unimpaired flow). If this adjustment occurs frequently or for extended durations, impacts under LSJR Alternative 2 could become more like the impacts under LSJR Alternative 3.

At the 30 percent unimpaired flow level, the impacts on groundwater would increase relative to the 20 percent unimpaired flow level (Table 9-12) and could reach the equivalent of 1.2 inches across the Extended Merced Subbasin (i.e., greater than the threshold of significance for Impact GW-1). Because portions of the Extended Merced Subbasin show evidence of subsidence (see Section 9.2.1, *San Joaquin Valley Groundwater Basin and Subbasins*), it is likely that increased groundwater depletion in the Extended Merced Subbasin could lead to increased subsidence. Subsidence in the other subbasins is less likely to occur given that there is little evidence that the soils in these subbasins are subject to inelastic compaction.

Therefore, under LSJR Alternative 2 with adaptive implementation method 1, subsidence due to a reduction in groundwater levels would potentially be significant and unavoidable.

An SED must identify feasible mitigation measures for each significant environmental impact identified in the SED. (Cal. Code Regs., tit. 23, § 3777, subd. (b)(3).) Mitigation to reduce significant impacts on groundwater resources could include the State Water Board or local agencies exercising their various authorities over groundwater users, including authorities under SGMA.

As discussed under Impact GW-1 for LSJR Alternative 2 with adaptive implementation, the State Water Board has several authorities independent of SGMA. However, under SGMA, it is local agencies that are vested with the mandatory duty to achieve sustainable groundwater management, which includes not causing undesirable results such as significant and unreasonable reduction of groundwater storage and significant and unreasonable land subsidence that substantially interferes with surface land uses. Therefore, the local agencies with authority over the Extended Merced Subbasin can and should exercise their full authorities to address substantial depletion of groundwater supplies and subsidence, both under SGMA and their police powers. Doing so would prevent groundwater depletion and subsidence, mitigate those impacts, or both. It is possible that subsidence under LSJR Alternative 2 with adaptive implementation could be limited to areas that would not cause interference with surface land uses. However, it is unlikely that subsidence would have no effect on surface uses. Furthermore, even if subsidence did not invoke actions under SGMA, the associated depletion of the groundwater resources, as described in Impact GW-1, could invoke SGMA triggers for state interaction. Actions taken under SGMA to protect the aquifer would also protect against subsidence. However, given the inherent uncertainty in the degree to which local agencies may implement mitigation actions, the subsidence impact under LSJR Alternative 2, with adaptive implementation, would remain potentially significant and unavoidable.

As discussed under Impact GW-1 for LSJR Alternative 2 with adaptive implementation, the State Water Board can and will revisit and analyze the groundwater condition during the periodic review of the water quality control plan. Where and when appropriate, it will also exercise its independent but complementary authorities under SGMA to ensure sustainable management of the groundwater basins in the plan area.

LSJR Alternative 3 (Significant and unavoidable/Significant and unavoidable with adaptive implementation)

As described under Impact GW-1, the average reduction in net irrigation district groundwater balance under LSJR Alternative 3 could exceed 1 inch across the Modesto, Turlock, and Extended Merced Subbasins (Table 9-12). As a result, LSJR Alternative 3 could potentially substantially deplete groundwater supplies in these subbasins. Because portions of the Extended Merced Subbasin show evidence of subsidence (see Section 9.2.1, *San Joaquin Valley Groundwater Basin and Subbasins*), it is likely that increased groundwater depletion in the Extended Merced Subbasin could lead to increased subsidence. Subsidence in the other subbasins is less likely to occur given that there is little evidence that the soils in these subbasins are subject to inelastic compaction.

Therefore, due to the increased likelihood of subsidence in the Extended Merced Subbasin, under LSJR Alternative 3 subsidence due to a reduction in groundwater levels would potentially be significant and unavoidable.

Adaptive Implementation

As described under Impact GW-1, LSJR Alternative 3 with adaptive implementation methods 2, 3, and 4 would not affect groundwater supplies or, therefore, cause subsidence. Adaptive implementation method 1 could cause a 10 percent increase or decrease in the specified percent of unimpaired flow. If the specified percent of unimpaired flow were changed from 40 percent to

30 percent or 40 percent to 50 percent on a long-term basis, the conditions and impacts could become more similar to LSJR Alternatives 2 or 4, respectively. If the adjustment occurs frequently or for extended durations, based on the modeling results for LSJR Alternative 2, with adaptive implementation method 1 incorporated (i.e., 30 percent unimpaired flow), and LSJR Alternative 4, with adaptive implementation method 1 incorporated (i.e., 50 percent unimpaired flow), impacts would remain potentially significant and unavoidable.

An SED must identify feasible mitigation measures for each significant environmental impact identified in the SED. (Cal. Code Regs., tit. 23, § 3777, subd. (b)(3).) Mitigation to reduce significant impacts on groundwater resources could include the State Water Board or local agencies exercising their various authorities over groundwater users, including authorities under SGMA.

As discussed under LSJR Alternative 2 with adaptive implementation, local agencies vested with the mandatory duty to achieve sustainable groundwater management and authority over the Extended Merced Subbasin, can and should exercise their full authorities to address substantial depletion of groundwater supplies and subsidence, both under SGMA and their police powers. Doing so would prevent groundwater depletion and subsidence, mitigate those impacts, or both. However, given the inherent uncertainty in the degree to which local agencies may implement mitigation actions, the subsidence impacts under LSJR Alternative 3 with adaptive implementation would remain potentially significant and unavoidable.

As further stated under Impact GW-1 for LSJR Alternative 2 with adaptive implementation, the State Water Board can and will revisit and analyze the groundwater condition during the periodic review of the water quality control plan. Where and when appropriate, it will also exercise its independent but complementary authorities under SGMA to ensure sustainable management of the groundwater basins in the plan area.

LSJR Alternative 4 (Significant and unavoidable/Significant and unavoidable with adaptive implementation)

As described under Impact GW-1, under LSJR Alternative 4, the average reduction in net irrigation district groundwater balance could exceed 1 inch across the Eastern San Joaquin, Modesto, Turlock, and the Extended Merced Subbasins (Table 9-12). As a result, LSJR Alternative 4 could potentially substantially deplete groundwater supplies in these subbasins. LSJR Alternative 4 could result in the greatest potential increase in groundwater pumping and reduction in recharge from the four subbasins, as compared to baseline levels (Table 9-12). Because portions of the Extended Merced Subbasin show evidence of subsidence (see Section 9.2.1, *San Joaquin Valley Groundwater Basin and Subbasins*), it is likely that increased groundwater depletion in the Extended Merced Subbasin could lead to increased subsidence. Subsidence in the other subbasins is less likely to occur given that there is little evidence that the soils in these subbasins are subject to inelastic compaction.

Therefore, due to the increased likelihood of subsidence in the Extended Merced Subbasin, under LSJR Alternative 4 subsidence due to a reduction in groundwater levels would potentially be significant and unavoidable.

Adaptive Implementation

As described under Impact GW-1, LSJR Alternative 4 with adaptive implementation methods 2, 3, and 4 would not affect groundwater supplies and therefore would not cause subsidence. Adaptive implementation method 1 could cause a 10 percent decrease in the specified percent of unimpaired flow. If the specified percent of unimpaired flow were changed from 60 percent to 50 percent on a long-term basis, the conditions and impacts could become more similar to LSJR Alternative 3. If the adjustment occurs frequently or for extended durations, based on the modeling results for LSJR Alternative 3, with adaptive implementation method 1 (i.e., 50 percent unimpaired flow), impacts would remain potentially significant and unavoidable.

An SED must identify feasible mitigation measures for each significant environmental impact identified in the SED. (Cal. Code Regs., tit. 23, § 3777, subd. (b)(3).) Mitigation to reduce significant impacts on groundwater resources could include the State Water Board or local agencies exercising their various authorities over groundwater users. including authorities under SGMA.

As discussed under LSJR Alternative 2 with adaptive implementation, local agencies vested with the mandatory duty to achieve sustainable groundwater management and authority over the Extended Merced Subbasin can and should exercise their full authorities to address substantial depletion of groundwater supplies and subsidence, both under SGMA and their police powers. Doing so would prevent groundwater depletion and subsidence, mitigate those impacts, or both. However, given the inherent uncertainty in the degree to which local agencies may implement mitigation actions, the subsidence impacts under LSJR Alternative 3 with adaptive implementation, would remain potentially significant and unavoidable.

As further stated under Impact GW-1 for LSJR Alternative 2 with adaptive implementation, the State Water Board can and will revisit and analyze the groundwater condition during the periodic review of the water quality control plan. Where and when appropriate, it will also exercise its independent but complementary authorities under SGMA to ensure sustainable management of the groundwater basins in the plan area.

9.4.4 Impacts and Mitigation Measures: Extended Plan Area

Bypassing flows, as described in Chapter 5, *Surface Hydrology and Water Quality*, would not impact groundwater resources. The extended plan area primarily has a shallow-to-bedrock geology. There is only one designated groundwater basin, the Yosemite Basin in Yosemite National Park in Mariposa County as the shallow-to-bedrock geology produces relatively small, localized, and isolated groundwater areas. If junior water right holders reduced their reliance on surface water diversions and extracted more groundwater to compensate for the reduction, more groundwater could be extracted over time in the extended plan area, primarily under LSJR Alternatives 3 and 4 with or without adaptive implementation. However, this extraction would be small based on the relatively small amount of consumptive use that occurs in the extended plan area. Thus, impacts would be less than significant in the extended plan area.

9.5 Cumulative Impacts

For the cumulative impact analysis, refer to Chapter 17, *Cumulative Impacts, Growth-Inducing Effects, and Irreversible Commitment of Resources.*

Chapter 10
Recreational Resources and Aesthetics

10.1 Introduction

This chapter describes the environmental setting for recreational resources and aesthetics (e.g., visual character and quality), and the regulatory background associated with recreational resources and aesthetics. This chapter also evaluates environmental impacts on recreational resources and aesthetics that could result from the Lower San Joaquin River (LSJR) alternatives and, if applicable, offers mitigation measures that would reduce significant impacts.

Recreationists enjoy a variety of water-dependent and water-enhanced activities in the plan area. As described in Chapter 1, *Introduction*, the plan area generally includes those portions of the San Joaquin River (SJR) Basin that drain to, divert water from, or otherwise support beneficial uses of water associated with, the three eastside tributaries[1] of the LSJR. This area includes the Stanislaus, Tuolumne, and Merced Rivers; the rim dams[2] and major reservoirs on each river; the LSJR; and southern Delta waterways.

The extended plan area, also described in Chapter 1, generally includes the area upstream of the rim dams. The area of potential effects for this area is similar to that of the plan area and includes the zone of fluctuation around the numerous reservoirs that store water on the Stanislaus and Tuolumne Rivers. (The Merced River does not have substantial upstream reservoirs.) It also includes the upper reaches of the Stanislaus, Tuolumne, and Merced Rivers. Unless otherwise noted, all discussion in this chapter refers to the plan area. Where appropriate, the extended plan area is specifically identified.

In Appendix B, *State Water Board's Environmental Checklist*, the State Water Resources Control Board (State Water Board) determined whether the plan amendments[3] would cause any adverse impact on resources in each of the listed environmental categories and provided a brief explanation for its determination. Impacts in the checklist that are identified as "Potentially Significant Impacts" are discussed in detail in this chapter. In Appendix B, the State Water Board determined that the impacts of the LSJR alternatives on recreational resources, as listed in the checklist, are either "Less than Significant" or "No Impact." However, as discussed in Appendix B, the State Water Board determined that other types of potential adverse impacts on recreational resources that are not in the checklist should be evaluated. Accordingly, this chapter evaluates impacts not explicitly identified in the checklist but that have been identified in Appendix B as potentially significant. This chapter evaluates whether the LSJR alternatives would substantially physically deteriorate existing recreation facilities on the rivers or at reservoirs. Appendix B also identified the LSJR alternatives as having a potentially significant impact on aesthetics because of the potential to substantially degrade the existing visual character or quality at reservoirs and its surroundings.

---

[1] In this document, the term *three eastside tributaries* refers to the Stanislaus, Tuolumne, and Merced Rivers.

[2] In this document, the term *rim dams* is used when referencing the three major dams and reservoirs on each of the eastside tributaries: New Melones Dam and Reservoir on the Stanislaus River; New Don Pedro Dam and Reservoir on the Tuolumne River; and New Exchequer Dam and Lake McClure on the Merced River.

[3] These plan amendments are the *project* as defined in State CEQA Guidelines, Section 15378.

The impact analysis in this chapter focuses on changes in surface water elevations that could degrade the existing visual character or quality of the reservoirs. In addition, this chapter addresses whether a substantial adverse effect on scenic vistas or substantial damage to scenic resources within a state scenic highway in the extended plan area would occur.

Recreational and aesthetic impacts in this chapter for the plan area are generally evaluated using the change in the frequency of acceptable average recreation seasonal flow and reservoir elevation level conditions between May and September. For rivers, changes in the volume flow are used to evaluate whether recreational facilities would substantially deteriorate and in-river activities would be significantly reduced. For reservoirs, reservoir elevation levels are evaluated by identifying changes during drier years to present a conservative analysis of the potential recreational and aesthetic impacts that could occur under the LSJR alternatives. This is done by evaluating changes in modeled results at the 30 percent cumulative distribution, representing the lowest one-third of reservoir elevation levels, which represents low elevation conditions typically experienced under drought or dry conditions. For the extended plan area, recreational and aesthetic impacts are generally addressed qualitatively by addressing potential changes to existing resources under the LSJR alternatives, particularly during drought periods.

As discussed in Appendix B, the southern Delta water quality (SDWQ) alternatives are not anticipated to adversely affect recreational resources or aesthetics in the southern Delta because water quality in the southern Delta is expected to remain within historical ranges (see Chapter 5, *Surface Hydrology and Water Quality*). Furthermore, any changes in salinity levels within historical ranges are expected to be imperceptible to recreationists. Therefore, the effects of the SDWQ alternatives are not analyzed further in this chapter. To comply with specific water quality objectives or the program of implementation under SDWQ Alternatives 2 or 3, construction and operation of different facilities in the southern Delta could occur, which could involve impacts on recreational resources or aesthetics. These impacts are evaluated in Chapter 16, *Evaluation of Other Indirect and Additional Actions.*

The potential impacts of the LSJR alternatives on recreational resources and aesthetics are summarized in Table 10-1. As described in Chapter 3, *Alternatives Description*, LSJR Alternatives 2, 3 and 4 each include four methods of adaptive implementation. This recirculated substitute environmental document (SED) provides an analysis with and without adaptive implementation because the frequency, duration, and extent to which each adaptive implementation method would be used, if at all, within a year or between years under each LSJR alternative is unknown. The analysis, therefore, discloses the full range of impacts that could occur under an LSJR alternative, from no adaptive implementation to full adaptive implementation. As such, Table 10-1 summarizes impact determinations with and without adaptive implementation.

Impacts related to the No Project Alternative (LSJR/SDWQ Alternative 1) are presented in Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*, and the supporting technical analysis is presented in Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1).* Chapter 16, *Evaluation of Other Indirect and Additional Actions,* includes discussion of impacts related to actions and methods of compliance.

Table 10-1. Summary of Recreational Resources and Aesthetics Impact Determinations

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
Impact REC-1: Substantially physically deteriorate existing recreational facilities on the rivers or at the reservoirs			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [b]	Significant	NA
LSJR Alternative 2	Under LSJR Alternative 2, modeled flows are not expected to cause substantial physical deterioration of on-bank recreational facilities because the seasonal average frequency of river flows (cubic feet per second [cfs]) would not change substantially from baseline. Modeled flows would also not affect in-water recreational activities because they would not change significantly from baseline. Under LSJR Alternative 2, there would be relatively small changes in reservoir elevations. These changes would not substantially deteriorate existing recreational facilities at the reservoirs because all boat ramps and other facilities would remain available to recreationists.	Less than significant	Less than significant
LSJR Alternative 3	Modeled frequencies of flows greater than 2,500 cfs would change little on the Merced and Stanislaus Rivers, and therefore on-bank recreational facilities would not experience substantially more inundation relative to baseline conditions. However, flows greater than 2,500 cfs would increase in frequency on the Tuolumne River in May and June, but would remain close to baseline values July – September. Although the flows on the Tuolumne River could result in an increase in the frequency of inundation of on-bank recreation areas during May and June, recreational facilities are not anticipated to substantially physically deteriorate along the river. On-bank recreational facilities are built to withstand periodic inundation with higher river flows. The modeled seasonal average frequency of low flows (less than 500 cfs) on the Merced and Tuolumne Rivers would decrease more than 10% relative to baseline conditions. However, during July-September, the most popular recreational months for the three eastside tributaries, the frequency of low flows would change by less than 10% relative to	Less than significant	Significant and unavoidable[c]

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
	baseline for the three eastside tributaries. Therefore, this alternative is not anticipated to affect in-water activities, with or without adaptive implementation. The change in reservoir elevations under LSJR Alternative 3 would not significantly affect recreation at New Melones Reservoir or Lake McClure. It is expected that there would be a substantial decrease in elevation of New Don Pedro Reservoir. However, because all boat ramps in New Don Pedro Reservoir would remain operable at the 30% cumulative distribution elevation (e.g., dry years), and because some boat ramps in New Don Pedro Reservoir are still operable at minimum reservoir elevations, there would be no physical deterioration nor reduction in the use of existing recreation facilities at this location. If adaptive implementation method 1 were implemented on a long-term basis (an increase in the February–June percent of unimpaired flow from 40% up to 50%), it is expected that the modeled seasonal average frequency of river flows above 2,500 cfs on the Tuolumne River would greatly increase, especially during May and June. The frequency of inundation of on-bank facilities on the Tuolumne River and, to a lesser extent, on the Stanislaus River is expected to increase compared to baseline. Accordingly, LSJR Alternative 3, with the incorporation of adaptive implementation method 1, would cause substantially deterioration of existing recreational facilities.		
LSJR Alternative 4	There would be a substantial increase in flows above 2,500 cfs on the Tuolumne and Stanislaus Rivers under LSJR Alternative 4, with or without adaptive implementation. Although on-bank recreational facilities are built to withstand periodic inundation, facilities may substantially physically deteriorate from the expected significant increase in inundation frequency relative to baseline. The modeled seasonal average frequency of low flows on the Merced and Tuolumne Rivers, without adaptive implementation, would decrease more than 10%. The decrease is mostly due to low flow reduction in May and June. However, because there would be little	Significant and unavoidable	Significant and unavoidable

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
	change in low flows on the Stanislaus, Tuolumne, and Merced Rivers relative to baseline during the warmest months in the San Joaquin Valley when swimming and wading are most popular (July–August), the reduced opportunity for swimming and wading on the three eastside tributaries in May, and particularly in June (i.e., early in the summer recreational season), is not expected to substantially reduce recreational use for the season. Seasonal average elevations at Lake McClure and New Melones Reservoir are expected to increase. The seasonal average elevation at New Don Pedro Reservoir is expected to decrease at the 30% cumulative distribution elevation. Decreased reservoir levels at New Don Pedro Reservoir would not substantially physically deteriorate existing recreation facilities at the reservoirs (marinas and boat ramps), and all boat ramps would remain operable. There would be no reduction in use of the facilities at New Don Pedro Reservoir. Therefore, given the significant increase in the modeled frequency of high seasonal average flows (greater than 2,500 cfs) on the Stanislaus and Tuolumne Rivers associated with LSJR Alternative 4, with and without adaptive implementation, substantial physical deterioration of existing recreational facilities is expected.		
Impact REC-2: Substantially degrade the existing visual character or quality of the reservoirs			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note. [b]	Significant	NA
LSJR Alternative 2	Under certain conditions, reservoir elevations at Lake McClure and New Melones Reservoir could increase and could result in an improvement to the existing views. The expected decrease in reservoir elevation at New Don Pedro Reservoir would not result in a substantial degradation of existing visual character or quality.	Less than significant	Less than significant
LSJR Alternatives 3 and 4	Under certain conditions, reservoir elevations would increase at Lake McClure and New Melones Reservoir and could improve the existing views.	Less than significant	Less than significant

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
	At New Don Pedro Reservoir, decreases in water surface elevation during some dry years could cause a substantial degradation of existing visual character or quality; however, views at this location are Class III, and changes to the character of the landscape can be moderate without compromising visual quality.		

[a] Four adaptive implementation methods could occur under the LSJR alternatives, as described in Chapter 3, *Alternatives Description*, and summarized in Section 10.4.2, *Methods and Approach,* of this chapter.

[b] The No Project Alternative (LSJR/SDWQ Alternative 1) would result in the continued implementation of flow objectives and salinity objectives identified in the 2006 *Water Quality Control Plan for the San Francisco Bay/Sacramento-San Joaquin Delta Estuary* (2006 Bay-Delta Plan). See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

[c] Implementing adaptive implementation method 1, on a more frequent basis can result in a change in the impact determination for LSJR Alternative 3, as summarized in this table, and described in detail in Section 10.4.3*, Impacts and Mitigation Measures*, of this chapter.

10.2 Environmental Setting

There are three distinct environments for water-based recreation on the Stanislaus, Tuolumne, and Merced Rivers, the LSJR, and the southern Delta: flowing rivers, controlled reservoirs, and open (i.e., tidal) Delta waterways. Recreation takes place in managed facilities, at informal access points, and in undeveloped areas. Much of the recreation use is water dependent (e.g., boating, swimming), but many other popular activities (e.g., camping, hiking) are simply enhanced by the presence of water. Recreational opportunities have been substantially influenced by the construction of reservoirs and the management of the water levels in those reservoirs and the resulting effect on river flows.

Typical recreational activities in the watersheds include: boating, fishing, swimming, water sports, horseback riding, hiking, biking, camping, picnicking, birding and nature viewing, hunting, and gold panning. Facilities constructed throughout the plan area permit similar recreational uses (e.g., boat-based fishing, kayaking, beach swimming, picnicking), although the spectrum of uses may shift depending on conditions. Swimming is more common in the reservoirs but may also occur on the rivers during low flows. Boating activities, such as whitewater rafting, kayaking, and canoeing, are popular on the rivers. Preferred recreational activities change with time, reflecting the current economic and cultural conditions. For example, undeveloped areas in the plan area, such as wildlife preserves, were once widely used for hunting, but are now becoming increasingly popular for other uses, such as nature viewing and bird watching (USBR 1999).

The existing recreational uses of the LSJR, its three eastside tributaries, the reservoirs at the rim dams, and the southern Delta are described below.

10.2.1 Rivers

Flows in the LSJR and eastside tributaries are regulated by the rim dams. Different ranges of flow releases from storage[4] support different recreational uses and facilities along the rivers. These flows also contribute to the aesthetic characteristic of the landscape in which they are located. The LSJR and eastside tributaries are generally characterized by a river channel flanked with a narrow ribbon of riparian vegetation, complemented in some areas by larger wildlife preserves and parks, and interrupted by agricultural development and urbanization. The viewsheds are variable, but unified by the natural aspect of the rivers and the interface with either the natural or augmented landside. Due to the variability of rivers and the dynamic shoreline, viewers are generally less sensitive to changes in river height, and are affected primarily by severely high or low flows. Details regarding the different recreational uses of the Stanislaus, Tuolumne, and Merced Rivers and the LSJR are discussed below.

Merced River

The lower reach of the Merced River, from below McSwain Dam to the river's confluence with the LSJR, is 50 miles long and crosses private agricultural and grazing land in Merced County. This reach of the Merced River includes contact water recreation (e.g., swimming, wading, water skiing, and fishing) and non-contact water recreation (e.g., hiking, picnicking, and boating) as designated beneficial uses (State Water Board 1998).

Major public recreation facilities on this river reach include Henderson County Park on Merced Falls Road east of Snelling, McConnell State Recreation Area (SRA) northeast of Livingston on State Route 99, Hagaman County Park at the State Route 165 river crossing, and George J. Hatfield SRA on Kelley Road near the LSJR confluence. The county parks are primarily day-use facilities, while the SRAs provide both day-use and camping areas (USBR 1999). The county parks do not have boat launch ramps, and they do not allow swimming because lifeguards are not present. Approximately 73,000 water-related visitor days are spent on the Merced River annually (USBR 1999). The Merced River is largely surrounded by private land, which limits the opportunities for public access (Merced ID 2011a).

Water-dependent activities include some canoeing and rafting in the lower portion of the river. Water-enhanced activities include picnicking, and camping (USBR 1999). Boat-based fishing is popular between the Merced Falls Dam and the Crocker–Hoffman Diversion Dam, especially during high flows. Generally, flows below 500 cubic feet per second (cfs) are considered too low for boating. Flows are currently below 500 cfs approximately 83 percent of the time in the summer months. Popular sport fish that are found in this stretch of the Merced River include catfish and smallmouth bass (USBR 1999).

Kayaking, rafting, and canoeing take place on the lower Merced River at flows of 250–3,200 cfs. In a study conducted in the winter of 2010, the boaters surveyed indicated that while the river's reach was floatable at the winter low flow levels down to 250 cfs, they would not likely return to boat the

---

[4] In this document, the term *releases from storage* means water is released from the reservoir.

Merced River because the flow did not provide a quality boating opportunity at that flow level (Merced ID 2011b). Overall, the boaters surveyed in the study identified a boatable flow range for canoes and kayaks of roughly 570 to 2,000 cfs (Merced ID 2011b). For kayakers and rafters, flows of approximately 300–350 cfs are considered appropriate for beginners, while high flows of 1,200-3,200 cfs are considered advanced (American Whitewater 2012).

During lower flows in the fall and winter, wading is more popular (Merced ID 2011b). Optimal flow ranges on the Merced River for swimming are 50–200 cfs (USBR 2001).

Tuolumne River

The lower Tuolumne River, from New Don Pedro Dam to the river's confluence with the LSJR, is approximately 52 miles long. This reach of the Tuolumne River includes contact and non-contact water recreation as designated beneficial uses (State Water Board 1998). This reach traverses mainly private open space and grazing lands, City of Modesto property, and several public parks; therefore, access to the river is limited.

Existing recreation facilities include: La Grange County Regional Park, Fox Grove County Regional Park, Riverdale, two golf courses adjacent to the river near the State Route 99 crossing, and the Shiloh fishing access. In addition, the Turlock SRA and Modesto Reservoir Regional Park provide camping facilities. There is also public access to the river at the Tuolumne River Regional Park near Modesto (San Joaquin River Partnership 2012).

Common water-dependent recreational activities on the Tuolumne River include boating, fishing, swimming, and rafting. Together with wildlife viewing, 150,000 visitor days were spent conducting these water-dependent recreational activities in 1992 (USBR 1999). Rafting season is generally April–October. The optimal flow for rafting is 300 cfs (TID and Merced ID 2011). Boating season on the lower Tuolumne River is typically May–October. The lowest boatable flow on the upper reaches of the lower Tuolumne River ranges from 100–150 cfs (TID and MID 2013a). Drift boaters and rafters identified the lower Tuolumne as unboatable at 150 cfs. Recent daily average flow data collected at the La Grange gage indicated flows were at or above 150 cfs approximately 84 percent of the time, and during the boating season flows were at or above 150 cfs 98 percent of the time in May and 56 percent of the time July–September (TID and MID 2013a).

Stanislaus River

The lower Stanislaus River runs 60 miles from the New Melones Dam to the river's confluence with the LSJR, crossing primarily private agricultural and grazing lands in Tuolumne, Stanislaus, and San Joaquin Counties (see Chapter 11, *Agricultural Resources*). This reach of the Stanislaus River includes contact and non-contact water recreation as designated beneficial uses (State Water Board 1998).

The Stanislaus River has numerous park facilities, many used for water-dependent activities, such as boat launching, fishing, camping, swimming, as well as water-enhanced activities, such as picnicking or camping. Parks include Knights Ferry Recreation Area, Horseshoe Park, Orange Blossom Park, Valley Oak Recreation Area, Oakdale Recreation Area, Jacob Meyers Park, McHenry Recreation Area, and Caswell Memorial State Park. There is also public access to the river at numerous road crossings. In 1999, there were an estimated 330,217 recreational visitor days spent on the Stanislaus River (McAfee 2000).

Water-dependent activities practiced on the Stanislaus River include fishing, swimming, and whitewater boating (rafting and kayaking). Popular sport fish found in this stretch of the Stanislaus River include catfish, crappie, largemouth bass, and smallmouth bass. Boating activities on the Stanislaus River generally take place when the flow is 25–1,200 cfs (Dreamflows 2011). Flows of 500 cfs–3,000 cfs can allow for advanced rafting and kayaking (All Outdoors 2011). Access to an advanced, 4-mile whitewater boating run is provided below Goodwin Dam (USBR 1999). Extensive boating use on the lower Stanislaus River has contributed to eroding beaches, excessive noise, trespassing, and other issues that degrade recreating visitor experiences (McAfee 2000).

Lower San Joaquin River

Public access to the LSJR is available at several road and highway crossings. Stanislaus County recreation facilities on the LSJR include the Las Palmas fishing access site and Laird County Park (USBR 2001). In addition, there is Durham Ferry SRA in San Joaquin County, and the San Joaquin National Wildlife Refuge between the Stanislaus and Tuolumne River confluences (San Joaquin River Partnership 2012). Most of the use of these recreational areas is assumed to come from the local counties (USBR 1999).

The LSJR includes contact and non-contact water recreation as designated beneficial uses (State Water Board 1998). An estimated 157,000 visitor days are spent boating and fishing in the LSJR annually (USBR 2001). Popular sport fish that occur in this stretch of the SJR include catfish and smallmouth bass (USBR 1999). Water-enhanced shore activities include picnicking and other activities.

The optimal flow range for non-motorized boating activities on the LSJR has been estimated to be 300-500 cfs, while motorized boating may occur at flows up to 750 cfs (USBR 1997; Frago pers. comm.). However, characterizing the optimal flows for recreation on the LSJR is much more complex than for the three eastside tributaries. This is due to the river’s variability in flow within the plan area; flow increases at each river confluence. South of the Merced River confluence, the river has been nearly dry at times in recent years, while summer flows in the SJR at Vernalis range between about 1,000 cfs in dry years to more than 10,000 cfs in wet years. The monthly median flows at Vernalis range between 5,000 cfs in the spring (May) and 2,000 cfs in the late summer (August and September).

10.2.2 Reservoirs

Peak visitation of California reservoirs is generally in the drier months of May through August. Recreational opportunities on and near the reservoirs are influenced by water levels; therefore, the manner in which a reservoir is operated directly affects visitor use and the quality of the recreational experience. Reservoir operations for water supply are usually adequate to support established recreation activities and facilities, particularly when surface runoff from precipitation is near normal. Recreation facilities, such as beaches, boat ramps, trails, restrooms, access roads, picnic areas, and camping facilities add to the quality of the recreation experience. Lower reservoir levels, however, result in water surface receding far from developed recreation facilities, such as campgrounds, picnic areas, and swimming beaches. Boat ramps, docks, and swimming areas become unusable if they are no longer submerged or are no longer close to the water. Declining surface area affects boating and water skiing and reduces aesthetic values. Recreation attendance decreases when water levels drop well below major recreation facilities and boat ramps. During the 1976-1977 drought, total attendance at state and federal reservoirs in California decreased approximately 30 percent, with some reservoirs experiencing declines of as much as 80 percent. Attendance at a few stable reservoirs actually increased. A similar pattern developed during the

1987–1992 drought, although there were even fewer stable reservoirs (DWR 1994). Viewers (e.g., recreationists) of the reservoirs experience both a managed aesthetic (e.g., changes in water elevation levels as a result of reservoir operation) and a natural aesthetic (e.g., surrounding forest and mountains). Generally, those participating in recreational activities in and around reservoirs are likely to highly value the natural environment, appreciate the visual experience, and be sensitive to changes in visual character and quality.

Lake McClure

The New Exchequer Dam impounds the Merced River, forming Lake McClure. The reservoir's visual character and quality is that of both a natural environment (e.g., surrounding forest and mountains) and a managed environment (e.g., recreation and hydropower facilities).

Generally, the surrounding area view is of the Sierra Nevada and includes low rolling hills and rugged mountains, with differing trees and vegetation bordering the reservoir. The dominant visual elements are the hills, ridges, small valleys, and patterns created by the vegetation on the hills and the surface of the water. The vegetative patterns are influenced by a combination of soil types, aspect, and fire history. The hills are occasionally accented by steep canyon walls. Native vegetation transitions to nonnative plants and trees in a few residential and more developed areas.

The managed environment in the vicinity of the reservoir presents varying visual contrast when compared to the natural environment that surrounds and extends beyond the reservoir. There are two-lane roads and highways around the reservoir that afford views of the mountains, trees, and reservoir. The Highway 49 Bridge, Lake McClure, and part of Bagby Recreation Area can be seen from the Highway 49 vista point just north of the bridge. The Sierra Nevada foothills are taller and more dramatic in this area than other areas around the reservoir, and the vegetation is similar to other areas around the reservoir. The New Exchequer Dam, support buildings, and spillway present a strong visual contrast relative to the natural landscape due to the geometric shapes and light colors. The New Exchequer Dike presents moderate visual contrast due to the gray tones and rough texture of the rock facing of the structure (Merced ID 2014).The small footprint of the Bagby Boat Launch facility presents a weak visual contrast to the surrounding natural landscape. The road presents strong visual contrast when compared to the natural surroundings due to the shape, texture, and color of the road (Merced ID 2011a).Low water elevations in the reservoir create a strip of bare land around Lake McClure that is sparse in vegetation, creating a strong visual contrast with the natural surroundings (Merced ID 2014).

Residential and recreational structures contrast with the surrounding foothill and mountain scenery. These rural developed areas are within close proximity of the reservoir and include towns and primary road networks; however, the setting is pastoral or rural because of interspersed forests, water resources, hills, and valleys.

The shoreline edges along the reservoir appear natural and include vegetation and land and water interface; however, these edges also exhibit unnatural features, such as human-made facilities (e.g., water control structures and recreation facilities) and large bands of exposed soil. Recreation facilities are prevalent around the shoreline edges of the reservoir, including boat docks, beaches, campgrounds, and marinas, all of which are also considered a contrasting visual quality to the surrounding natural setting of the Sierra Nevada foothills and mountains. There is no vegetation at the shoreline, which is characteristic of the shore/water interface given the daily, monthly, and seasonal fluctuations in water elevation (USBR 2007; USBR 2011a).

Lake McClure recreation facilities include 4 developed areas (McClure Point, Barrett Cove, Horseshoe Bend, and Bagby), with 530 camping units, 5 boat launch facilities, 2 marinas, 62 picnic units, and fish cleaning stations. Day-use facilities include sandy beaches and swim lagoons, most in grassy park-like settings with group facilities and play equipment (DWR 2001). The recreation facilities are owned and operated by Merced Irrigation District's (Merced ID) Parks Department, with the exception of two small areas within McClure Point Recreation Area and Horseshoe Bend Recreation Area that are owned by the U.S. Bureau of Land Management (BLM).

Outside of the four public access areas on Lake McClure, the remainder of the land surrounding the reservoir is private (Merced ID 2011a). Since most of the undeveloped reservoir shoreline is relatively far from roads and the shoreline is irregular and steep, little recreational activity occurs there (DWR 2001). Lake McSwain is a small reservoir located about 3 miles downstream of the New Exchequer Dam. Lake McSwain offers adjacent recreational opportunities.

Recreational activities on Lake McClure and McSwain Reservoir include camping, boating, swimming, hiking, bicycling, houseboating, and fishing. In 2010, nearly 1.4 million visitor days were spent on Lake McClure, and approximately 482,000 visitor days were spent on McSwain Reservoir (Merced ID 2014). Lake McClure is popular with water skiers because the surrounding tree covered hills protect the reservoir from the prevailing westerly winds (DWR 2001). In 2010, an average of 100 watercraft were reported on Lake McClure at one time (0.01 watercraft per acre), 94 percent of which were motorized (Merced ID 2011a). Recent surveys conducted by Merced ID have indicated that most visitors to Lake McClure are local (Merced ID 2011a).

Modeled reservoir elevation has ranged between approximately 865 feet (ft) mean sea level (MSL) and 635 ft MSL. Therefore, reservoir elevations during drought years can be 230 ft below the historical maximum elevation. Historically, the monthly average elevation of the reservoir has ranged from a minimum of 755 ft MSL in October to a maximum of 810 ft MSL in June. Boat access is provided at ramps located around the shoreline. Lake McClure boat ramps cease operation when reservoir elevation is 590–793 ft MSL. The ramp at Bagby is the first to close when the reservoir decreases to an elevation of 793 ft MSL, followed by Horseshoe Bend at 758 ft MSL, McClure Point at 650 ft MSL, southern Barrett Cove at 630 ft MSL, and northern Barrett Cove and Piney Creek, both at 590 ft MSL (USBR 1999). Reservoir visitors report that the current water levels in the reservoir are acceptable but can sometimes cause degraded scenery (Merced ID 2011a).

New Don Pedro Reservoir

The New Don Pedro Dam impounds the Tuolumne River, forming the New Don Pedro Reservoir. Generally, the visual character and quality that recreationists and others experience around the New Don Pedro Reservoir is similar to that described for Lake McClure. Numerous long expanses of flat water that stretch through a series of narrow valleys and inlets characterize New Don Pedro Reservoir's visual setting. Similar to Lake McClure, the Sierra Nevada foothills surround the reservoir, rising gradually from its shoreline to grant wide and open views. There are very few buildings in the vicinity of the reservoir. Views are not urban or suburban in nature. Two-lane roads and highways provide views of the mountains, trees, and water.

The largely tree-covered hillsides are interspersed with grassland areas that remain unvegetated during the dry summer months. As the water level falls, an unvegetated ring around the entire reservoir is clearly visible (San Francisco Planning Department 2007). Where the slopes are steeper, sandy brown soils are exposed. In some locations, the drawdown exposes large rocky areas which tend to match rocky areas above the high water mark and present little visual contrast. As the reservoir elevation gets lower and the drawdown zone expands, the visual lack of vegetation emphasizes a strong visual contrast between the natural, vegetated hillside and the exposed hillside (TID and MID 2013b). New Don Pedro Reservoir provides 160 miles of shoreline and 13,000 acres of surface area at maximum reservoir level. The reservoir has hiking trails, two marinas, a swimming lagoon, and 559 campsites in three locations (Fleming Meadows Recreation Area, Blue Oaks Recreation Area, and Moccasin Point Recreation Area). Outside of the three developed recreation areas, there is boat-in access to much of the shoreline and to the islands within the reservoir for dispersed use, including day use and primitive camping. The recreation facilities are operated by the Don Pedro Recreation Agency (DPRA), which is a department within Turlock Irrigation District (TID). The Modesto Irrigation District (MID) and the City and County of San Francisco (CCSF) sponsor the DPRA. The primary objective of the DPRA is to provide a quality family camping experience and a water sports-oriented environment (TID and Merced ID 2011).

The maximum reservoir elevation is 830 ft MSL. The monthly average elevation of the reservoir has ranged from a low of 750 ft MSL in October to a high of 790 ft MSL in June. The minimum elevation, recorded during a drought period, was 630 ft MSL. Therefore, the reservoir elevations can vary by approximately 200 ft. Boat launches are available at the Fleming Meadows campsite until the reservoir elevation drops below 600 ft MSL. The boat launches at Moccasin Point and Blue Oaks are usable above 722 ft MSL and 726 ft MSL, respectively. Boating activity on the reservoir declines at reservoir levels of 790–750 ft MSL (USBR 1999).

The maximum recreation capacity of New Don Pedro Reservoir is 500,000 visitor days annually (Barnes 1987). Peak recreation season is typically April–September. In 2012, the total recreation visitor use days during peak season was approximately 244,000. The highest use occurred during July, with nearly 87,000 recreation visitor use days (TID and MID 2013a). During the 2012 off-season (November–March), there were a total of 18,248 visitor use days, with fewer than 6,000 recreation visitor use days each month (TID and MID 2013a).

New Melones Reservoir

The New Melones Dam impounds the Stanislaus River, forming the New Melones Reservoir. New Melones Reservoir is relatively large with a varied geography that promotes many types of recreation. Generally, the visual character and quality of the reservoir is similar to that of Lake McClure and New Don Pedro Reservoir. The visual setting includes views of mountains and pine forest interspersed with grasslands. The shoreline is modified with recreational facilities.

The seasonal reservoir drawdown can result in an area of exposed soil with little or low-growing vegetation around the shoreline. Where the slopes are steeper, reddish brown soils are exposed; and where slopes are gentler, more grasses and low vegetation tend to become established. This view, typically experienced in summer, is exacerbated during periods of low precipitation and drought. The reservoir provides approximately 12,500 acres of surface area at capacity for recreation and supports approximately 800,000 visitor days annually (USBR 2011b). There are six recreation areas on New Melones Reservoir. The Mark Twain, Parrot's Ferry, Camp Nine, and Old Town areas are relatively undeveloped and offer few recreation facilities. The remaining recreation areas, Glory Hole and Tuttletown, offer the most structured visitor experience and are the most visited, with approximately 750,000 annual visitor days (McAfee 2000). The Glory Hole Recreation Area has two campgrounds with a total of 144 campsites, three day-use areas, hiking and biking trails, swim beaches, two boat launch ramps, and a marina with a store. The Tuttletown

Recreation Area has three campgrounds with a total of 161 campsites, two day-use areas, a boat ramp, and a visitor's center. USBR operates all recreation facilities on New Melones Reservoir.

Many recreational activities take place at New Melones Reservoir. Hunting is permitted on all of USBR's lands surrounding the reservoir, with the exception of Tuttletown and Glory Hole, but mostly takes place within or near the Peoria Wildlife Management Area. Bank fishing and gold panning takes place along the shoreline. Hiking, bicycling, and horseback riding are conducted on the approximately 25 miles of trails surrounding the reservoir. There are also several caves near the reservoir, and many visitors are involved in spelunking, or caving, in the handful of caves open to the public. The most frequented caves are the two Natural Bridges located within the Coyote Creek tributary (USBR 2007).

The average elevation of the reservoir has typically ranged from 948 ft (in October) to 973 ft (in March and June).Therefore, average seasonal drawdown is 25 ft. The minimum reservoir elevation was recorded at 712 ft MSL (July–November). The maximum reservoir elevation, typically recorded in June, is 1,085 ft MSL. Minimum reservoir elevations are below the lowest boat launch facilities. With the exception of the boat ramp at Glory Hole, all boat ramps become inoperable at reservoir elevations below 950 ft MSL. The Glory Hole boat ramp is a 2-lane facility that provides boat access at a reservoir elevation as low as 860 ft MSL. The optimal water level for recreational use of the reservoir is 950–980 ft MSL (State Water Board 1999). In the recreation areas used for camping, visitation tends to follow reservoir surface levels, declining when water levels are low. However, other recreational uses of the reservoir, such as boating and kayaking, increase when water levels recede (McAfee 2000). Prior to construction of the New Melones Dam, whitewater rafting was popular in what is now the northern portion of the reservoir near Camp Nine. This area is still rafted and kayaked when reservoir water levels are low and flow returns to the exposed channel, such as in drought years.

Tulloch Reservoir

The Tulloch Reservoir, located less than a mile downstream of the New Melones Dam, provides additional recreational opportunities. The Tulloch Reservoir is owned by the Oakdale Irrigation District (OID) and South San Joaquin Irrigation District (SSJID). Private development is extensive around the perimeter of the reservoir. Public access to the water is provided through two privately owned marinas, South Shore Campground and Marina in Tuolumne County, and Lake Tulloch Resort in Calaveras County. Private residences and private parks operated by housing developments provide additional access to the water (OID and SSJID 2008).

Tulloch Reservoir provides 1,260 acres of surface water for recreation. The surface elevation remains fairly constant, but the reservoir is regularly lowered by approximately 10 ft in the winter to provide space for flood control releases from New Melones Reservoir (OID and SSJID 2008).

10.2.3 Extended Plan Area

In general, views of the rivers in the extended plan area include features of the surrounding landscape, such as hills, mountains, valleys, vegetation, and other natural resources. Urban and suburban features are limited, and typically views of the natural landscape are uninterrupted with buildings or infrastructure. The Stanislaus National Forest comprises a large portion of the extended plan area. The extended plan area covers large parts of Calaveras, Tuolumne, and Mariposa Counties. These counties are primarily rural in nature and are characterized by rolling foothill and/or steep mountainous terrain, very low population density, and an attractive and unspoiled natural environment.

Reaches of the Tuolumne and Merced Rivers in the extended plan area are classified as wild and scenic (see Section 10.3.1, *Federal [Regulatory Background]*, for more information about the National Wild and Scenic Rivers Act); the Stanislaus River in the extended plan area is not classified as wild and scenic (National Wild and Scenic Rivers System 2016). A total of 122 miles of the Merced River is designated, with 71 designated as wild, 16 designated as scenic, and 35.5 miles designated as recreational. A total of 83 miles of the Tuolumne River is designated with 47 miles designated as wild, 23 miles designated as scenic, and 13 miles designated as recreational. Both rivers generally offer recreationists and other viewers uninterrupted views of the natural landscape that consist of glaciated peaks, lakes, and alpine and subalpine meadows. Depending on the location in the extended plan area, there are also uninterrupted and extensive views of the Merced and Tuolumne Rivers. Flows on the Merced River are generally not controlled by reservoirs because there are no major reservoirs on the Merced River in the extended plan area. Since the Merced River is relatively free-flowing, flows are primarily influenced by weather patterns including winter snow accumulation, spring and summer snowmelt, and summer precipitation (Dettinger et al. 2004; Yosemite National Park 2013). Flows on the Tuolumne River are highly regulated, primarily by releases from the Hetch Hetchy Reservoir, and viewers are subjected to these regulated flows (National Wild and Scenic Rivers System 2016.) Although the Stanislaus River is not identified as wild and scenic, flows are also highly regulated by releases from large reservoirs, such as Spicer Meadow, Donnell, and Beardsley Reservoirs, and viewers are subjected to these regulated flows.

There are several designated scenic highway routes in the extended plan area, including State Route 4, State Route 140, and State Route 120 (Caltrans 2016). One of the largest viewer groups affected by changes along a state scenic highway is the travelers along the roadways. Many of the roadways in close proximity to the reservoirs and along the rivers serve as commercial and commuter routes, as well as scenic routes used by recreationists. Viewers who frequently commute via these roadways generally have low visual sensitivity to their surroundings. The passing landscape becomes familiar, and their attention is typically focused elsewhere. At standard roadway speeds, views are fleeting, and travelers are more aware of surrounding traffic, road signs, the automobile's interior, and other visual features of the environment. However, these roadways also may be traveled for their scenic qualities, and recreational travelers on such roadways are likely to have moderate sensitivity because they seek out such routes for their aesthetic viewsheds. Therefore, viewers traveling along state-designated scenic highways for recreational purposes are considered moderately sensitive to the views they experience because these views typically are comprised of specific aesthetic resources (e.g., landscapes with variable topography, trees, rocks and rivers). A highway may be designated scenic depending upon how much of the natural landscape can be seen by travelers, the scenic quality of the landscape, and the extent to which development intrudes upon the traveler's enjoyment of the view. The designated routes and their general visual character and quality are summarized below.

- State Route 4 (also known as Ebbetts Pass Highway) is officially designated as a State Scenic Highway and a National Scenic Byway for approximately 56 miles in Calaveras and Alpine Counties in the extended plan area (Caltrans 2016; DOT 2016). It extends northward from Calaveras County, east of Arnold, to the Alpine County line, and then to State Route 89 (Caltrans 2016). This route traverses through forests of aspen, cedar, pine, fir, and tamarack; across high mountain meadows; around glacial lakes; and along mountain streams as it winds its scenic way above the canyon of the North Fork of the Stanislaus River (Caltrans 2016.). Throughout the length of the route are a number of spectacular vistas of far-off mountain peaks with intervening canyons plunging several thousand ft below the highway (Caltrans 2016.). Given the uninterrupted and relatively intact natural landscape and the sweeping views that can be experienced by drivers this route offers viewers a relatively high visual quality experience.

- State Route 140 is officially designated as a State Scenic Highway for approximately 27 miles in Mariposa County in the extended plan area (Caltrans 2016). It extends northward from the Mariposa Town planning area to the west boundary of the El Portal town planning area (Caltrans 2016). It climbs from oak woodlands in the Sierra foothills through the scenic and historic Merced River Canyon to Yosemite National Park (Caltrans 2016). Similar to Route 4, this route offers viewers a relatively high visual quality experience.
- State Route 120 is officially designated as a Connecting Federal Highway and National Scenic Byway in Mariposa County (County of Mariposa 2006). This route is within Yosemite National Park and offers views of Merced River Canyon and the park. Similar to State Routes 4 and 140, this route also offers viewers a relatively high visual quality experience.

There are two eligible scenic highways in the extended plan area: State Routes 49 and 108. State Route 49 extends through Calaveras, Tuolumne, Marisposa, and Madera Counties within the general proximity of the Stanislaus River, New Melones Reservoir, and Tulloch Reservoir; the Tuolumne River and New Don Pedro Reservoir; and the Merced River, Lake McClure, and New Exchequer Dam (Caltrans 2011). The eligible portion of State Route 49, traveling from north to south, begins in Calaveras County, crosses New Melones Reservoir, the Tuolumne County line, the Tuolumne River as the river enters New Don Pedro Reservoir, the Merced River as it enters Lake McClure, and extends to the southern Mariposa County line (Caltrans 2011). Views available to viewers using the roadway generally consist of the eastern Sierra Nevada, comprised of variable topography (mountains, hills, valleys, meadows), trees, rocks, etc. Some rural residential buildings are interspersed along this route along with small towns. The following reservoirs and rivers are visible as the road crosses them: New Melones Reservoir in Calaveras County, Tuolumne River in Tuolumne County, and the Merced River in Mariposa County. The Stanislaus River and Tulloch Reservoir are generally not visible from this route because of intervening landscape and topography (e.g., elevation changes associated with hills and trees). The surface water elevation in the reservoirs is influenced by seasonal changes and the seasonal operation of the dams and this seasonal variation creates an area of exposed sediment with no vegetation growing (also known as the fluctuation zone).The eligible portion of State Route 108 begins at the junction of State Route 49, east of New Melones and New Don Pedro Reservoirs in the extended plan area, and travels past Sonora to the northern Tuolumne County line (Caltrans 2011). Visibility of the south fork of the Stanislaus River is generally limited due to distance and intervening topography; however, views of other reservoirs in the extended plan area (e.g., Donnell Lake) are afforded to drivers.

The extended plan area primarily includes major portions of the Stanislaus National Forest and all of Yosemite National Park (USFS 2016a). A small portion of the Sierra National Forest is located in the south portion of the extended plan area along the South Fork Merced River in Mariposa and Madera Counties. The extended plan area is bordered by the Humboldt-Toiyabe National Forest and the Inyo National Forest to the west and south. The Stanislaus and Tuolumne Rivers in the Stanislaus National Forest and the Tuolumne and Merced Rivers in Yosemite National Park are used for recreational purposes by a wide variety of different recreationists, including hikers, kayakers, campers, and anglers (USFS 2016b). In-river recreation is typically influenced by the operation of the upstream reservoirs on the Stanislaus and Tuolumne Rivers, similar to the plan area below the three rim dams. For example, the Tuolumne River is well known for some of the most noted whitewater in the high Sierras and is an extremely popular rafting stream below the national park boundary of Yosemite. It is one of the most challenging river runs in California. All private floaters, kayakers, and rafters must obtain permits between May 1 and October 15. Typically, the best floating occurs May through September. However, river flows can be particularly high in the spring, and between the end of the high spring runoff and the beginning of September, the flows on the river are heavily determined by the releases from the Hetch Hetchy Reservoir. Generally flows are high for boaters in the early morning and remain high, and then are reduced to minimum flows in the afternoon. In addition to the in-water activities on the upper Tuolumne River, there are many campsites available to private citizens on a first-come, first-serve basis. (National Wild and Scenic River Systems 2016.)

The reservoirs in the extended plan area are typically smaller than those in the plan area. They generally have less urban and suburban infrastructure around them and offer relatively intact views of the natural landscape including the water vegetation interface along the edge of the reservoirs. The reservoirs offer numerous recreational opportunities. There are numerous recreational opportunities in the extended plan area as it primarily consists of national forests and parks. Recreation at the Stanislaus and Tuolumne River reservoirs in the extended plan area include non-motorized boating, fishing, swimming and camping (USFS n.d.). The Stanislaus National Forest plan has a range of standards and guidelines addressing rural, semi-primitive motorized and primitive recreation (Stanislaus National Forest 2010).

10.2.4 Southern Delta

The majority of the land within the Delta is privately owned, which reduces the availability of land-based recreation (Delta Protection Commission 2010). Navigable waterways in the Delta, however, are publicly accessible and currently constitute the majority of available recreational opportunities (Delta Protection Commission 2010). The southern Delta, specifically, encompasses miles of navigable channels along the San Joaquin, Middle, and Old Rivers. The Clifton Court Forebay, the SWP primary collection reservoir is located northwest of the southern Delta (The Dangermond Group and LSA Associates 2006).

Both privately owned and publicly operated marinas exist throughout the area, including Durham Ferry SRA, Mossdale Marina, Dos Reis Park, Haven Acres Marina, and Tracy Oasis Marina. In addition to boating amenities, these locations provide opportunities for various shore activities, such as fishing and hiking.

A recreation survey conducted by the Department of Recreation in 1996 found that waterskiing, boat cruising, fishing, and swimming were the most popular water-dependent activities in the southern Delta. Of water-enhanced activities, sightseeing was the most common, followed closely by fishing from shore and viewing wildlife (Delta Protection Commission 1997). Sport fishing in the Delta occurs year-round and may take place on private vessels or from shore. Popular sport fish include striped bass, white sturgeon, salmon, American shad, catfish, and largemouth bass (USBR 1999).

The 1996 survey found that recreational use of the southern Delta is proportionally less than the recreational use in other regions of the Sacramento–San Joaquin Delta. The southern Delta is currently estimated to support only 11 percent of the total boating use in the Delta. There are fewer boating and water-associated facilities in the southern Delta compared to the adjoining portions of the Delta to the north. In 2000, an estimated 6.4 million visitor days were associated with boating throughout the Delta (Division of Boating and Waterways 2003).

The water flows in the southern Delta are heavily managed because Central Valley Project (CVP) and SWP pumps are located along the western boundary of the southern Delta. The volume of water in the navigable waterways and the relative quantity of navigable waterways influence available recreational opportunities in the southern Delta. Many of the channels are currently impassable due to snags and vegetation encroachment (Delta Protection Commission 1997). Additionally, during heavy flows, sediment and debris can accumulate, affecting the navigability of the channels and the viability of marinas. Salinity conditions in the southern Delta do not influence the water-dependent or water-enhanced recreational opportunities.

10.3 Regulatory Background

10.3.1 Federal

Relevant federal laws, programs, policies, or regulations related to recreation and/or aesthetics are described below.

Federal Power Act

The Federal Power Act requires the Federal Energy Regulatory Commission (FERC) to give equal consideration to the protection of recreational opportunities and other values when licensing hydropower facilities within its jurisdiction. New Don Pedro and New Exchequer Dams are under FERC's jurisdiction.

Clean Water Act

Section 401 of the federal Clean Water Act requires any applicant for a federal license or permit to conduct any activity, which may result in any discharge to navigable waters, to obtain water quality certification from the State Water Board that the discharge will comply with specified provisions of the Clean Water Act. In issuing water quality certification, the State Water Board certifies that the project will comply with specified provisions of the Clean Water Act, including water quality standards developed pursuant to state law. Water quality standards include beneficial uses, such as recreation. Conditions of certification become conditions of any federal license or permit for the project.

Sierra Resource Management Plan of 2008

Consistent with the Federal Land Policy and Management Act, BLM prepared the Sierra Resource Management Plan to set goals and objectives for various resources, including recreation and aesthetics, on land BLM owns and operates. BLM owns and operates New Exchequer Dam and Lake McClure on the Merced River, New Don Pedro Dam on the Tuolumne River, and portions of land surrounding the reservoirs. This management plan identifies the Lake McClure/Highway 49 and New Melones Reservoir/Stanislaus River viewsheds as Class II visual resources and the Don Pedro Reservoir/Highway 49 viewshed as a Class III visual resource. The plan's objectives include maintaining the existing visual quality of these resources and providing for continued availability of outdoor recreational opportunities while protecting other resources and uses. Specifically, Class II views have an objective to retain the existing character of the landscape and to keep levels of change to the characteristic landscape low. Class III views have an objective to partially retain existing characteristics and moderate changes to the characteristic landscape are acceptable (BLM 2008).

Water and Land Recreation Opportunity Spectrum User's Handbook of 2011

USBR prepared a handbook establishing the Water and Land Recreation Opportunity Spectrum as a tool to understand the type and location of six types of water-related recreation opportunities, which include urban, suburban, rural developed, rural natural, semi-primitive, and primitive recreation opportunities. A particular "package" of activities, setting attributes, experiences, and benefits defines each type. New Melones Reservoir, operated by USBR, has three types: rural developed, rural natural, and semiprimitive. The visual quality objectives of these three types include modification, partial retention, and retention, respectively (USBR 2011a).[5]

New Melones Lake Area Resource Management Plan

The Resource Management Plan (RMP) provides a range of alternatives for managing USBR-administered lands within the New Melones Lake Area. The RMP addresses the interrelationships among the various resources at the New Melones Lake Area and provides options to balance resource management with public use and USBR's mission and authority.

U.S. Forest Service Scenery Management Handbook

Scenery management in the Stanislaus National Forest, which covers much of the extended plan area, is addressed by the *Forest Service Scenery Management Handbook* (USFS 1995). The objective of managing all lands to attain the highest possible visual quality commensurate with other appropriate public uses, costs, and benefits (USFS 2004).

National Wild and Scenic Rivers Act

The Wild and Scenic Rivers Act of 1968 established the National Wild and Scenic River System to preserve certain rivers with outstanding natural, cultural, and recreational values in a free-flowing conditions for the enjoyment of present and future generations. Approximately 2,000 river miles in California have been designated as wild and scenic. This is approximately 1 percent of the state's river miles. Rivers are classified as wild, scenic, or recreational depending on the characteristics of the river (National Wild and Scenic Rivers System 2016).

The definitions of wild, scenic, and recreational as defined by the act are as follows.

- Wild: Those rivers, or sections of rivers, free of impoundments and generally inaccessible except by trail, with watersheds or shorelines essentially primitive and waters unpolluted. These represent vestiges of primitive America.
- Scenic: Those rivers, or sections of rivers, free of impoundments, with shorelines or watersheds still largely primitive and shorelines largely undeveloped, but accessible in places by roads.

---

[5] New Don Pedro Dam and New Exchequer Dam are not operated by USBR.

- Recreational: Those rivers, or sections of rivers, readily accessible by road or railroad, that may have some development along their shorelines, and that may have undergone some impoundment or diversion in the past.

10.3.2 State

Relevant state programs, policies, or regulations related to recreation and/or aesthetics are described below.

Porter-Cologne Water Quality Control Act

The Porter-Cologne Water Quality Control Act is California's comprehensive water quality control law and is a complete regulatory program designed to protect water quality and beneficial uses of the state's water. It requires by adoption of water quality control plans by the state's nine regional water quality control boards for watersheds within their regions. The State Water Board may also adopt water quality control plans.

San Francisco Bay/Sacramento–San Joaquin Delta Estuary Water Quality Control Plan

The State Water Board's 2006 Bay-Delta Plan identifies beneficial uses of water in the Bay-Delta to be reasonably protected, water quality objectives for the reasonable protection of beneficial uses. Recreation is one of the designated beneficial uses of surface water bodies, including the LSJR and its three eastside tributaries.

California State Scenic Highway Program

California's Scenic Highway Program was created by the legislature in 1963. Its purpose is to protect and enhance the natural scenic beauty of California highways and adjacent corridors through special conservation treatment. A highway may be designated scenic depending on how much of the natural landscape can be seen by travelers, the scenic quality of the landscape, and the extent to which development intrudes upon the traveler's enjoyment of the view (Caltrans 2016).

10.3.3 Regional or Local

Relevant regional or local programs, policies, or regulations related to recreation and/or aesthetics are described below. Although local policies, plans and regulations are not binding to the State of California, below is a description of relevant ones.

Mariposa County General Plan

Chapter 12 of the *County of Mariposa General Plan* includes goals and policies to achieve local recreation service, create programs to provide a range of recreation opportunities and facilities, and cooperate with regional agencies in the development of recreation opportunities. The general plan also contains policies that provide for the establishment of measures for the protection of large-scale views and viewsheds through comprehensive development standards. Standards must take into account the scenic aspect of the county to conserve designated views and viewsheds.

Merced General Plan

The *Recreation and Cultural Resources Element* of the *2030 Merced County General Plan* sets goals and policies to achieve its vision for recreational opportunities. The goals and policies are meant to preserve, enhance, expand, and manage Merced County's system of regional parks, trails, and natural resources.

Tuolumne County General Plan

Chapter 8 of the *Tuolumne County General Plan* includes goals and policies to provide adequate and equitable distribution of recreation facilities, cooperate with other public agencies and private enterprises to provide recreation facilities, acquire and develop land for recreation facilities, and obtain revenue sources to fund recreation. One of the goals of the Tuolumne County General Plan *Conservation and Open Space Element* is to conserve the scenic environment and rural character of the county. The policies for preserving scenic resources address the history of agricultural and timberlands, the natural scenic quality and rural character along designated transportation routes, conserving the natural scenic quality of hillsides and hilltops, and voluntary efforts to protect clusters of native trees and conserve the county's scenic resources.

Stanislaus County General Plan

Chapter 3 of the *Stanislaus County General Plan* emphasizes the conservation and management of natural resources and the preservation of open space for outdoor recreation. It sets goals and policies to maintain the natural environment in areas dedicated as parks and open space and to provide for the open-space recreational needs of the residents of the county.

Calaveras County General Plan

The *Open Space Element* of the *Calaveras County General Plan* states there are significant topographic variations and several resources which contribute to scenic quality. The primary attributes include the lakes, rivers and streams, rolling hills with oak habitat, ridgelines, and forests.

San Joaquin County General Plan

Goals of the *San Joaquin County General Plan* include the preservation of open space for recreation, encouraging the use of waterways for recreation, recognition of scenic routes within the county, providing that water-diversion projects ensure adequate water for recreation, and recognizing that local vegetation communities are important to the recreational experience.

10.4 Impact Analysis

This section identifies the thresholds or significance criteria used to evaluate the potential impacts on recreational resources and aesthetics. It further describes the methods of analysis used to determine significance. Measures to mitigate (i.e., avoid, minimize, rectify, reduce, eliminate, or compensate for) significant impacts accompany the impact discussion, if any significant impacts are identified.

10.4.1 Thresholds of Significance

The thresholds for determining the significance of impacts for this analysis are based on the State Water Board's Environmental Checklist in Appendix A of the State Water Board's CEQA regulations. (23 California Code of Regulations [Cal. Code Regs.], §§ 3720–3781.) The thresholds derived from the checklist were modified, as appropriate, to refine the analysis and more accurately describe the impacts of the alternatives. The recreational resource and aesthetic impacts, which were determined as potentially significant in the State Water Board's Environmental Checklist (see Appendix B, *State Water Board's Environmental Checklist*), are discussed in this analysis as to whether the alternatives could result in the following:

- Substantially physically deteriorate existing recreational facilities on the rivers or at the reservoirs.
- Substantially degrade the existing visual character or quality of the reservoirs.
- Have a substantial adverse effect on a scenic vista.
- Substantially damage scenic resources, including trees, rock outcroppings, and historic buildings within a state scenic highway.

Where appropriate specific quantitative or qualitative criteria are described in Section 10.4.2, *Methods and Approach*, for evaluating these thresholds.

As discussed in Appendix B, the new flow requirements would not significantly degrade the visual character or quality of the rivers within the landscape because flows would generally be within the baseline historical range. Viewers would not be sensitive to any changes in flows and associated visual changes. Therefore, potential impacts on the visual character or quality of the riverine landscape are not discussed in this chapter. In addition, as indicated in Appendix B, the LSJR and SDWQ alternatives would have either no impact or less than significant impacts on the following areas related to recreational resources and aesthetics and, therefore, are not discussed within this chapter.

- Increase the use of existing neighborhood and regional parks or other recreational facilities such that substantial physical deterioration of the facilities would occur or be accelerated.
- Include recreational facilities or require the construction or expansion of recreational facilities that might have an adverse physical effect on the environment.
- Create a new source of substantial light or glare which would adversely affect day or nighttime views in the area.

10.4.2 Methods and Approach

This chapter evaluates the potential recreation and visual quality impacts associated with the LSJR alternatives using modeling results from the State Water Board's Water Supply Effects (WSE) model for flows and reservoir elevations (Chapter 5, *Surface Hydrology and Water Quality*, and Appendix F.1, *Hydrologic and Water Quality Modeling*). The modeling results for the LSJR alternatives are compared to the baseline modeled conditions. Recreation surveys were not conducted for the analysis, and existing setting information is based on the most recent available information regarding recreational opportunities at the LSJR, three eastside tributaries, and reservoirs.

The results of the hydrologic modeling are presented below, along with an assessment of the implications of the modeled results for potential impacts on recreation. The analysis identifies the frequency with which flow ranges support different types of flow-dependent recreational activities. Reservoir elevation levels predicted from the hydrologic modeling also are used to determine if the exposed shoreline would modify the aesthetics (i.e., visual character and quality) of the reservoirs experienced by recreationists. The impact analysis then qualitatively discusses if the LSJR alternatives would substantially impact recreation or substantially degrade the visual character and quality of the reservoirs.

This chapter evaluates the potential recreation and aesthetic impacts associated with the LSJR alternatives. Each LSJR alternative includes a February–June unimpaired flow[6] requirement (i.e., 20, 40, or 60 percent) and methods for adaptive implementation to reasonably protect fish and wildlife beneficial uses, as described in Chapter 3, *Alternatives Description*. In addition, a minimum base flow is required at Vernalis at all times during this period. The base flow may be adaptively implemented as described below and in Chapter 3. State Water Board approval is required before any method can be implemented, as described in Appendix K, *Revised Water Quality Control Plan*. All methods may be implemented individually or in combination with other methods, may be applied differently to each tributary, and could be in effect for varying lengths of time, so long as the flows are coordinated to achieve beneficial results in the LSJR related to the protection of fish and wildlife beneficial uses.

The Stanislaus, Tuolumne, and Merced Working Group (STM Working Group) will assist with implementation, monitoring, and assessment activities for the flow objectives and with developing biological goals to help evaluate the effectiveness of the flow requirements and adaptive implementation actions. The STM Working Group may recommend adjusting the flow requirements through adaptive implementation if scientific information supports such changes to reasonably protect fish and wildlife beneficial uses. Scientific research may also be conducted within the adaptive range to improve scientific understanding of measures needed to protect fish and wildlife and reduce scientific uncertainty through monitoring and evaluation. Further details describing the methods, the STM Working Group, and the approval process are included in Chapter 3 and Appendix K.

Without adaptive implementation, flow must be managed such that it tracks the daily unimpaired flow percentage based on a running average of no more than 7 days. The four methods of adaptive implementation are described briefly below.

1. Based on best available scientific information indicating that more flow is needed or less flow is adequate to reasonably protect fish and wildlife beneficial uses, the specified annual February–June minimum unimpaired flow requirement may be increased or decreased to a percentage within the ranges listed below. For LSJR Alternative 2 (20 percent unimpaired flow), the percent of unimpaired flow may be increased to a maximum of 30 percent. For LSJR Alternative 3 (40 percent unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 30 percent or increased to a maximum of 50 percent. For LSJR Alternative 4 (60 percent

---

[6] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.

unimpaired flow), the percent of unimpaired flow may be decreased to a minimum of 50 percent.

2. Based on best available scientific information indicating a flow pattern different from that which would occur by tracking the unimpaired flow percentage would better protect fish and wildlife beneficial uses, water may be released at varying rates during February–June. The total volume of water released under this adaptive method must be at least equal to the volume of water that would be released by tracking the unimpaired flow percentage from February–June.
3. Based on best available scientific information, release of a portion of the February–June unimpaired flow may be delayed until after June to prevent adverse effects to fisheries, including temperature that would otherwise result from implementation of the February–June flow requirements. The ability to delay release of flow until after June is only allowed when the unimpaired flow requirement is greater than 30 percent. If the requirement is greater than 30 percent but less than 40 percent, the amount of flow that may be released after June is limited to the portion of the unimpaired flow requirement over 30 percent. For example, if the flow requirement is 35 percent, 5 percent may be released after June. If the requirement is 40 percent or greater, then 25 percent of the total volume of the flow requirement may be released after June. As an example, if the requirement is 50 percent, at least 37.5 percent unimpaired flow must be released in February–June and up to 12.5 percent unimpaired flow may be released after June. If after June the STM Working Group determines that conditions have changed such that water held for release after June should not be released by the fall of that year, the water may be held until the following year. See Chapter 3 and Appendix K for further details.
4. Based on best available scientific information indicating that more flow is needed or less flow is adequate to reasonably protect fish and wildlife beneficial uses, the February–June Vernalis base flow requirement of 1,000 cfs may be modified to a rate between 800 and 1,200 cfs.

The operational changes made using the adaptive implementation methods above may be approved if the best available scientific information indicates that the changes will be sufficient to support and maintain the natural production of viable native SJR Watershed fish populations migrating through the Delta and meet any biological goals. The changes may take place on either a short-term (for example monthly or annually) or longer-term basis. Adaptive implementation is intended to foster coordinated and adaptive management of flows based on best available scientific information in order to protect fish and wildlife beneficial uses. Adaptive implementation could also optimize flows to achieve the objective, while allowing for consideration of other beneficial uses, provided that these other considerations do not reduce intended benefits to fish and wildlife. While the measures and processes used to decide upon adaptive implementation actions must achieve the narrative objective for the reasonable protection of fish and wildlife beneficial uses, adaptive implementation could result in flows that would benefit or reduce impacts on other beneficial uses that rely on water. For example, terrestrial riparian species could benefit by receiving additional flows during key germination times in the late spring.

The quantitative results included in the figures, tables, and text of this chapter present WSE modeling of the specified unimpaired flow requirement for each LSJR alternative (i.e., 20, 40, or 60 percent). The modeling does allow some inflows to be retained in the reservoirs after June, as could occur under adaptive implementation method 3, to prevent adverse temperature effects and this is included in the results presented in this chapter. If the percent of unimpaired flow is not specified in this chapter, these are the percentages of unimpaired flow evaluated in the impact analysis. However, as part of adaptive implementation, method 1 would allow the required percent of unimpaired flow to change by up to 10 percent if the STM Working Group agrees to adjust it. The highest possible percent of unimpaired flow associated with an LSJR alternative is also evaluated in the impact analysis if long-term implementation of method 1 has the potential to affect a determination of significance. For example, if the determination for LSJR Alternative 3 at 40 percent unimpaired flow is less than significant, but the determination for LSJR Alternative 4 at 60 percent unimpaired flow is significant, then LSJR Alternative 3 is also evaluated at 50 percent unimpaired flow. This use of modeling provides information to support the analysis and evaluation of the effects of the alternatives and adaptive implementation. For more information regarding the modeling methodology and quantitative flow and temperature modeling results, see Appendix F.1, *Hydrologic and Water Quality Modeling*.

LSJR and Tributary Modeling Methodology and Results

Streamflow affects the recreational water-based opportunities in the rivers below the rim dams. Recreational use of the LSJR and its tributaries occurs year-round, although the most frequent use is during the warmer spring and summer months. Therefore, the effects of the proposed changes in river flows are analyzed for the months of May–September. Unacceptable flows can occur when flows are lower than optimal for boating or swimming or when flows are too high and result in potentially unsafe velocities. Higher flows may also inundate and reduce access to existing on-bank recreation facilities (e.g., campsites).

For in-water recreational opportunities, the flow for different known activities on each of the rivers is compared to the expected modeled flow under each of the alternatives to determine how often the expected modeled flow would fall within the flow ranges. Although optimal flows vary for each river based on hydrologic and geologic conditions, flows can generally be classified into the following optimal flow ranges to evaluate the hydrologic modeling results.

- Less than 500 cfs for swimming, floating, canoeing and kayaking.
- Between 500 and 1,500 cfs for motorized boating, rafting, and kayaking.
- Between 1,500 and 2,500 cfs for advanced rafting or kayaking.

A flow above 2,500 cfs is generally considered unsafe for recreational activities, although advanced whitewater rafting and kayaking often still take place.

The WSE model results are presented as monthly distributions of river flows to provide the basis for the evaluation of potential impacts on recreational opportunities and visual experiences. Average monthly flow conditions that would result from LSJR Alternatives 2, 3, and 4 during the summer recreation season are compared to baseline conditions to determine the magnitude and frequency of the changes in flows that support recreation.

Potential recreation impacts were determined using the WSE model results in a three-step procedure. The first step described recreational opportunities in May–September (i.e., the recreation season) with values for the acceptable range of flows known to support recreation. The second step calculated the frequency of monthly flows that are within this range, based on the monthly WSE model results. In step three, for LSJR Alternatives 2, 3, and 4, the frequency of flows (or reservoir elevations) within this optimal range was then compared to those associated with the baseline. As described in Chapter 5, *Surface Hydrology and Water Quality*, baseline was developed using an 82-year simulation period.

The results of this assessment are presented below, first using the Merced River as an example (Tables 10-2 through 10-4). Summary tables are then presented for the Tuolumne River (Table 10-5) and Stanislaus River (Table 10-6). If the frequency of flows generally supporting a specific recreational activity would decrease more than 10 percent when averaged over the summer recreation season (i.e., the seasonal monthly average frequency of flows within a range that supports a type of recreation would decrease more than 10 percent) a significant impact on a particular type of river recreation may be identified.

The alteration of flow under the LJSR alternatives would not constitute a significant change in visual quality because expected flows are generally within the historical range and views are not as sensitive to these changes. Furthermore, the LSJR alternatives would not influence flood flows currently produced by the rim dams and would reduce the frequency of low flows during critical and critically dry years. Therefore, visual character and quality of the rivers are not discussed further.

Merced River

Common water-dependent recreational activities on the Merced River include swimming, boating, fishing, rafting, and kayaking. Tables 10-2 to 10-4 show the baseline flows suitable for recreation on the Merced River. Table 10-2 gives the full range of monthly flows in the cumulative distribution[7] format, using 10 percent increments from the minimum flow (at the top) to the maximum flow (at the bottom), with the average monthly flow below the maximum value. Table 10-3 shows the percentage of the years that the monthly flows were greater than specified flows of 250–2,500 cfs, in increments of 250 cfs. Tables 10-2 and 10-3 are shown as examples of the type of flow frequency information that is used to generate the summary tables for recreational flow frequencies for each river (i.e., Tables 10-4, 10-5, and 10-6).

Table 10-4 shows the percentage of the years when the Merced River monthly flows were within the four ranges of flows for recreation (e.g., less than 500 cfs, between 500 and 1,500 cfs, etc.) for baseline and the LSJR alternatives. The frequency percentages for the peak recreation season months and the average percentages are shown for all alternatives.

As identified in Table 10-4, the seasonal monthly averages indicate that flows were suitable for swimming in 72 percent of the years, rafting and motorized boating 18 percent of the years, advanced kayaking in 5 percent of the years, and were too high for anything except whitewater boating in 6 percent of the years. The LSJR alternatives would change the Merced River flows primarily in May and June, with less frequent average monthly flows (i.e., less than 500 cfs) and more frequent higher flows. Changes during the months of July–September were smaller. For July and August, the LSJR alternatives had the opposite effect than what they had for May and June; average monthly flows of less than 500 cfs increased, whereas higher flows decreased. The effects of LSJR Alternatives 3 and 4 on river flow during September showed a decrease in the frequency of the lowest flows, as a result of adaptive implementation method 3. For the Merced River, the LSJR

---

[7] The cumulative distribution of a particular variable (i.e., reservoir elevations) provides a basic summary of the distribution of values. This term is not referring to, and should not be confused with, the term cumulative impacts, which is a specific CEQA term. A discussion of cumulative impacts for CEQA purposes is provided Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*; Chapter 16, *Evaluation of Other Indirect and Additional Actions;* and Chapter 17, *Cumulative Impacts, Growth-Inducing Effects, and Irreversible Commitment of Resources.*

alternatives are not expected to have a large effect on the frequency of river flows above 2,500 cfs, except in May under LSJR Alternative 4.

The modeled seasonal average frequency of all flow ranges would generally increase or stay the same under all of the alternatives when compared to baseline, except the frequency of flows less than 500 cfs under LSJR Alternatives 3 and 4, which would decrease to 53 percent and 46 percent, respectively.

Table 10-2. Monthly Cumulative Distributions of Merced River Flow (cubic feet per second [cfs]) at Stevinson for Baseline Conditions (WSE Model Results for 1922–2003)

Notes:
The sum of percentages for each month may not equal 100 due to rounding of values for each flow range.
Gray cells indicate a decrease in the seasonal average greater than 10 percent relative to baseline.
Outlined cells in the table indicate an increase in the seasonal average greater than 10 percent relative to baseline.

Tuolumne River

Common water-dependent recreational activities on the Tuolumne River include boating, fishing, swimming, rafting and kayaking. Table 10-5 shows the percentage of years over the 82-year simulation period in which flows are within specified recreational ranges. The LSJR alternatives are expected to change the Tuolumne River flows in May and June, with flows tending to increase progressively with each LSJR alternative. For example, in June, each of the LSJR alternatives is expected to cause a substantial reduction in the frequency of flows less than 500 cfs. For LSJR Alternative 2, some of the flows would shift from less than 500 cfs under baseline to the 500-1,500 cfs range, whereas for LSJR Alternatives 3 and 4, the flows shift to a range greater than 1,500 cfs. LSJR Alternatives 3 and 4 would cause a large increase in the frequency of flows over 2,500 cfs in May and June. The alternatives generally would cause only small changes in river flows from July–September, except for LSJR Alternative 4, which is expected to cause a moderate decrease in flows greater than 2,500 cfs and an increase in flows from 500–1,500 cfs in July.

The modeled seasonal average flow frequencies show increases in flow under all of the alternatives when compared to baseline. As a result, the frequency of flows less than 500 cfs under LSJR Alternatives 3 and 4 would decrease more than 10 percent to 33 percent and 32 percent, respectively. In addition, the modeled seasonal average frequency of flows of greater than 2,500 cfs would increase more than 10 percent to 23 percent under LSJR Alternative 3 and to 31 percent under LSJR Alternative 4.

Outlined cells in the table indicate an increase in the seasonal average greater than 10 percent relative to baseline.

Stanislaus River

Common water-dependent recreational activities on the Stanislaus River include boating, fishing, swimming, rafting, and kayaking. Table 10-6 shows the percentage of years when monthly Stanislaus River flows would be within the specific recreational ranges. LSJR Alternative 2 would be expected to have only a small effect on Stanislaus River flows. LSJR Alternatives 3 and 4 would be expected to increase average monthly Stanislaus River flows in May and June, with more frequent average monthly flows over 1,500 cfs in May for LSJR Alternative 3 and more frequent average monthly flows over 2,500 cfs in May and, to a lesser extent, in June (over 1,500 cfs) for LSJR Alternative 4. The alternatives generally would have little effect on river flows July–September, although there would be a moderate increase in flows from 500–1,500 cfs for LSJR Alternative 3. The modeled seasonal average frequency of all flow ranges would generally change little under all of the alternatives when compared to baseline. However, the modeled seasonal average frequency of flows of greater than 2,500 cfs would increase by more than 10 percent to 14 percent under LSJR Alternative 4.

Table 10-6. Percentage of Years with Monthly Stanislaus River Flows within Specified Recreational Ranges (cubic feet per second [cfs]) (WSE Model Results for 1922–2003)

Outlined cells in the table indicate an increase in the seasonal average greater than 10 percent relative to baseline.

Lower San Joaquin River

Available data on the optimal flows on the LSJR do not follow the general trends described above for the eastside tributaries. Sources indicate that boating conditions are optimal at flows less than 750 cfs, while swimming and canoeing are best conducted when flows are less than 300 cfs (USBR 1997; Frago pers. comm.). Opportunities for land-based recreation are limited by flows and access.

Chapter 5, *Surface Hydrology and Water Quality*, and Appendix F.1, *Hydrologic and Water Quality Modeling*, present modeled flows on the SJR at Vernalis. Because the LSJR flows would be incrementally increased by inflow from the three eastside tributaries, the flows downstream at Vernalis are higher than those upstream (south of the confluence of the Merced River). At Vernalis, the SJR frequently experiences flows that are too high for any in-water recreation other than motorized boating or advanced kayaking and rafting (generally greater than 1,000 cfs in dry years). The hydrologic modeling predicts that LSJR flows would generally continue to be too high to support any in-water recreational opportunities under all alternatives.

LSJR Alternative Reservoir Modeling Methodology and Results

The evaluation of impacts on recreational opportunities at reservoirs is based on the reservoir water surface elevations. When critical low elevations are reached, boat ramps are no longer operational, marinas close, and camping and picnicking opportunities become limited by the small surface area of the reservoir available for recreation. Lower water levels can also reduce the visual character and quality of the reservoir's surroundings. Thus, although reservoirs are subject to a large variation in elevation associated with water releases, weather conditions, and seasonal changes, the quality of the recreation experience is best when the reservoir is full and elevation change is minimal.

Peak recreation seasons vary amongst reservoirs and predominate recreation uses. The majority of use typically occurs during the summer months, between Memorial Day and Labor Day. Thus, this recreation impact analysis focuses on May–September, the period of time when changes in water elevations are most likely to impact recreation.

Visual quality is evaluated qualitatively by identifying the existing visual setting (using the descriptions in Section 10.2.2, *Reservoirs*) of the reservoirs and their assigned visual classifications. It was then determined whether the change in elevation under LSJR Alternatives 2, 3, and 4 would result in a substantial degradation of visual quality. Table 10-7 identifies the visual classifications and the potential for modifying the existing visual setting.

Table 10-7. Summary of Visual Characteristics and Classifications

Reservoir	View Summary	Classification	Potential for Modification
Lake McClure[a]	Lake McClure and Highway 49 viewshed; the Sierra Nevada and aesthetics associated with foothills and mountains	Class II	Retain existing character of the landscape; levels of change to the characteristic landscape should be low
	Developed recreation areas around the reservoir (e.g., Horseshoe Bend) and water infrastructure of dam	Class III	Partially retain existing visual characteristics; the change to the characteristic landscape can be moderate
New Don Pedro[b]	New Don Pedro Reservoir and Highway 49 viewshed; the Sierra Nevada and aesthetics associated with foothills and mountains; developed recreation areas around the reservoir and water infrastructure of the dam	Class III	Partially retain existing visual characteristics; the change to the characteristic landscape can be moderate
New Melones[c]	New Melones Reservoir/Stanislaus River; the Sierra Nevada and aesthetics associated with foothills and mountains	Class II	Retain existing character of the landscape; levels of change to the characteristic landscape should be low
	Residential areas surrounding reservoir; the recreation areas of Tuttletown and Glory Hole; water infrastructure of the dam	Rural Developed	Views can experience modification
	Less developed recreation areas and opportunities; hiking trails	Rural Natural	Views should be partially retained
	Surrounding landscape of the Sierra Nevada	Semi-Primitive	Views should be preserved

Baseline conditions and LSJR Alternative 2–4 conditions are compared using the lowest one-third of reservoir elevations experienced over the 82-year simulation period for May–September. The lowest one-third is represented by the 30 percent cumulative distribution of reservoir elevations during this time period. This distribution provides a conservative method of evaluating the reservoir elevation data because it represents low elevation conditions typically experienced under drought or dry conditions.

To more fully evaluate the range of potential effects, reservoir recreational conditions are also assessed using the minimum reservoir elevations experienced over the 82-year simulation period for May–September. While the lowest elevations occur infrequently, they result in conditions that can be most detrimental to recreation. Because the alternatives may establish minimum carryover storage requirements, it is possible that the effect of the alternatives on minimum elevation levels may be different than the historical effect observed at the 30 percent cumulative distribution levels over the 82-year simulation period. An increase in the lowest reservoir elevations (i.e., the minimum values out of all 82 years) would represent an improvement in what would be the worst-case conditions for reservoir access. Such an increase may compensate for any effects that might be associated with a decrease in reservoir elevations at the 30 percent cumulative distribution level.

Recreational opportunities and visual character and quality would be potentially restricted during these dry conditions because reduced reservoir elevations affect the usability of recreation facilities and the aesthetics of a reservoir. Recreational opportunities or visual character and quality could be significantly affected if there is a seasonal (May–September) average decrease in reservoir elevation greater than 10 ft, or a decrease below critical elevation levels for certain recreation activities (e.g., elevation levels associated with a boat launch), relative to baseline conditions. Quantifying the conditions in feet provide the actual reservoir elevation under baseline conditions compared to the conditions under the LSJR alternatives. A change of 10 or more feet is expected to result in a visible change to the reservoir elevations noticeable to recreationists. The reservoir elevations are already expected to be low because the evaluation is conducted using reservoir elevations at the 30 percent cumulative distribution level, which represents drier year conditions, as well as the minimum elevations, which represent the driest conditions. These conditions are expected to result in limitations of recreational facilities or visual quality that might not otherwise occur under average baseline conditions. Therefore, this chapter presents a conservative analysis of potential changes when compared to baseline.

Lake McClure

Lake McClure boat ramps cease operation at reservoir levels of 590–793 ft MSL. The ramp at Bagby is the first to close when the reservoir decreases to an elevation of 793 ft MSL, followed by Horseshoe Bend at 758 ft MSL, McClure Point at 650 ft MSL, southern Barrett Cove ramp at 630 ft MSL, and northern Barrett Cove and Piney Creek, both at 590 ft MSL (USBR 1999).

Table 10-8 presents the modeled reservoir elevations of Lake McClure for the LSJR alternatives during May–September. Modeled reservoir elevations under baseline conditions during May–September result in a seasonal change of approximately 81 ft for the 30 percent cumulative distribution and can support the use of most boat ramps. Similarly, the baseline minimum elevations would decrease by 55 ft over the May–September season and could support the use of some boat ramps, although fewer than at the 30 percent cumulative distribution level elevations (Table 10-8).

With the LSJR alternatives, elevations would stay well above 590 ft (the level at which all boat ramps are inoperable). Under LSJR Alternatives 3 and 4, seasonal average reservoir elevations would be greater than baseline by 11 and 9 ft, respectively, at the 30 percent cumulative distribution, and would be 23 ft relative to baseline elevations under LSJR Alternative 2. Seasonal average minimum elevations would be substantially higher than baseline by more than 80 ft under LSJR Alternatives 2 and 3, and by more than 40 ft under LSJR Alternative 4 (Table 10-9).

Table 10-8. Lake McClure May–September Minimum Elevations and Elevations at 30 Percent Cumulative Distribution (feet)

New Don Pedro Reservoir

The maximum reservoir level for recreational use of New Don Pedro Reservoir is 830 ft MSL. Reservoir levels below 790 ft MSL generally result in lower recreational use (USBR 1999). At 780 ft MSL, beach use declines. Below 720 ft MSL some boat ramps become inoperable, reservoir surface area is limited, and campground and picnicking use declines (USBR 1999). At 630 ft MSL, the marina at Moccasin Point closes, and at 600 ft MSL, the boat launch and marina at Flemming Meadows become inoperable (USBR 1999).

Table 10-10 presents the modeled reservoir elevations at New Don Pedro Reservoir for the LSJR alternatives May–September for minimum elevations and at the 30 percent cumulative distribution. New Don Pedro Reservoir baseline elevations are below 780 ft MSL July–September at the 30 percent cumulative distribution and the minimum elevations are well below 780 ft for May–September. Reservoir elevations do not decrease to 630 ft under baseline (i.e., two marinas remain operational). Under baseline conditions, the seasonal May–September change in reservoir elevation is 51 ft for the 30 percent cumulative distribution and 42 ft for minimum elevations.

As presented in Table 10-11, implementation of LSJR Alternatives 3 and 4 would result in a decrease in the seasonal average reservoir elevations of more than 15 ft at the 30 percent cumulative distribution. Under LSJR Alternative 2, there would be a 3-foot decrease in the seasonal average reservoir elevation at the 30 percent cumulative distribution. However, reservoir elevation at the 30 percent cumulative distribution would not decrease below 720 ft (the level at which some boat ramps become inoperable and campgrounds and picnicking use begin to decline) for any of the alternatives. The seasonal average minimum elevation under LSJR Alternative 2 would be more than 15 ft higher than baseline. Under LSJR Alternatives 3 and 4, seasonal average minimum elevations would be 10 or more feet higher relative to baseline.

Table 10-10. New Don Pedro Reservoir May–September Minimum Elevations and Elevations at 30 Percent Cumulative Distribution (feet)

Month	Baseline Conditions	LSJR Alternative 2	LSJR Alternative 3	LSJR Alternative 4

New Melones Reservoir

On New Melones Reservoir, the optimal reservoir water level for recreation is 950–980 ft MSL (State Water Board 1999). Below 900 ft MSL, use of beaches declines. Below 880 ft MSL, the marina closes. At 860 ft MSL, the last official boat ramp (Glory Hole) becomes inoperable, reservoir surface area is limited, and campground and picnicking use declines. Below 850 ft MSL, all boat launches are inoperable (USBR 1999).

Table 10-12 shows modeled New Melones Reservoir elevations for the LSJR alternatives from May–September. New Melones Reservoir has experienced elevations below 950 ft (the lowest level for optimal recreation), resulting in baseline reductions to recreational opportunities. Under baseline conditions, the seasonal May–September change in reservoir elevation is 32 ft for the 30 percent cumulative distribution and 35 ft for the minimum elevations.

Hydrologic modeling of the LSJR alternatives predicts higher reservoir elevations than the predicted baseline seasonal elevations for the May–September period. Under baseline conditions, minimum reservoir elevations were below 850 ft MSL, the level at which boat launches become inoperable. In contrast, under all of the alternatives, minimum elevations would be above 850 ft.

As presented in Table 10-13, under LSJR Alternative 2, the seasonal average reservoir elevation would be 26 ft higher than baseline at the 30 percent cumulative distribution level. Seasonal average reservoir elevations for LSJR Alternatives 3 and 4 would increase 14 ft and 8 ft above baseline, respectively. Seasonal average minimum elevations would be higher than baseline by more than 120 ft under all LSJR alternatives.

Table 10-12. New Melones Reservoir May–September Minimum Elevations and Elevations at 30 Percent Cumulative Distribution (feet)

Month	Baseline Conditions	LSJR Alternative 2	LSJR Alternative 3	LSJR Alternative 4
Elevations at 30 Percent Cumulative Distribution				
May	944	966	953	938
June	941	967	952	942
July	929	957	944	937
August	917	945	934	934
September	913	938	930	932
Minimum Elevations (0 Percent Cumulative Distribution)				
May	770	883	890	880
June	758	880	887	877
July	747	877	884	873
August	738	874	881	870
September	735	874	881	870

Table 10-13. Changes in New Melones Reservoir Minimum Elevations and Elevations at 30 Percent Cumulative Distribution Compared to Baseline (feet)

Month	LSJR Alternative 2	LSJR Alternative 3	LSJR Alternative 4
Change in Elevations at 30 Percent Cumulative Distribution			
May	22	8	-6
June	27	11	2
July	27	15	8
August	27	17	17
September	25	17	19
Seasonal Average	26	14	8
Minimum Elevations (0 Percent Cumulative Distribution)			
May	113	120	110
June	123	129	119
July	130	137	126
August	136	143	132
September	139	146	135
Seasonal Average	128	135	124

Tulloch Reservoir

Water surface levels in Tulloch Reservoir are maintained through coordinated water releases from the New Melones Dam upstream and the Tulloch Dam downstream. Although the LSJR alternatives could alter the quantity of water flowing into Tulloch Reservoir, equivalent quantities of water would be released through Tulloch Dam. Therefore, while there would be different monthly flows through Tulloch Reservoir in LSJR Alternatives 2, 3, and 4, the surface elevations of the reservoir would not change.

Extended Plan Area

The analysis of the extended plan area generally identifies how the impacts may be similar to or different from the impacts in the plan area (i.e., downstream of the rim dams) depending on the similarity of the impact mechanism (e.g., changes in reservoir levels, reduced water diversions, and additional flow in the rivers) or location of potential impacts in the extended plan area. Where appropriate, the program of implementation is discussed to help contextualize the potential impacts in the extended plan area.

SDWQ Alternatives

As discussed in Chapter 5, *Surface Hydrology and Water Quality*, salinity levels in the southern Delta are expected to remain within their historical range (i.e., 0.2–1.2 deciSiemens per meter). Salinity levels in the southern Delta have a strong relationship with the salinity measured at Vernalis, and the SDWQ alternatives would not change historical water quality Vernalis. As part of these alternatives, reservoirs would continue to operate to meet the existing Vernalis EC[8] objective through the SDWQ program of implementation, thereby maintaining flows and water quality at Vernalis. As discussed in Appendix B, *State Water Board's Environmental Checklist*, changes in salinity do not result in changes to water-dependent or water-enhanced recreational opportunities in the southern Delta. Salinity fluctuations within the historical range are imperceptible to recreationists that use the southern Delta for water-dependent activities, such as boating or kayaking, and water-enhanced activities, such as wildlife viewing. As discussed in Chapter 7, *Aquatic Biological Resources*, salinity fluctuations within the historical range would not affect fish that inhabit the LSJR and southern Delta channels. Since salinity fluctuations fall within the historical range of salinity in the southern Delta, recreational fishing in the southern Delta would not be affected. Therefore, the SDWQ alternatives are not discussed further in this chapter with respect to recreational resources. To comply with specific water quality objectives or the program of implementation under SDWQ Alternatives 2 or 3, construction and operation of different facilities in the southern Delta could occur, which could involve impacts on recreational resources or aesthetics. These impacts are evaluated in Chapter 16, *Evaluation of Other Indirect and Additional Actions.*

As discussed in Appendix B, changes in salinity would not result in substantial changes to visual character or quality or aesthetics. The SDWQ alternatives are not applicable to the reservoirs and eastside tributaries. SDWQ alternatives are not discussed further in this chapter with respect to

---

[8] In this document, EC is *electrical conductivity*, which is generally expressed in deciSiemens per meter (dS/m). Measurement of EC is a widely accepted indirect method to determine the salinity of water, which is the concentration of dissolved salts (often expressed in parts per thousand or parts per million). EC and salinity are therefore used interchangeably in this document.

aesthetics. To comply with specific water quality objectives or the program of implementation under SDWQ Alternatives 2 or 3, construction and operation of different facilities in the southern Delta could occur, which could involve impacts on recreational resources or aesthetics. These impacts are evaluated in Chapter 16.

10.4.3 Impacts and Mitigation Measures

Impact REC-1: Substantially physically deteriorate existing recreational facilities on the rivers or at the reservoirs

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

The LSJR alternatives may substantially physically deteriorate the condition of existing recreation facilities at reservoirs or on rivers. The condition of an existing recreational facility or feature is considered impaired if it is physically damaged or deteriorated in such a way that recreationists are unable to use it.

At recreational areas along the Stanislaus, Tuolumne, and Merced Rivers and the LSJR, an increase in the magnitude and frequency of high-flow conditions, such as conditions above 2,500 cfs or flood control releases, could damage existing on-bank recreation facilities (e.g., canoe/kayak put-ins, picnic areas, campgrounds, restrooms, and parking areas). Many recreational activities are limited to range of flows. A substantial increases in flows during the summer months could result in certain recreationists being unable to use the river for certain types of in-water activities.

Reductions in reservoir water elevations, as expected under the LSJR alternatives, could increase the distance between established facilities and the water, or reducing available reservoir area. Reservoir recreational use is known to decrease as receding water levels reduce water surface area, make boat ramps less accessible, and leave recreation facilities farther from shorelines (DWR 1994; USBR 1999).

LSJR Alternative 2 (Less than significant/Less than significant with adaptive implementation)

Rivers

Under LSJR Alternative 2, the frequency and magnitude of higher flows on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR would be similar to baseline, exhibiting little fluctuation in July, August, and September. Modeled frequencies of flows greater than 2,500 cfs under LSJR Alternative 2 would generally decrease or stay the same on the three eastside tributaries (Tables 10-4, 10-5, and 10-6). These flows are not expected to result in more frequent inundation of on-bank recreation facilities during the recreation season. Therefore, existing facilities are not expected be substantially deteriorated as a result of implementing LSJR Alternative 2.

The Tuolumne River and Merced River would generally experience fewer low flows (i.e., flows less than 500 cfs) in May and June and more mid-range flows (i.e., 500–1,500 cfs) optimal for boating and fishing during this time (Tables 10-4 and 10-5), although there would be an 11 percent decrease in flows between 500 and 1500 cfs relative to baseline in May on the Tuolumne River. On the Stanislaus River between May and June, there would be little change in flow compared to baseline conditions, with the exception of a 10 percent increase in mid-range flows in June (Table 10-6). The seasonal average frequency of flows within the ranges that support recreation would not decrease substantially (i.e., more than 10 percent) relative to baseline on any of the three eastside tributaries (Tables 10-4, 10-5 and 10-6). Therefore, in-water recreational conditions on these rivers are not expected to be substantially reduced under LSJR Alternative 2. The flows on the downstream end of the SJR at Vernalis are expected to increase in May and June, but generally remain the same July–September. These flows are generally too high for swimming or wading, but motorized boating or advanced kayaking or rafting could continue.

The historic hydrology of the three eastside rivers and the LSJR influences the types and conditions of recreational facilities and features, as well as the designated beneficial recreational uses, in and around these rivers. A change in the magnitude or duration of flows in rivers may somewhat alter the in-water recreational uses of the rivers under LSJR Alternative 2, as described above. While increased flows may lead to slightly fewer opportunities for swimming, these flows would likely lead to improved conditions for kayaking and whitewater rafting. Increased flows may also lead to more opportunities for on-bank recreational activities, such as wildlife viewing. In addition, increased flows are expected to improve conditions for fish (see Chapter 19, *Analyses of Benefits to Native Fish Populations from Increased Flow between February 1 and June 30*, for details regarding expected fish benefits). While it is unknown whether any increase in fish populations would be large enough to specifically and measurably enhance sport fishing opportunities on the rivers, some beneficial effects related to recreational fishing are anticipated. Accordingly, the rivers would continue to support the designated beneficial uses of recreation, as described in the Basin Plan (State Water Board 1998), and would not conflict with the support and continuation of recreational facilities and features as identified in local plans and policies.

Implementation of LSJR Alternative 2 would not substantially physically deteriorate existing recreation facilities on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR. Therefore, use of these facilities would not decrease and impacts on recreational resources at these rivers would be less than significant.

Reservoirs

At Lake McClure, the simulated seasonal average elevation (May–September) under LSJR Alternative 2 would increase by 23 ft at the 30 percent cumulative distribution, and the seasonal average of the minimum elevations would increase substantially (89 ft [Tables 10-8 and 10-9]). At New Don Pedro Reservoir, there would be a small decrease (3 ft) in the seasonal average elevation at the 30 percent cumulative distribution and an increase of 16 ft for the minimum elevations (Tables 10-10 and 10-11). At New Melones Reservoir, substantial increases in elevation are expected for both the minimum elevations and elevations at the 30 percent cumulative distribution under LSJR Alternative 2 (Tables 10-12 and 10-13). These modeled reservoir elevations under LSJR Alternative 2 would generally maintain recreational facilities at the reservoirs (e.g., boat launches) and it is expected that changes in reservoir elevations would not substantially affect the condition of existing recreation facilities. Accordingly, it is anticipated this alternative would not conflict with existing plans and policies supporting recreation and recreational facilities at the reservoirs. Therefore, impacts on recreational resources would be less than significant.

Adaptive Implementation

Based on best available scientific information indicating that a change in the percent of unimpaired flow is needed to reasonably protect fish and wildlife, adaptive implementation method 1 would allow an increase of up to 10 percent over the 20-percent February–June unimpaired flow requirement (to a maximum of 30 percent of unimpaired flow). A change to the percent of unimpaired flow would take place based on required evaluation of current scientific information and would need to be approved as described in Appendix K, *Revised Water Quality Control Plan.* Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time. However, an increase of up to 30 percent of unimpaired flow would potentially result in different effects as compared to 20-percent unimpaired flow, depending upon flow conditions and frequency of the adjustment. For example, an increase to 30 percent of unimpaired flow would result in a greater opportunities for in-water recreation at higher river flows, than at 20-percent unimpaired flow.

Based on best available scientific information indicating that a change in the timing or rate of unimpaired flow is needed to reasonably protect fish and wildlife, adaptive implementation method 2 would allow changing the timing of the release of the volume of water within the February–June time frame. While the total volume of water released February–June would be the same as LSJR Alternative 2 without adaptive implementation, the rate could vary from the actual (7-day running average) unimpaired flow rate. Method 2 would not authorize a reduction in flows required by other agencies or through other processes, which are incorporated in the modeling of baseline conditions. Method 3 would not be authorized under LSJR Alternative 2 since the unimpaired flow percentage would not exceed 30 percent.

Adaptive implementation method 4 would allow an adjustment of the Vernalis February–June flow requirement. The WSE model results show that under LSJR Alternative 2 the 1,200-cfs February–June base flow requirement at Vernalis would require a flow augmentation in the three eastside tributaries and LSJR only 2.7 percent of the time in the 82-year record analyzed. Similarly, flow augmentation would be required 0.7 percent of the time to meet a 1,000-cfs requirement and 0.5 percent of the time for an 800-cfs Vernalis base flow requirement. These results indicate that changes due to method 4 under this alternative would rarely alter the flows in the three eastside tributaries or the LSJR.

Impacts associated with adaptive implementation method 1 may be slightly different from those associated with methods 2 and 3. With method 1, if the specified percent of unimpaired flow were changed from 20 percent to 30 percent on a long-term basis, the conditions and impacts could become more similar to those described under LSJR Alternative 3 (e.g., 30 percent unimpaired flow). It is anticipated that over time the unimpaired flow requirement could increase or not change at all within a year or between years, depending on fish and wildlife conditions and hydrology. If method 2 is implemented, the total annual volume of water associated with LJSR Alternative 2 (i.e., 20 percent of the February–June unimpaired flow) would not change. It is unlikely that alteration of the timing of the river flows would result in substantial modification to the May through September flows or that alteration of the timing of the flows would produce large changes in monthly reservoir storage values. Ultimately, the reservoirs would release the same total amount of water. On average, there would be little change in reservoir elevations. Further, given that this method would not allow flows to go below what is required by existing requirements on the three tributaries and the SJR, impacts would be similar to those described above for LSJR Alternative 2 without adaptive implementation. Implementing method 4 is expected to have little effect on conditions in the three eastside tributary rivers and LSJR because it rarely would cause a change in flow and the volume of water involved would be relatively small. Consequently, the impact determination for LSJR Alternative 2 with adaptive implementation would be the same as described above for LSJR Alternative 2 without adaptive implementation. Impacts would be less than significant.

LSJR Alternative 3 (Less than significant/Significant and unavoidable with adaptive implementation)

Rivers

Under LSJR Alternative 3, modeled frequencies of flows greater than 2,500 cfs would generally change little on the Merced and Stanislaus Rivers (Table 10-4 and 10-6). Thus, on-bank recreation facilities would not experience substantially more inundation compared to baseline conditions. Flows greater than 2,500 cfs would increase in frequency on the Tuolumne River in May and June, but would remain about the same relative to baseline July–September (Table 10-5). Although the flows on the Tuolumne River would likely result in an increase in the frequency of inundation of on-bank recreation areas during a few months in the recreation season, this inundation is not anticipated to substantially physically deteriorate the recreation facilities along the river. Recreation facilities are constructed in close proximity to rivers and are capable of withstanding periodic inundation by higher flows. Furthermore, higher flow events would not impact recreation areas at higher elevations. For example, the 250 acre Caswell Memorial Park contains some campsites that inundate at flows greater than 5,000 cfs. However, other campsites in the park remain available at high flows. Moreover, the existing capacity of similar facilities in the region would allow use to shift to facilities at higher elevations during these periods of high flow.

Lower flows would be less frequent on the three eastside tributaries in May and June under LSJR Alternative 3. On the Merced River, this would correspond to an increase in the frequency of 500-2,500 cfs flows, while on the Tuolumne and Stanislaus Rivers, flows greater than 1,500 cfs (including flows greater than 2,500 cfs) would be more common than under current and past conditions (Tables 10-4, 10-5 and 10-6). The modeled seasonal monthly average frequency of low flow conditions known to support swimming and wading would decrease nearly 20 percent on the Merced River and more than 10 percent on the Tuolumne River (Tables 10-4 and 10-5, respectively). However, on these two rivers, the frequency of low flows (less than 500 cfs) in July-September would experience little net change compared to baseline conditions (Tables 10-4 and 10-5). Therefore, during the warmest months in the San Joaquin Valley, when swimming and wading are typically the most popular, there would be little change relative to baseline conditions. As such, overall, the reduced condition for swimming and wading on the Merced and Tuolumne Rivers during May and June (i.e., early in the summer recreational season) is not expected to substantially reduce in-water recreation for the season.

The flows on the SJR at Vernalis are expected to increase in May and June, but generally remain the same July–September. These flows would generally remain too high for swimming or wading, but motorized boating or advanced kayaking or rafting may continue. Conditions for water-dependent recreation would be expected to be similar to past and present conditions.

The historic hydrology of the three eastside rivers and the LSJR influence the types and conditions of recreational facilities and features, as well as the designated beneficial recreational uses, in and around these rivers. A change in the magnitude or duration of flows in rivers may somewhat alter the in-water recreational uses of the rivers under LSJR Alternative 3, as described earlier. While increased flows may lead to slightly fewer opportunities for swimming, they would likely lead to improved conditions for kayaking and whitewater rafting. They may also lead to more opportunities for on-bank recreational activities such as wildlife viewing. In addition, increased flows are expected to improve conditions for fish (see Chapter 19, *Analyses of Benefits to Native Fish Populations from Increased Flow between February 1 and June 30,* for details regarding expected fish benefits). While it is unknown whether any increase in fish populations would be large enough to specifically and measurably enhance sport fishing opportunities within the rivers, some beneficial effects related to recreational fishing are anticipated. Accordingly, the rivers would continue to support the designated beneficial uses of recreation, as described in the Basin Plan, and would not conflict with the support and continuation of recreational facilities and features as identified local plans and policies.

Implementation of LSJR Alternative 3 would not substantially physically deteriorate existing recreation facilities on the Stanislaus, Tuolumne, and Merced Rivers and the LSJR. Therefore, use of these facilities would not be reduced, and impacts on recreational resources at these rivers would be less than significant.

Reservoirs

LSJR Alternative 3 would not significantly affect reservoir elevations at Lake McClure. Relative to baseline, seasonal average elevation would increase 11 ft at the 30 percent cumulative distribution, while seasonal average minimum elevation would increase 83 ft (Tables 10-8 and 10-9). Under LSJR Alternative 3, greater increases of both the minimum elevation (135 ft) and the elevation at the 30 percent cumulative distribution (14 ft) are expected at New Melones Reservoir (Tables 10-12 and 10-13). Accordingly, it is anticipated that this alternative would not conflict with existing plans and policies supporting recreation and recreational facilities at the reservoirs. Therefore, implementation of LSJR Alternative 3 would not substantially physically deteriorate, and thereby reduce the use of, existing recreation facilities at Lake McClure and New Melones Reservoir.

At New Don Pedro Reservoir, a substantial decrease in elevation is expected at the 30 percent cumulative distribution (seasonal average decrease of 19 ft). A 10-foot increase in seasonal average minimum elevations will dampen but not completely compensate for this decrease in seasonal average elevation (Tables 10-10 and 10-11). Reservoir elevation at the 30 percent cumulative distribution would not decrease below 720 ft (the level at which some boat ramps become inoperable and campgrounds and picnicking use begin to decline).Therefore all boat ramps are expected to remain operable under LSJR Alternative 3 at the 30 percent cumulative distribution elevation, with some boat ramps operable at minimum reservoir elevations. While lower elevations may somewhat impinge upon recreationists’ access to boat ramps, the shoreline, or other recreational facilities, these change would not substantially physically deteriorate existing recreation facilities. Accordingly, it is anticipated this alternative would not conflict with existing plans and policies supporting recreation and recreational facilities at this reservoir. Implementation of LSJR Alternative 3 would not substantially physically deteriorate, and thereby reduce the use of, existing recreation facilities at New Don Pedro Reservoir.

Implementation of LSJR Alternative 3 would not substantially physically deteriorate or reduce the use of existing recreation facilities at Lake McClure, and New Melones and New Don Pedro Reservoirs. Accordingly, it is anticipated this alternative would not conflict with existing plans and policies supporting recreation and recreational facilities at these reservoirs. Therefore, this impact would be less than significant.

Adaptive Implementation

Under LSJR Alternative 3, impacts associated with adaptive implementation method 1 may be slightly different from those associated with adaptive implementation methods 2 and 3. Implementing method 1 would allow an increase or decrease of up to 10 percent in the February–June, 40-percent unimpaired flow requirement (with a minimum of 30 percent and maximum of 50 percent) to optimize implementation measures to meet the narrative objective, while considering other beneficial uses, provided that these other considerations do not reduce intended benefits to fish and wildlife. Adaptive implementation must be approved using the process described in Appendix K. Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time.

Adaptive implementation method 1 could affect the amount of water available for water supply and the volume of water and level of flow in the LSJR and its tributaries. However, an increase of up to 50 percent of unimpaired flow would potentially result in different effects as compared to the 40 percent unimpaired flow, depending upon flow conditions and the frequency of the adjustment. If the adjustment occurs frequently or for extended durations, impacts under LSJR Alternative 3 could become more like the impacts under LSJR Alternative 4. Model results indicate that if flow were increased from 40 percent of unimpaired flow to 50 percent of unimpaired flow, there would be substantial increases in the percent of time that May and June flows on the Tuolumne River would exceed 2,500 cfs (Tables 10-5 and 10-6). Accordingly, LSJR Alternative 3, with adaptive implementation method 1, would cause substantial deterioration of existing recreational facilities.

Under adaptive implementation methods 2 or 3, the overall volume of water from the February–June time period or after June would be the same as LSJR Alternative 3 without adaptive implementation, but the volume within each month could vary. It is unlikely that alteration of the timing of the river flows would result in substantial modification to the May through September flows or that alteration of the timing of the flows would produce large changes in monthly reservoir storage values. Ultimately, the same total amount of water would be released, so on average, there would be little change in reservoir elevations. Further, given that these two methods would not allow flows to go below what is required by existing requirements on the three tributaries and the SJR, impacts would be similar to those described above for LSJR Alternative 3 without adaptive implementation. Adaptive implementation method 4 would allow an adjustment of the Vernalis February–June minimum flow requirement. The WSE model results indicate changes due to method 4 under this alternative would rarely alter the flows in the three eastside tributaries or the LSJR, and thus would not affect recreation. Accordingly, LSJR Alternative 3, with adaptive implementation methods 2, 3, and 4, would not substantially affect recreational resources.

The historic hydrology of the three eastside rivers and the LSJR influence the types and conditions of recreational facilities and features, as well as the designated beneficial recreational uses, in and around these rivers. A change in the magnitude or duration of flows in rivers may somewhat alter the in-water recreational uses of the rivers under LSJR Alternative 3 with adaptive implementation method 1, as described earlier. Specifically, a shift to higher-flow recreational uses would be expected with more frequent higher flows on the Stanislaus and Tuolumne Rivers. This may result in more opportunities for boating on the LSJR and fewer opportunities for swimming and wading; however, there are ample locations for swimming in the area, including in the Upper SJR and plan area reservoirs. Higher flows may also lead to more opportunities for on-bank recreational activities such as wildlife viewing or bird watching. In addition, increased flows are expected to improve conditions for fish (see Chapter 19, *Analyses of Benefits to Native Fish Populations from Increased Flow between February 1 and June 30,* for details regarding expected fish benefits). While it is unknown whether any increase in fish populations would be large enough to specifically and measurably enhance sport fishing opportunities within the rivers, some beneficial effects related to recreational fishing are anticipated. Accordingly, the rivers would continue to support the designated beneficial uses of recreation, as described in the Basin Plan (State Water Board 1998), and would not conflict with the support and continuation of recreational facilities and features as identified in local plans and policies. However, because the frequency of the higher flows is expected to substantially increase under LSJR Alternative 3, with adaptive implementation, it is likely that existing on-bank recreational facilities would be inundated more frequently and substantial physical deterioration would occur, thus reducing the use of the facilities. Therefore, impacts are significant.

An SED must identify feasible mitigation measures for each significant environmental impact identified in the SED. (Cal. Code Regs., tit. 23, § 3777, subd. (b)(3).) Reducing the occurrence of flows greater than 2,500 cfs, particularly in May and June on the Tuolumne River, could reduce this significant impact, but such a reduction would directly contradict the purpose of LSJR Alternative 3, with adaptive implementation, to potentially increase the flow, based on best available scientific information, for the beneficial use of wildlife and fish. This mitigation is, therefore, infeasible. Furthermore, evaluating the effects of lower flows on the different rivers is part of LSJR Alternative 2 and is separately considered in this document. Owners and operators of on-bank recreational facilities should operate and maintain the facilities to minimize physical deterioration from increased inundation, such as increased facility inspections and repairs. The State Water Board, however, lacks authority to require this mitigation measure. As such, LSJR Alternative 3, with the implementation of adaptive implementation method 1, would remain significant and unavoidable.

LSJR Alternative 4 (Significant and unavoidable/Significant and unavoidable with adaptive implementation)

Rivers

In May and June, modeled frequencies of flows greater than 2,500 cfs under LSJR Alternative 4 would substantially increase on the three eastside tributaries, particularly in the Tuolumne and Stanislaus Rivers (Tables 10-5 and 10-6, respectively). There would be little change in high flows from July–September (Tables 10-5 and 10-6). Although on-bank recreation facilities at all of these rivers are purposefully built adjacent to, and within close proximity of, rivers and are able to withstand periodic inundation by higher flows, the frequency of flows predicted under LSJR Alternative 4 would likely result in much more regular inundation of adjacent on-bank recreational facilities along the Tuolumne River than is currently experienced under baseline. This increase in frequency would likely contribute to substantial physical deterioration over time, thus resulting in a substantial reduction in use of the facilities. This could potentially result in increased use of other nearby facilities by recreationists or a shift to water-enhanced activities (such as hiking). Therefore, impacts would be significant.

Lower flows would be less frequent on the three eastside tributaries in May and June under LSJR Alternative 4. On the Merced River, the modeled seasonal average frequency of flows less than 500 cfs would decrease by 26 percent relative to baseline, and there would be a 13 percent and 9 percent decrease on the Tuolumne River and Stanislaus River, respectively. Thus, the frequency of flows for lower flow recreational uses such as swimming, particularly in May and June, would substantially decrease (Tables 10-4 and 10-5). As a result of the increases in flow, the Merced River may experience increases in all recreational flow categories other than those for swimming and floating, and the Tuolumne River may provide more opportunity for advanced kayaking recreationists. Because there would be little change in high flows on the Merced River July–September, and on the Tuolumne River August and September, the warmest months in the San Joaquin Valley, when swimming and wading are typically the most popular, there would be little change relative to baseline conditions. As such, overall, the reduced opportunity for swimming and wading on the Merced and Tuolumne Rivers during May, and particularly during June (i.e., early in the summer recreational season), is not expected to substantially change in-water recreation conditions for the season. Low-flow water-dependent recreational conditions conducive to swimming in the Stanislaus River would be most affected during June, but the seasonal average frequency of flows supporting various recreation types are not expected to decrease more than 10 percent through the summer recreation season (Table 10-6).

Flows on the LSJR would remain generally too high for in-water recreational activities other than motorized boating and advanced rafting or kayaking at Vernalis in the northern extent of the plan area. While there is little known use of the southern portion of the LSJR for swimming, conditions for water-dependent recreation would be expected to be similar to past and present conditions.

The historic hydrology of the three eastside rivers and the LSJR influence the types and conditions of recreational facilities and features, as well as the designated beneficial recreational uses, in and around these rivers. A change in the magnitude or duration of flows in rivers may somewhat alter the in-water recreational uses of the rivers under LSJR Alternative 4, as described above. Specifically, a shift to higher-flow recreational uses would be expected with more frequent higher flows on the Merced and Tuolumne Rivers in May and June flow into the LSJR. This may result in more opportunities for boating on the LSJR and fewer opportunities for swimming and wading; however, there are ample locations for swimming in the area, including in the Upper SJR and at the plan area reservoirs. Higher flows may also lead to more opportunities for on-bank recreational activities such as wildlife viewing or bird watching. In addition, increased flows are expected to improve conditions for fish (see Chapter 19, *Analyses of Benefits to Native Fish Populations from Increased Flow between February 1 and June 30,* for details regarding expected fish benefits). While it is unknown whether any increase in fish populations would be large enough to specifically and measurably enhance sport fishing opportunities within the rivers, some beneficial effects related to recreational fishing are anticipated. Accordingly, the rivers would continue to support the designated beneficial uses of recreation, as described in the Basin Plan (State Water Board 1998), and would not conflict with the support and continuation of recreational facilities and features as identified local plans and policies.

However, because the frequency of the higher flows is expected to substantially increase under LSJR Alternative 4, it is likely that existing on-bank recreational facilities would be inundated more frequently, and substantial physical deterioration would result, thus reducing the use of the facilities. Therefore, impacts are significant.

An SED must identify feasible mitigation measures for each significant environmental impact identified in the SED. (Cal. Code Regs., tit. 23, § 3777, subd. (b)(3).) Reducing the occurrence of flows greater than 2,500 cfs, particularly in May and June on the Stanislaus and Tuolumne Rivers could reduce this significant impact, but such a reduction would directly contradict the purpose of LSJR Alternative 4. Furthermore, evaluating the effects of lower flows on the different rivers is part of the other alternatives and is separately considered in this document. Requiring less flow, beyond that prescribed by adaptive implementation method 1 further described below, cannot be independently applied under LSJR Alternative 4 as a mitigation measure because requiring flow reductions would be inconsistent with the terms of LSJR Alternative 4, with or without adaptive implementation, and is, therefore, infeasible. Owners and operators of on-bank recreational facilities should operate and maintain the facilities to minimize physical deterioration from increased inundation, such as increased inspections and repairs. The State Water Board, however, lacks authority to require this mitigation measure. As such, impacts under SJR Alternative 4 would remain significant and unavoidable.

Reservoirs

LSJR Alternative 4 seasonal average reservoir elevations at Lake McClure would increase by 9 ft at the 30 percent cumulative distribution and would increase by 41 ft at minimum (Tables 10-8 and 10-9). At New Melones Reservoir, substantial increases in seasonal average minimum elevations (124 ft) are expected and seasonal average elevations at the 30 percent cumulative distribution (8 ft) would be minimally affected under LSJR Alternative 4 (Tables 10-12 and 10-13). Therefore, implementation of LSJR Alternative 4 would not substantially physically deteriorate nor reduce the use existing recreation facilities at these reservoirs.

At New Don Pedro Reservoir, a substantial decrease in elevation is expected at the 30 percent cumulative distribution (seasonal average decrease of 23 ft), which would be somewhat, but not entirely, compensated for by increases in the minimum elevations (seasonal average increase of 14 ft) (Tables 10-10 and 10-11). It is expected that these changes would not substantially physically deteriorate existing recreation facilities. At the 30 percent cumulative distribution, all boat ramps would remain operational under LSJR Alternative 4 at New Don Pedro Reservoir. Minimum elevations at New Don Pedro Reservoir were below 726 ft for both baseline and LSJR Alternative 4, but were generally higher for LSJR Alternative 4 than for baseline. LSJR Alternative 4 would not render existing recreation facilities inoperable and, therefore, would not results in physical deterioration of the existing facilities.

Implementation of LSJR Alternative 4 would not substantially physically deteriorate the existing recreation facilities at Lake McClure, and New Melones and New Don Pedro Reservoirs. Therefore, use of these facilities would not be reduced, and this impact would be less than significant.

Adaptive Implementation

As discussed under LSJR Alternative 2, adaptive implementation methods 2 and 4 are not expected to result in impacts on recreational resources. As discussed under LSJR Alternative 3, adaptive implementation method 3 would result in similar impacts to those described above. Adaptive implementation method 1 would allow a decrease of up to 10 percent in the February–June, 60-percent unimpaired flow requirement (to 50 percent) to optimize implementation measures to meet the narrative objective, while considering other beneficial uses, provided that these other considerations do not reduce intended benefits to fish and wildlife. Adaptive implementation must be approved using the process described in Appendix K. Accordingly, the frequency and duration of any use of this adaptive implementation method cannot be determined at this time. If the specified percent of unimpaired flow were changed from 60 percent to 50 percent on a long-term basis, the conditions and impacts could become more similar to LSJR Alternative 3, with adaptive implementation. The modeling results show that if the adjustment occurs frequently or for extended durations, impacts would be significant and are no different than those presented for LSJR Alternative 4.

Impact REC-2: Substantially degrade the existing visual character or quality of the reservoirs

No Project Alternative (LSJR/SDWQ Alternative 1)

The No Project Alternative would result in implementation of flow objectives identified in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1),* for the No Project Alternative technical analysis.

LSJR Alternatives

Low water levels at reservoirs can expose a less visually pleasing shoreline to recreationists that is devoid of vegetation due to fluctuating water elevations (DWR 1994; USBR 1999). As summarized in Table 10-7 in Section 10.4.2, *Methods and Approach*, views at the Lake McClure and New Don Pedro and New Melones Reservoirs are classified to indicate if modification of the views or visual character and quality of each reservoir are acceptable or if retention of views is recommended. The views of Lake McClure and New Melones Reservoir are classified as Class II, indicating that views and retention of the existing character of the landscape is recommended. The views of Don Pedro Reservoir are classified as Class III, indicating that views and changes to the character of the landscape can be moderate.

LSJR Alternative 2 (Less than significant/Less than significant with adaptive implementation)

The change in the three reservoir elevations would not result in a substantial change to the existing visual character of the reservoirs. The changes in reservoir elevations at Lake McClure and New Melones Reservoir could result in an improvement to the existing views as reservoir elevations are expected to increase under certain conditions. As described under Impact REC-1, there would be a minimal decrease in reservoir elevations at New Don Pedro Reservoir at the 30 percent cumulative distribution relative to baseline; however, it is not anticipated this 3-foot seasonal average decrease would result in a substantial degradation of the visual character of the reservoir. Adaptive implementation is not anticipated to substantially change this effect. Therefore, viewers would continue to experience the water–land interface and would continue to see water from viewpoints, and this visual experience would not conflict with existing plans or policies meant to support or maintain existing views. Impacts would be less than significant.

LSJR Alternative 3 (Less than significant/Less than significant with adaptive implementation)

Reservoir elevations are expected to change as described above for Impact REC-1. The changes in elevations at Lake McClure and New Melones Reservoir could result in an improvement to the existing views as reservoir elevations are expected to increase under certain conditions. This visual experience would not conflict with existing plans or policies meant to support or maintain existing views. Adaptive implementation is not anticipated to substantially change these effects. Therefore, impacts would be less than significant.

As described under Impact REC-1, there would be a substantial decrease in reservoir elevations at New Don Pedro Reservoir at the 30 percent cumulative distribution relative to baseline. However, it is not anticipated this decrease would result in a substantial degradation of the visual character of the reservoir. This is because the views of Don Pedro Reservoir are classified as Class III views. These views are considered lower quality under existing conditions and can, therefore, be more readily modified as a result of the Class III designation. Reservoir elevation fluctuations are typical of this environment. Furthermore, viewers would still experience the reservoir, the existing fluctuation of elevation, and lack of vegetation within the fluctuation zone, all within the context of the foothills and mountains. Finally, although the water elevations would change, recreationists would continue to experience the water–land interface. This visual experience would not conflict with existing plans or policies meant to support or maintain existing views. Adaptive implementation is not anticipated to substantially change these effects. Therefore, impacts would be less than significant.

LSJR Alternative 4 (Less than significant/Less than significant with adaptive implementation)

Reservoir elevations are expected to change as described above for Impact REC-1. The changes in elevations at Lake McClure and New Melones Reservoir could result in an improvement to the existing views as a reservoir elevations are expected to increase under certain conditions. This visual experience would not conflict with existing plans or policies meant to support or maintain existing views. Adaptive implementation is not anticipated to substantially change these effects. Therefore, impacts would be less than significant.

As described under Impact REC-1 for LSJR Alternative 4 there would be a substantial decrease in reservoir elevations at New Don Pedro Reservoir at the 30 percent cumulative distribution relative to baseline; however, it is not anticipated this decrease would result in a substantial degradation of the visual character of the reservoir because of the Class III designation of views at this reservoir, the typical fluctuations of reservoirs, and the land–water interface experience of recreationists. This visual experience would not conflict with existing plans or policies meant to support or maintain existing views. Adaptive implementation is not anticipated to substantially change these effects. Therefore, impacts would be less than significant.

10.4.4 Impacts and Mitigation Measures: Extended Plan Area

Bypassing flows in the extended plan area, as described in Chapter 5, *Surface Hydrology and Water Quality*, could potentially impact recreational resources and the visual character and quality of upstream reservoirs on the Stanislaus and Tuolumne Rivers differently in the extended plan area than described in the plan area. Particularly, existing scenic vistas and scenic highways could be affected. These impacts could occur if reservoirs experienced substantial changes in reservoir volume, especially under drought conditions, particularly under LSJR Alternatives 3 and 4 with or without adaptive implementation, which are not experienced by the rim reservoirs. However, under baseline conditions these reservoirs undergo substantial annual water level and volume fluctuations as water is released from the reservoirs for hydropower production, consumptive use, and instream flow requirements (USGS Reservoir Gage Data). Under baseline conditions, these fluctuating reservoir volumes impact recreation at individual reservoirs by reducing the lake area available for boating or fishing, potentially isolating boat ramps and thereby limiting boat access to the reservoir, and potentially isolating swimming beaches from the reservoir. For example, this type of reduction has occurred during the recent drought (UGSG Reservoir Gage Data). However, these volume reductions could occur more frequently, and could be more pronounced during drought conditions, particularly under LSJR Alternative 3 and LSJR Alternative 4 with or without adaptive implementation, but also under LSJR Alternative 2 with adaptive implementation. Consequently, there could be significant recreation impacts at reservoirs under the LSJR Alternative 2 with adaptive implementation and LSJR Alternatives 3 and 4 with or without adaptive implementation, in the extended plan area, as explained below.

The aesthetic quality of these reservoirs would be affected when the reservoir levels are drawn down enough the unvegetated rim around their perimeter is visible. Exposure of the unvegetated rim occurs during normal operations; however, as noted above, exposure could occur more frequently under drought conditions, particularly under LSJR Alternatives 3 and 4 with or without adaptive implementation, but also under LSJR Alternative 2 with adaptive implementation. Consequently, there could be significant aesthetic impacts at reservoirs in the extended plan area, as explained below.

There is some potential that drawdown in upstream reservoir storage could result in reduced flows in the fall on the Stanislaus and Tuolumne Rivers. Flow reductions could have a substantial adverse effect on scenic views along the Stanislaus and Tuolumne Rivers if flows are reduced such that viewers (e.g., recreationists) cannot see water in the river and the river becomes less of a feature defining the overall landscape. Flow reductions could substantially degrade the visual character and quality of views of the Tuolumne River, many parts of which are designated as wild and scenic (total 83 miles) (National Wild and Scenic River System 2016). The degradation of views could damage a scenic resource (the river itself) as seen from eligible state scenic highways adjacent to the river (e.g., Highway 49). While no sections of the Stanislaus River are designated as wild and scenic, flow reductions could substantially degrade the visual character and quality of the views of the Stanislaus River, which can be viewed from designated State Scenic Highways 108 and 4 (National Wild and Scenic River System 2016; Caltrans 2016; DOT 2016). Impacts would could be significant, even though higher spring flows and lower fall flows are reflective of what would occur in a natural system. Providing more flows in the fall could mitigate this impact; however, it is counter to each alternative's purpose to provide additional flows during February to June to more closely mimic the natural hydrograph for the protection of fish and wildlife beneficial uses, and is therefore infeasible. There are no other feasible mitigation measures that the State Water Board may impose. Impacts would remain significant and unavoidable.

Many sections of the Merced River are designated wild and scenic (total 122 miles) or within view of designated state scenic highways (Highways 140 and 120) (National Wild and Scenic River System 2016; Caltrans 2016; DOT 2016); however, given the lack of substantial upstream reservoirs, it is unlikely that flow reductions would occur on the Merced River. Therefore, the visual character and quality of the Merced River would not be affected.

Rivers flows on the Stanislaus and Tuolumne Rivers could potentially impact recreational resources in the extended plan area on the Stanislaus and Tuolumne Rivers similar to the impacts described in the plan area. Under LSJR Alternatives 3 and 4 with or without adaptive implementation, the rivers may have higher and more frequent flows when compared to baseline conditions during the bypass period. The higher flows could occur when junior water is bypassed during the snow melt season. As such, on-bank recreational facilities along the three rivers could be inundated more frequently, which could result in the deterioration of facilities. Impacts could be significant. Reducing flows could reduce this impact; however, such a reduction would directly contradict the purpose of these alternatives and is, therefore, infeasible. Owners and operators of on-bank facilities should operate and maintain facilities to minimize the physical deterioration from the increased frequency of inundation, such as increased inspections and repairs; however, the State Water Board lacks authority to impose this mitigation measure, and the impact remains significant. In addition, the combination of snowmelt and possible increases in bypass flows under LSJR Alternatives 3 and 4 with or without adaptive implementation may result in flows that are too high to support in-water recreational uses (e.g., swimming, rafting, kayaking). However, these high flow impacts are expected to be of short duration as the snow pack progressively melts and the related snow-melt flow declines. These impacts are also similar to those that occur under baseline conditions. Conversely, after the bypass period the rivers may have lower flows compared to baseline conditions under LSJR Alternatives 3 and 4 with or without adaptive implementation if reservoir volumes are then low due to the bypassed flow. This could affect in-river recreational uses on the Stanislaus and Tuolumne Rivers.

The increased frequency of lower reservoir levels resulting from the LSJR alternatives and the associated physical changes to recreation and aesthetics would be limited by the program of implementation under each of the LSJR alternatives. The program of implementation requires minimum reservoir carryover storage targets or other requirements to help ensure that providing flows to meet the flow objectives will not have adverse or other impacts on fish and wildlife or, if feasible, on other beneficial uses (i.e., recreation). Other requirements, for example, include, but are not limited to, limits on required bypass flows for reservoirs that store water only for non-consumptive use so that some water can be temporarily stored upstream. The program of implementation also states that the State Water Board will take actions as necessary to ensure that implementation of the flow objectives does not impact supplies of water for minimum health and safety needs, particularly during drought periods. Accordingly, when the State Water Board implements the flow objectives in a water right proceeding, it will consider impacts on fish, wildlife, and, if feasible, on other beneficial uses, and health and safety needs, along with water right priority. Until the State Water Board assigns responsibility to meet the flow objectives in the Bay-Delta Plan, it is speculative to identify the exact extent, scope, and frequency of reduced diversions, reduced reservoir levels and their effects on recreation and aesthetics within the extended plan area. When implementing the flow objectives, the State Water Board would identify project-specific impacts and avoid or mitigate, to the extent feasible, significant impacts of lower reservoir levels on recreation and aesthetics in accordance with CEQA.

At the time of preparation of this programmatic analysis, it is unclear to what extent any significant impacts on recreation and aesthetics could be fully mitigated. Thus, the potential exists for significant impacts. Therefore, this analysis conservatively concludes that impacts associated with lower reservoir levels under LSJR Alternative 2 with adaptive implementation, and LSJR Alternatives 3 and 4 with or without adaptive implementation are significant. The following mitigation measure is proposed: when considering carryover storage and other requirements to implement the flow water quality objectives in a water right proceeding, the State Water Board shall ensure that reservoir levels upstream of the rim dams do not cause significant recreation and aesthetic impacts, unless doing so would be inconsistent with applicable laws. Even with mitigation, the impact is considered significant, because the mitigation may not fully mitigate the impact in all situations.

Chapter 11
Agricultural Resources

11.1 Introduction

This chapter describes the environmental setting for agricultural resources and the regulatory background associated with these resources. It also evaluates environmental impacts on agricultural resources that could result from the Lower San Joaquin River (LSJR) alternatives and, if applicable, offers mitigation measures that would reduce significant impacts.

LSJR Alternatives 2, 3, and 4 require sufficient flows for the reasonable protection of fish and wildlife beneficial uses. This chapter analyzes those alternatives and assumes that any increases in unimpaired flows[1] would reduce surface water supplies that are available for irrigation purposes. For Prime Farmland, Unique Farmland, or Farmland of Statewide Importance, the analysis then assumes that reduced surface water supplies could potentially lead to reductions in crop acreages, and, where applicable, equates those changes to possible conversions of those lands to nonagricultural uses. It should be noted that this likely presents a more conservative (i.e., "worst case") estimate of potential acreage reduction than may actually occur. Conversions of land to nonagricultural uses are governed by many factors, including the proximity of land to a developable area and the decision of a landowner whether to remain in agriculture. Moreover, the management decisions of individual agricultural producers (farmers) are more sophisticated and driven by more variables than can be accounted for in modeling. For example, land with less irrigation could still remain in agricultural production due to one or more factors, including: efficiency improvements that reduce water demand, crop type or agricultural use changes to less water-intensive applications, dry land farming, or, increased crop rotation among plots of acreage. However, these actions are too speculative to be modeled as they are within the control of the individual farmer, not the State Water Resources Control Board (State Water Board).

This chapter includes assumptions based on past levels of groundwater pumping. Potential impacts on the groundwater subbasins, as a resource, resulting from the LSJR alternatives are addressed in Chapter 9, *Groundwater Resources*. Potential groundwater impacts related to municipal and domestic needs are addressed in Chapter 13, *Service Providers*, and Chapter 22, *Evaluation of Groundwater and Drinking Water Supply of Municipal and Domestic Needs*. Those chapters also reference the recently-passed Sustainable Groundwater Management Act (SGMA), which requires that groundwater basins be locally-managed to ensure reliable levels of groundwater supplies and to prevent continued chronic overdrafting of groundwater basins and other undesirable results.

The LSJR area of potential effects for agricultural resources includes Merced, Stanislaus, and part of San Joaquin Counties. Figure 11-1 identifies the location and type of farmland within the LSJR area

---

[1] *Unimpaired flow* represents the water production of a river basin, unaltered by upstream diversions, storage, or by export or import of water to or from other watersheds. It differs from natural flow because unimpaired flow is the flow that occurs at a specific location under the current configuration of channels, levees, floodplain, wetlands, deforestation and urbanization.

of potential effects. The area of potential effects is based on California Department of Water Resources (DWR) Detailed Analysis Units (DAUs) used in the Statewide Agricultural Production (SWAP) model[2] and is comprised of six geographic areas. These six geographic areas include Stockton East Water District/Central San Joaquin Water Conservation District (SEWD/CSJWCD), South San Joaquin Irrigation District (SSJID), Oakdale Irrigation District (OID), Modesto Irrigation District (MID), Turlock Irrigation District (TID), and Merced Irrigation District (Merced ID).

As described in Chapter 1, *Introduction*, the extended plan area generally includes the area upstream of the rim dams.[3] Unless otherwise noted, all discussion in this chapter refers to the plan area. Where appropriate, the extended plan area is specifically identified.

The SWAP model is a regional economic model for irrigated agricultural production that simulates the decisions of farmers in California. The model assumes that farmers maximize profit subject to resource, technical, and market constraints and that farmers sell and buy in competitive markets in which no one farmer can affect or control the price of any commodity. The SWAP model incorporates project water supplies (State Water Project [SWP] and Central Valley Project [CVP]), other local water supplies, and groundwater in its analysis. SWAP is the best available model for estimating the regional agricultural response to a change in water availability in the LSJR area of potential effects.

However, it should be noted that the SWAP model has limitations. The SWAP model uses a simplified assumption that water use will shift from lower net revenue crops to high-value crops. This means that under the modeling scenarios, irrigation shifts almost completely from Alfalfa and Pasture to higher net revenue crop types. As noted previously, this likely presents a more conservative estimate than may actually occur. The model also calculates the value of the Alfalfa or Pasture as a commodity and cannot factor in its proximity to an affiliated agricultural enterprise such as dairy or beef cattle, which could increase the crop value to an individual producer because of the reduced transportation costs or other factors.

Southern Delta water quality (SDWQ) alternatives are also analyzed throughout this chapter. However, no reduction or conversion of agricultural acreage under the SDWQ alternatives is likely for several reasons. The principle factor influencing water quality in the southern Delta is the salinity level of water coming from the San Joaquin River (SJR) Watershed. However, the program of implementation requires the U.S. Bureau of Reclamation (USBR) to meet and maintain the same salinity requirements that are currently measured at Vernalis on the SJR. Therefore, water quality within the southern Delta is expected to remain unchanged. In addition, as explained in this chapter and Appendix E, *Salt Tolerance of Crops in the Southern Sacramento–San Joaquin Delta,* under SDWQ Alternatives 2 and 3, even salt-sensitive crops would not be considered significantly impacted. The SDWQ area of potential effects is comprised of agricultural resources in the southern Delta, which are primarily within the boundaries of the Southern Delta Water Agency (SDWA). Figure 11-2 shows the location of the SDWQ area of potential effects and the SDWA boundary with respect to San Joaquin County and the legal boundary of the Delta.

---

[2] The LSJR alternatives area of potential effects includes: DAUs 182, 205, 206, 208, and 210.

[3] In this document, the term *rim dams* is used when referencing the three major dams and reservoirs on each of the eastside tributaries: New Melones Dam and Reservoir on the Stanislaus River; New Don Pedro Dam and Reservoir on the Tuolumne River; and New Exchequer Dam and Lake McClure on the Merced River.

Figure 11-2
Agriculture within the SDWQ Area of Potential Effects

In Appendix B, *State Water Board's Environmental Checklist*, the State Water Board determined whether the plan amendments would cause any adverse impact for each environmental category in the checklist and provided a brief explanation for its determination. Impacts on agricultural resources that are listed as "Potentially Significant Impacts" are discussed in detail in this chapter. Appendix B, Section II, identified potentially significant impacts of the LSJR and SDWQ alternatives on agricultural resources as: (1) those that result in the conversion of Prime Farmland, Unique Farmland, and Farmland of Statewide Importance (e.g., irrigated farmland); (2) changes in the existing environment which, due to their location or nature, could result in the conversion of farmland to nonagricultural uses; or (3) those that conflict with existing zoning for agricultural uses or Williamson Act contracts. In addition, Appendix B, Section X identified potentially significant impacts of the LSJR and SDWQ alternatives as those that conflict with any applicable land use plan, policy, or regulation of an agency with jurisdiction over a project adopted for the purpose of avoiding or mitigating an environmental effect.[4]

As noted previously, this evaluation generally focuses on the potential conversion of irrigated farmland to nonagricultural uses as a result of a reduction in surface water supplies (LSJR alternatives) or a change in water quality (SDWQ alternatives). Impacts associated with the LSJR alternatives were assessed using the State Water Board's Water Supply Effects (WSE) model and the SWAP model to determine whether reduction in surface water diversions for crop production in the LSJR area of potential effects or a change in water quality could result in a change in the distribution of crops or crop production. The analysis uses this information to qualitatively discuss the potential conversion of designated agricultural lands to nonagricultural land. The qualitative assessment of impacts associated with the SDWQ alternatives on agricultural resources was based on the expected water quality in the southern Delta under the different alternatives, in conjunction with the LSJR alternatives, and the tolerance of salt-sensitive crops in the southern Delta.

A summary of the potential impacts of the LSJR and SDWQ alternatives on agricultural resources is provided in Table 11-1. As described in Chapter 3, *Alternatives Description*, LSJR Alternatives 2, 3, and 4 each include four methods of adaptive implementation. This recirculated substitute environmental document (SED) provides an analysis with and without adaptive implementation because the frequency, duration, and extent to which each adaptive implementation method would be used, if at all, within a year or between years under each LSJR alternative is unknown. The analysis, therefore, discloses the full range of impacts that could occur under a LSJR alternative, from no adaptive implementation to full adaptive implementation. As such, Table 11-1 summarizes impact determinations with and without adaptive implementation.

Impacts related to the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1) are presented in Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*, and the supporting technical analysis is presented in Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*. Chapter 16, *Evaluation of Other Indirect and Additional Actions,* includes discussion of impacts related to compliance and methods of compliance.

---

[4] This language is applicable when put in an agricultural context.

Table 11-1. Summary of Agricultural Resources Impact Determinations

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
Impact AG-1: Potentially convert Prime Farmland, Unique Farmland, or Farmland of Statewide Importance to nonagricultural use			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note.[b]	Significant	NA
LSJR Alternative 2	Potential environmental impacts from the conversion of Prime Farmland, Unique Farmland, or Farmland of Statewide Importance to nonagricultural use are less than significant under LSJR Alternative 2 without adaptive implementation because potential reductions in surface water diversions could result in a less than 4% average reduction in irrigated acreage for the irrigation districts in the LSJR area of potential effects. However, if adaptive implementation method 1 were implemented on a long-term basis (an increase in the February–June percent of unimpaired flow from 20% up to 30%), environmental impacts would be potentially significant and unavoidable as it is estimated that OID could experience a 4.4% average reduction in irrigated crops, which equates to 2,356 acres receiving reduced irrigation, and MID could experience a 4.5% average reduction in irrigated crops, which equates to 2,589 acres receiving reduced irrigation. It is reasonable to assume that a portion of the reduced irrigated acreage is Prime Farmland, Unique Farmland, or Farmland of Statewide Importance, and that some portion of acreage with reduced irrigation could potentially be converted to nonagricultural uses even though there are many factors affecting whether land is converted. Conversely, land can be maintained in agricultural use through crop substitution, crop rotation, fallowing, and dry land farming.	Less than significant	Significant and unavoidable

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
LSJR Alternative 3	Environmental impacts from the conversion of Prime Farmland, Unique Farmland, or Farmland of Statewide Importance to nonagricultural uses are considered potentially significant and unavoidable because approximately 22,879 acres, on average, of Prime or Unique farmland or Farmland of Statewide Importance requiring irrigation could have reduced surface water diversions, and it is reasonable to assume that a portion could potentially be converted to nonagricultural uses, even though there are many factors affecting whether land is converted. Conversely, land can be maintained in agricultural use through crop substitution, crop rotation, and dry land farming. Specifically, reductions in surface water diversions could result in reduced acres of irrigated land for Alfalfa for SSJID, MID, and TID; Grain in MID; Field Crops in SSJID, MID and TID; Pasture in SSJID, OID, MID, and TID; Rice in SSJID and MID; and Dry Beans and Processing Tomatoes in SSJID. Those potential average reductions in irrigated acreage range from 0.8% for Merced ID to 9.9% for MID.	Significant and unavoidable	Significant and unavoidable
LSJR Alternative 4	Environmental impacts from the conversion of Prime Farmland, Unique Farmland, or Farmland of Statewide Importance to nonagricultural uses are potentially significant and unavoidable because approximately 70,640 acres, on average, of Prime or Unique Farmland or Farmland of Statewide Importance requiring irrigation could have reduced surface water diversions, and it is reasonable to assume that a portion could potentially be converted to nonagricultural uses, even though there are many factors affecting whether land is converted. Conversely, land could be maintained in agricultural use through the crop substitution, crop rotation, and dry land farming. Specifically, reductions in surface water diversions could result in reduced acres of irrigated land for Alfalfa, Pasture, Corn, Grain, and Field in SSJID, OID, MID, and Merced ID; Rice and Safflower in SSJID, OID, and MID; Dry Bean and Cucurbits in	Significant and unavoidable	Significant and unavoidable

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
	SSJID, OID, MID, and Merced ID; Processing and Fresh Tomato and Truck in SSJID, and Truck in SSJID, MID, and TID. Those potential average reductions in irrigated acreage range from 2.6% for Merced ID to 27.5% for MID.		
SDWQ Alternatives 2 and 3	No reduction or conversion of agricultural acreage is likely because water quality within the southern Delta is expected to remain unchanged as USBR would be responsible for complying with the same salinity requirements that currently exist at Vernalis.	Less than significant	NA
Impact AG-2: Involve other changes[c] in the existing environment which, due to their location or nature, could result in a conversion of farmland to nonagricultural use			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note.[b]	Less than significant	NA
LSJR Alternative 2	Impacts on irrigated agriculture from a high water table resulting from increased river flows on the Stanislaus River are expected on less than 0.1% of irrigated acreage; therefore, crop production would not be substantially reduced.	Less than significant	Less than significant
LSJR Alternative 3	Impacts on irrigated agriculture from a high water table resulting from increased river flows on the Stanislaus River are expected on less than 0.1% of irrigated acreage; therefore, crop production would not be substantially reduced. Given cost of feed input compared to other dairy inputs and the availability of the feed input, the value of dairy production in the LSJR area of potential effects, and the potential use of equitable distribution of local water suppliers, it is unlikely dairies, as an agricultural use, would be converted to nonagricultural uses.	Less than significant	Less than significant
LSJR Alternative 4	Impacts on irrigated agriculture from a high water table resulting from increased river flows on the Stanislaus River are expected on less than 0.1% of irrigated acreage; therefore, crop production would not be substantially reduced. Given cost of feed input compared to other dairy inputs and the availability of the feed input, the value of dairy production in the LSJR area of potential effects, and the potential use of	Less than significant	Less than significant

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
	equitable distribution of local water suppliers, it is unlikely dairies, as an agricultural use, would be converted to nonagricultural uses		
SDWQ Alternatives 2 and 3	Conversion of farmland to nonagricultural use is not expected because water quality within the southern Delta is expected to remain unchanged as USBR would be responsible for complying with the same salinity requirements that currently exist at Vernalis.	Less than significant	NA
Impact AG-3: Conflict with existing zoning for agricultural use or a Williamson Act contract			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note.[b]	Less than significant	NA
LSJR Alternatives 2, 3, and 4	The LSJR alternatives would not conflict with existing zoning for agricultural use or Williamson Act contracts because the LSJR alternatives would not change zoning and lands that are under Williamson Act contracts must be maintained in the compatible uses specified in those contracts until non-renewed, canceled or otherwise withdrawn from contract. Lands that experience a reduction in surface water supply could be dryfarmed, rotated, or fallowed, all of which would be agricultural activities that are consistent with agricultural zoning and Williamson Act contracts.	Less than significant	Less than significant
SDWQ Alternatives 2 and 3	The SDWQ alternatives would not conflict with existing zoning for agricultural use or Williamson Act contracts because the SDWQ alternatives would not change zoning, and agricultural lands would continue to divert water from existing waterways and rely on suitable water quality to irrigate crops.	Less than significant	NA
Impact AG-4: Conflict with any applicable land use plan, policy, or regulation related to agriculture of an agency with jurisdiction over a project (including, but not limited to the general plan, specific plan, local coastal program, or zoning ordinance) adopted for the purpose of avoiding or mitigating an environmental effect			
No Project Alternative (LSJR/SDWQ Alternative 1)	See note.[b]	Less than significant	NA

Alternative	Summary of Impact(s)	Impact Determination without Adaptive Implementation	Impact Determination with Adaptive Implementation[a]
LSJR Alternatives 2, 3, and 4	The LSJR alternatives would not conflict with applicable land use plans, policies, or regulations because the LSJR alternatives are not proposing amendments to existing land use plans, policies, or regulations. While some agricultural land could be taken out of irrigated agricultural use as a result of the LSJR alternatives (particularly LSJR Alternatives 3 and 4), many of these lands could remain in agricultural use, even if they are not irrigated and must remain in uses that are compatible with applicable local land use plans, policies or regulations.	Less than significant	Less than significant
SDWQ Alternatives 2 and 3	The SDWQ alternatives would not conflict with applicable land use plans, policies, or regulations because the SDWQ alternatives would not change zoning, and agricultural lands would continue to divert water from existing waterways and rely on suitable water quality to irrigate crops.	No impact	NA

CSJWCD = Central San Joaquin Water Conservation District
LSJR = Lower San Joaquin River
Merced ID = Merced Irrigation District
MID = Modesto Irrigation District
NA = not applicable
OID = Oakdale Irrigation District
SDWQ = southern Delta water quality
SEWD = Stockton East Water District
SSJID = South San Joaquin Irrigation District
TID = Turlock Irrigation District
USBR = U.S. Bureau of Reclamation

[a] Four adaptive implementation methods could occur under the LSJR alternatives, as described in Chapter 3, *Alternatives Description*, and summarized in Section 11.4.2, *Methods and Approach*, of this chapter. There is no adaptive implementation or adaptive implementation methods for the SDWQ alternatives.

[b] The No Project Alternative (LSJR/SDWQ Alternative 1) would result in the continued implementation of flow objectives and salinity objectives established in the 2006 Bay-Delta Plan. See Chapter 15, *No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*, for the No Project impact discussion and Appendix D, *Evaluation of the No Project Alternative (LSJR Alternative 1 and SDWQ Alternative 1)*, for the No Project Alternative technical analysis.

[c] The "other changes" to the existing environment included in the Impact AG-2 analysis are high water tables that could potentially affect fields due to seepage and potential reductions in farmland upon which other agricultural production relies.

11.2 Environmental Setting

This section characterizes the agricultural resources in the LSJR area of potential effects and SDWQ area of potential effects (or SDWA). The description of agricultural resources includes soils, farmland, crop mix, methods of irrigation, drainage, and water supply and describes the connection between crop production and water quality. General information regarding soil and water quality is first discussed to provide context for crop production in the LSJR area of potential effects and SDWQ area of potential effects. Information on soils and farmland is from the Natural Resources Conservation Service (NRCS) and the California Department of Conservation (DOC); crop production and cropping trends are from DWR land use surveys; water supply and quality information is from previous chapters in this document. Additionally, the current state of knowledge for salinity and its applicability to the LSJR area of potential effects and SDWQ area of potential effects is fully discussed in Appendix E, *Salt Tolerance of Crops in the Southern Sacramento–San Joaquin Delta*.

11.2.1 Soil and Water Quality
